THURSDAY, MAY 5, 1898.

SCIENTIFIC WORTHIES.

XXXI.—ALBERT VON KÖLLIKER.

ALBERT VON KÖLLIKER was born at Zürich on July 6, 1817; he therefore is the eldest of the illustrious teachers who have brought down to the present day the tradition of that active spirit of biological inquiry which had its most complete expression, during the first part of the century, in the life and work of Johannes Müller.

After visiting several universities, and so hearing the lectures of many eminent biologists (among whom Johannes Müller himself may be specially mentioned), Kölliker took the degree of M.D. in Heidelberg in 1842; and in 1843 he commenced his teaching career as Prosector to Henle in Zürich. In 1846 he became Professor extraordinarius in Zürich, and in the autumn of 1847 he was called to Würzburg as Professor of Human Anatomy. This chair he has continuously occupied ever since. The remarkable Festschrift, recently published in his honour, contains a long list of names of men who are proud to call themselves his pupils; and the scientific position which so many of these men have won is evidence of the way in which he has fulfilled the highest function of a teacher, imparting to his hearers not only a great store of knowledge, but a just perception of the point where knowledge ends, and something of his own determination and energy in the acquisition of new scientific truth.

It is impossible to give anything like a detailed account of Prof. von Kölliker's scientific work, the results of which are embodied in some couple of hundred memoirs (written with apparently equal facility in any one of four languages) and in a series of text-books. All that can be attempted is an outline of its most important features.

The publication, in 1838, of Schwann's great work drew attention to a number of problems; and Kölliker was one of the first to realise that the complete justification of the cell-theory must be accomplished by a study of the whole history of animal tissues, from the fertilised egg onwards. The first results of this conviction are seen in his monograph of the development of Cephalopods (1844), and in a series of papers on the development of Amphibia (1846-1847). These memoirs are of great importance in the history of embryology, because they definitely bring the phenomena of the segmentation of fertilised ova into the category of normal cell divisions, and lay the foundation of the modern doctrine that an ovum is to be regarded as a single cell. Speaking in 1860 of his work on the Cephalopoda, Prof. von Kölliker points out, with justifiable pride, that he had already in 1844 asserted

"Dass in der ganze Reihe der Entwicklung der thierischen Gewebe, ebensowie bei den Pflanzen, keine Zellenbildung ausserhalb der schon vorhandenen sich finde, vielmehr alle Erscheinungen als die ununterbrochene Folge von Veränderungen ursprünglich gleichbedeutender und alle von Einem ersten abstammender Elementarorgane aufzufassen seien"—

the process of derivation being always a cell-division comparable with the division of cells in a later embryo, or in the adult body (cf. *Entwicklungsgeschichte*, ed. 1861). But besides this important general proposition, the memoir contains a detailed account of Cephalopod development, so far as it could be studied by the methods available at the time, which is of great and permanent value to students of molluscan embryology. The papers on the development of Amphibia describe in outline the process by which the cells of cartilage and blood, the walls of blood-vessels and the elements of embryonic muscle are derived from blastomeres, and therefore have an important bearing on the fundamental problems of histogenesis.

A second series of early papers (1841-1847) was of great assistance, although in a different way, to the study of animal development. The acceptance of Caspar Wolff's doctrine of epigenesis, while it led to a right understanding of the structure of the ovum, was accompanied for a time by a curious belief concerning spermatozoa. After the discovery of these bodies in Leeuwenhoek's laboratory (1677) they were held by many supporters of the hypothesis of "evolution" to contain the whole preformed germ of the future animal, which unfolded and grew after entering the egg. This view never obtained universal acceptance, and it was abandoned by every one at the close of the eighteenth century, as Wolff's view of development became fashionable; but the belief which then grew up was further from the truth than that previously held, for it was maintained that spermatozoa were parasites of extraneous origin, which played no part whatever in the process of fertilisation. This belief was finally destroyed by the researches of Kölliker, who showed conclusively that spermatozoa arise from the tissues of the male gonad, and said in 1847: "Ich betrachte sie als befruchtende Princip und glaube, dass sie durch Berührung der Eier in denselben ein neues Leben erwecken"—thus leading the way directly to modern views. These papers again, besides establishing an important general proposition, contain statements of value on many points of detail, among which the descriptions of the large non-motile male elements of the higher Crustacea may be mentioned.

The two series of memoirs referred to contain perhaps the most fundamental results achieved before going to Würzburg in 1847; but they give no idea of the amount of work actually done before that date. In the field of pure histology must be mentioned the memoir on the Pacinian bodies, written in cojunction with Henle (1844); the important demonstration of the whole course of the connection between a medullated nerve fibre and a nerve cell (1845); a memoir on the spleen, and another on the synovial membranes (1847); also a preliminary account of the researches on the structure of smooth muscle, which were fully described later. Of more purely zoological interest are the papers on the hectocotylus of Cephalopods, in which the trematode hypothesis is shown to be untenable; the paper on the marginal bodies of Medusæ (1843), which contains the earliest recognition of the nature of the otocysts in these animals; the description of the remarkable *Rhodope Varanii* (1847), discovered by v. Kölliker; and two papers, written in conjunction with Löwe, on the presence of cellulose in the test of Tunicata (1846).

On going to Würzburg, Prof. v. Kölliker's activity was if anything increased. He almost immediately joined von Siebold in founding the *Zeitschrift für wissenschaftliche Zoologie*; and it is not the least of his claims to the gratitude of biologists that he has continued for half a century to edit this valuable journal. The first numbers contain a series of papers written by himself, of which the following are the most important.

The essay on *Actinophrys* recognises the rhizopod nature of this animal, and contains a remarkable discussion of the manner in which rhizopods generally ingest their food. The suggestion is clearly made that the contractile substance of *Actinophrys* and *Amœba* is identical in nature with that of *Hydra* and of the higher animals; so that this paper, and Ecker's paper on the contractile substance of *Hydra* which is printed immediately after it, mark an important step in the general conception of what is now called protoplasm.

The monograph of the *Gregarinidæ*, also in the first volume, clearly recognises the unicellular nature of an adult *Gregarina*, and in it the *pseudonavicellæ* are stated to represent stages in the life-history of the *Gregarina*. Many species of Gregarines are described.

[The description of *Dicyema* (1849) may be most conveniently referred to here, although it was not published in the *Zeitschr. f. w. Zoologie.*]

Of papers relating to vertebrate histology, published in the early numbers of the *Zeitschrift*, the most important are the memoirs on smooth muscle, and on the skin. In the first the result of the work already referred to is more fully described. This memoir contains a description of the cellular elements of smooth muscular tissue, and a detailed account of its occurrence in the vertebrate body, including a final demonstration of its presence in the walls of the blood-vessels, which was doubted by several anatomists at the time. In the second memoir, the development of the epidermis is described, and a full account of the development of sweat-glands, hairs, and sebaceous glands is also given.

A paper on nerve-cells, and a note upon the distinction between the two classes of cranial bones, according to their method of ossification, must also be mentioned.

The first published volume of the "Mikroskopische Anatomie," the first of the series of text-books which Prof. von Kölliker has produced, appeared in 1850. This volume was the second of the projected work, and contained a systematic account of the various organs, illustrated by a large series of original figures, many of which have been copied by subsequent writers continuously until the present day. Within two years this was followed by the celebrated "Handbuch der Gewebelehre des Menschen," translated into English, soon after its appearance, by Busk and Huxley, and again (from a subsequent edition) by Bowman.

These masterly works are remarkable not only for their complete treatment of adult histology, but for the way in which the development of each tissue is described, whenever such description is possible, as a means of elucidating its adult structure. The necessity for such a study of the whole history of a tissue, from the egg upwards, is emphatically dwelt upon in the introduction to the "Gewebelehre." Among points of interest in special sections must be mentioned the whole treatment of the derivatives of the ectoderm (other than the central nervous system), including the development of the sweat-glands, the sebaceous and the mammary glands, and a description of the structure, development and succession of hair, which seems, if an English reader may presume to judge, clearer in some respects than the description given in the *Zeitschr. f. w. Zoologie.* The relation between striped muscles and their tendons is described so as to confirm, by independent evidence, many of the statements of Bowman; and a special point of interest in the account of muscular tissues is the description of the branched muscle-plates of the heart and certain other organs, which had been described by Leeuwenhoek, although the description seems to have been forgotten until the rediscovery of the structures by Prof. Kölliker. The chapters on the bones and on the process of ossification describe the mode of addition to bone beneath the periosteum, and include a detailed description of the growth of bone, together with the ossification of membrane bones. These chapters, in which the results of Prof. von Kölliker's researches were shown to be in complete agreement with those conducted in this country by Sharpey, had an important influence upon scientific opinion. The formation of "membrane bones" had been asserted by Nesbitt in 1736, and since his time by Rathke, Jacobson, and others; but the researches of Sharpey in this country, and von Kölliker in Germany, gave the first intelligible account of the process from a histological point of view. The chapters dealing with the spleen, and with the organs of reproduction, must be mentioned; and the account of the ear is especially interesting, from the remarks upon the work of Corti, which had recently been carried out in Würzburg itself, and described in the third volume of the *Zeitschr. f. w. Zoologie*. It is characteristic of Prof. von Kölliker's scrupulous care that, although this work had been done so lately in his own University, he investigated the whole matter again for himself before writing the chapters dealing with it.

During the next ten years many important papers were published. In 1853 Kölliker paid a visit to Messina in the company of H. Müller; and after their arrival the two naturalists were joined by Gegenbaur. The visit has become celebrated among zoologists because of the investigations which were then begun. An account of the work done by each of the three naturalists is given in a joint paper (*Zeitschr. f. w. Zoologie*, Bd. iv.). Prof. Kölliker occupied himself chiefly with observations on the structure and development of hydrozoa; a sketch of his observations is given in the paper referred to, and his fuller quarto work on the Siphonophora was published in the following year, while a paper on the development of Pneumodermon, by Profs. Gegenbaur and Kölliker together, appeared in the *Zeitschr. f. w. Zoologie* for 1853.

Between this time and 1861 appeared a series of papers on the vertebrate notochord, in its relation to the adult vertebral column and to the skull. The investigations recorded in these papers constitute an important step in the detailed knowledge of the cranial notochord of the lower Fishes; while the description of the post-cephalic notochord leads to a classification of vertebral columns generally, based upon the degree to which the chordal sheath persists, and the share taken by this structure and by the "skeletogenous layer" of tissue outside it, in the formation of vertebral centra. The classification suggested was not accepted for many years; but it has lately been justified, and has formed the starting-point for important recent work. Of great value are the papers on the minute structure of the bony skeleton of adult fishes, published during the same period.

In 1861 the first edition of the "Entwicklungsgeschichte des Menschen u. d. höheren Thieren" was published. This edition is of interest not only from its scientific value, but because of its form. It is printed, after some revision, from the shorthand notes of a course of lectures delivered in Würzburg in 1860; and one can, therefore, gather from it some faint idea of the author's method and style of exposition. As usual, the book contains the result of several original investigations. Especially interesting are the lectures on the nature of meroblastic ova, and on segmentation of ova generally, and those relating to the development of the nervous system and the organs of special sense.

In the meantime the "Handbuch der Gewebelehre" had passed through three editions, and had been again translated into English. In 1863 the fourth edition appeared.

In 1864 Prof. v. Kölliker made his first statement of opinion upon questions raised by the publication of the "Origin of Species." While he accepted a doctrine of descent with modification as a statement of the way in which species had appeared upon the earth, he refused to admit that Natural Selection had been the agency by which the modification had been produced, and he argued against the assumption that "utility" in the Darwinian sense had determined the survival of varieties. He also urged the possibility that variations of considerable magnitude might suddenly appear and survive. In his subsequent writings he has maintained essentially the same position, postulating an *allgemeine Entwicklungsgesetz*, working independently of any utilitarian effect, which determines the evolution of living things. His conception of the process of evolution is, therefore, allied to that of Nägeli and his school rather than to that of Darwin himself.

From 1865–1875 appeared a series of papers dealing with the anatomy of Cœlenterates, and including the celebrated memoirs on the Alcyonaria (on *Renilla*, 1871; on the *Pennatulida*, 1872; on *Umbellula*, 1875). These papers, with their account of the remarkable dimorphism of the pennatulid zooids, and the mass of anatomical information they contain, are of fundamental importance to the student of the Alcyonaria. In 1879 the report on the *Pennatulida* collected during the voyage of H.M.S. *Challenger* was written.

A fifth edition of the "Gewebelehre" appeared in 1867.

Other work during these years deals with the development and resorption of bone, and with various points in the development of Vertebrates, especially of Mammals.

In 1876 the second edition of the "Entwicklungsgeschichte des Menschen u. d. höheren Thiere" was published. This edition is much larger than the first, and contains what Balfour, in his notice of the book calls "the most complete description which has yet beer given of the early development of the Bird and Mammal" (*Journ. Anat. Physiol.*, 1876). Especially interesting are the account of the development of the Fowl during the first three days of incubation; the statements concerning the origin of the heart and the Wolffian bodies; and the whole account of the early development of the Rabbit. The great number of original figures shows how largely the whole work is based on personal observation.

The considerable series of embryological and other papers published since that time cannot here be noticed. The little space remaining must be given to a mention of the last edition of the "Handbuch der Gewebelehre," of which the first volume was published in 1889. This is, as the author declares in the preface, rather an altogether new treatise than a new edition of an old one; and as usual every page shows how largely it is based on Prof. von Kölliker's own observations, whether original or in confirmation of results obtained by others. The first volume deals with the simple tissues, with the skin and its derivatives, with bone and with muscle. The second volume, which deals with the nervous system, appeared in parts from 1893 onwards.

The advance in knowledge since the fifth edition of the "Gewebelehre" is nowhere so striking as in the case of the central nervous system. The extended study of degeneration following upon injury, and the histological methods introduced by Erlich, Golgi, and others, have led to a rapid increase in knowledge concerning the distribution of nerve fibres both within the central nervous system and outside its limits; while an altogether new conception of the anatomical relations of ganglion cells has been established. Prof. von Kölliker was one of the first to recognise the importance of Golgi's work; and after visiting him in Padua in 1887, he adopted the new method in a series of investigations, some of which are described in seven papers published between 1889 and 1891 (cf. especially *Zeitschr. f. w. Zoologie*, vols. xlix. and li.), while the results of others appear for the first time in the second volume of the "Gewebelehre." This volume, of nearly 900 closely-printed pages, illustrated by 840 figures, most of which are as usual original, attempts nothing less than an outline of the comparative histology of the central nervous system in Vertebrata generally. The value of this enormous work arises not only from the new statements of fact which it contains, but from the systematic treatment of the mass of detail, constituting almost a new science, by a man who knows every fact referred to from his own observation.

This is not the place in which to speak of the numerous and well-merited honours conferred upon Prof. von Kölliker by the Government of his own country and by scientific societies and academies in almost every land. It is hoped that the foregoing imperfect outline of his work may give some idea of his position as one of the founders of modern systematic histology, and of his valuable services to embryology and comparative anatomy. Those who are best able to judge the imperfections of this sketch will be best able to understand the magnitude of the attempted task.

W. F. R. WELDON.

NITRO-EXPLOSIVES.

Explosifs Nitrés. By J. Daniel. Pp. viii + 235. (Paris: Gauthier-Villars et Fils.)

BY far the greater portion of this book is a fairly literal translation of Mr. Sanford's work on nitro-explosives, published in 1894. It suffers therefore, in many respects, from the same defects, though in others it is a decided improvement. Like the original it gives, for example, a description of all the gelatinised nitroglycerine preparations before giving the manufacture of the various nitro-cottons used in gelatinising them, which is, in several respects, an inconvenient arrangement. Like Sanford's work, it describes the manufacture of nitroglycerine and nitrocellulose in greater detail than is necessary for the use of a general chemist, and yet insufficiently so to serve as a complete guide to the manufacturer. The description of nitroglycerine is, however, a marked improvement on the original, and does not, for example, leave the reader in doubt as to whether nitroglycerine should be regarded as a nitric ether or not. It is, therefore, all the more surprising to find that M. Daniel, like Mr. Sanford, has apparently failed to grasp the great importance, from a theoretical as well as a practical point of view, of the fundamental difference between a nitric ether, on the one hand, and a true nitro-compound on the other. The former, although, when pure, perfectly stable at ordinary temperatures, decompose readily at, comparatively speaking, low temperature, and are one and all unstable at ordinary temperature in the presence of even minute traces of strong mineral acids as well as in the presence of many organic acids. Hence, in order to ensure the stability of a powder containing a nitric ether, it is absolutely essential not only to exclude all free acids, but also all compounds likely to become acid. Hence ammonium salts, like nitrate of ammonium, for example, may be used with perfect safety in admixture with a nitro-compound, such as dinitrobenzole in the manufacture of bellite, roburite, securite, &c., whereas the presence of this salt would be fatal in an explosive containing a nitric ether such as guncotton or nitroglycerine.

The preparation of the various nitro-celluloses, soluble and insoluble, is given very fully—too fully for the general chemist; but the author, in following too closely his original, fails to point out that the question of solubility or non-solubility of nitro-cotton is, in great measure, at least, one of method of manufacture and not one of degree of nitration, and also depends, in a measure, on the temperature of the ether alcohol mixture. This is very remarkable, seeing that the Cordite trial, during the progress of which this question of soluble and insoluble guncotton was very fully discussed, is several times alluded to in the work. The statement, found in both works, that the sulphuric acid in the manufacture of guncotton does not take part in the reaction, is, at least, open to doubt. The manufacture of celluloid, to which eight pages are devoted, however interesting in itself, should scarcely occupy so much space in a work of only 271 pages devoted to nitro-explosives.

A very useful addition of M. Daniel consists in a description of the physiological effects of nitroglycerine and dinitrobenzole. The baneful effects of this latter compound on the health of the workpeople employed in the manufacture of explosives containing it, was first clearly established by a small Departmental Committee of the Home Office, and it is curious to find it taken up by a Frenchman and omitted from the work of an Englishman.

Most of the more commonly used explosives are shortly, but sufficiently described; but the mistakes found in the original unfortunately reappear in the translation. Thus roburite never was a mixture of ammonium nitrate and chlorodinitrobenzole, but one of the former salt with chlorinated dinitrobenzole containing, at most, 2 per cent. of chlorine, a very different thing. This original roburite is no longer manufactured in England. M. Daniel also, like Mr. Sanford, gives what may be called the ideal composition of dynamite (25 per cent. kieselguhr and 75 per cent. nitroglycerine) as the ordinary one, whereas, as a matter of fact, commercial dynamite practically never contains 75 per cent. nitroglycerine, and almost always contains mineral matters besides kieselguhr.

As a further interesting addition by the translator may be mentioned the statement regarding the curious difference in the behaviour of frozen gelatine dynamite and blasting gelatine respectively, to shock or percussion, gelatine dynamite, when frozen, being, if anything, rather more sensitive to percussion than when unfrozen, while with blasting gelatine the reverse is the case. This is a point of some importance when these two explosives have to be dealt with in winter, and it is curious to note that this fact, like the baneful effects of dinitrobenzole, although first established in England, is not found in the English work, but appears in the French translation.

We must also raise our protest against the statement, repeated in the translation, that blasting gelatine, when ignited in the open, burns but does not explode; this is true only when the blasting gelatine is in relatively small quantities, or in an unfrozen condition. The burning of large quantities of blasting gelatine frequently ends in a violent explosion, and the burning of even a pound or two of the frozen material nearly always leads to explosion. This is one of those careless statements which, unfortunately, frequently lead to accidents.

As regards this portion of the work we should have been grateful to the author if he had given us a little more information as to the various explosives, propulsive as well as disruptive, used in the French army. We in England, foolishly perhaps, have few or no secrets in such matters; it is, in fact, one of the most difficult things imaginable to keep anything secret. In France they manage these things better, or at least differently, and we are still, many years after their introduction, ignorant of the exact nature of the powder and other explosives used by the French army. Any information on these points from M. Daniel would have met with our warmest appreciation.

The chapters on the analysis of explosives are practically a simple translation of Mr. Sanford on the same subject, and suffer from the same defects, and have the same excellencies as the original. Here we can only point out one more instance of want of care in the translator. M. Daniel, like Mr. Sanford, dries moist guncotton at 100° C. to estimate the proportion of water, a proceeding which every one who has tried it must know to be impossible.

One of the greatest, if not the greatest, advances made in the production of smokeless powder, consisting in their complete gelatinisation, whereby they are converted into hard non-porous masses which burn only on the surface, is scarcely hinted at in this work.

Lastly, the list of explosives given at the end of the work suffers from the same defect as did the similar list in Mr. Sanford's book, and several explosives are given, which from the nature of their constituents must be unstable, and therefore dangerous to keep, without a word of warning being added; such as, for example, ammonia dynamite (amidogene) and poudre au nitrate d'ammoniac, which latter contains two salts incompatible with each other, viz. nitrate of ammonium and chlorate of potassium.

In conclusion we welcome this book as a useful addition to our library, but cannot refrain from expressing a hope that Mr. Sanford may soon have an opportunity of giving us a second edition of his work, free from the mistakes and shortcomings of his own first edition as well as those in the French translation of the same.

A. D.

PSYCHICAL RESEARCH.

Studies in Psychical Research. By Frank Podmore, M.A., author of "Apparitions and Thought-Transference." Pp. xi + 458. (London: Kegan Paul, Trench, Trübner, and Co., 1897.)

MR. FRANK PODMORE'S "Studies in Psychical Research" is at once a critically sifted account of facts and the story of a movement. The facts, or alleged facts, concern spiritualism, poltergeists, thought-transference, telepathic hallucinations, ghosts, haunted houses, premonitions, previsions, secondary consciousness, impersonation, obsession, clairvoyance. The movement is the persistent transfer of the facts from the region of myth to the region of verified science. This movement is typified by the work of the Psychical Research Society, which, as Mr. Podmore in his opening chapter shows, was founded by competent persons for the special purpose of ascertaining whether the popular belief in certain phenomena had any basis in scientific evidence. Some ten years ago "Phantasms of the Living" set men thinking on these topics. The theories, as much as the facts there adduced, have stimulated reflection at every hand. Mr. Podmore now aims at placing in a simple form the critical result of twenty years' labour. He is lucid, exact and critical. He pushes no hypothesis except so far as the evidence seems to justify it. Even his favourite "telepathy" is offered as a "working hypothesis" chiefly because it is the smallest "draught upon the unknown."

In Chapter ii., Mr. Podmore gives an account of "spiritualism as a popular movement." The testimony is, he finds, more "copious than cogent." The high-water mark in the scientific observation of spiritualism was Mr. Crookes' experiments with Home and others. The facts narrated in this chapter are subjected to a thorough criticism in Chapter iii. The two chapters are in admirable contrast—the facts of the one melting away under the scrutiny of the other. "Perhaps they heard Dr. Hodgson and the new generation knocking at the door" (p. 81). As the scientific search-light grows stronger, the marvels grow smaller and less numerous. Yet, negative conclusions notwithstanding, the year 1894 witnessed the performances of Eusapia Palladino. In regard to Mr. Crookes and his experiments, Mr. Podmore is becomingly respectful; but the best critical faculty may be taken in by trickery (*e.g.*, p. 111, "Miss Cook, Miss Fay, and other mediums with whom Mr. Crookes experimented"). Mr. Podmore concludes: "Unless and until some feat is performed which fraud cannot explain, the presumption that fraud is the all-sufficient cause remains unshaken" (p. 124). The "unless" and "until" rest with spiritualism, and were it for this result alone, the S.P.R. has not worked in vain. The poltergeists (Chapter v.) are, in brief, demonstrated trickery. In Chapter vi., Madame Blavatsky and her theosophy are, after a narrative that leaves no doubt, dismissed with a *decipiantur*. The grosser theosophy, like the grosser spiritualism, now receives its "unless" and "until." In Chapter vii. ("experimental thought-transference"), however, we are on more solid ground. Much of the material reminds one of Mr. Podmore's former book. He states the cases, and lets the reader "judge for himself" (p. 199). But this assumes that all the necessary data are supplied—a large assumption. Fraud, at least conscious fraud, may be held as excluded by the conditions, which have all the seeming of true scientific methods. Agent and percipient are strictly watched and guarded. The most obvious sources of error are forestalled. Silent choosing of cards, and the like, obviate any risk of suggestion by normal channels—the purpose being to isolate the fact of the actuality of transference. How difficult it is so to isolate the fact may be guessed from the somewhat extraordinary results of Hansen and Lehman with "involuntary whispering." Their results, as even Parish (" Hallucinations and Illusions," p. 320) allows, are not necessarily conclusive against any experiments recorded by the Society, but they show how extremely difficult it is to establish, in this kind, the ordinary conditions of strict physiological experiment. But apart from these possible errors, the accounts seem somewhat wanting everywhere in psychological "context." This is specially true of the telepathic hallucinations (Chapter viii.), where, once more, the "method of agreement" predominates. A detached mental fact, when once it is subjectively assigned to so simple a cause as telepathic agency, is apt to escape from its mental current. The immediate association may be forgotten instantaneously, or pass utterly unrecognised. It is a more distingushed and impressive thing to have thoughts inspired by an outside source than following in the orthodox way of contiguous or similar association, This defect is very obvious in many of the cases (*e.g.*, p. 245). Several of the recorders of hallucinations state that this is their only experience of the kind. This seems to be a fairly complete proof of bad self-observation. It is true that a well-defined hallucination is, in the ordinary acceptation, a relatively uncommon experience; but Mr. Podmore admits (p. 244) that dreams and waking hallucinations differ, not in essence, but in the accident of sleeping or waking. Obviously, the recorders of those isolated experiences do not take hallucinations in this wide sense. Consequently, a doubt arises as to their competence to record the psychological context. Further, if dream and hallucination are thus to play into each other, the long arm of coincidence is made yet longer, and telepathy, while the marvel of it is none the less, becomes all the more difficult to establish. Mr. Podmore's exposition is so persuasive, and he obviously holds in reserve so much more information, that one hesitates to express doubts crudely. Yet he seems to allow too little for the "submerged dream," for the coincidences that (in excess of chance) must result from the general similarity of mental venue of friends or relatives or acquaintances. He seems to accept too easily the "veridicality" (Parish) of the alleged coincidence, for in some of his instances the precise nature of the fact is just what escapes. Thus the "come to me" of case iv., p. 245, and of her telepathic correlate, may have been, in each case, the end of a normal associational sequence. But the data are not enough to settle the point. The same difficulty in fixing evanescent processes of association has been pointed out by Prof. W. James (*Psych.*, ii. 83), and by Miss Helen Dendy (*Mind*, N.S., 7, 370), in connection with subconscious processes. Many disputes might be raised on the time that hallucinations take to emerge after the alleged telepathic message has been sent, and the suggestions to meet the difficulty are sometimes more "copious than cogent."

Ghosts (Chapter ix.) and haunted houses (Chapter x.) are investigated only to be discredited, and Mr. Podmore then concentrates himself on a very important subject, "secondary consciousness," which, in its turn, is found not proven as a coherent system of ideas. That is, he does not regard as sufficient the argument that contends for separate subconscious personality acting in a hidden way alongside of the normal supraliminal consciousness. The ordinary doctrine of subconscious storage of memories in the nerve centres is considered enough. These subconscious personalities are "manufactured articles," and indicate rather the possible education of special centres for special ends than any fresh revelation of "transcending" consciousness. Once or twice in this book we seem to catch a tendency to meet popular explanations half-way (*e.g.*, p. 378), but there is proof enough that Mr. Podmore has a firm hold of positive psychology, and his fair-minded restatements of somewhat inflated doctrines are excellent instances of an investigator's patience. Although he seems to give too little to "veridicality" of coincidence, too little to mental venue, the submerged dream, the psychological context, dissociation of consciousness, the state of health and the "pathologic" element generally, yet he presents a residuum that will compel explanation, and that is at once the final justification of the Society he represents and of his elegantly narrated studies.

W. LESLIE MACKENZIE.

BRITISH EAST AFRICA.

Travels in the Coastlands of British East Africa and the Islands of Zanzibar and Pemba. By W. W. A. FitzGerald. Pp. xxiv + 774. Maps and illustrations. (London: Chapman and Hall, 1898.)

THIS handsome volume deals with a part of East Africa which, in spite of its apparent accessibility, has down to the present day remained surprisingly little known to the world at large. In the general rush to explore the more remote recesses of the African continent, many of the immediate coastlands have been left comparatively unheeded, and nowhere, perhaps, has this been more the case than in the northern districts of the British sphere along the East African coast. The present book, therefore, fills a decided blank in the literature of the continent.

Commissioned in 1891 by the late British East Africa Company to study the agricultural capabilities of the coastal zone falling within its sphere of operations, Mr. FitzGerald during the space of two years traversed that region in all directions, from Mombasa in the south to Port Durnford in the north, besides extending his inquiries to the two largest islands lying off the coast. He was thus able to gain an intimate acquaintance with the country, and the record of his experiences possesses a solid value, which fully atones for the slight delay noticeable in its presentation to the public. With the aid of the numerous illustrations, all of them reproductions of photographs, we gain a vivid idea of the characteristic features of the East African coastlands—their labyrinth of creeks and backwaters, their miles of waterless scrub, or groves of *Hyphæne* palms, perhaps the most typical tree of a large part of their area. In the more northern districts traversed, on the borders of the Galla territories south of the Jub River, Mr. FitzGerald was actually breaking new ground, and the result of his journeys has been to modify considerably our ideas of the general character of the country, by showing that the vegetation is in parts of the interior much more luxuriant than has been generally supposed. Throughout his residence in the country he was in close touch with the native inhabitants, for whom he shows a genuine liking, and of whose life and customs many interesting details are given.

It is, however, in the treatment of the agricultural capabilities of the country that the chief value of the book will be found to exist. During the whole of his travels, the author devoted his constant attention to this subject, so that the information collected was unusually varied and complete, and the picture presented of the various aspects of life in the African "shambas" (plantations) is full of interest. The general reader may, perhaps, find the mass of details on agricultural subjects hardly to his taste; but to all who require a trustworthy guide to the capabilities of British East Africa in such matters, the book will prove of sterling value. A special weight attaches to Mr. FitzGerald's views from his wide experience of agriculture as carried out in Southern India, and he has done good service in calling attention to what he considers the great possibilities which lie before British enterprise in this direction in the East African coastlands. Much of the country is, in his opinion, eminently adapted for the growth of cotton and coco-nuts, while other products, such as fibre-plants and india-rubber, would also repay attention. Much apposite information regarding all these, drawn from sources not widely accessible, is printed in the form of appendices.

In the second part of the book, Mr. FitzGerald enlarges upon his report, made to the Directors of the East Africa Company in 1892, on the agricultural capabilities of Zanzibar and Pemba Islands. He treats exhaustively of the clove cultivation there carried on, describing minutely the requirements of the clove tree, the present methods employed in its culture, and various improvements which should be introduced. He also treats of other products to which attention should be paid, in order that the prosperity of the islands may not depend, as it does at present, on one crop alone. In the case of Zanzibar the ground has, it is true, been already covered to some extent by Dr. Baumann's useful monograph, but it is valuable to have also a professed agriculturist's views on the subject, which the German traveller approached rather from the standpoint of a scientific geographer. A point of special interest at the present time, when the slavery question seems to await its final solution, is the discussion of the sources of labour supply, into which Mr. FitzGerald enters fully. He holds that the introduction of Indian coolies will afford the best hope of a satisfactory solution of the problem.

A useful feature in the book is the lavish supply of maps (compiled by Mr. Reeves, of the Royal Geographical Society), in which the whole of the author's routes can be followed, and which contain material not hitherto published. The index—also a point of special importance in a work intended, like the present, to be used for reference—is particularly full and well arranged.

OUR BOOK SHELF.

Notes on Observations. By Sydney Lupton, M.A. Pp. ix + 124. (London: Macmillan and Co., 1898.)

THE sub-title of this book describes the contents as "an outline of the methods used for determining the meaning and value of quantitative observations and experiments in physics and chemistry, and for reducing the results obtained." It is very important that students of science should be logical in their arguments and sound in their conclusions; and Mr. Lupton's concise description of the methods which must be followed before a scientific law or any general proposition can be established conduce to this end. The opening chapters of the book remind us of Huxley's inspiring little "Introductory" Science Primer. After these more or less metaphysical, but distinctly serviceable, statements as to ideas, premisses, and laws, come short chapters on units, averages, interpolation, the law of error, the method of least squares, the expression of results by graphical and by empirical methods, and many other subjects of interest to all who are engaged in quantitative physical and chemical experimentation. The treatment is but brief in most cases, and questions involving higher mathematics are not introduced. Sufficient is said, however, to show students how to apply to his own results the methods described; and for those who desire to go into the subjects more thoroughly, a list of references to standard works is appended to each chapter.

The book should find a place in the library of every physical and chemical laboratory, and all students of the laws and phenomena of nature should make themselves familiar with the principles described; for they will thereby learn the methods of sound reasoning, and be instructed in the art of computation for the purposes of science.

Prospecting for Minerals: a Practical Handbook for Prospectors, Explorers, Settlers, and all interested in the Opening-up and Development of New Lands. By S. Herbert Cox. Pp. xi + 239. With illustrations. (London: Charles Griffin and Co., Ltd., 1898.)

THIS little work forms the first volume of a new series of handbooks to be edited by Prof. Grenville Cole, and issued under the title of "The New Land Series." Although it can hardly be said that the title of the series is very happily chosen, it will be immediately admitted that the object of the series is distinctly good. The explorer or the settler in any new country needs, in most cases, some instruction as to the best means of discovering and developing its resources. Of all pioneers of civilisation, the mineral prospector is the most likely nowadays to lead the way; and the first volume of the series is, therefore, appropriately devoted to the subject of prospecting. The preparation of the work has been entrusted to Mr. Herbert Cox, a well-known mining engineer in London, who has in his day travelled widely and seen much of mines and minerals. Those who know the character of his professional work will feel no doubt as to his ability to lead the prospector in the way he should go; and an examination of the volume shows that its value is beyond dispute. Mr. Cox has furnished the prospector with a portable guide, which, while essentially practical, contains sufficient geology and mineralogy to explain the scientific principles on which the search for minerals should be based. The rough-and-ready prospector may probably think that the science is too much in evidence, and may grow impatient as he turns over pages about such things as "anhydrous silicates of lime and alumina and their crystallographic allies." But the explorer should clearly understand that, notwithstanding occasional accidents, the most trustworthy results in the search for minerals will, in the long run, be reached by that man who brings to bear upon his work the widest range of scientific knowledge.

The Process of Creation Discovered; or, the Self-evolution of the Earth and Universe by Natural Causes. By James Dunbar. Pp. viii + 290. (London: Watts and Co., 1898.)

To review this book would be to give prominence to a volume every page of which exemplifies the dangerous character of a little knowledge. We will merely remark that the author finds himself at variance with very many physical facts and theories, disbelieves the results of spectroscopic analysis applied to celestial bodies, and regards the solar photosphere as a deep ocean of water. According to his theory of inorganic evolution, "the only elements employed or necessary in the formation of the sun, solar system, and universe are those composing atmospheric air and water." Students of science may be left to form their own opinion upon a book containing an assertion of this kind.

Domestic Science Readers. Book vii. By Vincent T. Murché. Pp. 298. (London: Macmillan and Co., 1898.)

The subject of domestic economy is taught in the various standards of our elementary schools; and this book is adapted to supply girls in the highest standards with the information which the Education Department expects them to possess. The laws of health, infant management, common ailments and their remedies, common accidents, infectious diseases, and management of the sick-room are the subjects dealt with in the six parts of the book, and they are treated in a very clear and instructive manner. Mr. Murché knows how to interest the young readers for whom he writes, and this little school book will doubtless be as successful as the others of which he is the author. Moreover, the pupils who read the book will receive a large amount of sensible advice which will give them a sound understanding of the laws of health, and thus be of service to them and to future generations.

A Course in Mechanical Drawing. By John S. Reid. Pp. 128. (New York: John Wiley and Sons. London: Chapman and Hall, 1898.)

Teachers of the elements of mechanical drawing to students in marine, electrical, railway, and mechanical engineering will find that this book contains a concise statement of the essential principles of the subject. In the five chapters, the author deals with drawing instruments, geometrical drawing, or the use of the instruments, conventional methods of drawing used by draughtsmen, lettering and figuring, and orthographic projection. The author is instructor in mechanical drawing and designing in Sibley College, Cornell University, and his experience has enabled him to produce a useful work.

Flower Favourites, their Legends, Symbolism and Significance. By Lizzie Deas. Pp. viii + 229. (London: George Allen, 1898.)

Many pretty stories concerning common flowers have been collected from folk-lore and classic myths by the author, and are presented here in an attractive setting. The nursery traditions and love legends referring to flowers and flower-names are numerous and interesting enough, but very little attention is devoted to the subject of "plants and flowers in their widest relationships" referred to in the preface.

LETTER TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Röntgen Rays and Ordinary Light.

I quite agree with the physical principles in Lord Rayleigh's article on "Röntgen Rays and Ordinary Light" in Nature of April 28, and think that the difference between us is one of terminology. I am accustomed to restrict the word wave to disturbances in which the harmonic character is well developed, and not to use it in physics in the sense in which it is used in the phrase "a wave of enthusiasm." It would never have occurred to me to speak of a disturbance localised in a thin shell as a wave of short wave-length. I should speak of it as a pulse, and though such pulses can of course be resolved by Fourier's theorem into trains of waves, yet it seems to me that when a simple pulse is so resolved (except for some special purpose), there is a loss of clearness both in expression and conception analogous to that which would occur if we regarded a straight line as an aggregate of harmonic curves.

The term pulse has the advantage that it suggests the fundamental property of the Röntgen rays, that their action on matter in their path is an *impulsive* action, *i.e.* that the time constant of the disturbance (the time taken by the pulse to pass over a point) is small compared with the time constant of the system in their path (the time of vibration of the molecules).

I am not aware that I have ever regarded these pulses as possessing any physical property which would be inconsistent with the physical properties of the constituents into which they can be resolved by Fourier's theorem. Personally I should expect that if a train of waves of wave-length λ were refracted, a pulse of thickness λ would be refracted too, and if the thickness of these pulses were of the order of the wave-length of ordinary light, that the Röntgen rays would be like ordinary light.

I believe the Röntgen rays to be pulses rather than waves of small wave-length, not because I think the properties of the latter would be different from those of Röntgen rays as far as we know them, but because electromagnetic theory shows that pulses, and not short waves, are produced by the impact of kathode rays. J. J. Thomson.

Cambridge, April 30.

SLEEP, AND THE THEORIES OF ITS CAUSE.

The theory of the origin of sleep which has gained the widest credence is the one that attributes it to anæmia of the brain. It has been shown by Mosso, and many others, that in men with defects of the cranial wall the volume of the brain decreases during sleep. At the same time, the volume of any limb increases as the peripheral parts of the body become turgid with blood. In dogs, the brain has been exposed, and the cortex of that organ has been observed to become anæmic during sleep. It is a matter of ordinary observation that in infants, during sleep, the volume of the brain becomes less, since the fontanelle is found to sink in. It has been supposed, but without sufficient evidence to justify the supposition, that this anæmia of the brain is the cause and not the sequence of sleep. The idea behind this supposition has been that, as the day draws to an end, the circulatory mechanism becomes fatigued, the vasomotor centre exhausted, the tone of the blood vessels deficient, and the energy of the heart diminished, and thus is the circulation to the cerebral arteries lessened. By means of a simple and accurate instrument (the Hill-Barnard sphygmometer), with which the pressure in the arteries of man can be easily reckoned, it has been recently determined that the arterial pressure falls just as greatly during bodily rest as during sleep. The ordinary pressure of the blood in the arteries of young and healthy men averages 110–120 mm. of mercury. In sleep, the pressure may sink to 95–100 mm.; but if the pressure be taken of the same subject lying in bed, and quietly engaged on mental work, it will be found to be no higher. By mental strain or muscular effort, the pressure is, however, immediately raised, and may then reach 130-140 mm. of mercury. It can be seen from considering these facts that the fall of pressure is concomitant with rest, rather than with sleep. As, moreover, it has been determined on strong evidence that the cerebral vessels are not supplied with vasomotor nerves, and that the cerebral circulation passively follows every change in the arterial pressure, it becomes evident that sleep cannot be occasioned by any active change in the cerebral vessels. This conclusion is borne out by the fact that to produce in the dog a condition of coma like to sleep, it is necessary to reduce, by a very great amount, the cerebral circulation. Thus, both carotids and both vertebral arteries can be frequently tied at one and the same time without either producing coma or any very marked symptoms. The circulation is, in such a case, maintained through other channels, such as branches from the superior intercostal arteries which enter the anterior spinal artery. While total anæmia of the brain instantaneously abolishes consciousness, partial anæmia is found to raise the excitability of the cortex cerebri By estimation of the exchange of gases in the blood which enters and leaves the brain, it has been shown that the consumption of oxygen and the production of carbonic acid in that organ is not large. Further, it may be noted that the condition of anæsthesia is not in all cases associated with cerebral anæmia. Thus, while during chloroform anæsthesia the arterial pressure markedly falls. Such is not the case during anæsthesia produced by ether or a mixture of nitrous oxide and oxygen.

The arterial pressure of man is not lowered by the ordinary fatigue of daily life. It is only in extreme states of exhaustion that the pressure may be found decreased when the subject is in the standing position. The fall of pressure which does occur during rest or sleep is mainly occasioned by the diminished rate of the heart. The increase in the volume of the limbs is to be ascribed to the cessation of muscular movement, and to the diminution in the amplitude of respiration. The duty of the heart is to deliver the blood to the capilliaries. From the veins the blood is, for the most part, returned to the heart by the compressive action of the muscles, the constant change of posture and by the respiration acting both as a force and suction pump. All of these factors are at their maximum during bodily activity, and at their minimum during rest. On exciting a sleeper by calling his name, or in any way disturbing him, the limbs, it has been recorded, decrease in volume while the brain expands. This is so because the respiration changes in depth, the heart quickens, the muscles alter in tone, as the subject stirs in his sleep in reflex response to external stimuli. Considering all these facts, we must regard the fall of arterial pressure, the depression of the fontanelle, and the turgescence of the vessels of the limbs as phenomena concomitant with bodily rest and warmth, and we have no more right to assign the causation of sleep to cerebral anæmia than to any other alteration in the functions of the body, such as occur during sleep.

We may well here summarise these other changes in function.

(1) The respiratory movement becomes shallow and thoracic in type.

(2) The volume of the air inspired per minute is lessened by one-half to two-thirds.

(3) The output of carbonic acid is diminished by the same amount.

(4) The bodily temperature falls.

(5) The acidity of the cortex of the brain disappears.

(6) Reflex action persists; the knee jerk is diminished, pointing to relaxation in tone of the muscles; consciousness is suspended.

Analysing more closely the conditions of the central nervous system, it becomes evident that, in sleep, consciousness alone is in abeyance. The nerves and the special senses continue to transmit impulses, and to produce reflex movements. If a blanket, sufficiently heavy to impede respiration, be placed upon the face of a sleeping person, we know that it will be immediately pushed away. More than this, complicated movements can be carried out: the postillion can sleep on horseback; the punkah-wallah may work his punkah, and at the same time enjoy a slumber; a weary mother may sleep, and yet automatically rock her infant's cradle. Turning to the histories of sleep-walkers, we find it recorded that, during sleep, they perform such feats as climbing slanting roofs, or walking across dangerous narrow ledges and bridges. The writer knew of the case of a lad, who, when locked into his room at night to prevent his wandering in his sleep, climbed a partition eight to ten feet in height which separated his sleeping compartment from the next, and this without waking.

The brain can carry out not only such complicated acts as these, but it has been found to maintain during sleep its normal inhibitory control over the lower reflex centres in the spinal cord.

Thus, in sleeping dogs, after the spinal cord has been divided in the dorsal region, reflexes can be more easily evoked from the lumbar than from the cervical cord, because the former is freed from the inhibitory control of the brain.

The strength of stimulus necessary to pass the threshold of consciousness, and to produce an awakening, has been measured in various ways. It has been determined that it takes a louder and louder sound, or a stronger and stronger electric shock to arouse a sleeper during the first two or three hours of slumber; after that period, the sleep becomes lighter, and the required stimulus need be much less.

The alternative theories, which have been suggested to account for the onset of sleep, may be classed as chemical and histological.

In relation to the first, it has been suggested that if consciousness be regarded as dependent upon a certain rate of atomic vibration, it is possible that this rate depends on a store of intramolecular oxygen, which, owing to fatigue, may become exhausted; or it may be supposed that alkaloidal substances may collect as fatigue products within the brain, and choke the activity of that organ. Against this theory may be submitted the facts that monotony of stimulus will produce sleep in an unfatigued person, that over-fatigue, either mental or bodily, will hinder the onset of sleep, that the cessation of external stimuli by itself produces sleep. As an example of this last, may be quoted the case recorded by Strumpel of a patient who was completely anæsthetic save for one eye and one ear, and who fell asleep when these were closed. Moreover, many men possess the power, by an effort of will, of withdrawing from objective or subjective stimuli, and of thus inducing sleep.

The histological theories of sleep are founded on recent extraordinary advances in the knowledge of the minute anatomy of the central nervous system, a knowledge founded on the Golgi and methylene-blue methods of staining. It is held possible that the dendrites or branching processes of nerve cells are contractile, and that they, by pulling themselves apart, break the association pathways which are formed by the interlacing or synapses of the dendrites in the brain. Ramon y Cajal, on the other hand, believes that the neuroglia cells are contractile, and may expand so as to interpose their branches as insulating material between the synapses formed by the dendrites of the nerve cells. The difficulty of accepting these theories is that nobody can locate consciousness to any particular group of nerve-cells. Moreover, the anatomical evidence of such changes taking place is at present of the flimsiest character.

If these theories be true, what, it may be asked, is the agency that causes the dendrites to contract or the neuroglia cells to expand? Is there really a soul sitting aloof in the pineal gland, as Descartes held? When a man like Lord Brougham can at any moment shut himself away from the outer world and fall asleep, does his soul break the dendritic contacts between cell and cell; and when he awakes, does it make contacts and switch the impulses evoked by sense stimuli on to one or other tract of the axons, or axis cylinder processes, which form the association pathways? Such an hypothesis is no explanation: it simply puts back the whole question a step further, and leaves it wrapped in mystery. It cannot be fatigue that produces the hypothetical interruptions of the dendritic synapses and then induces sleep, for sleep can follow after fatigue of a very limited kind. A man may sleep equally well after a day spent in scientific research, as after one spent in mountain-climbing, or after another passed in idling by the sea-shore. He may spend a whole day engaged in mathematical calculation, or in painting a landscape. He fatigues—if we admit the localisation of function to definite parts of the brain—but one set of association tracts, but one group of cells, and yet, when he falls asleep, consciousness is not partially, but totally suspended.

We must admit that the withdrawal of stimuli, or their monotonous repetition, are factors which do undoubtedly stand out as primary causes of sleep. We may suppose, if we like, that consciousness depends upon a certain rate of vibration which takes place in the brain structure. This vibration is maintained by the stimuli of the present, which awaken memories of former stimuli, and are themselves at the same time modified by these. By each impulse streaming into the brain from the sense organs, we can imagine the structure of the cerebral cortex to be more or less permanently altered. The impulses of the present, as they sweep through the association pathways, arouse memories of the past; but in what way this is brought about is outside the range of explanation. Perhaps an impulse vibrating at a certain rate may arouse cells or fibrils tuned by past stimuli to respond to this particular rate of vibration. Thus may be evoked a chain of memories, while by an impulse of a different rate, quite another set of memories may be started. Tracts of association are probably formed in definite lines through the nervous system, as during the life of a child repeated waves of sense-impulses beat against and overcome resistances, and make smooth pathways here and there through the brain structure. Thus may be produced growth of axons in certain directions, and synapses of this cell with that. If the same stimulus be often repeated, the synapses between groups of cells may become permanent. A memory, a definite line of action which is manifested by a certain muscular response, may thus become structurally fixed. If the stimulus be not repeated, the synapses may be but temporary, and the memory fade as the group of cells is occupied by a new memory of some more potent sense stimulus. Many association tracts and synapses are laid down in the central nervous system when the child is born. These are the fruits of inheritance, and by their means, we may suppose, instinctive reflex actions are carried out.

So long as the present stimuli are controlled by past memories and are active in recalling them, so long does consciousness exist, and the higher will be the consciousness the greater the number and the more intense the character of the memories aroused. We may suppose that when all external stimuli are withdrawn, or the brain soothed by monotony of gentle repetition, and when the body is placed at rest, and the viscera are normal and give rise to no disturbing sensations, consciousness is then suspended, and natural sleep ensues. Either local fatigue of the muscles, or of the heart, or ennui, or exhaustion of some brain centre usually leads us to seek those conditions in which sleep comes. The whole organism may sleep for the sake of the part. To avoid sleeplessness, we seek monotony of stimulus either objective or subjective. In the latter case, we dwell on some monotonous memory picture, such as sheep passing one by one through a gap in the hedge. To obtain our object, we dismiss painful or exciting thoughts, keep the viscera in health, so that they may not force themselves upon our attention, and render the sense-organs quiet by seeking darkness, silence and warmth. L. H.

A PROPOSED REVOLUTION IN NAUTICAL ASTRONOMY.

DURING the last two years a movement has been set on foot, which seems likely to be attended by somewhat important results in the simplification of the formulæ of astronomical navigation for every-day use. Any one who has looked even cursorily into a text-book of navigation of the Raper type, can hardly fail to have been impressed by the multiplicity and variety of the precepts, and can easily understand how complicated the various rules must appear to the unlearned men, upon whom, for the most part, the daily routine of practical navigation at sea must devolve.

And the difficulty of comprehending and putting into practice the various rules, is undoubtedly increased by the fact that at one time or another all the trigonometrical functions of an angle are brought into play. Sines, cosines, tangents, cotangents, secants and cosecants, versed sines and half-versed sines, all make their appearance, adding to the bewilderment of the unskilled computer, and introducing the liability to take a required function from a wrong column as a very frequent source of error.

Nautical astronomy, for the most part, may be regarded as simply a practical application of the formulæ employed in the solution of spherical triangles, so that the object to be attained by those who would simplify the various problems, is to devise a system of formulæ in logarithmic shape, which, without materially adding to the amount of arithmetic employed, should introduce but one function of an angle throughout, such as the sine, the cosine, or the tangent. In the verbal precepts, into which, for the benefit of those possessing no knowledge of mathematics, the formulæ have to be translated, the simple word "logarithm" would then take the place of "log sine," "log cosine," &c., and a single table of a few thousand logarithms would do the work formerly effected by the aid of a large collection of different tables.

To M. E. Guyou, an officer of the French navy, belongs the credit of having first devised such a system. As far back as the year 1885 he published in a small pamphlet entitled "Tables de Poche," methods of finding hour angle and azimuth of a heavenly body by means of a single table of logarithms. During the next ten years he employed himself in further researches, and early in 1896 there appeared in connection with the "Annales Hydrographiques," published periodically by the Hydrographic Department of the French navy, a more exhaustive account of his methods, with a special arrangement of the required table, intended to enable his processes to be more easily and effectively carried out.[1]

The particular table employed by M. Guyou does not give logarithms for one of the ordinary functions of the

[1] "Les problèmes de Navigation et la Carte Marine. Types de calcul et tables complètes." Par M. le capitaine de frégate E. Guyou, Membre de l'Académie des Sciences. (Paris: Imprimerie Nationale, 1895.)

angle, but is a table which is made use of daily in the calculations which belong to Mercator sailing, and which is consequently to be found in every collection of nautical tables. It is known as the table of "meridional parts," or, as the French call it, "*latitudes croissantes*." The meridional parts for a given latitude are defined by some writers as "the value in minutes of a great circle of the line on the Mercator's chart, into which the true difference of latitude is expanded."

For a given latitude l the meridional parts represent the sum of the series

$$\sec 0' + \sec 1' + \sec 2' + \sec 3' + \ldots + \sec (l^{\circ} - 1')$$

which is found by the integral calculus to be

$$r \log_e \tan \left(45^{\circ} + \frac{l}{2}\right)$$

or

$$\frac{10800}{\pi} \log_e \tan \left(45^{\circ} + \frac{l}{2}\right)$$

when r is expressed in minutes.

In the table of meridional parts we have then a series of logarithms to the base $e^{\frac{\pi}{10800}}$, which has been found to lend itself in a remarkable manner to the purpose which we have in view.

It should be mentioned here that M. Guyou's general method is to deduce his formulæ from a study of the properties of the curves of equal altitude on a Mercator's chart. To other writers, especially in Italy, where considerable attention has been bestowed upon the new formulæ, it has appeared more satisfactory, while accepting the expressions, to deduce them directly from fundamental trigonometrical formulæ.

Shortly before the issue of M. Guyou's second work there was published, in the numbers of the *Nautical Magazine* for November and December 1895, a system of formulæ, for the solution of all the ordinary problems of nautical astronomy, by the aid of this table of meridional parts alone, the general principle adopted being to break up the spherical triangle, or "triangle of position," as it is generally called in nautical astronomy, into two right-angled triangles, and thus obtain expressions which, containing three terms only, would be more manageable than the general formulæ involving four terms.

This treatment of the subject was based upon certain easily established lemmas, the most important of which may be thus stated. (The abbreviation MP will be adopted for meridional parts throughout.)

$$\mathrm{MP}(180^{\circ} - \theta) = \mathrm{MP}(\theta) \quad \ldots\ldots \quad (1)$$

$$\mathrm{MP}(-\theta) = -\mathrm{MP}(\theta) \quad \ldots\ldots\ldots \quad (2)$$

If

$$\tan x = \sin \theta,$$

then will

$$\mathrm{MP}(2x) = 2\mathrm{MP}(\theta) \quad \ldots\ldots\ldots \quad (3)$$

If

$$\tan a = \tan b \tan c \ldots$$

then will

$$\mathrm{MP}(2a - 90^{\circ}) = \mathrm{MP}(2b - 90^{\circ}) + \mathrm{MP}(2c - 90^{\circ}) \quad . \quad (4)$$

With regard to (1) it may be stated that from the form of the expression

$$\mathrm{MP \ for \ lat} \ l^{\circ} = r \log e \tan \left(45^{\circ} + \frac{l^{\circ}}{2}\right),$$

the meridional parts in the first instance have reference to angles in the first quadrant only. The lemma enables us to pass to angles in the second quadrant.

Similarly by lemma (2) we can introduce negative angles also.

The result involved in (3) is exceedingly important, for it follows from this that if we have a logarithmic formula connecting the sines and cosines of parts of a spherical triangle, we may pass by means of auxiliary angles to other logarithmic formulæ, involving only the meridional parts of the angles employed, and that not only for right-angled and quadrantal triangles, as in the *Nautical Magazine*, but for any spherical triangle whatever.

As an example we may take one of the family of formulæ which express a function of an angle of a spherical triangle in terms of functions of the sides, supposed known. These expressions are perhaps, from a navigator's point of view, the most important which spherical trigonometry presents; for in the problem of finding the hour angle of a body, and thence the longitude of the place, such a formula may have to be brought into requisition on board a fast steam-ship as many as four or five times in the course of twenty-four hours. And while many of the problems of navigation may be, to some extent, "dodged" or evaded by the use of some of the many tables which ingenious persons have devised, there is no getting away from the hour-angle problem, because in that case the necessary degree of accuracy is more minute than any table of reasonable size could be expected to afford, unless we are content to spend more time and trouble in interpolating for variations in the values of the elements from the arguments given in the tables, than would suffice for the actual calculation by logarithms.

Let us assume that in the spherical triangle A B C we have to deal with the expression

$$\tan \frac{A}{2} = \sqrt{\frac{\sin (s - b) \sin (s - c)}{\sin s \sin (s - a)}}.$$

Assume that

$$\sin (s - b) = \tan x \qquad \sin s = \tan w,$$
$$\sin (s - c) = \tan y \qquad \sin (s - a) = \tan z.$$

So that

$$\tan \frac{A}{2} = \sqrt{\frac{\tan x \tan y}{\tan w \tan z}}.$$

By lemma (3) we have

$$\mathrm{MP}(2x) = 2\mathrm{MP}(s\text{-}b),$$

and so on for y, w, z; a system of equations which will determine $2x$, $2y$, $2w$, $2z$.

Then by lemma (4)

$$\mathrm{MP}(A - 90^{\circ}) = \tfrac{1}{2}\{\mathrm{MP}(2x - 90^{\circ}) + \mathrm{MP}(2y - 90^{\circ}) - \mathrm{MP}(2w - 90^{\circ}) - \mathrm{MP}(2z - 90^{\circ})\},$$

whence A is readily determined.

The formula here established is only given as an illustration of the ease with which by the aid of lemma (3) we may pass from a sine or cosine formula to one involving meridional parts only by the simplest possible transformations.

The processes deduced by M. Guyou from the curves of altitude upon the Mercator's chart are probably somewhat shorter, and more likely, therefore, to be adopted for general use. His methods of procedure however, although, as has been well said of them by an Italian critic, "of high scientific interest for their originality and rigorous analysis," may be found somewhat subtle and difficult to follow by any but expert mathematicians. At all events, although, as has been said, the Guyou formulæ were received in Italy with much favour, mathematicians in that country lost no time in setting to work to establish them upon a basis purely trigonometrical.

An interesting article in the *Rivista Marittima* (Rome) for January 1897, by Signor P. L. Cattolica, "Capitano di corvetta," gives a summary of the work done in 1896 by Signor Molfino and other writers, whence it appears that the principal Guyou formulæ may be deduced with little difficulty from the well-known Napier's analogies as follows.

Let us suppose, as before, that in a spherical triangle the three sides a, b, c being given, it is required to determine the angles A, B.

We have

$$\tan\frac{a+b}{2} = \frac{\cos\frac{A-B}{2}\tan\frac{c}{2}}{\cos\frac{A+B}{2}}$$

$$= \frac{\cos\frac{A}{2}\cos\frac{B}{2} + \sin\frac{A}{2}\sin\frac{B}{2}}{\cos\frac{A}{2}\cos\frac{B}{2} - \sin\frac{A}{2}\sin\frac{B}{2}}\tan\frac{c}{2}$$

$$= \frac{1 + \tan\frac{A}{2}\tan\frac{B}{2}}{1 - \tan\frac{A}{2}\tan\frac{B}{2}}\tan\frac{c}{2}.$$

Let

$$\tan\frac{A}{2}\tan\frac{B}{2} = \tan\frac{x}{2} \quad . \; . \; . \; . \; . \; . \; . \; . \quad (1)$$

Then

$$\tan\frac{a+b}{2} = \frac{1+\tan\frac{x}{2}}{1-\tan\frac{x}{2}}\tan\frac{c}{2} = \tan\left(45^\circ + \frac{x}{2}\right)\tan\frac{c}{2}.$$

Whence

$$\text{MP}(x) = \text{MP}(90^\circ - c) - \text{MP}(90^\circ - \overline{a+b}) \quad . \; . \quad (2)$$

An equation which determines x.

While from equation (1) it may be deduced that

$$\text{MP}(90^\circ - \text{A}) + \text{MP}(90^\circ - \text{B}) = \text{MP}(90^\circ - x) \quad . \quad (3)$$

Proceeding in the same manner to expand

$$\sin\frac{A+B}{2},\ \sin\frac{A-B}{2}$$

in the expression

$$\tan\frac{a-b}{2} = \frac{\sin\frac{A-B}{2}}{\sin\frac{A+B}{2}}\tan\frac{c}{2},$$

and assuming that

$$\tan\frac{B}{2}\cot\frac{A}{2} = \tan\frac{y}{2} \quad . \; . \; . \; . \; . \; . \; . \quad (4)$$

we arrive at the equations

$$\text{MP}(y) = \text{MP}(90^\circ - \overline{a-b}) - \text{MP}(90^\circ - c) \quad . \; . \quad (5)$$

$$\text{MP}(90^\circ - \text{B}) - \text{MP}(90^\circ - \text{A}) = \text{MP}(90^\circ - y) \quad . \quad (6)$$

By adding and subtracting each side of the two equations (3) and (6), we obtain equations which will enable us to determine the values of A and B respectively.

In place of the notation "MP," M. Guyou adopts the Greek letter λ (lambda). Thus, meridional parts for an angle $\theta = \lambda(\theta)$.

He also indicates the meridional parts of the complement of an angle by the symbol Co-λ, so that meridional parts for the angle $(90^\circ - \theta) = \text{Co-}\lambda(\theta)$.

And in his excellent collection of tables the values of λ and Co-λ are given for each angle side by side, an arrangement which much facilitates the work of computation.

The ordinary employment of Napier's analogies in practical work is limited to finding the remaining two sides when two angles and the included side are given, or to finding the remaining angles when two sides and the included angle are known. It is a somewhat remarkable extension of their functions to find that they suffice also to furnish satisfactory logarithmic formulæ for solving a triangle where the three sides are the given parts. In a similar manner formulæ may be found which will determine the sides when the three angles are given, so that formulæ of the type which gives $\tan\frac{A}{2}$ in terms of functions of the sides, or $\tan\frac{a}{2}$ in terms of functions of the angles may be dispensed with altogether.

It would be premature at present to hazard a conjecture as to whether the new processes will come into general use in England. In these matters we move slowly. The British mariner does not easily surrender the methods upon which he has been brought up, the practice of which becomes almost automatic with him, and he looks with feelings of doubt, tempered with suspicion, upon any novelties that may be brought to his notice. But some advantages, at least, of a system of rules involving the use of only one table of logarithms must be obvious to all. In the first place, as has been already mentioned, we have that of the greater simplicity in the statement of rules, and the diminished risk of error through the taking out of a logarithm from a wrong column. But even more important than these is the saving of time lost at present in turning over the leaves of tables in hunting for sines and cosines in different parts of a somewhat bulky book. In the table of meridional parts we have but 5400 logarithms, occupying some nine pages of Inman's collection, not more than might be printed on a sheet of cardboard of moderate size, so as to save the turning over of leaves altogether.

These logarithms furnish results correct to the nearest minute of arc, which is the usual limit of accuracy aimed at by the practical navigator.

As the case stands at present, the new system is well thought of in France; it has excited considerable attention in Italy, and has won the approbation of at least one distinguished authority in Spain; so that, perhaps, M. Guyou is not over-sanguine in his expectation that "the table of meridional parts is destined to become sooner or later the universal instrument of computation amongst mariners."

H. B. G.

THE NEW PHYSICAL RESEARCH LABORATORY AT THE SORBONNE.

AN interesting account of the new physical laboratory at the Sorbonne recently appeared in *La Nature.*

This laboratory, originally situated in the old Sorbonne, was founded in 1868 by M. Jamin, who was its director until his death in 1886. In 1894 it was transferred to the new Faculty of Sciences, and was reconstructed by the architect M. Nénot. At the present time M. Lippmann, member of the Institute, is the director. Although this change took place in 1894, the work has only recently been carried on in the usual manner.

The new buildings are surrounded by other buildings connected with the Sorbonne, and are therefore away from any disturbances caused by passing vehicles. On the ground floor, after passing an entrance hall with a cloak-room, there is a large room (Fig. 1) two stories high, and measuring 16 metres (about 52 feet) long by 12 metres broad (about 39 feet). Six physicists can work here, provided their work does not require any special conditions with regard to light and isolation. In the middle of the room, and at the corners there are solid stone pillars isolated from the floor; a "comparateur" is attached to the one in the middle. Each of the six places has four jets of gas, two incandescent lamps, one arc lamp, and a water-tap. About two yards above each table there is a joist, thus making it possible to suspend apparatus if necessary; the tables themselves are of slate.

Next to this large room is the sub-director's room and laboratory; then we come to a small chemical laboratory, and finally the machine-room. The latter is built over a vault, and contains two Lenoir gas machines of 16 horse-power each, three dynamos, and a large switch-board, which makes it possible to distribute the current for various uses in the laboratory, such as illumination, experiments and accumulators. Above this room, and accessible by a staircase from it, is the mechanical workshop, well equipped with apparatus and under the direction of two mechanics and an electrician. All the machines are worked by electricity. On the same floor there is an open terrace for the accumulators, which include a battery of the Tudor system used for illuminating purposes (60 elements), and another battery, of the Peyrusson system (80 elements), for experiments. Facing the workshop is a large hall, used as a laboratory by the assistants. This is connected with the workshop by a gallery, which is at present given up to experiments on electric waves. Next to this laboratory there is a terrace and a photographic room, and in the large entrance hall on the first floor are M. Lippmann's private room and laboratory. The latter is divided into three parts, a light and a dark room, and another room for optical researches, with optical benches of slate. The ore-dresser occupies the last room on this floor.

A tower 40 metres (nearly 131 feet) high contains the general staircase, and also leads to the extensions of the upper stories. This tower extends 18 metres (59 feet) in the ground, by which means a long vertical range is procured, and experiments in height can be made. The extensions of the upper floors referred to consist of a large hall, two stories high, comprising the library and laboratory of the sub-director, M. G. Maneuvrier, whose room adjoins it; the next floor has a dark room for optical researches. Lastly, on the third floor are three small rooms for private students. It may also be added that this tower connects the different parts of the laboratory with the physical amphitheatre, and with the collections of apparatus for the various courses. Under the large hall on the ground floor there are three cellars completely fitted up as laboratories, and a Gauss magnetometer mounted on solid stone pillars. On the ground floor there is a dark room isolated by three stone pillars, and used for electrical measurements and measurements of precision.

It will thus be seen that the laboratory is very complete in itself; but the money allowed for its maintenance (12,000 francs) is quite insufficient, when the general expenses, experiments, and course of lectures are taken into consideration. Nevertheless, the work of the students who have been through the laboratory is a proof of the thoroughness of the instruction. MM. Bouty, Pellat, Foussereau and Leduc (professors of physics at the Sorbonne) all studied at this laboratory, and qualified for their doctor's degrees in it. Several well-known Roumanians and Russians studied there also, and M. Benoît, director of the Bureau of Weights and Measures of Sèvres, wrote his thesis under Jamin. The laboratory has, indeed, become celebrated by M. Lippmann's own work, for it has all been done there, from the investigations on the electro-capillary phenomena to the wonderful discovery of colour photography. It is, therefore, to be hoped that the additional funds required will be forthcoming, and that the enlarged Institute may be even more successful than the old one.

We are indebted to the editor of *La Nature* for the accompanying illustration of the laboratory

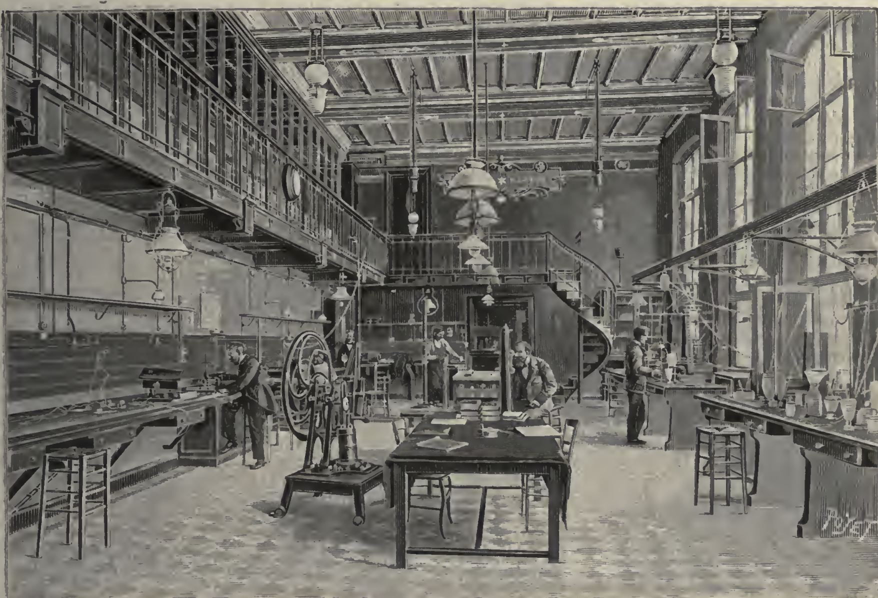

FIG. 1.—New Physical Research Laboratory at the Sorbonne.

PHOTOGRAPHY AT THE CRYSTAL PALACE.

PHOTOGRAPHY as a practical art of interest to others than a few investigators dates from 1839, when the Daguerreotype was introduced. Its development and applications were well illustrated at the Great Exhibition of 1851, but since that time there have been very few attempts, and none altogether successful, to show its further progress. The Royal Photographic Society has held more than forty annual exhibitions, but as each of these has dealt with its current year only, the Council of the Society considered it desirable to arrange an exhibition that should demonstrate, not only the last year's advances, but the present position of photography and its applications as well as the history of its development.

The exhibition that was opened last week by the Prince of Wales is the result of the Society's endeavours. It must be regarded as eminently satisfactory, for it is not possible to call to mind many individuals or firms intimately connected with photography that have not contributed characteristic and interesting exhibits. The large areas of the north and south naves of the Crystal Palace, and of many of the courts, are well filled. The catalogue, which is published by the Society, will form an important historical work of reference, because of the numerous descriptive notes, references to original literature, dates, and examples of work that it contains. It is particularly fortunate that such an exhibition as this should have been inaugurated now rather than ten or twenty years later, as those of the older generation who are best able to speak of some of the older processes that are obsolete, and the introduction of the methods of to-day, are fast disappearing from our midst. There are, for example, but few left who are skilled enough in the Daguerreotype process to work it with a fair average of certainty, but Messrs. Negretti and Zambra have arranged a studio for taking Daguerreotypes of any who may desire it while the exhibition remains open. This is an opportunity that in all probability will never occur again.

The exhibition is divided into seven sections, namely: (1) the historical collection, (2) pictorial photography, (3) apparatus and material, (4) scientific and industrial applications, (5) photography in colours, (6) photography as a science, and (7) general technical photography. The Society's collection of portraits of eminent workers in connection with photography has been largely reinforced by loans from private individuals, and the series includes the elder and the younger Niepce, Fox Talbot, five of Daguerre, Andrew Ross, Sir David Brewster, Baron Pollock, Sir John Herschell, Mungo Ponton, W. B. Woodbury, F. von Vöigtlander, Dr. Draper, and many others; and in the catalogue there is a short biographical notice of each. Among the works of the elder Niepce there are exhibited the first camera photograph, taken in 1824, and some of the specimens that he submitted to the Royal Society in 1827. The Daguerreotype process is well represented. Daguerre's history and description of the process, dated 1839, and a translation of it into English published in the same year, are on view. The collection of Daguerreotypes and apparatus for producing them dates from 1842. Fox Talbot's callotype process, which was also made public in 1839, is even better represented; but space forbids further reference to these, and the various collodion and gelatine processes. The first methods and the developments of carbon printing are fully illustrated, including the gum-bichromate process, which, after being nearly forgotten, has lately been reintroduced and extolled.

After the examples of early work in the production of photo-etched plates and photo-typographic blocks, there follows the optical section. This is certainly the most complete collection of lenses ever got together. Examples of nearly ninety different kinds are shown, ranging from the early form of single lens by Chevalier and the first lens made in England for portraiture (in 1841, by Andrew Ross) to the stigmatics of Dallmeyer and Zeiss' planars. Sectional drawings of nearly fifty different kinds of lenses are given in the catalogue, and also a print from a photograph taken for the purpose with Sutton's panoramic water lens and his camera carrying curved plates.

Passing a very fine loan collection of photographs, which includes many examples by deceased workers, particularly Mrs. Cameron, D. O. Hill, O. G. Rejlander, B. B. Turner, and Colonel Stuart Wortley, and also the whole section of present-day apparatus and materials for photographic and photo-mechanical processes, there follows the section of the scientific and industrial applications of photography. The importance of photographic methods of observation was never more fully realised than it is at present. From almost the earliest days of photography the "recording science" has been applied in scientific investigations with the result not only of greater accuracy, but of the discovery of many facts that could never have been known by the use of the eye alone. Astronomy was one of the first of the sciences to derive benefit from photography; and in the delineation of the forms and features of celestial bodies, as well as in the spectroscopic analysis of their constitution, photographic processes have now almost entirely replaced the old method of drawing by hand what it was thought the eye could see. In many other domains of science photography is daily becoming more important, and it must continue to do so, especially as the scientific investigation of photography itself progresses. This important and universal method of work does not yet receive the attention and encouragement that it deserves in our teaching colleges; but this is due doubtless to the fact that, although it has done so much, it is still in its infancy so far as years are concerned. At the next exhibition of this kind there will without doubt be a far richer harvest of results to show, though this section, as it is here represented, well indicates not merely the directions in which future work is possible, but the very fine results that have already been accomplished, some of which it is difficult to believe can ever be surpassed. The Royal Observatory, Greenwich, contributes many exhibits, including some 12 × 10 prints of photographs of the recent solar eclipse, taken with the Thompson coronograph. Numerous other astronomical photographs are shown by the Royal Astronomical Society, Colonel Waterhouse, Dr. Common and Dr. Gill. Messrs. R. and J. Beck show twelve of De La Rue's original negatives of the moon. Photography as applied to spectroscopy, geology (including forty-one specimens from the B.A. Geological Photographs Committee), meteorology, zoology, botany, and Röntgen-ray work is well illustrated. In connection with the last, six large stereoscopic "skiagrams," by Dr. Mackenzie Davidson, mounted in reflecting stereoscopes, are strikingly good. The Kew Observatory Committee of the Royal Society sends photographs of various photographic recording apparatus, lens-testing apparatus, and other examples.

The section illustrating military photographs is of especial interest just now. The examples date from the Crimean war, and include balloon apparatus and photographs, the pigeon-post film used in the siege of Paris in 1871, and various examples from the School of Military Engineering at Chatham. But probably what will strike photographers as the most wonderful exhibits in this section is the telephotographic work contributed by the Italian Minister of War. The magnifications are far greater than we have been accustomed to, ranging up to one hundred diameters. Photo-micrography forms a large section, and includes a "complete photo-micrographic apparatus" by Zeiss, an apparatus that would probably be regarded as an extreme luxury by most microscopists.

Photography in colours, by all the current methods, is well illustrated, many examples being of historic interest. G. Lippmann, A. Lumière, L. Vidal and H. W. Vogel and several English exhibitors contribute to this section.

"Photography as a science" refers apparently to what might be called *pure* photography to distinguish it from *applied*. But the distinction is neither clear nor precise. This section includes apparatus for measuring the densities of photographs, including opacities and blacknesses, by Captain Abney, Hurter and Driffield, and Chapman Jones; besides sensitometers, actinometers, and similar apparatus. Many results of the various treatments of photographic plates are shown, such as the sensitising for various colours, and the getting of an image free from stain, &c., that it may be of definite opacity. E. Sanger Shepherd shows an ingenious form of slit for spectroscopes, that is stated to be specially suitable for photographic use.

The National Photographic Record Association, that has recently become established through the energy of Sir Benjamin Stone, is well represented. Sir Benjamin himself contributes twenty-one photographs relating to the Houses of Parliament, every one of which is of general interest. There are numerous other examples of technical work to which we cannot refer in even the most general terms, except to a case exhibited by the Bolt Court Technical School of the London County Council Technical Educational Board, which illustrates the working of some of the most important photomechanical processes arranged for educational purposes.

While there are some exhibits that claim attention because of their novelty, these are the exception; the chief interest centres round the old rather than the new, and the complete presentation of the capabilities of photography in its numerous applications at the present day. But those whose knowledge of photography is of the general kind, and those who have not followed up its developments during the last few years, will find more that is new, of both examples and processes, than they will be able to appreciate in a single visit. Such an exhibition has never before been organised, and it must obviously be impossible to arrange another of similar extent until after the lapse of several years. The exhibition will close on May 14.

MICRO-BIOLOGY AS APPLIED TO HYGIENE.

AT the Congress of Hygiene and Demography recently held at Madrid, many matters of scientific interest and importance were introduced and discussed. Unfortunately the papers were not printed and distributed among the members, and as the majority were read in Spanish, the discussions were curtailed. The Section of Micro-biology as applied to Hygiene attracted the largest share of attention. Among the more important contributions was that of Dr. Behring, who announced that, as the result of experimental work with the toxin and antitoxin of tuberculosis, he had isolated a substance from the tubercle bacillus a hundred times more powerful than Koch's tuberculin, and had obtained, by passing the virus through the horse, an antitoxin which he believed to be an efficient cure for the disease. Experiments on a large scale are to be carried out at the Berlin Veterinary University. Dr. A. Calmette, of the Pasteur Institute of Lille, demonstrated in a highly successful manner the prophylactic effect on snake-bitten patients of serum of the blood of horses subjected to small doses of the venom. For this purpose a rabbit was injected with a large dose of a mixture of venom of the cobra, naja, and bothrops; this proved fatal in twenty minutes. Two rabbits were then injected with the protective serum, and in ten minutes each received a dose of the mixture equal in amount to that which killed the first rabbit. These rabbits appeared to suffer no ill-effects. Further experiments gave unquestionable evidence as to the prophylactic property of the serum, which is easily prepared and retains its protective power for an indefinite period. Great interest was evinced in the paper read by M. Nocard, of the Alfort Veterinary School, and delegate of the French Academy of Medicine, describing a method of cultivating the microbe of pleuro-pneumonia of cattle, the demonstration of which had baffled the efforts of bacteriologists for nearly half a century. This destructive disease of cattle is communicable only by cohabitation, and heretofore has not been communicated to animals of other than the bovine species. As long ago as 1850, Willems had established the fact that the virus existed in the liquid exuding from affected lungs, and laid down rules for a protective inoculation which has been regarded to a great extent efficacious. His method was to introduce into the subcutaneous connective tissue of the animal to be protected a drop of the serosity from an affected lung. The necessity for having an absolutely fresh lung from which to obtain the inoculating material renders Willem's method very inconvenient and often impracticable. It is hoped that the discovery of the specific microbe and the power of cultivating it for indefinite periods, independent of animals suffering from the disease, will afford the means of providing an effectual, protective vaccine at all times available when necessity for preventive inoculation may occur. Heretofore, failure to cultivate the virus has followed sowing in all ordinary media in air or *in vacuo*, and no method of staining has been successful in demonstrating the virus. Nocard and Roux have, however, applied with success the plan adopted by Metchnikoff on the toxin and antitoxin of cholera. Very thin-walled capsules of collodion, rendered sterile by heat, are filled with sterile bouillon, sown with a very small quantity of virulent matter from a fresh pleuropneumonia lung and hermetically sealed. The capsules are then inserted into the peritoneal cavity of a rabbit. The collodion wall proves an absolute barrier to the egress of the microbe and to the ingress of the cells of the animal, which ordinarily have a destructive effect on each other. The wall, however, is permeable to liquids and dissolved matters. Products of the microbe pass out, and sometimes prove fatal to the animal; while it is usually found that products of the animal body, favouring the growth of the microbe, pass inside the capsule, so that after a longer or shorter period, according to the nature of the microbe and the animal, a rich culture is found inside the capsule. The microbe of pleuropneumonia thus cultivated is exceedingly minute. When examined under a very high power (2000 diameters magnification) the culture shows innumerable refractile, motile specks, so fine that, even after staining, their form cannot be exactly determined. Experiments with cows indicate that subcutaneous inoculation of small quantities of these cultures afford protection from the disease. Another interesting fact in connection with these experiments, is the discovery that if collodion capsules filled with sterile bouillon be inserted into the peritoneal cavity of the rabbit or the cow, and remain there for fifteen to twenty days, they are found to contain a medium suitable for cultivation of the microbe *in vitro*. Beyond the definite results in relation to the special disease under consideration, facts elicited concerning the method of providing favourable culture media would appear to have a broad significance.

Among the most novel suggestions for the application of bacteriological science were those of Dr. E. Vallin, of the French Academy of Medicine, who drew attention to the existence of saltpetre on the walls of dwelling-houses, and its ill-effects on the health of the dwellers therein. Dr. Vallin states that the salt is produced by nitrifying bacilli, and indicates that the prevention and cure are to be effected by removal of conditions favourable to their life and development. Mortar should be mixed with germicides, as coal-tar, sulphate of copper, &c., and where disease of the walls exist, the cure should be effected by inoculation of the walls with anti-nitrifying bacilli.

NOTES.

THE Council of the Institution of Civil Engineers have made the following awards for papers read and discussed before the Institution during the past session:—Watt medals and premiums to Prof. H. L. Callendar, F.R.S., and Mr. J. T. Nicolson; a Telford medal and premium to Mr. A. H. Preece; George Stephenson medals and premiums to Messrs. Whately Eliot and W. O. E. Meade-King; a Crampton prize to Mr. E. W. Anderson; Telford premiums to Messrs. L. B. Atkinson, Henry Fowler, and W. L. Strange. The presentation of these awards, together with those for papers which have not been subject to discussion and will be announced later, will take place at the inaugural meeting of the next session.

THE Reception Committee of the Fourth International Congress of Zoology have issued a circular containing particulars with regard to lodgings and other accommodation at Cambridge during the meeting in August next, and giving information as to the railway fares from various parts of the Continent, and other arrangements for the Congress. The circular is accompanied by a reply-form, to be filled up and returned to the Secretaries by any member of the Congress who wishes rooms to be taken for him. These circulars have been sent to all who have already informed the Reception Committee that they hope to be present at the meeting, and will be sent to other zoologists on application to the Secretaries of the Reception Committee, The Museums, Cambridge.

THE Select Committee appointed to inquire into and report upon the administration and cost of the Museums of the Science and Art Department have agreed to the following preliminary report:—Since the issue of the report of the Museums of the Science and Art Department Committee in July 1897, your Committee have continued the inquiry, but reserve for a further report the publication of additional evidence with their final review and recommendations. They feel, however, bound to report without delay certain conclusions at which they have arrived, on consideration of the evidence, as regards the South Kensington Museum and the Geological Museum in Jermyn Street. They are unanimously of opinion that with a view to present efficient management, to economy of administration, to future development of the collections, and to their full use for the purpose of exhibition and of instruction, it is necessary—(1) That the whole area on the east side of Exhibition Road (except that occupied by the Royal College of Science, which cannot be sacrificed except at great cost) be exclusively devoted to the Art Museum and the Art Library, with provision for the conduct of the business connected with Loans of Art Objects, and the Art Schools. They are satisfied that the whole of this space is required for the Art Schools, the due exhibition of the Art Collections, and the administration connected with such a museum. (2) That provision for the whole of the Science Collection, the Science Library, for Loans of Scientific Objects, and for the Science Schools be made on the west side of the Exhibition Road. They are convinced that this concentration of Art on one side of the road and of Science on the other is essential to good administration, to satisfactory results from the money expended, and efficiency both in the museum and in the schools. This arrangement would allow space for the future development both of the Art and of the Science branches. They also unanimously recommend that the Geological Museum in Jermyn Street be no longer occupied for the same purposes as now; and that the collections there exhibited be removed to the west side of Exhibition Road, and made part of the Science collections.

THE address of the British Institute of Preventive Medicine is now Grosvenor Road, London, S.W., instead of Great Russell Street, London, W.C.

THE death is announced of M. Demontzey, Correspondant of the Section of Rural Economy of the Paris Academy of Sciences.

WE regret to notice the announcement of the death of Dr. Samuel Gordon, president of the Royal Academy of Medicine in Ireland, and successor to the late Dr. Haughton as president of the Royal Zoological Society, Dublin.

AT the Royal Institution on Thursday, May 12, Lord Rayleigh will deliver the first of a course of three lectures on "Heat," and on Saturday, May 21, Mr. J. Arthur Thomson will begin a course of two lectures on "The Biology of Spring." The Friday evening discourse to-morrow is by Mr. E. A. Minchin, whose subject is "Living Crystals."

THE death is announced of Dr. Karl Ludwig Fridolin von Sandberger, who until recently was Professor of Mineralogy and Geology in the University of Würzburg, and Director of the Mineralogisches Institut. Although known for his many important contributions to mineralogical science, to the study of ore deposits and to the microscopic structure of eruptive rocks, he was likewise distinguished for his researches on the fossil Mollusca of various formations in the Rhenish provinces and other parts of Germany. His published works date back to 1847. During the years 1850–56 he issued, in conjunction with his brother Dr. Guido Sandberger, "Die Versteinerungen des rheinischen Schichten-systems in Nassau"—a work remarkable for the beauty of its illustrations and the fidelity of its descriptions, and one which was honoured by the award of the Wollaston Fund, which was given to the authors by the Council of the Geological Society in 1855. In 1863 Dr. Fridolin Sandberger published "Die Conchylien des Mainzer Tertiärbeckens"; in 1870–75 he issued, in two volumes, "Die Land-und Süsswasser-Conchylien der Vorwelt"; and in 1882–5, "Untersuchungen über Erzgänge," an authoritative work on the subject of mineral veins. In the course of his long labours he turned his attention to the Mollusca of many different formations, from those of Devonian age to those of Pliocene and Pleistocene deposits. In later years his work became more concentrated on mineralogical science. In 1875 he was elected a Foreign Member of the Geological Society of London. He was born in 1826, and died at Würzburg on April 11.

MR. W. J. LEWIS ABBOTT sends us the following particulars concerning the career of Mr. Henry Lewis, who died on April 10, at the age of sixty-four:—Though apprenticed to a bootmaker, throughout his early life Lewis spent much of his time in the pursuit of natural history subjects, and thirty years ago was led to the subject of flint implements, and forthwith became one of the most ardent collectors. For many years weekly visits were made to pits in the Thames Valley, in each of which he set workmen hunting. He also successfully worked the Botany Bay section, securing much more material than Skertchley, consisting of worked flakes as well as finished implements. His next work was upon the plateau, where he secured valuable spoil. For the last ten years he visited the glacial and pre-glacial deposits in search of worked flints and implements, glacially striated and otherwise, and accumulated a mass of material at present undescribed. His late Celtic discoveries at

Aylesford were of singular interest and importance, and were described by Mr. Arthur Evans before the Society of Antiquaries. A large amount of material obtained by him still waits description. But, after all, it is this collection of material which is so indispensable and important; and hence great credit is due to Henry Lewis for the part he played in unravelling the secrets of prehistoric anthropology.

THE sixty-ninth anniversary meeting of the Zoological Society of London was held on Friday last, the chair being taken by Sir William H. Flower, K.C.B., F.R.S., President of the Society. Mr. P. L. Sclater, F.R.S., read the report of the Council, from which it appeared that the occurrence of the Queen's Diamond Jubilee in 1897, together with the very favourable weather experienced during the summer and autumn of that year, resulted in a large number of visitors to the Society's gardens, and the total income of the Society consequently reached the large amount of 28,713*l.*, being 1631*l.* more than in 1896, and greater than that of any year since the year 1884. The principal new building opened in the Society's gardens in 1897 was the new ostrich and crane-house, which was commenced in the autumn of 1896. During the past summer, also, a new glass-house for the reception of the Society's collection of tortoises was built, adjoining the reptile-house. The Council referred to the loss sustained by the death of Mr. A. D. Bartlett, for thirty-eight years superintendent of the Society's gardens, and recorded their deep sense of the services rendered by him during the long period he held his post. The vacancy thus caused has been filled up by the appointment, as superintendent, of Mr. Bartlett's second son, Mr. Clarence Bartlett. The number of visitors to the gardens in 1897 was 717,755, being 52,751 more than the corresponding number in 1896. The number of animals in the collection on December 31 last was 2585, of which 792 were mammals, 1362 birds, 431 reptiles and batrachians.

WE learn from the thirty-first annual report of the Peabody Museum of American Archæology and Ethnology, that Miss Maria Whitney has made a gift of great scientific interest from the estate of her brother, the late Prof. J. D. Whitney. This consists of the world-famous "Calaveras skull" and all the original documents relating to its discovery and history; with the gravel, small human bones, and other objects found in the cemented débris in which the skull was enclosed at the time of its discovery, as shown by the photograph taken before the cemented material was removed. With these are also a rude stone mortar, stone pestle and steatite dish, found under similar geological conditions in California. The full history of the discovery of the skull by Mr. Mattison, in 1866, under four beds of lava in a shaft he had sunk to the depth of 127 feet, is given in Prof. Whitney's volume on the "Auriferous Gravels of California," published in 1879 as vol. vi. of the *Memoirs* of the Museum of Comparative Zoology. When taken in connection with other discoveries under similar geological conditions in California, there seems to be no reason to doubt that these human remains were found in the gravel under the lava, as stated by Mr. Mattison. The principal question still in doubt is the exact age of the lava beds and gravels. The skull itself, so far as can be judged by a comparative study of the portion preserved, is of the type which there are reasons for regarding as the oldest on the Pacific coast. The objects, fashioned by the hand of man, found in the gravel, have been considered by some authors to be of a character too advanced in the development of the arts of man on the American continent to have come from so old a deposit. It is pointed out, however, that one cannot apply to American archæology the old classification of the culture epochs which, during the growth of science, has been used to distinguish several periods of prehistoric culture in Europe. In addition to Miss Whitney's valuable gift, the Museum received during the past year a number of other objects of scientific importance, including gifts from friends and collections made by expeditions to Yucatan and Honduras. A description of some of the results of archæological explorations in Central America and Yucatan recently appeared in these columns (p. 568).

THE Deutsche Seewarte has rendered a valuable contribution to meteorology by the publication of means for the ten years 1886–1895, based upon the observations made three times daily at nine stations connected with that institution. Dr. Neumayer has always carefully adhered to the regulations made by the various meteorological conferences, and the present work, which continues the means previously published for the years 1876–1885, contains monthly, seasonal, and annual values and extremes made with trustworthy instruments and trained observers.

SINCE 1882, the Royal Meteorological Institute of Utrecht has published a yearly volume relating to the thunderstorms and optical phenomena observed in the Netherlands. The number of stations at which thunderstorms are observed is 254; the days on which storms were recorded amounted to 119 during the year 1897. With the exception of the months of January and February, during which no thunderstorms were observed, they were regularly distributed throughout the year. The report contains a discussion of the storms in each month, and is accompanied by various charts.

A VERY useful feature which is being introduced into Russian schools is the sending out of the pupils in summer for small natural science and ethnographic excursions, during which they explore some region and make all sorts of collections and observations. The Caucasus School administration is especially active in that direction. One such excursion will be made to the foot of the Elbrus this summer by fifty pupils of the Ekaterinodar Gymnasium. The party intends to visit the Great Karachai region, to ascend the Elbrus up to the snow-line, and to cross the Main Ridge. The excursion will last fifty days, during which the pupils will collect natural history specimens and ethnographical data, take photographs, sketch landscapes, and live amidst the beautiful pine forests of the Main Caucasus ridge. Some of the boys will take musical instruments with them to enliven the party.

A JOINT expedition of the West Siberian branch of the Geographical Society and the Moscow Society of Amateurs of Natural Sciences will this summer explore the hydrography and the fauna of the lakes in the South of Omsk. The collections will be divided between the two Societies.

PROF. J. TROWBRIDGE, Rumford professor of the application of science to the useful arts, Harvard University, describes in the *Century Magazine* some experiments he made with a view to determining the nature of Röntgen rays. He concludes as follows:—"I believe that the experiments which I have described support the theory that there are really two classes of phenomena—one an electrical disturbance in a medium, another the conversion of this electrical disturbance into fluorescent and phosphorescent light at the surfaces of suitable screens or in the body of suitable crystals. My experiments certainly show that there are anode rays as well as kathode rays, and that both are subject to the well-known laws of electrical induction. One should not expect, therefore, that the electrical rays or lines of force should be reflected and refracted like waves of light."

SOME interesting properties of Röntgen rays were recently described by Prof. Röntgen in a communication to the Berlin Academy of Sciences, and are summarised in the *Electrical*

World. If a fluorescent screen is protected from the direct action of rays emitted by a tube, by means of an opaque plate, a slight fluorescence is nevertheless seen when the tube is in action. Röntgen has now shown that this is due to the fact that the air around the tube gives forth X-rays. The brightness of a screen illuminated with rapidly intermittent rays depends on a number of properties which he enumerates. The X-rays from a platinum focus plate which are most active for showing mages are those which leave the plate at the greatest angle, but not much greater than 80°; thick plates have a relatively arger transparency than thin ones, that is, the specific transparency of a body is greater the thicker the body; the same body has different transparencies with different tubes, "soft tubes" being those requiring a small potential, and "hard tubes" those requiring a high one. The quality of the rays from the same tube depends on: the way in which the interrupter works, the insertion of a Tesla transformer, the vacuum, other processes in the tube which are not yet fully investigated. The smallest pressure at which X-rays are produced is very likely below 0·0002 mm. of mercury. The composition of the rays from a platinum anode depends largely on the element in the current; the quality of the rays does not change with changes of the primary current, or at least very little, but the intensity is proportional to the strength of the primary current between certain limits. The following conclusions are stated: the radiation consists of a mixture of rays of different intensity and absorbability; the composition depends greatly on the time element in the current; the rays produced by the absorption of bodies are different for different bodies; as X-rays are produced by kathode rays, and as both have common properties, it is probable that both processes are of the same nature. If two screens are illuminated with two tubes of different hardness, the illumination being made equal, and if then replaced by photographic plates, the one illuminated by the harder tube will be blackened much less than the other; rays which produce equal fluorescence can be photographically quite different; the usual photographic plates are very transparent for X-rays (in a pile of ninety-six filaments exposed for five minutes the last one showed photographic action); the eye is not entirely passive to X-rays.

Prof. Louis Boutan, lecturer on zoology at the Sorbonne, contributes to the *Century Magazine* (May) an account of his experiments in submarine photography. To procure photographs under water, Prof. Boutan uses a camera enclosed in a water-tight case, a blue glass being arranged in front of the lens to suit the conditions of submarine illumination, and so give a picture having pleasing contrasts. He descends under water in a diver's costume, and the camera is sent down to him from an anchored boat. The spot to be photographed is then selected, and the exposure is made in precisely the same way as on land. When no artificial light is used, submarine photographs require a rather long exposure, the time often extending to twenty-five minutes, and depending upon the depth of the water. Four reproductions of photographs obtained at depths from six and a half feet to sixteen and a half feet, accompany Prof. Boutan's article, and they are sufficient to show that submarine photography can produce useful results. It is estimated that not more than one hundred square metres of area can be photographed under water, but even with this limitation the pictures obtained will contain more valuable information than divers can furnish. The problem to be solved is to construct an apparatus which will take photographs in artificial light in any depth of water without needing a submarine photographer to manipulate it.

The immunity of bee-keepers from the effects of bee-poison, forms the subject of a paper, by Dr. Langer, read before the sixty-ninth Congress of German Naturalists and Physicians in Brunswick. The author sent circulars to all parts of the country addressed to bee-keepers, and from the answers he received he has compiled some interesting statistics. One hundred and forty-four bee-keepers stated that they were immune to the sting of bees, nine mentioning that they were naturally immune to the poison, whilst twenty-six replied that they could not acquire immunity. The number of bee-stings necessary to produce the much-desired immunity appears to vary considerably, sometimes thirty being sufficient, but in other cases as many as 100 being necessary to accustom the system to the poison. The remedies applied range over a large variety of substances, and include tobacco juice, French brandy, rum, water, spirits of ammonia, seltzer water, acetate of alumina, loam, saliva, cognac, besides massage and heat. The most favourite means of dealing with bee-stings appears to be spirits of ammonia. Dr. Langer states that a 5 per cent. solution of permanganate of potash will counteract the poison, and he recommends an injection of a 2–5 per cent. solution of this substance. Bee-poison is extraordinarily resistant to both dessication and heat, whilst it is quite unaffected by additions of alcohol. It used to be commonly supposed that the irritating nature of bee-poison was due to the presence of formic acid; but inasmuch as it can withstand heat and retain its poisonous activity, which would effectually volatilise the formic acid were it present, this idea must be abandoned. The opinion now appears to be that the toxic substance present partakes of the nature of an alkaloid.

A copy of the Act of Incorporation, bye-laws, and list of officers of the recently-established Washington Academy of Sciences has been sent to us. The particular business and objects of the Academy are stated to be the promotion of science, with power to acquire, hold, and convey real estate and other property, and to establish general and special funds; to hold meetings; to publish and distribute documents; to conduct lectures; to conduct, endow, or assist investigation in any department of science; to acquire and maintain a library; and, in general, to transact any business pertinent to an Academy of Sciences. The Academy will act as a federal head of the affiliated scientific societies of Washington, with power to conduct joint meetings, publish a joint directory and joint notices of meetings, and take action in any matter of common interest to the affiliated societies. The term "affiliated societies" at present covers the Anthropological, Biological, Chemical, Entomological, National Geographic, Geological, Medical, and Philosophical Societies, each society nominating a vice-president. The President of the Academy is Mr. J. R. Eastman, and the Secretary Prof. G. K. Gilbert.

Curators of museums know that the papers read at the annual meetings of the Museums Association, and the discussions which take place upon them, are serviceable in indicating the best systems of classification and arrangement of specimens, and in evoking expert opinions upon museum technique. The Report of the proceedings of the Oxford meeting of the Association, edited by Mr. James Paton, has just been published by Messrs. Dulau and Co., and from it much valuable information can be gained by the officers of local museums. Among the contents is an address by the president, Prof. E. Ray Lankester, F.R.S., and papers on the methods of setting and labelling Lepidoptera for Museums, by Prof. E. B. Poulton, F.R.S.; the arrangement of the mineral collection in the University Museum, Oxford, by Prof. H. A. Miers, F.R.S.; the arrangement of ethnographical collections, by Mr. F. W. Rudler; popular museum exhibits, the relation of museums to elementary education, and a description of the Colombo Museum. Opinions and conclusions based upon successful experience are always valuable, therefore this report of the Museums Association will be of service not only to the organised provincial museum officer, but will also educate the curators and managers of local institutions of the "curiosity shop" type to a sense of their responsibilities and opportunities.

IN March 1848, Louis Agassiz began his instruction at Harvard College, and with it a new era in zoological science commenced in America. To commemorate the jubilee of his appearance as a teacher in America, the March number of the *American Naturalist*, which has only just reached us, contains a sketch of the life of Agassiz and reviews of some aspects of his work. It is peculiarly appropriate that the *American Naturalist* should take advantage of the opportunity which this fiftieth anniversary presents to pay a tribute to Agassiz's work, seeing that the periodical was founded by four pupils of that distinguished investigator—Alpheus Hyatt, Edward Sylvester Morse, Alpheus Spring Packard, and Frederick Ward Putnam. The anniversary thus commemorated is also the anniversary of a change in the character of zoological science in America, and of a change in the academic position of zoology in the educational institutions in the New World. To these changes must be ascribed the advances which American students have made in morphological science, and have gained for their country a foremost position among the nations of the earth.

FRIENDLY intercourse between men working in various fields of natural knowledge tends to broaden views and sympathies. With this aphorism in mind, and also the fact that the number of persons in the University of Durham interested in the progress of science is increasing, some members of the University met towards the end of 1896 and formed themselves into a Philosophical Society having for its principal objects the promotion of research and the communication of facts and ideas bearing upon scientific questions. The first number of the *Proceedings* of this Society has just been issued, and it is a creditable production which may, we trust, be taken as an earnest of greater things to come. Among the subjects of papers printed in the *Proceedings* are: education and instruction in England and abroad; the effect of alternating currents upon the frog's heart; native methods of fire-making; and the Great Ice-Age.

THE popular science lectures delivered on Tuesday evenings at the Royal Victoria Hall, Waterloo Bridge Road, provide a valuable means for instructing a large section of the general public in the methods and results of scientific work. The lecturers give their services, and only a few pence is charged for admission, the object being not to make the lectures commercially profitable, but to encourage interest in the pursuit of natural knowledge. After the lecture a short variety entertainment is provided, and it says much for the character of the audience that more people leave at the end of the lecture than are admitted to the entertainment. During May several distinguished men of science will lecture at the Hall. On Tuesday, Prof. Tilden delivered a discourse in which he described "What a Chemist can get out of a Brick"; on May 10, Prof. McLeod will lecture on "A Simple Experiment, and its Explanation"; Prof. Sollas will take as his subject "Funafuti, or three months on a Coral Island," on May 17; and Prof. Marshall Ward will say "Something about Wood," on May 24. The Hon. Secretary of the Hall should feel gratified at being able to offer such an attractive programme as this.

THE many subjects covered by the articles which have appeared in *Science Progress* since its commencement, and the satisfactory way in which they have usually been treated, make the volumes which have been published almost an encyclopædia of science. There are few scientific subjects of prime importance in which advances have been made in recent years but what have been dealt with by our solid contemporary, and surveyed in sufficient detail to make the volumes very serviceable to students of science. The April number of this "quarterly review of current scientific information" contains an article on Julius Sachs by Prof. K. Goebel, and one on the germination of seeds by Mr. F. Escombe. Prof. H. Crompton describes association and dissociation; Dr. T. Gregor Brodie, the phosphorus-containing substances of the cell; Dr. F. A. Dixey, recent experiments in the production of insect hybrids; Mr. A. Harker, the forms and habits of igneous rocks; Dr. J. S. Haldane, F.R.S., the secretion and absorption of gas in the swimming-bladder and lungs; and Prof. J. Reynolds Green, F.R.S., oxidases or oxidising enzymes.

THE additions to the Zoological Society's Gardens during the past week include a Mona Monkey (*Cercopithecus mona*, ♂) from West Africa, presented by Mrs. Christiana G. R. Potter; a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Mrs. Burrell; a Ring-tailed Coati (*Nasua rufa*) from South America, a Mantled Buzzard (*Leucopternis palliata*) from Brazil, presented by Mr. Basil T. Freeland; a Daubenton's Curassow (*Crax daubentoni*) from Venezuela, presented by Mr. Emil A. Goeldi; two Silver-bills (*Munia malabarica*) from India, presented by Lady Charlotte Amherst; two Moorish Toads (*Bufo mauritanica*) from North-west Africa, presented by Mr. D. P. Turner; a Humboldt's Lagothrix (*Lagothrix humboldti*, ♀) from the Upper Amazons, two Beautiful Grass Finches (*Poëphila mirabilis*) from Australia, two Yellow-legged Herring Gulls (*Larus cacchinnans*) from Egypt, twelve Midwife Toads (*Alytes obstetricans*), European, purchased; a Californian Sea Lion (*Otaria californiana*) from California, received in exchange; four Barbary Wild Sheep (*Ovis tragelaphus*), a Grey Ichneumon (*Herpestes griseus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET PERRINE (MARCH 19).—The ephemeris of this comet for the ensuing week is as follows:—

12h. Berlin Mean Time.

1898.	R.A. h. m. s.	Decl. ° ′	Br.
May 5	0 58 43	+52 18·3	0·46
6	1 4 9	52 38	
7	9 35	52 56·9	
8	15 0	53 14·7	0·42
9	20 24	53 31·5	
10	25 46	53 47·4	
11	31 6	52 2·4	
12	1 36 25	+54 16·3	0·38

TEMPEL'S COMET (1867 II.).—M. Gautier publishes (*Astr. Nach.*, No. 3490, Beilage) an ephemeris of this periodic comet, which was discovered by Tempel at Marseilles in 1867. The comet has a period of about 6·5 years, and it was observed at its returns in 1873 and 1879, but since that time has not been seen, although two returns have been due. M. Gautier, who has interested himself in this comet, calculated that the last return ought to have occurred in 1892, owing to the perturbating action of Jupiter on its orbit. If this be so, then probably we should expect its return during the present year. The region of the sky which should be swept for picking up this object is, according to M. Gautier, for the present week between R.A. 11h. 20m. and 11h. 43m., and between Declinations +16° 46′ and +18° 7′.

KIRCHHOFF'S SPECTROSCOPE.—The Potsdam Astrophysical Observatory has just become possessed of the celebrated spectroscope which Kirchhoff used in his well-known investigations on the solar spectrum. Although this instrument has been previously described, detailed information on several points connected with it was lacking. To remedy this Prof. H. C. Vogel brings together (*Sitzungsberichte der Königlich Preussischen Akademie der Wis., Berlin*, February 1898) such information as is supplementary to that already known, obtaining his facts from a minute examination of the instrument itself. As regards the optical parts, Prof. Vogel says: "The objectives are very beautiful and colourless; the prisms are masterpieces of workmanship; the glass of which they are composed is pure, colourless and free from streaks, and only in two prisms do a few air bubbles appear." The spectra given by the prisms are said by Prof. Vogel to be very excellent, and the working of the whole set of prisms exceeds even to-day any other instrument of the same dispersion. The refractive angles of the prisms, as measured by Dr. Hartmann, are 44° 57′·1, 45° 6′·9, 45° 26′·9 and 59° 50′ 8, and the relative refractive indices at a temperature of 18° C. was found by the same observer to be for the lines—

B 1·6093	D 1·6158	F 1·6275
C 1·6110	E 1·6220	Hγ 1·6375
a 1·6129	b_1 1·6230	g 1·6403

JUPITER'S RED SPOT.—Jupiter is now in a good position for observation, and his surface markings have become of late of great interest in consequence of the numerous spots which many observers have seen on his disc. Dr. A. A. Nijland draws attention to two very curious spots (*Astr. Nachr.*, No. 3488) which are situated on the northern hemisphere, their coordinates in longitude and latitude (according to "Marth's System," ii., *Monthly Notices*, lviii. p. 107) being $\lambda = 272°$ $\beta + 31°$, $\lambda = 289°$ $\beta = + 38°$. Dr. Fauth, from the private observatory at Landstuhl, gives us a continuation of the list of longitudes of several prominent spots observed by him. Another short communication of interest is that which appears in the *Astr. Nach.*, No. 3490. In this Dr. Lohse discusses the movement of the great red spot from observations extending over a period of twenty years. The proper motion of the spot is, according to him, distinct and regular, and this will be clearly seen from the short table given below.

The method of reducing this proper motion was to obtain for each opposition a normal position for the centre of the spot on the surface of Jupiter, on the assumption of a fixed meridian and a regular velocity of rotation of the planet. In plotting the positions of these deduced normal positions on paper with the time as abscissæ and the Jovian longitudes as ordinates, a regular and symmetrical curve was brought to light. The following figures give the Jovian normal longitudes of this spot as shown in this manner, together with the name of the observer:—

Epoch.	Normal longitude	Obs.
1878·65	° 249·5	L.
1878·86	237·1	Tr.
1879 73	182·7	L.
1880 71	128 5	L.
1881·70	89·2	L.
1882 14	78·0	L.
1883·14	50·4	L.
1884·15	32 6	L.
1885·27	15·8	L.
1886·27	8·3	L.
1887·27	2·9	St. D.
1888·27	358·9	L.
1890 15	353·6	T. P.
1891·74	352·0	L.
1892·76	356·2	L.
1894·03	358·8	L.
1895·18	5·2	L.
1896·13	10·1	L.
1897·27	20·4	L

The observers mentioned above were Lohse, Trouvelot, Stanley Williams, Denning, Terby, and Pritchett. From the curve it can be seen at a glance that the spot in the year 1891 rotated in the same time as that assumed for the rotation of the planet. The curve at this period has reached a turning point, and the longitudes of the spot commence now to increase instead of decrease. The observations show that for thirteen years (1878–1891) this spot has moved through nearly three-quarters of the whole circumference of the planet, and since that interval has begun to retrace its path. The fact of such a distinct acceleration and retardation of the motion of this large spot will, if the observations be continued, help us probably to gain some knowledge of the system of circulation involved in the Jovian atmosphere. It would be interesting to know whether any other comparatively large marking on the planet's surface follows the same or a similar law.

PETROLIFEROUS SANDS AND MUD VOLCANOES IN BURMA.

THE occurrence of petroleum in Burma, and its technical exploitation have, in a recently published volume, been very fully treated by Dr. Fritz Noetling, palæontologist to the Geological Survey of India (*Mem. Geol. Survey India*, vol. xxvii. part 2). The Yenangyaung oil-fields occupy an area of about 350 acres on the borders of the left bank of the Irawadi, a few miles distant from the river. They have been known from time immemorial, while the methods of obtaining the oil at the present day differ but little from those of a hundred years ago. In 1855 there were about 130 productive wells; there are now about 600, together with six or seven bore-holes. The oil-field is situated in a low but rugged table-land which is intersected by numerous ravines, and the strata which yield the oil have been bent into a gentle dome-like anticline. The strata consist of sands or soft sandstones, and shales of Tertiary ages overlaid by drift. The oil is held in the sandy beds, the thickest of which (though not the richest in oil) is a little over 130 feet. As many as ten bands yielding oil may occur in vertical succession; but water and petroleum occur independently in different beds, or in the same layer, and in the latter case the petroleum generally rests on the water.

Oil has been found by boring in a bed of sandstone 900 to 1000 feet deep, but the main oil-sand is from 200 to 350 feet from the surface. The sands are somewhat inconstant in character, and the strata generally exhibit false-bedding. They have yielded numerous remains of land mammalia and reptiles, as well as some marine fossils, so that Dr. Noetling believes the strata were accumulated in shallow water not far from land, and that carcases of animals brought down by a river were entombed in the estuarine sediment. He regards the petroleum as indigenous in these sandy estuarine or deltaic deposits. The clays contain no trace of it. Moreover, he considers that the strata were laid down on a plane gently inclined towards the sea, and that this inclination facilitated a sliding of the sediments seawards, whereby certain minor folds and irregularities, otherwise difficult to explain, were produced. These folds were intersected by cracks, which became filled with mud—like veins of eruptive material.

Turning his attention to the mud volcanoes of Minbu, Dr. Noetling points out that they are connected with subterranean petroliferous strata: both volcanoes and mud-wells produce a

The Mud Volcanoes of Minbu, in Burma (Dr. F. Noetling).

greyish-blue mud more or less saturated with petroleum. The low temperature of the ejected mud, seldom so much as 85°, indicates that its source is not deep-seated. Some of these mud volcanoes are figured (the accompanying illustration is reduced from a Plate in the *Memoir*.) The largest had, in 1888, a crater about 6 feet in diameter, and this was filled with viscous mud from which rose enormous bubbles of inflammable gas with a strong odour of petroleum. The temperature was 76°. Some of the other cones rise about 30 feet from the ground. It seems at first difficult to say why mud volcanoes occur at Minbu and not at Yenangyaung, but Dr. Noetling points out that at Minbu these volcanoes arise through fissures in the Tertiary strata beneath an alluvial cover, and he considers that the pressure of gas and petroleum forced a way through this comparatively thin overlying deposit. No fiery eruptions have been recorded; in fact, there are no known instances of spontaneous combustion.

Dr. Noetling traces some connection between the fluctuating heights of the river and the production of petroleum at the wells.

There is also some relation between the activity of the mud volcanoes and the height of the river. The explanation is that during rains the ground-water presses on the petroliferous sands, and it is noteworthy that the main bed of oil-sand is found at about the level of high-water of the river.

Some signs of exhaustion in the oil-field are noticed by the author, but it is possible that further productive beds may be found by boring. H. B. W.

EXPERIMENTS ON THE WORKING OF GAS-ENGINES.

A GENERAL meeting of the Institution of Mechanical Engineers was held last week, when the President, Mr. Samuel W. Johnson, delivered an inaugural address dealing chiefly with the progress of locomotive engineering on the Midland Railway, of which he is chief mechanical engineer. The most interesting feature in the ordinary proceeding was the discussion of the first report to the Gas-Engine Research Committee of the Institution. The author of the report was Prof. Frederick W. Burstall, under whose superintendence the investigations had been carried out. The object of the experiments was to determine the effect produced upon the economy of gas-engines by altering one or more of the conditions which governed their working. In internal combustion engines there are a much larger number of factors to consider than in steam-engines, and it is difficult to ascertain where to look for economy. The factors to be considered are the amount of compression, the speed, the ratio of air to gas, and the amount of heat which is to be ejected through the walls of the cylinder. An increase of compression, for example, is often regarded as conducive to more economical results; but it is uncertain whether the attendant increase in economy is really due to compression alone. To ascertain this, the conditions of working should be altered successively one at a time. This has been done for the steam-engine, but all published results of tests made on gas-engines are based upon only one fixed set of conditions.

A small engine was used by the committee, but was one specially constructed for experimental purposes. Small size was an advantage, inasmuch as it allowed measurements, such as those of volumes of air, to be made with accuracy. The work of the committee appears to have been undertaken with commendable care, and a precision was aimed at more typical of the physical laboratory than of ordinary engineering experiments. This is particularly noticeable in the arrangement of the apparatus and methods of calibration followed. It would take far too much space to follow these in detail, interesting and instructive as they are to engineers, and we can only hope to give a partial idea of the methods followed. This report, it should be remembered, is but introductory to the description of the actual work of testing, most of which has yet to be undertaken. As the author stated, experimental work is often compromised by being carried out with instruments upon the accuracy of which no information is furnished. When a comparison is made of a number of results, it is always difficult to discover how far differences are due to working conditions or to inevitable experimental error. In purely physical experiments, the report continued, accuracy may be obtained to the degree of one part in a thousand; in a few special cases, even better results may be reached. In an engineering experiment it is hopeless to expect such accuracy, owing to the great difficulty of keeping the working conditions sufficiently steady from beginning to end of the experiment. With ordinary care, and the use of appliances which are found in all works, probably all that can be expected is to get results correct to 3 or 4 per cent. With special care, half of 1 per cent. may be reached; but the author does not suggest that all the results of the experiments made by the committee have this high degree of accuracy, but in the principal measurements probably the experimental error involved does not in any case exceed 1 per cent.

The engine used was of 2-horse nominal power, capable of developing a maximum of 5 I.H.P.; it has a 6-inch cylinder and 12-inch stroke. The valves are worked in the ordinary manner; there is an ordinary Watt governor acting on a small roller, and causing a charge of gas to be cut off when the speed is too high. To effect changes in compression the connecting-rod is made so that its length can be varied. Compressions employed in the experiment varied between 35 and 90 lbs. per square inch; variation in the amount of gas admitted was effected by throttling. For measuring the supply of gas a calibrated holder was used; the wet test meter being discarded, as it does not control the fluctuations of pressure in the mains. By this instrument accuracy to the extent of one-tenth of 1 per cent. was obtained; calibration was effected by means of a standard cubic foot measure. To determine the air supply per stroke, a meter was used in place of trusting to the usual method of calculation. The arrangement followed was practically that employed by Dr. A. Slaby, of Berlin. The meter employed was a 400-light standard wet meter made by Alexander Wright and Co., of Westminster. Air is passed in by a blower, the pressure being kept constant by a governor. After passing through the meter the air is delivered into a safety-box, which is used to prevent inflammable gas from passing back into the meter, and also to give relief in case of back ignition. A rubber-bag is used to prevent fluctuations in the meter during the suction stroke. The direct measurement of air supply is usually considered a difficult and dangerous undertaking; but the author stated that no trouble had been found with this portion of the apparatus. The air meter was checked by blowing air through it into the gas-holder, and was found to be correct to the half of 1 per cent.

The amount of heat passed into the jacket was measured by running all the cooling water for a single test into a tank, and taking the temperature by means of thermometers. Samples of exhaust gases were taken and analysed. In this detail the great difficulty is not in making the analysis, but in obtaining a true sample. A single bubble of gas was taken from just below the exhaust valve after each explosion. The apparatus for doing this was illustrated by means of wall diagrams, which showed that the object aimed at was obtained by an electrical relay which actuated a small needle valve that allowed a single bubble of gas to be sucked into the gas receiver. Power developed was ascertained by a Wayne indicator; an instrument found superior to others tried. Prof. Burstall states that it is in careful hands, apparently the most accurate indicator of the present time. It has a rotating piston in place of the ordinary reciprocating piston. This piston does not touch the containing cylinder at its outer extremities, but is guided at the centre on circular bearings. In this way friction is small and not liable to change, because the bearings can be well lubricated. There are many interesting points about its mechanism which were described in the report. Thin sheets of smoked mica are used in place of the ordinary metallic faced paper or "cards." This device is highly spoken of by those who have had experience in its use.

As the engine was not fitted with a timing valve—a device which the author considers absolutely necessary to all sizes of gas-engines—it was decided to attempt to ignite the charge by means of an electric spark, and it was hoped that electric ignition would prove more certain than any form of hot-tube igniter. This, however, did not prove to be the case; and not the least interesting part of the report is contained in the discussion of the failure in this detail. The rope-break used was of the ordinary kind, having dead weights on the lower end of the rope and a spring balance at the upper end. A Harding counter for ascertaining the number of revolutions was employed, and analyses of the coal-gas were made by Mr. G. N. Huntly, who also supervised the analyses of the exhaust gas. The results of seventeen preliminary experiments made were given in a table contained in the report, and on copies of indicator diagrams attached. The mechanical efficiency of the engine varied from 76 to 84 per cent., the mean value of the whole seventeen tests being 81 per cent. It must be remembered, however, that these experiments are, as stated, preliminary, and, it may be added, they have been carried out under circumstances of exceptional difficulty, which conditions, however, will not recur. The report states that it would seem probable that the influence of increased compression on economy is due to the fact that weaker charges can be burnt completely during the stroke when the compression is high. The tests seem to indicate, the report continues, that economy depends on the choice of the correct ratio of air to gas; and this ratio increases with the compression. The number of experiments, however, are, as the report states, not yet sufficient to determine what this ratio is for any given compression. It is intended to make a series of tests sufficient for determining this important point. Further experiments are to be made at a constant speed; the variables being the load, the ratio of air to gas, and the compression. It is stated that, so far as these additional experiments have been carried, the first results have been borne out in regard to the advantage of using a suitable mixture, and in showing the importance of making an accurate analysis of the exhaust gases.

The discussion which took place on the presentation of the report did not add materially to information on the subject. Some of the criticisms were very wide of the mark, more especially in regard to one point, upon which much stress was laid, viz. the leakage of gas through the indicator. This was supposed by some speakers to be sufficient to vitiate the value of the experiments, but, according to Prof. Burstall's tests, made in order to elucidate this point, the consumption of gas by the indicator was so minute as to be imperceptible. It was stated during the discussion by Mr. Burstall, a brother of the author, that, according to calculation, if diagrams were taken every five minutes, when running at 200 revolutions, and if the whole of the gas escaped on the stroke, the loss would be one-fiftieth of 1 per cent.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—A combined examination of non-resident candidates for open scholarships, exhibitions, &c., will be held at Trinity College, Clare College and Trinity Hall, beginning on November 1. At Trinity College there will be offered for competition about ten scholarships, about ten exhibitions, and about three sizarships. Scholarships include (1) major scholarships, of the value of 80*l.* a year, (2) minor scholarships, of the value of 75*l.* a year or of 50*l.* a year. Exhibitions are generally of the value of 40*l.* a year. Scholarships and exhibitions are tenable for two years from the commencement of residence. Sizarships are of the value of about 100*l.* a year (namely, a payment in money of 80*l.*, and a remission of College fees and dues to the extent of about 20*l.*). They are tenable until the expiration of nine terms from the commencement of residence, unless the holder is previously elected to a major scholarship. Candidates for sizarships must send satisfactory evidence to one of the Tutors that they are in need of the assistance given to sizars. The subjects of examination will be classics, mathematics, natural sciences, moral sciences, and history. A candidate may take any one of these subjects, or any combination of subjects so far as the arrangement of the papers in the examination permits. At Clare College about eight scholarships of values varying from 80*l.* to 40*l.*, and at Trinity Hall six scholarships at least, ranging between the same values, will be awarded. These scholarships are offered for proficiency in classics, or mathematics, or natural science, or history. Deserving candidates who do not attain the standard for these scholarships may be awarded exhibitions of the annual value of 30*l.* Forms of application for admission to the examination may be obtained from any of the Tutors of the Colleges named.

IN the House of Commons on Thursday, in reply to a question whether it was the intention of the Government to take the second reading of the London University Commission Bill before Whitsuntide, Mr. Balfour said he could not give any definite promise in view of the present state of public business, but he would not discourage the hope that they might have a chance of reaching the Bill as early as some time before Whitsuntide.

A PARLIAMENTARY paper issued by the Science and Art Department states that the total amount expended on technical education during the year 1895–96 in the United Kingdom was 787,467*l.*, and that the estimated total expenditure for the year 1896–97 was 847,62c*l.*, exclusive of the sums allocated to technical education under the Welsh Intermediate Education Act, 1889. The total amount of the residue received under the Local Taxation Act by counties and county boroughs in England in 1895–96 was 775,944*l.*, of which 616,607*l.* was appropriated to educational purposes, and 159,336*l.* to relief of rates, the latter sum including 121,558*l.* devoted by the London County Council to that purpose. In Wales the whole of the residue grant of 37,236*l.* paid to thirteen counties and three county boroughs is devoted to intermediate and technical education. The amount of residue received by Scottish authorities was 38,262*l.*, of which 28,999*l.* was apportioned to technical education, and 9158*l.* to relief of rates. In Ireland the residue is not applicable to technical education, but eleven local authorities are making grants out of the rates for that purpose.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xx. No. 2.—On the focal surfaces of the congruences of tangents to a given surface, by A. Pell. This paper is based upon two theorems given by Darboux ("Théorie générale des Surfaces," vol. iii. p. 121) and Kœnigs ("Sur les propriétés infinitésimal de l'espace réglé"), viz.: the locus of the centres of geodesic curvature of lines of curvature of any surface is the edge of regression of the developable surface, generated by the tangent planes of the surface at all points of the lines of curvature, and the edges of regression of the developable surfaces of a congruence form two families of curves on the focal surfaces (say S_A and S_B corresponding to the focal surfaces A and B), the osculating planes of which are tangent to the surfaces B and A respectively, and the points of contact describe on these surfaces two families of conjugate lines S_A and S_B. Other theorems discussed are due to T. Caronnet (*Comptes rendus*, 1892), E. Cosserat (*C.R.*, 1894) and A. Demoulin (*C.R.*, 1894).—Displacements depending on one, two and three parameters in a space of four dimensions, by T. Craig. This is a concise generalisation to a space of four dimensions of the kinematical methods developed by Darboux in the first two volumes of his "Théorie générale des Surfaces." The author employs Poincaré's nomenclature (*cf.* "Sur les résidus des intégrales doubles," *Acta Math.*, t. 9, p. 385).—Further researches in the theory of quintic equations, by Emory McClintock. The paper contains four parts. The first part is a preliminary classification of quintics into reducible and irreducible, and again into resolvable and unresolvable quintics. The second is a simplified restatement of the author's earlier discoveries. The third contains a presentation of the necessary form of the coefficients of the general resolvable quintic; and the last part is occupied with the development of a theorem according to which any given resolvable quintic engenders another for which the author's sextic resolvent has the same rational value. The memoir was read at the Toronto meeting of the American Mathematical Society in August last.

Symons's Monthly Meteorological Magazine, April.—The climate of Paris, by M. J. Jaubert. This is an account of an interesting and useful book by the meteorologist of the Montsouris Observatory, compiled from all available sources in the Paris district. The mean temperature at the National Observatory is 51°·3, but in the suburbs it is less, *e.g.*, Parc St. Maur, 50°·0. The lowest temperature recorded in the neighbourhood was −17°·5, in December 1871, and the highest was 101°·1 in 1874 and 1881. Fogs are rather frequent, about forty in a year, but a foggy day is defined as one on which objects at a distance of a mile cannot be distinguished. The mean rainfall is about 22 inches, but the amount varies in different parts of the city. About thirty thunderstorms occur in a year, mostly in summer. Very little hail falls, and the stones are seldom more than ¾ of an inch in diameter. The yearly average amount of cloud is 6·0.—Results of meteorological observations at Camden Square for forty years, 1858–97. The average rainfall was 1·71 inches; the amount last March was 1·46 inches. The mean of all the highest shade temperatures was 61°·9, and the mean of all the lowest minimum temperatures was 25°·3. In March last the absolute extremes were 59°·1 and 25°·1, while the temperature on the grass fell below freezing point on twenty-four nights.

Bollettino della Società Sismologica Italiana, vol. iii. No. 7.—Some modifications of the doubly sensitive electric seismoscope, and instructions for its installation and working, by G. Agamennone.—The seismic recorder with increased velocity on the occasion of the earthquake of September 21, 1897, by P. Tacchini.—Diurnal movement of the obelisk of Washington, by E. Oddone.—Notices of earthquakes recorded in Italy (May 14–23, 1897), the most important being an elaborate account of the earthquake of the Tyrrhenian Sea on May 15.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 10.—"On the Rotation of Plane of Polarisation of Electric Waves by a Twisted Structure." By Jagadis Chunder Bose, M.A., D.Sc., Professor of Physical Science, Presidency College, Calcutta. Communicated by Lord Rayleigh, F.R.S.

"On the Production of a 'Dark Cross' in the field of Electromagnetic Radiation." By Jagadis Chunder Bose, M.A., D.Sc., Professor of Physical Science, Presidency College, Calcutta. Communicated by Lord Rayleigh, F.R.S.

Chemical Society, April 21.—Prof. Dewar, President, in the chair.—The following papers were read:—The carbohydrates of barley-straw, by C. F. Cross, E. J. Bevan and C. Smith. The ratio of the furfural-yielding carbohydrates to total carbohydrates in barley-straw is not affected by removing the ears at the flowering stage; the constancy of this ratio under wide variations of the conditions of growth has now been established.—Isomeric bornylamines, by M. O. Forster. The base obtained from the formyl derivative got by heating camphor with ammonium formate, and from the reduction of camphoroxime, is a mixture of bornylamine and an isomeride which the author terms neobornylamine.—Some derivatives of benzophenone, by F. E. Matthews. The author has obtained a benzophenone hexachloride, $C_6H_5Cl_6.COPh$, which yields a mononitro-derivative and a sulphonic acid.—Experiments on lauronolic acid, by S. B. Schryver.—The drying of ammonia and of hydrogen chloride, by H. B. Baker. A repetition of the author's previous work shows that ammonia and hydrogen chloride can be dried by phosphorus pentoxide, and that dry ammonium chloride is not dissociated at 350°; Gutmann's strictures on the work are hence unfounded.—Note on some of the properties of methylene diiodide, by H. G. Madan. Methylene iodide darkens appreciably in colour on a few hours' exposure to sunlight, and in the cold dissolves sufficient sulphur to raise its refractive index for the D line from 1·756 to 1·778; it dissolves phosphorus readily, giving a light yellow solution which has the refractive index for D of 1·95 at 14°, and is not spontaneously inflammable on evaporation in the air.—The condensation of chloral hydrate with orcinol, by J. T. Hewitt and F. G. Pope. Chloral hydrate and orcinol condense on heating in aqueous solution, yielding an acid of the composition $C_{16}H_{16}O_6$, which is easily converted into a lactone $C_{16}H_{14}O_5$.—Note on hexamethylene and its derivatives, by Miss E. C. Fortey. Gallician petroleum, like American light petroleum, contains hexamethylene; it boils at 81·75°, and has the specific gravity of 0·7899 at 0°/0°. Its mono- and dichloro-derivatives have been prepared and investigated.—The yellow colouring matter of the leaves of *Arctostaphylos uva ursi*, by A. G. Perkin. In addition to gallic acid, arbutin, ericolin and gallotannin, the author has separated a yellow colouring matter of the composition $C_{15}H_{10}O_7$ from the leaves of this plant, and has also demonstrated the presence of ellagitannin.—The yellow colouring matters of various adulterants of Sicilian sumach, Part iv., by A. G. Perkin and P. J. Wood.—The hydrolysis of starch by acids, by H. Johnson.—Synthesis of cis- and trans-caronic acids, by W. H. Perkin, jun., and J. F. Thorpe. On hydrolysing the alkylic salts of α-bromodimethylglutarate, a mixture of cis- and trans-caronic acid is obtained; caronic acid is therefore, as Baeyer concluded, a dimethyltrimethylenedicarboxylic acid of the constitution

$$CMe_2\left\langle\begin{array}{l}CH.CO_2H\\ |\\ CH.CO_2H.\end{array}\right.$$

—Preparation of solid ammonium cyanate, by J. Walker and J. K. Wood. On mixing a solution of ammonia and of cyanic acid in anhydrous ether at − 20° and filtering, a residue of solid ammonium cyanate is obtained.—The chlorine derivatives of pyridine, Part i., by W. J. Sell and F. W. Dootson.—Simple experimental illustrations of the law of multiples, by A. W. Jones. Equivalent weights of potassium chlorate and perchlorate are heated, and it is shown that the residues of potassium chloride are equal in weight, and that the volumes of the oxygen evolved are as three to four in the two cases.—Lauronolic acid, by R. W. Collinson and W. H. Perkin, jun. Lauronolic acid yields a hydrobromide, $C_9H_{15}O_2Br$, and when oxidised gives a syrupy acid of the composition $C_9H_{14}O_5$.—The action of aluminium chloride on camphoric anhydride, by F. H. Lees and W. H. Perkin, jun.—On the action of bromacetal on the sodium derivative of ethylic malonate, by W. H. Perkin, jun., and C. H. G. Sprankling. On heating bromacetal with ethylic sodiomalonate at 140-150, ethylic acetalmalonate, $(CO_2Et)_2CH.CH_2.CH(OEt)_2$ is obtained.—The sulphonation of benzophenone and of diphenylmethane, by A. Lapworth.—The separation of optical isomerides, by F. S. Kipping and W. J. Pope. It is shown that enantiomorphously related substances are not equally soluble in a solution containing a third enantiomorphous substance.

Zoological Society, April 19.—Prof. Howes, F.R.S., in the chair.—Mr. Ernest W. L. Holt read a paper on the breeding of the Dragonet (*Callionymus lyra*) in the Marine Biological Association's aquarium at Plymouth, and made some remarks on the significance of the sexual dimorphism of this fish, the courtship and pairing of which were described in detail.—A communication from the Rev. H. S. Gorham contained an account of the Serricorn Coleoptera of St. Vincent, Grenada, and the Grenadines, obtained through the operation of the West India Committee of the Royal Society and the British Association, for the exploration of the fauna of the West Indies.—A second communication from the Rev. H. S. Gorham on the Coleoptera of the families *Erotylidæ*, *Endomychidæ*, and *Coccinellidæ* from the West Indies, obtained in the same manner, was also read.—A communication was read from Dr. Bashford Dean, describing further evidence of the existence of possible paired fins in the problematical Devonian organism *Palæospondylus*. He maintained his former views, as opposed to those of Dr. R. H. Traquair expressed in a former communication to the Society.

Mathematical Society, April 7.—Dr. Hobson, F.R.S., Vice-President, in the chair.—The following communications were made:—An essay towards the generating functions of ternariants, by Prof. Forsyth, F.R.S.—On systems of forces in space of n dimensions, by W. H. Young.—Zeroes of the Bessel functions, by H. M. Macdonald.

PARIS.

Academy of Sciences, April 25.—M. Wolf in the chair.—The Secretary announced to the Academy the death of M. Demontzey, Correspondant in the section of Rural Economy.—Influence of the place and mode of introduction on the development of the immunising effects of anti-diphtheric serum, by M. S. Arloing. When the anti-diphtheric serum is administered separately its complete antitoxic action is at a maximum when it is introduced into the blood, at a minimum when introduced into the conjunctive tissue.—On rectilinear congruences, by M. C. Guichard.—On differential equations of the second order with fixed critical points, by M. Paul Painlevé.—On groups which occur in the generalisation of analytical functions, by M. P. Medolaghi.—On the resistance of thick plates, by M. Ribière.—On a new standard of light, by M. Ch. Féry. The flame proposed is that of acetylene burnt from a special jet of thermometer tube, 0·5 mm. in diameter. For flames whose heights are between 10 mm. and 25 mm., the relation between the intensity and the height of the flame is a linear one. The apparatus is suggested as a suitable one for rapidly determining the quality of a commercial calcium carbide.—On the thermo-electric electromotive forces in crystallised bismuth, by M. Louis Perrot. The chief difficulty in these determinations was obtaining the bismuth in large, clearly-defined crystals, a difficulty surmounted by slowly cooling the pure metal in a Perrot furnace. The other metal chosen for the couple was copper, measurements being made at temperatures varying from 11° to 100° C. on surfaces parallel and perpendicular respectively to the principal axis. The ratios found for the electromotive forces in the two positions of the crystal were between 2·0 and 2·4 according to the temperature, the crystalline structure thus exerting a greater influence than had been previously supposed upon the thermo-electric constants of bismuth.—On the constitution of the explosive spark in a dielectric liquid, by M. L. Décombe. Photographs from a rapidly revolving mirror of a spark between metallic poles in melted vaseline, show that the spark differs from that obtained in air in possessing a uniform brightness throughout its whole length.—Remarks on the kathode rays, by M. E. Goldstein. A discussion of some results of M. Deslandres, and more especially of the relation between the kathode rays, and the repulsion of the tails of comets by the sun.—Study of the speaking voice by the phonograph, by M. Marage. The quality of each vowel is due to a certain number of harmonics, I, U, OU being formed by one only, A by three.—On the industrial treatment of the emerald in the electric furnace, by M. P. Lebeau. A mixture of 100 kilograms of emerald with half its weight of coke, submitted for an hour to a current of 1500 amperes in the electric furnace, gave two layers, the upper consisting of silicides of aluminium and beryllium, the lower of impure crystallised silicon.—On the quinoneoximes, by M. Amand Valeur. A thermochemical paper giving the heats of combustion and formation of quinoneoxime, thymoquinoneoxime, and α- and β-napthoquinoneoximes. As a general result it is found that the replacement of the quinonic oxygen atom by the residue N(OH) raises the heat of combustion about sixty calories.—On the products of hydrolysis of ouabaïne, by M. Arnaud. A study of the sugar produced shows that the crystals were identical in form and habit with rhamnose, with which the other physical constants and chemical properties also agreed. The other product of hydrolysis was a resin, the further study of which is deferred.—Chlorinating action of ferric chloride in the aromatic series, by M. V. Thomas. By the action of ferric chloride upon boiling benzene, monochlorbenzene is readily obtained. This again, submitted to the action of more ferric chloride, gives a mixture of dichlorbenzenes. The reaction can be pushed as far as the hexachloride. Toluene behaves similarly, the substitution being always in the ring and not in the side chain.—On the dialkyl phosphoric ethers, by M. J. Cavalier.—On the acid phosphoglycerates, by MM. Adrian and Trillat.—On the saccharification of starch by malt, by M. Henri Pottevin. The experiments given show that the transformation of starch into maltose is the result of two distinct operations, dextrine being always an intermediate product. The differences observed between the various dextrines are differences in physical state only.—Hepatic pigments in the Vertebrates, by MM. A. Dastre and N. Floresco.—On the ferments causing the diseases of wines, by M. J. Laborde.—On some points of external morphology of the *Aphroditæ*, by M. G. Darboux.—On the nitrogenous nutrition of phanerogamous plants by the aid of amines, salts of ammonium compounds, and alkaloids, by M. L. Lutz. The amines can be assimilated directly without previous conversion into ammoniacal salts or nitrates. Amines of low molecular weight are more easily taken up by the plant.—Influence of some poisons on the antitoxic power of the blood, by MM. C. J. Salomonsen and Th. Madsen.—Remarks on a paper of M. Daniel Berthelot, entitled "On the rigorous determination of the molecular weights of gases," by M. G. Marqfoy.

DIARY OF SOCIETIES.

THURSDAY, MAY 5.

ROYAL SOCIETY, at 4.30.—Observations on the Action of Anæsthetics on Vegetable and Animal Protoplasm: Dr. Waller, F.R.S., and Prof. Farmer.—On certain Structures formed in the Drying of a Fluid with Particles in Suspension: Miss C. A. Raisin.—On Photographic Evidence of the Objective Reality of Combination Tones: R. W. Forsyth and R. J. Sowter.—The Relations between the Hybrid and Parent Forms of Echinoid Larvæ: H. M. Vernon.

LINNEAN SOCIETY, at 8.—On some Spitsbergen Collembola: Sir John Lubbock, Bart., M.P., F.R.S.—On the Structure and Development of *Soranthera*: Miss Ethel Barton.—The Species, the Sex, and the Individual: J. T. Cunningham.

CHEMICAL SOCIETY, at 8.—The Reactions of the Carbohydrates with Hydrogen Peroxide: C. F. Cross, E. J. Bevan, and Claud Smith.—The Properties and Relationships of Dihydroxytartaric Acid, Part II.: H. J. H. Fenton.—The Affinity Constants of certain Hydroxy-acids: S. Skinner.—Molecular Weights in Solution of Permanganates, Perchlorates, and Periodates: J. Murray Crofts.

INSTITUTION OF ELECTRICAL ENGINEERS (Society of Arts), at 8.—The Prevention of Interruptions to Electricity Supply: Leonard Andrews.

FRIDAY, MAY 6.

ROYAL INSTITUTION, at 9.—Living Crystals: Edward A. Minchin.

GEOLOGISTS' ASSOCIATION, at 8.—Notes on Skye: Horace B. Woodward, F.R.S.—Observations in Lapland: Aubrey Strahan.

SATURDAY, MAY 7.

GEOLOGISTS' ASSOCIATION.—Excursion to Hillmorton and Rugby. Director: Beeby Thompson.

MONDAY, MAY 9.

SOCIETY OF ARTS, at 8.—Electric Traction: Prof. Carus Wilson.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Journey across Tibet from West to East: Captain M. S. Wellby.

TUESDAY, MAY 10.

ANTHROPOLOGICAL INSTITUTE, at 8.30.

RÖNTGEN SOCIETY, at 8.—Notes on the Description of a New Induction Coil in *Electrical Review*, February 4, 1898: A. Apps.—Some Notes on Contact Breakers: Dr. J. Macintyre.

ROYAL VICTORIA HALL, at 8.30.—A Simple Experiment and its Explanation: Prof. McLeod.

WEDNESDAY, MAY 11.

SOCIETY OF ARTS, at 8.—Water Gas and its Applications: Vivian B. Lewes.

THURSDAY, MAY 12.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: The Electrical Response of Nerve to a Single Stimulus investigated with the Capillary Electrometer. Preliminary Communication: Prof. Gotch, F.R.S., and G. J. Burch.—A Study of the Phyto-Plankton of the Atlantic: G. Murray, F.R.S., and V. H. Blackman.—Effects of Prolonged Heating on the Magnetic Properties of Iron: S. R. Roget.—On the Connection of Algebraic Functions with Automorphic Functions: E. T. Whittaker.

ROYAL INSTITUTION, at 3.—Heat: Lord Rayleigh.

MATHEMATICAL SOCIETY, at 8.—On the Numerical value of $\int_0^h e^{x^2}\,dx$: H. G. Dawson.—On the Reflection and Transmission of Electric Waves by a Metallic Grating: Prof. Lamb, F.R.S.—Notes on some Fundamental Properties of Manifolds: A. E. H. Love, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS (Society of Arts), at 8.

FRIDAY, MAY 13.

ROYAL INSTITUTION, at 9.—Recent Experiments on certain of the Chemical Elements in Relation to Heat: Prof. W. A. Tilden, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 8.

PHYSICAL SOCIETY, at 5.—Galvanometers, Part II.: Prof. W. E. Ayrton and T. Mather.

MALACOLOGICAL SOCIETY, at 8.

SATURDAY, MAY 14.

GEOLOGISTS' ASSOCIATION (King's Cross, G.N.R.), at 1.20.—Excursion to Ayot and Hatfield. Directors: J. Hopkinson and A. E. Salter.

BOOKS AND SERIALS RECEIVED.

BOOKS.—A Student of Nature: R. M. Fergusson (A. Gardner).—Royal University of Ireland Calendar, 1898 (Dublin, Thom).—A Course in Mechanical Drawing: J. S. Reid (Chapman).—Quantitative Chemical Analysis by Electrolysis: Drs. A. Classen and W. Löb, translated by W. H. Herrick and B. B. Boltwood (Chapman).—Technical Mycology: Dr. F. Lafar, translated by C. T. C. Salter, Vol. 1 (Griffin).—Electro-Physiology: Prof. W. Biedermann, translated by F. A. Welby, Vol. 2 (Macmillan).—Text-Book of Physical Chemistry: Prof. C. L. Speyers (Spon).—Methods for the Analysis of Ores, Pig Iron and Steel (Easton, Pa., Chemical Publishing Company).—First Stage Magnetism and Electricity: Dr. R. H. Jude (Clive).—A Northern Highway of the Tsar: A. Trevor-Battye (Constable).—Elementary General Science: A. T. Simmons and L. M. Jones (Macmillan).—Journal of the Iron and Steel Institute, Name-Index, Vols. I to L: edited by B. H. Brough (Spon).

SERIALS.—National Geographic Magazine, April (Washington).—American Journal of Psychology, Vol. ix. No. 3 (Worcester, Mass.).—Good Words, May (Isbister).—Sunday Magazine, May (Isbister).—Natural Science, May (Dent).—Botanische Jahrbücher, Vierundzwanzigster Band, v. Heft (Leipzig, Engelmann).—Century Magazine, May (Macmillan).—American Naturalist, March (Boston, Ginn).—Humanitarian, May (Hutchinson).—Proceedings of the University of Durham Philosophical Society, Part 1 (Newcastle-on-Tyne).—Journal of the Royal Microscopical Society, April (Williams).—Journal of Botany, May (West).—Bulletin of the American Mathematical Society, April (N.Y., Macmillan).—Contemporary Review, May (Isbister).—Scribner's Magazine, May (Low).—National Review, May (Arnold).—Brain, Part 80, May (Macmillan).—Fortnightly Review, May (Chapman).—Among British Birds in their Nesting Haunts: O. A. J. Lee. Part xi. (Edinburgh, Douglas).—Knowledge, May (High Holborn).—Zeitschrift für Physikalische Chemie, xxv. Band, 4 Heft (Leipzig, Engelmann).

THURSDAY, MAY 12, 1898.

ZOOLOGY AS A HIGHER STUDY.

A Text-book of Zoology. By Prof. T. Jeffery Parker, D.Sc., F.R.S., and Prof. William A. Haswell, M.A., D.Sc., F.R.S. 2 vols. Pp. xxxv + 779 and xx + 683. (London: Macmillan and Co., Ltd., 1897.)

Traité de Zoologie Concrète. By Prof. Yves Delages and E. Hérouard. Vols. i. and v. Pp. xxx + 584 and xi + 372. (Paris: Reinwald, Schleicher frères, 1896 and 1897.)

THOSE who write books to assist the University professor and the advanced student of zoology are entitled to great consideration on the part of those to whom their work is addressed, for their self-appointed task is a most difficult and in many ways an elusive one. The mass of detailed concrete fact with which such authors attempt to grapple is simply prodigious, and increases yearly at an enormously rapid rate. The generalisations and theories which hold these facts together are in proportion delicate and flimsy structures which, though they are absolutely essential, yet are easily strained, misrepresented, ignored or ludicrously accentuated by any but the most careful and judicious writer.

In judging an expository treatise dealing with a branch of science, it is necessary that a reviewer should not only recognise the claims upon his gratitude which the long labour of an author may possess, but should also distinctly appreciate the precise purpose of the treatise under notice—the point of view adopted by the author, and his reason for adopting it. The book by Profs. Parker and Haswell is addressed to University students, but yet is intended to be fitted for beginners. It consists essentially in an extended application of the method of teaching by detailed examination of a series of types or examples, now used almost universally for a preliminary or elementary course of zoological study. This method was started in this country not by Huxley, as our authors state, but by Rolleston. It is probably the best way of commencing the study of zoology. It should, however, be limited to a course involving some six or eight well-selected examples. To carry it on as the staple or main form of study after the preliminary course is, in my judgment, a serious error. An acquaintance with the large generalisations of zoology, a determined grasp of some of its unsolved problems, a concrete appreciation of the actual range and extent of genera and species, recent and fossil, in at any rate some large groups in a *complete* manner, and not by mere vague sampling, are what the University student needs to have offered him by way of education. He will, of course, examine and dissect carefully as many animals as he can; but they will not necessarily be those selected as examples by our authors. Nor should the student, I venture to think (after his preliminary course), mechanically demonstrate and identify a host of details in animal after animal, simply because those details are there capable of being identified, and are mentioned in the text-book. This would tend to make our delightful and romantic comparative anatomy as dreary and soul-destroying as is what Rolleston termed "Anthropotomy." A kind of training, it is true, may be given in this way, but it is a bad and injurious training, and does not lead to the progress of zoology or comparative anatomy.

It seems to me that, as a book to guide the student to a second course rather than one dealing with a further series of common-place examples treated with measured, not to say exasperating, detail, we should welcome one which treated only of exceptional, puzzling and debateable animals, such, for example, as Trichoplax, Limnocodium, Ctenoplana, a Cystid, Sternaspis, Acanthobdella, Lingula, Limulus, Peripatus, Neomenia, Balanoglossus, Hippocampus, Siphonops, Hatteria, Rhea and Ornithorhynchus. In such a book it would, at any rate, be necessary to consider the *significance* of the structures described, and to make them really the means of *discussing* the affinities of the several animals.

The publication of Profs. Parker's and Haswell's text-book was almost simultaneous with the sad and untimely death of one of its authors, Jeffery Parker. Many of the beautiful original drawings (more than one thousand in number!) with which the book is illustrated are from his pencil. There can be no doubt that his health suffered for a year or more before he succumbed, and hence we are justified in assigning responsibility for the very numerous and curious errors which the book contains to Prof. Haswell and to Prof. W. N. Parker, of Cardiff, who undertook a final revise of the sheets in this country, rather than to Jeffery Parker.

I have already indicated that I do not think that the unlimited extension of the method of teaching by detailed examination of representative types is satisfactory as *the* method to be pursued in a University course. Nevertheless the student will undoubtedly find Parker's and Haswell's book useful in assisting him in dissection and in examination of skeletons. The authors give a general account of the structure of the larger and smaller groups, illustrated by the selected examples, and a brief exposition of the classification and contents of each group of the animal kingdom; but there is no profession of making this exposition complete. Chapters on geographical distribution and the history of zoology are given at the end of the book, which are so well done that one could wish they were longer.

The authors have deliberately adopted a course of procedure with regard to the citation of authorities and references to monographs and other literature, which they defend in their preface at some length. Their procedure is simply this—that they give no references at all; they never cite the name of an authority, nor give the vaguest intimation as to whether the statement they are making is as old as Cuvier, or is a brand-new discovery, or a special opinion of their own. Even when they copy a woodcut from a previous work, they often omit to state the name of the author to whom it is due, and only quote the copyist who preceded them in taking it from the original author. I can not sufficiently strongly condemn this policy of omission. To me it appears simply disastrous. The authors of the present book have only imitated the example of some recent German writers in thus effacing the discoverer's claim to recognition, and, whilst reducing their own statements to a condition of puzzling confusion, have rendered their book useless to the serious student who wishes to consult original authorities.

In addition to this objection to the omission of reference to authors, there is the fact that it suggests (perhaps rightly, perhaps wrongly) that the author is ignorant of the correct name with which to connect a particular view or discovery, or that he is too lazy to look the matter up, or that he wishes fraudulently to give the impression that he makes such and such a statement of his own knowledge and independently. Finally there is the objection, that by the omission of authors' and discoverers' names, and by thus failing to pursue the historical method of exposition, a very great means of lending interest to a vast mass of detail is sacrificed. Not only is the student deprived of what is often, when present, a very important aid to his memory, but what is in many cases the best and simplest scheme for the presentation of the subject to the student—viz. its actual historical development—is rendered impossible. I hope that others who feel as strongly as I do as to the injury done by those zoologists who deliberately ignore or refuse to cite the names and writings of their predecessors and contemporaries, will join in taking steps to condemn and, if possible, arrest, by the expression of authoritative public opinion, what seems to me a mischievous and mean kind of literary injustice.

The omission of reference to authorities is no doubt to some extent the cause of the existence in Parker's and Haswell's "Text-book of Zoology" of mistakes which either Prof. Haswell or Prof. W. N. Parker would have seized upon and corrected had they appeared as unverified by reference to a recent author in an ordinary treatise. But since no statement in the book is so supported, a reader revising the proof for the author would, on seeing an extraordinary assertion, say to himself, "Dear me! I suppose that is something new; something I've missed." It is probably owing to this that blunders have been left to mislead the student, and to undermine our confidence in all the statements made in the book which have any appearance of novelty. I have not searched the "Text-book" for errors, but I have come across the following in "sampling" its pages. Many of them are so serious that they should certainly be corrected in a new edition with the least possible delay, and steps should be taken to ascertain whether others of a like kind exist, and if so to remove them.

The most astonishing of these errors is the assertion by two sons of W. Kitchen Parker, that ossification occurs in the Selachii. They say (vol. ii. p. 158):

"The skeleton is composed of cartilage with, in many cases, deposition of bony matter in special places—notably in the jaws and the vertebral column. The entire spinal column may be nearly completely cartilaginous (Hexanchus and Heptanchus), but usually the centra are strengthened by radiating or concentric lamellæ of bone; or they may be completely ossified."

On the other hand (an inconsistency due probably to duplicate authorship and multiple responsibility) we find in the description of Chiloscyllium on p. 136, the statement that the skeleton is composed entirely of cartilage with, in certain places, depositions of calcareous salts. And, moreover, in the histological introduction in the first volume "calcified cartilage" is very properly mentioned and distinguished from bone. In attempting to follow up this extraordinary blunder, viz. the assertion that ossification takes place in the cartilage of Selachii, I have looked into the translation of Wiedersheim's "Comparative Anatomy of Vertebrates," and there I find the same assertion, the word which in the original German is "Verkalkung" being translated "ossification" (as though the German had been "Verknocherung"). Now the translator who made this mistake is Prof. W. N. Parker, of Cardiff. Hence we may conclude that it is he who is responsible for the similar statement in the "Text-book," and not either the late Jeffery Parker nor Prof. Haswell of Sydney. But whose soever the fault may be, the sooner so grossly misleading a statement is removed from a book addressed to young students, the better.

The following erroneous statements occur in vol. i. On p. 423 we read:

"Externally each nephridium [of the earthworm] opens by one of the small excretory pores which have already been mentioned as occurring on the ventral surface; internally it ends in a funnel-shaped ciliated extremity with an aperture, the *nephrostome*, opening into the cavity of the corresponding segment."

As a matter of fact, it is a curious and characteristic thing that the nephridia of Chætopoda do *not* open into the segment corresponding to the external pore, but into the segment next in front of it.

P. 372. In the description of Holothuria, our authors state:

"Opening into the cloaca is a pair of remarkable organs of doubtful function, the so-called *respiratory trees*. . . . Each of the terminal branches ends in a ciliated funnel opening into the cœlome."

As a matter of fact, the Holothurian respiratory tree does not possess such ciliated funnels, and in this differs notably from the so-called "posterior nephridia" of the Echiurids.

P. 561. In the description of Peripatus we read:

"A layer of cœlomic epithelium lines the wall of the cœlome and invests the contained organs. Incomplete muscular partitions divide the cavity into a median and two lateral compartments."

Nevertheless the authors elsewhere recognise the fact demonstrated by Sedgwick and myself, that the blood-holding body-cavity of Arthropods is *not* the cœlom but an enlarged system of blood-sinuses the hæmocœl; whilst the cœlom is reduced to perigonadial and perinephridial rudiments.

P. 732. We read that in Nautilus

"A large *vena cava* occupies a position corresponding closely with that of Sepia. It presents the remarkable peculiarity of being in free communication by numerous (valvular) apertures with the viscero-pericardial cavity of the cœlome."

A remarkable peculiarity, indeed, and one which has no existence in fact! The vena cava communicates with veinous blood-spaces by those apertures, and *not* with the cœlom.

In addition to such down-right errors as the above, it must be noted that the authors have too readily accepted the statements of some writers whose names, however, as usual, they do not give. Thus they describe and figure the so-called "Salinella" of Frenzel as though some evidence worthy of attention had been produced in support of the existence of such a creature; and they declare that a species of Apus "has been shown to be" hermaphrodite. They allude to the assertions of Mr. H. M. Bernard. It is well that that gentleman's attention should be drawn to the fact, and that he should at once either withdraw or confirm by some evidence his published statement that a species of Apus is hermaphrodite.

As to faults of omission—there is no doubt always room for divergence of opinion as to what should and should not be comprised within the area of a book necessarily selective and limited. But nothing can, it seems to me, justify the omission of all reference to the important Leech, *Acanthobdella*, when the affinities and origin of the Hirudinea are discussed; nor such an inadequate account of the tubular continuations of the pericardial cœlom of Lamellibranchs as that which is given at p. 640, where Keber's organ is treated as an excretory organ, and nothing said of its morphological significance.

Opinions, no doubt, may differ as to the exact form and spelling of many zoological terms. At the same time, I fail to see the justification for writing "cœlome" in the place of "cœlom," "Cœlenterata" in place of "Cœlentera," and "Echinodermata" in the place of "Echinoderma."

It will thus be seen that although there is a great deal of excellent description in the new "Text-book," and many beautiful and useful figures, there is yet a very serious amount of inaccuracy, and in some matters of great importance a want of sound judgment which must seriously interfere with its utility.

It is not uninteresting to compare with the text-book of Parker and Haswell, one of the four text-books of zoology which are in course of publication at the present moment in France. We have that by Prof. Delages and M. Hérouard, also a text-book by Prof. Edmond Perrier of comprehensive scope and abundant detail; one edited by M. Raphael Blanchard, to which a whole series of authors contribute each his fascicle; and one by Prof. Roule, of Toulouse. The work projected by Prof. Delages is the most original of these, on account of the method pursued. Prof. Delages aims at a complete logical exposition of the characters of each phylum, class, order, family and genus of the animal kingdom. Not only that, but he gives a schematic figure which corresponds with his description of each group—so that the student realises in concrete form the characteristics of a class—an order or a family—characteristics which may be modified by greater or less development, but give the essential features of the group. Hence the term "Zoologie Concrète," which forms the title of the work. The plan is a carrying out into a complete system of the method which I (borrowing it from older writers) made use of when in my article Mollusca ("Encycl. Brit."), I drew an Archi-mollusc. Prof. Delages will, when he comes to that group, draw and describe not only an archi-mollusc, but an archi-gastropod, archi-cephalopod, &c., and also an archi-prosobranch, an archi-diotocardian, and an archi-patellid, and similar schematic forms—"types morphologiques," as he terms them—for every group—down to the actual genera. It is essential to the plan of Prof. Delages' work that every genus shall be not only named and cited, but described at sufficient length to enable the reader to identify the genus of a specimen concerning which he is interested, and thus to obtain a reference to more detailed monographic literature.

It is evident at once that the project is a very large one. Such a work fully carried out with complete anatomical detail such as is necessary to give a true conception of the relations of large and small groups, would be an ideal treatise for the advanced student. The only objections to it seem to be (1) that if thoroughly done it must be a work of enormous size, extending to at least twenty large octavo volumes. (2) That it is impossible for one or even two authors to possess a sufficiently detailed knowledge of the whole animal series to produce a really accurate and judicious account of every group with the minuteness proposed.

We have, however, two volumes already published—the first dealing with the structure of the Cell and with the group Protozoa, the second devoted to what MM. Delages and Hérouard call the "Vermidea," namely certain small groups of debated affinities; to wit, the Gephyræa, Polyzoa, Rotifera, Chætognatha, Kinorhyncha (Echinoderes), and Brachiopoda—names which Prof. Delages prefers to alter into Gephyria, Bryozoaria, Trochelmia, Kinorhynchia and Brachiopodia. Some of the changes in names and the classification adopted by MM. Delages and Hérouard (especially in regard to the Protozoa) are valuable and likely to secure general assent. But it is difficult to approve of the word Vermidea—a Greek adjective made from a Latin substantive—and one which, to me at any rate, seems not to be necessary for classificatory purposes.

In these two volumes we can see how the "concrete" system of exposition works. It certainly results in a very useful treatise on the Protozoa. Numerous process blocks (no less than eight hundred and seventy) are introduced into the text, and though they are by no means equal in beauty to the woodcuts of the text-book by Parker and Haswell, they are yet sufficient for their purpose. In the second volume published (that on the Vermidea), which is vol. v. of the series as planned by Prof. Delages, forty-five coloured plates are introduced as well as five hundred and twenty cuts. Many of the coloured plates are occupied with diagrammatic figures, showing by means of strong conventional colouring the anatomy of Gephyræans, Rotifers, Polyzoa and Brachiopods, but two are devoted to highly-finished coloured drawings of the living appearance of selected species of Sipunculids and Echiurids respectively. It is probably the first time that a treatise intended for students has been so fully illustrated. Naturally, in attempting to test the quality of such a book, one looks at the treatment of subjects specially familiar to one's self. In this volume I looked with curiosity at the account of Rhabdopleura. I find it excellent, occupying eight pages, with seven large process blocks—some coloured, which are diagrams, others copied from originals duly acknowledged. The only objection I have to offer is that here as elsewhere the authors yield to a very natural tendency, and instead of using the terms "tubarium," "pectocaulus," and "gymnocaulus," as applied to certain parts in the original description from which their information is derived, invent new descriptive terms which seem neither necessary nor advantageous. As showing how difficult it is to quote accurately detailed accounts of an organism of which the writer who quotes has no special knowledge, the following is an instance. MM. Delages and Hérouard say "Ray Lankester a décrit à droit du rectum un testicule qui s'ouvrirait à la marge de l'anus; mais Fowler a nié son existence." Whilst I thoroughly agree with Prof. Delages in the propriety and usefulness of citing the names of authors responsible for statements, and admire the thorough and conscientious way in which he has thus brought his work up to the latest date so as to make it a really valuable source of references, I note that it is difficult to be always exact in such citations. Fowler had no opportunity for denying the existence of the testis described by me in Rhabdopleura. Of its existence there is no possibility of doubt; it was observed in several specimens, and figures of several of these were published by me. All that Fowler said was that he did not find it in certain specimens observed by him. This is entirely in accordance with what I had stated, since in by far the majority of living specimens studied by me it was absent, and only present in exceptional individuals which happened to be in a state of sexual maturity.

I will venture also to enter a protest against the citation by M. Delages of a genus of Protozoa based on the "ciliated pots" of Sipunculus. Every one knows that these are two-celled structures belonging to Sipunculus itself, and not parasites.

The plan of the "Zoologie Concrète" comprises nine volumes royal octavo of about 500 pages each; but it seems to me impossible that the larger groups can be treated with the same thoroughness as are those dealt with in the two published volumes unless a much larger number of volumes is produced. We are promised a volume on the Prochordata in the present year, a volume on the Cœlentera in 1899, and separate volumes subsequently on each of the following groups:—Echinoderma, Vermes, Articulata, Mollusca, Vertebrata. Whether the work can be thus completed or not, there is no doubt that the volumes published are of considerable value, and their successors will be looked for with great interest by all zoological colleagues of MM. Delages and Hérouard.

The proper limitations of size and the true scope of zoological text-books form a subject which may be endlessly debated. After all, is it not the fact that Bronn's "Thierreich" is the only treatise which is sufficiently comprehensive and detailed? Do we not know that it will never be finished, but that it must be re-written volume by volume so long as zoology endures? And is not Gegenbaur's "Grundriss" the only really masterly condensation and convincing exposition of the great generalisations of comparative anatomy hitherto written?

Gegenbaur's book is nearly twenty-five years old. A brief survey of the genealogical significance of animal structure is needed now, which shall as firmly and clearly present the morphological doctrines of 1900 as did the "Grundriss" present those of 1875.

E. RAY LANKESTER.

WEATHER PREDICTION.

Die Wettervorhersage. Im auftrage der Direktion der deutschen Seewarte bearbeitet von Prof. Dr. W. J. van Bebber, Abtheilungsvorstand der deutschen Seewarte. Zweite verbesserte und vermehrte Auflage. (Stuttgart: Ferdinand Enke, 1898.)

SOME years ago Prof. van Bebber put before the world a popular account of the principles underlying weather prediction. His long experience at the Deutschen Seewarte enabled him to give the latest information concerning the processes employed in the most authoritative manner, and the result was necessarily a very interesting book. It is therefore not a matter of surprise that this treatise should have run out of print, and a second edition be peremptorily called for. Such a result must, however, be gratifying to the Professor, because he has recognised the fact, that the full value of the information supplied to the public through the weather bureau, supplemented as it is by weather charts and tables, cannot be fully appreciated so long as those for whose benefit such information is disseminated, remain ignorant of the general principles of meteorology. Guided by this motive, he has systematically endeavoured to popularise the science, while working in the forefront as a scientific meteorologist. His method of making the information useful, and of instructing those who are possibly far removed from a meteorological station, and therefore thrown to a considerable extent on their own resources, consisted in preparing a large number of weather charts, something like two hundred in all, arranged in a systematic order, in which might be found represented the conditions of the weather obtaining at any subsequent epoch. A judgment or forecast could then be formed from the similar data supplied in the book, and possibly the effect of local circumstances taken into account. The same method is pursued in the present edition; indeed it has not been found necessary to alter the maps in any essential particular, judging by the dates to which they refer.

If there be any who doubt the efficacy of the modern system of forecasting the weather, or the utility of the practice, it will be to a certain extent reassuring to learn that, after twenty-two years' daily study of the weather maps of Europe, Prof. van Bebber still relies confidently on their accuracy and trustworthiness. And although individual judgment may be disposed to prefer its own conclusions in this matter of weather and the value of forecasts, the question is one on which authority should be at least heard with respect. For it is only those who systematically compare the forecasts with actual results, and who also are able to draw their information from reports covering large areas, who can judge of the success of a system which is more or less upon its trial. One failure to issue a storm warning from which suffering and disaster result, is remembered far more easily than the many more numerous cases in which the signal sends out its warning with due effect. It must be admitted that there is apparently not the same tendency to cover the Meteorological Bureau with ridicule, when the forecast proves glaringly incorrect, as was noticeable some years ago; but this greater leniency may simply indicate that the joke has been worn threadbare, and not imply any degree of greater respect to the meteorological authority. Increased confidence can only come with greater knowledge, and therefore we are inclined to welcome the demand for a new edition of Prof. van Bebber's book as an indication that more attention is being paid to a subject, at least abroad, which nearly concerns the comfort of the community and the prosperity of many trades and callings.

Moreover, it is distinctly reassuring to find that the methods of weather prediction are in a measure stereotyped. That no particular change or improvement has been made in these methods, in the space of time covering the issue of the two editions, is a clear indication that they are based on well-ascertained scientific lines, from which the elements of chance have been eliminated. The two sections of the work into which the greatest amount of alteration has been introduced is, first, that dealing with the probable character of the weather over longer periods than twenty-four hours in advance, and in a lesser degree the movements of areas of low barometric pressure. The discussion of the paths along which cyclonic movements preferably travel, has been an inquiry on which Prof. van Bebber has long worked, and though the information derived from the examination of a greater number of instances might be expected to modify the conclusions derived entirely from experience, no great alteration seems to be necessary, and no fresh results appear to be indicated. The percentages of successful forecast or repetition of the same character of weather before, during, and after the passage of a cyclone, shown in the tabular statement, are those derived from a fourteen years' study of the behaviour of these systems. Seven years' further study has apparently only confirmed the conclusions originally drawn.

Only in the section on the possibility of predicting the weather some days in advance, do we meet with weather charts of a tolerably recent date, an evidence of the author's work during the last few years. Taking it for granted, as we may, that the weather of any region is mainly determined by the barometric pressure and the interchange of areas of high and low barometer, Van Bebber defines five conditions of weather type, determined by the relative positions of atmospheric pressure over the continent of Europe, which conditions are repeated in their general features with great frequency, and can be easily recognised. The length of continuance of the same weather after the establishment of one or other of these typical systems will vary at different times of the year, and according to the relative positions of high and low pressure; but, on the average, one can reckon upon the weather remaining unchanged for about three and a half days, and in favourable conditions on even greater permanency. What is now wanted is the means to predict with certainty the transference of one determining type of weather to another. When this knowledge exists, and the author looks forward hopefully to a time when it will be within our reach, we shall be able to make those longer forecasts which are demanded by the necessities of practical life.

OUR BOOK SHELF.

Maryland Geological Survey. Vol. I. Pp. 539. (Baltimore: The Johns Hopkins Press, 1897.)

Iowa Geological Survey. Vol. VI. *Report on Lead, Zinc, Artesian Wells, &c.* (Des Moines: Iowa Geological Survey, 1897.)

THE first volume of the "Maryland Geological Survey" is one of which Prof. W. B. Clark, the State Geologist, and others who have been concerned in its production, should be proud. The volume consists primarily of a summary of past and present knowledge concerning the physical features of Maryland, and embraces an account of the geology, physiography and natural resources of the State, with a bibliography of all publications relating to these matters. Of exceptional interest is an admirable report by Dr. L. A. Bauer upon magnetic surveys in general and the magnetic conditions of Maryland in particular. This report is an inspiring statement of the development and purposes of magnetic surveys, and the valuable information which Dr. Bauer has obtained should induce other States to institute similar inquiries to those carried out by him. The results of such work are not only of great importance to the county surveyors and others who are engaged in determining the boundaries of lands, but are also of wider value on account of the relations which exist between geology and terrestrial magnetism, many magnetic features of a district being related to the geological structure of the underlying rocks. Several fine plates, and other figures, illustrate the report.

A number of separate papers of general economic interest are included in the sixth volume published by the Iowa Geological Survey, under the direction of Dr. S. Calvin, the State Geologist. Prof. A. G. Leonard describes the lead and zinc deposits of the State, and Dr. S. W. Beyer the Sioux quartzite and certain associated rocks. Prof. W. H. Norton gives a detailed account of the artesian wells of Iowa, which should be found of considerable value by the citizens of the State; and Mr. H. F. Bain describes the relations of the Wisconsin and Kansan drifts in Central Iowa. The volume thus constitutes a worthy contribution to the economic geology of Iowa.

Elementary Chemistry, Practical and Theoretical. First Year's Course. By T. A. Cheetham, F.C.S. Pp. 128. (London: Blackie and Son, Ltd., 1898.)

THIS is an addition to the class of school books containing experiments which aim at developing a pupil's thinking powers rather than at supplying "useful knowledge" of the kind contained in elementary books of science a few years ago. It is an exercise book constructed on sound principles by a teacher of experience; therefore the experiments have an educational value, and are also practicable. The pupil is instructed to "observe what happens when mercury is heated," "observe the effects of heating sulphur under different conditions," "heat a weighed quantity of chalk, and find whether there is a gain or loss of weight," and so on, instructions being given how to proceed in each case. The course of work and study follows closely that proposed in the British Association Report on the Teaching of Chemistry, and the scope of the treatment includes the laws of chemical combination. The first part of the book is devoted to practical work, while the second contains material for lecture experiments and theoretical information to be studied in connection with the practical work of the laboratory.

The plan and execution have much to commend them, and the volume is a distinct advance upon the text-books of the days before the new methods of teaching chemistry had been developed. No book of science should, however, be published without an index.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Nomenclature and Notation in Calorimetry.

ALL who are engaged in thermal investigations themselves, as well as those who have occasion to study the published work in this department of science, must have been frequently annoyed by the use of the word *calorie* with its varying signification. It has been sought to remove the inconvenience by qualifying the calorie as small or great, and in other ways; but on opening a book at any place where the results of thermal determinations are given, it is in most cases difficult to discover at once what unit of heat the author is using.

As different classes of investigation are carried on on different scales, it is obvious that it is a convenience, if not a necessity, to have different heat units at disposal. The unit which is suitable to express the thermal changes in a beaker in the laboratory, would manifestly be inconvenient when dealing with the daily or seasonal changes in a lake or an ocean. It is therefore natural and necessary to have heat units of different magnitudes, but it is neither natural nor necessary to call them all by the same name, and it is extremely inconvenient not to have a short form of notation which will show on its face the actual heat unit used.

In the early literature of the equivalence of heat and work in this country, one unit of heat is universally used; it is the pound-degree-Fahrenheit, and in the writings of Joule, Thomson, Rankine and others of that time, it is simply called "heat unit," as there was no other competing with it. With the rise and development of thermal chemistry, it was necessary to fashion the compound unit out of the simple units in common use in chemical laboratories; these are the gramme and the Celsius degree.

The heat given out by one gramme of water cooling by 1° C. at ordinary temperatures, is the unit most used in such researches; and it received the name of calorie, sometimes now called small calorie.

For many purposes this unit proved itself inconveniently small, and several larger units have been used, such as the heat given out by one kilogramme of water cooling 1° C. at ordinary temperatures, or the heat given out by one gramme of water cooling from 100° C. to 0° C.; but the name of calorie was retained in connection with them all, and in the specification of a quantity of heat by a number, the nature of the unit was indicated by the syllable cal. or the letter K, neither of which, of itself gives any information.

In my own work, and in the study of the writings of others, I have adopted a form of notation which I have found so useful that I propose to lay it before the readers of NATURE. I do not doubt that others who interest themselves in calorimetric work have been driven to adopt some similar, perhaps the same, perhaps a better form of notation; and I think they will agree with me that some system of self-interpreting notation should be universally adopted without loss of time.

Just as, when dealing with work, we use currently the expressions foot-pound and kilogramme-metre, so in calorimetry it is quite common to talk of a gramme-degree, or a kilogramme-degree; and what I propose is to use no other expression than these compound and self-explaining ones, and, in writing, to express them shortly by $g°$ and $k°$ respectively, to which for clearness the symbol of the thermometric scale must be added, so that they become $g°$ C. and $k°$ C. when Celsius' scale is used, or $g°$ F. and $k°$ F. when Fahrenheit's scale is used.

On this system the expression $g°$ C. would replace the ordinary "cal." and Ostwald's K would be represented by $100\,g°$ C. or $0.1\,k°$ C., or by $h°$ C., to mean hectogramme-degree C. With perfect exactness K would be expressed by $g\,100°$ C., but the difference between $100\,g°$ C. and $g\,100°$ C. is much less than the probable experimental error in any calorimetric operation. In a table containing a column of quantities of heat expressed in numbers of gramme-degrees-Celsius, the nature of the unit would be indicated at the top of the column by $g°$ C.; exactly as, in a column of temperatures, the unit is indicated by the symbol °C. or °F. The original British heat unit is then clearly expressed by lb.° F.

A heat unit made up of any unit of weight and any unit of temperature can be perfectly expressed in this system. Thus, if there were any advantage in doing so, we might have $g°$ F., lb.° C., $k°$ R. and many others, and their meaning would be at once apparent on inspection.

In oceanographical work, where the heat exchanges between one layer of water and another, or between the water and the air are under discussion, I have found the most convenient heat unit to be the fathom-degree-Fahrenheit, or the metre-degree-Celsius, which are abbreviated for the purposes of notation into $f°$ F. and $m°$ C., respectively. The nature of this unit will be most easily understood by considering an example.

In a paper, "On the Distribution of Temperature in Loch Lomond in the Autumn of 1885," read before the Royal Society of Edinburgh, and published in its *Proceedings* for the session 1885–86, I have given, at page 420, a table of the changes in the distribution of heat in the direction of depth, between several pairs of dates, in the Luss basin of Loch Lomond. At a certain depth, indicated by the intersection of the temperature curves, the temperature of the water is the same on both dates. The season being autumn, the layer above this depth has been losing heat, partly to the air above and partly to the water beneath, while the layer below the depth of common temperature has been on the whole the gainer. Thus, taking the dates September 5 and October 15, the intersection of the temperature curves is found at a depth of 16 fathoms; and in the interval of forty days the mean temperature of the water above this depth has fallen by 5·8° F., from 55·0° F. to 49·2° F. The thickness of the layer is 16 fathoms; therefore the loss of heat has been $16 \times 5{\cdot}8 = 92{\cdot}8\,f°$ F., or 92·8 fathom-degrees-Fahrenheit. The total depth of the lake at the spot was 35 fathoms, therefore the layer of water below the depth of common temperature was 19 fathoms thick. The mean temperature of this layer was 47·1° F. on September 5, and 48·9° F. on October 15, showing a rise of 1·8° F. in the interval. This corresponds to a gain of heat represented by $19 \times 1{\cdot}8 = 34{\cdot}7\,f°$ F. Assuming that the heat gained by the lower layer has been entirely at the expense of the upper one, we see that the loss of heat of the upper layer, during the interval, has been to the extent of 37·4 per cent. to the deeper water, and 62·6 per cent. to the air. The upper layer of water has thus been passing heat at the average rate of $1{\cdot}485\,f°$ F. into the air, and into the deeper water at the rate of $0{\cdot}85\,f°$ F. per day.

It is worthy of remark that the fathom-degree-Fahrenheit and the metre-degree-Celsius are interchangeable in heat calculations, because the fathom is 1·8 metre and the Celsius degree is 1·8° F.

This is a great convenience, and its usefulness will be apparent by applying it to the above example.

We have seen that, during the interval of forty days, the average transmission of heat from the upper layer of water has been at the daily rate of $1{\cdot}485\,f°$ F. to the air and of $0{\cdot}85\,f°$ F. to the deeper water. Writing $m°$ C. for $f°$ F., and considering a horizontal area of one square centimetre, we find at once that the average daily supply of heat from the water to the air has been at the rate of $148{\cdot}5\,g°$ C., and to the deeper water at the rate of $85\,g°$ C. (gramme-degrees-Celsius) per square centimetre of superficial area.

It is unnecessary to provide for special cases where specially suitable units will be chosen as a matter of course; but for ordinary work of constantly recurring type it is important to have a system of nomenclature and of notation, each of which will tell its own story. J. Y. BUCHANAN.

May 4.

Future Rainfall.

MOST people probably suppose that we have no light whatever on the fluctuations of our rainfall in future years, and that he would be a bold meteorologist who offered to forecast them. Yet, if there be truth in the conclusions arrived at by Prof. Brückner, we are not wholly without light on the subject; for a part of this country, at least, in common with probably the greater part of the globe, is subject to a regular recurrence of cold and wet periods, at about 35 years intervals (measuring from the centre of one such period to that of the next); these periods alternating with others which are hot and dry. It seems useful to inquire how we at present stand, and, if possible, what are our present prospects in respect of this theory.

For this purpose I will here employ a simple meteorological method, which seems to have been little used among us hitherto, viz. algebraic addition, step by step, of a series of plus and minus values; the resulting figures being then plotted as a curve.

Suppose *e.g.* any set of such values, as follows:

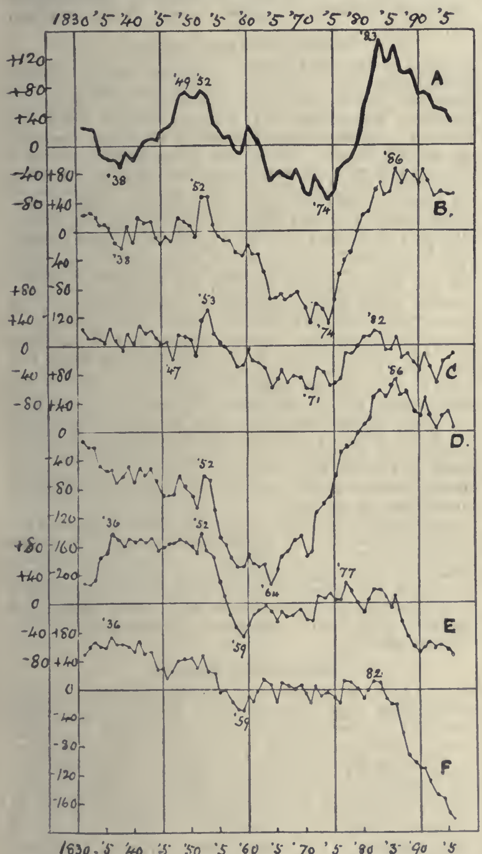
+ 3 + 6 − 2 + 8 + 12 − 3 − 9, &c.

By addition we get this series:

+ 9 + 7 + 15 + 27 + 24 + 15, &c.

This latter series is thrown into a curve.

In his *British Rainfall* for 1881, 1891, &c., Mr. Symons has given a series of rainfall values for a number of stations in



A, Boston; B, Oxford; C, Chilgrove; D, Exeter; E, Kendal; F, Bolton.

different parts of England (from 1830 onwards); also the percentage equivalents of these, the average for each station being taken as 100. These latter I have made use of, taking the excess over 100 as a plus value, and the deficiency under 100 as a minus. Thus *e.g.* 106 would be + 6; 94 would be − 6.

When this has been done with the values for Boston, in Lincolnshire, and the series treated by the addition-method described, we get the curve marked A in the diagram; and it is to this curve I would especially invite attention. For it is to the eastern parts of our country that Brückner's cycle applies; the west belongs to what he calls *Ausnahmegebiete*, or exceptional regions.

Bearing in mind that these curves rise for plus values and fall for minus, we note in this Boston curve a general rise from 1838 to 1849 (or 1852), also from 1874 to 1883; while we have general fall from 1852 to 1874, and from 1883 to 1896 (the last point dealt with). In other words, the two former were *wet* periods, the two latter *dry* periods.

The following figures show this:

	Years.	Dry.	Wet.
1838–52	14	4	10
1874–83	9	none	all
1852–74	22	17	5
1883–96	13	9	4

Between the wave crests 1849 and 1883 are 34 years; and between the wave hollows 1838 and 1874 are 36 years. Or, if we like to take as approximate centres of the wet periods (say) 1843 and 1878, we have about the same interval, 35 years.

These fluctuations, standing alone, would clearly be too slender evidence of a cycle. But Brückner claims that his cycle of 35 years has been in evidence in various parts of the globe through these two centuries at least (since 1700).[1] If the eastern part of England, then, may be expected to conform to the law in future, we might reasonably, perhaps, look for the centre of another wet period somewhere in the second decade of next century. And for the near future (without attempting detail) a continuation for some years of the recent *régime* seems not unlikely, dry years preponderating over wet. That is, the curve should go down further, on the whole, for some years yet.

I have given a number of other curves for comparison, viz. B, Oxford; C, Chilgrove, in Sussex (near Chichester); D, Exeter, less reliable perhaps (see *Brit. Rf.*, 1881); E, Kendal; and F, Bolton, in Lancashire. As we go westwards, the curve seems to degrade somewhat (regarded from our standpoint), though the same type may be discerned. In the northern curves, Kendal and Bolton, we find little in common with the Boston curve, though something like a 35 years' interval may, in cases, be made out.

It may be well to state that other stations in the east of England yield very similar curves to that for Boston.

A. B. M.

Prehistoric Egypt.

I NOTICE a review in NATURE containing some statements about my own work which are inaccurate.

The term "New Race" is quite correct, as the race was entirely new to us, whatever their age; and as a tentative name which commits us to no theories, it can hardly be said that I "did not understand the facts of the case" in using it. In dating the race to at least 3000 B.C., I was doing all that the facts warranted at the time; and if we all agree now that they are older, it is by mere consensus of guessing, for no absolute proof of earlier age by juxtaposition with other things has even yet been found.

Further, Dr. Verneau's erroneous assumption that the condition of the bones could be produced by exposure to the air alone, is quoted, with the remark that my "sensational discovery therefore falls to the ground." How exposure to the air can possibly break off the ends of bones and scoop out the cellular structure, while the bone remains hard and firm, not even Dr. Verneau can explain. To deny cannibalism in such a case, reminds one of the indignant repudiation of the intention to smoke by a man who already has a pipe in his mouth and a match in his fingers.

No one values more than I do the discoveries of M. de Morgan; but had he dealt more with strict evidence and full details, and given weight to many facts which he has ignored, I venture to think that his work would have needed less revision in future.

W. M. FLINDERS PETRIE.

University College, W.C.

I HAVE read Mr. Petrie's letter, and I still think that M. de Morgan is right, and that Mr. Petrie is wrong. I also think that Dr. Verneau is right, and that his "assumption" is not "erroneous." Mr. Petrie's reference to the revision which he thinks M. de Morgan's work will need is remarkable; for his own will—in my opinion—need much more! however much M. de Morgan's may need!

THE REVIEWER.

[1] We may here recall that Bacon seems to have been aware of such a cycle.

Photographic Action of Printer's Ink.

In your issue dated April 28, I notice an article reporting the Bakerian Lecture given by Dr. W. J. Russell.

One paragraph states that printing ink *at a distance* will act upon a photographic film. Is that the explanation of the following curious circumstance?

An Ilford ordinary plate, which I had kept in its box unopened for five years, was exposed recently upon a poorly-lighted subject; upon development I found, instead of my subject, the matter of the advertisement which was upon the outside wrapper. This came up strong and quickly, but nothing was seen of the subject upon which the plate had been exposed in the camera.

The image was a positive, and the large type word "Ilford" was very prominent.

So it would appear that the sensitised plate had been acted upon by the printer's ink, through the lid of the box and three wrappers of paper, two of which were brown.

W. Trueman Tucker.

Parkside, Loughborough, May 8.

A very interesting result. The picture no doubt arose from the printer's ink, and it shows what great length of time will do. The plate must have been face upwards. W. J. R.

May 9.

Electrical Impressions on Photographic Plates.

Some simple variations of the inductoscript may be of general interest.

A photographic glass negative is placed on a plate, and a ¾-inch induction coil is sparked for one or two minutes on the outsides: a perfect positive with fine detail can be developed.

If printed paper is so treated, a clear image of the reading is made, white letters on a dark ground: a coin gives dark letters.

If the exposure to the spark is prolonged, an indistinct image of the print, which is on the other side of the paper, will also appear.

More or less perfect images can be made, if ink or pencil writing or a photographic print be put on the plate. When thin paper is placed between a coin and a plate, a fair, but less perfect, reproduction of the coin will be produced.

It makes very little difference whether fast or slow plates are employed. A. S. Bates.

Winchester College.

Bacteria on an Ancient Bronze Implement.

A few days ago an ancient bronze implement was brought to me showing small excrescences, the centres of rapid oxidisation, which the owner told me had only very recently developed.

On examining the material scraped off one of these excrescences under the microscope with fairly high powers (a ⅙ inch and ⅛ inch objective), it was found to be swarming with bacteria, which seemed to be the cause of the rapid oxidisation. I have not been able to trace any reference to bacteria inhabiting a similar nidus, and I should be much obliged to any correspondent who could direct me to the literature on the subject, and inform me of the best way of sterilising the implement without injury. Wm. Edward Nicholson.

Lewes, May 3.

THE ROYAL SOCIETY SELECTED CANDIDATES.

The following are the names and qualifications of the fifteen candidates selected by the Council of the Royal Society, to be recommended for election into the Society this year:—

Henry Frederick Baker,

M.A., Fellow and Lecturer of St. John's College, Cambridge; University Lecturer in Mathematics. Author of "A Treatise on Abel's Theorem and the Allied Theory" (1897); and of the following papers, among others:—"Weierstrassian Formulæ applied to the Binary Quartic and Ternary Cubic" (*Quart. Journ. Math.*, vol. xxiv., 1889); "Gordon's Series in the Theory of Forms" (*Messenger Math.*, vol. xix., 1889); "The Full System of Concomitants of Three Ternary Quadrics" (*Camb. Phil. Soc. Trans.*, vol. xv., 1889); "The Application of Newton's Polygon to the Singular Points of Algebraic Functions" (*ibid.*, vol. xv., 1893); "On Euler's ϕ-Function" (*Proc. Lond. Math. Soc.*, vol. xxi., 1890); "Fundamental Systems for Algebraic Functions" (*ibid.*, vol. xxvi., 1895); "On Noether's Fundamental Theorem" (*Math. Annalen.*, vol. xlii., 1893); "On a Geometrical Proof of Jacobi's I-Function Formulæ" (*ibid.*, vol. xliii., 1893); "On the Theory of Riemann's Integrals" (*ibid.*, vol. xlv., 1894); "The Practical Determination of the Deficiency and Adjoint ϕ-Curves for a Riemann Surface" (*ibid.*, vol. xlv., 1894); "On a Certain Automorphic Function" (*Camb. Phil. Soc. Proc.*, vol. viii., 1895); "On the Hyperelliptic Sigma-Functions" (*Amer. Journ. Math.*, vol. xx., 1897).

Ernest William Brown,

Professor in Haverford College. Formerly Fellow of Christ's College, Cambridge. Author of the following papers:—In the *American Journal of Mathematics*—"On the Part of the Parallactic Inequalities in the Moon's Motion, which is a Function of the Mean Motions of the Sun and Moon" (vol. xiv., pp. 141–160, 1892); "The Elliptic Inequalities in the Lunar Theory" (vol. xv., pp. 244–263, 321–338, 1893); "Investigations in the Lunar Theory" (vol. xvii., pp. 318–358, 1895). In the *Monthly Notices Royal Astronomical Society*—"On the Determination of a Certain Class of Inequalities in the Moon's Motion" (vol. lii. pp. 71–80, 1891); "Notes on Lunar Theory" (vol. lii. pp. 408–9, 1892; liv. p. 471, 1894; lv. pp. 3–5, 1894); "Note on Hansen's Lunar and Planetary Theories" (lvi. pp. 52–3, 1895); "Note on Mr. Stone's paper, 'Expressions for the Elliptic Coordinates of a Moving Point to the Seventh Order of Small Quantities,'" 1896. In the *Proceedings Cambridge Philosophical Society*—"On the Part of the Parallactic Class of Inequalities in the Moon's Motion which is a Function of the Ratio of the Mean Motions of the Sun and Moon" (vol. vii. pp. 220–1, 1891). Before the London Mathematical Society, November 1896—On "The Application of Jacobi's Dynamical Method to the General Problem of the Three Bodies"; "On Certain Properties of the Mean Motions, and the Secular Accelerations of the Principal Arguments used in the Lunar Theory." Author of "An Introductory Treatise on the Lunar Theory" (Cambridge University Press, 1896, pp. viii.–292).

Supplementary Certificate.—"On the Mean Motions of the Perigee and Node"; "On the Theoretical Values of the Secular Accelerations of the Lunar Theory"; "Note on the Mean Motions of the Perigee and Node," in the *Monthly Notices R. Astron. Soc.*, 1897; "Theory of the Moon, containing a New Calculation of the Coordinates of the Moon in Terms of the Time" (Part I.–IV. *Memoirs R. Astron. Soc.*, vol. liii., 1897, pp. 39–116).

Alexander Buchan,

M.A., LL.D., F.R.S.E. Secretary, Scottish Meteorological Society, from 1860. Member of the Meteorological Council from 1873. Author of the following contributions to Meteorology: "Mean Atmospheric Pressure and Prevailing Winds of the Globe and Handy Book of Meteorology," 1868; "Weather and Health of London," jointly with Sir Arthur Mitchell, 1875; "*Challenger* Report on Atmospheric Circulation in 1889"; "*Challenger* Report on Oceanic Circulation in 1895"; "Specific Gravities and Oceanic Circulation in 1896"; "Meteorology," in the "Encyclopædia Britannica"; Reports on the Meteorology of Ben Nevis, &c.

Sidney Frederic Harmer,

M.A., Superintendent of the University Museum of Zoology, and Fellow of King's College, Cambridge. Engaged for many years in researches in Embryology and Comparative Anatomy. Discoverer of important facts connected with the Anatomy of Cephalodiscus, which largely assisted in fixing its systematic position; and of the occurrence of a process of extensive Embryonic Fission in certain Polyzoa. Author of numerous papers on zoological subjects, including the following:—"On the Structure and Development of *Loxosoma*" (*Quart. Journ. Micros. Sci.*, vol. xxv., 1885); "On the Life-history of Pedicellina" (*ibid.*, xxvii., 1887); "On the British Species of *Crisia*" (*ibid.*, xxxii., 1891); "On the Nature of the Excretory

Processes in Marine Polyzoa" (*ibid.*, xxxiii., 1892); "On the Occurrence of Embryonic Fission in Cyclostomatous Polyzoa" (*ibid.*, xxxiv., 1893); "Preliminary Note on Embryonic Fission in *Lichenopora*" (*Roy. Soc. Proc.*, lvii.); "Appendix to the *Challenger* Report on *Cephalodiscus*" (*Challenger* Reports, vol. xx.); "Sur l'Embryogénie des Bryozoaires Ectoproctes" (*Arch. de Zool.*, 1887); "Notes on the Anatomy of *Sinophilus*" (*Journ. Marine Biol. Assoc.*, 1889). Joint Editor of the Cambridge Natural History. Member of Council of the Marine Biological Association. Is attached to science, and anxious to promote its progress.

ARTHUR LISTER,

F.L.S. Distinguished for his researches on the Mycetozoa. Author of "Notes on the Plasmodium of *Badhamia utricularis* and *Brefeldia maxima*" (*Annals of Botany*, vol. ii., 1888, pp. 1–24, plates 1, 2); "Notes on *Chondrioderma difforme* and other Mycetozoa" (*ibid.*, vol. iv., 1890, pp. 281–298, plate 1); "Notes on the Ingestion of Food-material by the Swarm-cells of Mycetozoa" (*Journ. Linn. Soc.*, vol. xxv., Bot., 1890, pp. 435–441); "Notes on Mycetozoa" (*Journ. of Bot.*, vol. xxix., 1891, pp. 257–268, plates 308–312); "On the Division of the Nuclei in the Mycetozoa" (*Journ. Linn. Soc.*, vol. xxix., Bot., 1893, pp. 529–542, plates 35, 36); "Monograph of the Mycetozoa," being a descriptive Catalogue of the Species in the Herbarium of the British Museum (1894, pp. 224, plate 78); "Guide to the British Mycetozoa exhibited in the Department of Botany, British Museum" (1895, p. 42); "Notes on British Mycetozoa" (*Journ. Bot.*, vol. xxxiii., 1895, pp. 323–325); "A New Variety of *Enteridium olivaceum*" (*ibid.*, vol. xxxiv., 1896, pp. 210–212); "On Some Rare Species of Mycetozoa" (*ibid.*, vol. xxxv., 1897, pp. 209–218); and other memoirs.

CHARLES ALEXANDER MCMAHON,

Lieut.-General. Formerly Commissioner of the Amritsar Division, Punjab. President of the Geologists' Association and Vice-President of the Geological Society of London. Distinguished for his acquaintance with the sciences of Petrology and Geology. He was the first to demonstrate (discover), by study in the field, and with the microscope, the truly granitic origin of the "Granitoid Gneiss" of the N.W. Himalaya, thereby affording a conceivable interpretation of the mountain structure. See his numerous papers (23) in the "Records of the Geological Survey of India" (1876-87). Later, General McMahon has contributed much to the elucidation of the structure and origin of crystalline rocks and rock-making minerals, notably in his papers "On the Rocks of the Lizard" (*Quart. Journ. Geol. Soc.*, vol. xlv., 1889, and, conjointly with Prof. Bonney, in vol. xlvii., 1891); "On the Dartmoor Granite and its Relation to the Surrounding Rocks" (*ibid.*, vol. xlix., 1893); "On Micro-chemical Analysis of Rock-making Minerals" (*Min. Mag.*, vol. x., p. 79); and "On Optical Characters of the Globules and Spherulites of Lithium Phosphate," &c. (*ibid.*, p. 229); and numerous minor papers in the *Geological Magazine* and the *Proceedings* of the Geologists' Association.

WILLIAM OSLER,

M.D., F.R.C.P. Professor of Medicine in the Johns Hopkins University and Physician-in-Chief to the Johns Hopkins Hospital, Baltimore; formerly Professor of the Institutes of Medicine, McGill College, Montreal; and Professor of Clinical Medicine in the University of Pennsylvania, Philadelphia. Has been during many years actively engaged in the advancement of scientific medicine, and has published a large number of communications, some of great interest and importance, chiefly dealing with clinical and pathological matters. Of these only a very few can be here enumerated, viz.: "On the Systolic Brain Murmur of Children" (*Bost. Med. and Surg. Journ.*, 1880); "Infectious Endocarditis" (*Arch. of Med.*, 1881, and Congr., London, 1881); "On Certain Parasites in the Blood of the Frog" (*Canada Naturalist*, 1882); "The Gulstonian Lectures on Malignant Endocarditis" (*Lancet*, 1885); "On the Morbid Anatomy of Typhoid Fever" (*Canada Med. and Surg. Journ.*, 1885); "On Certain Problems in the Physiology of the Blood Corpuscles" (*Phil. Med. News*, 1886); "The Relation of the Corpuscles to Coagulation Thrombosis" (*Brit. Med. Journ.*, 1886); "The Bicuspid Conditions of the Aortic Valves" (*Trans. Assoc. Amer. Physicians*, 1886); "The Cardiac Relations of Chorea" (*Amer. Journ. Med. Sci.*, 1887); "The Cerebral Palsies of Children" (*Med. News*, 1888); "On the Situation of the Anovesical Centre in Man" (*ibid.*); "On Phagocytes" (*ibid.*, 1889); "On Intrathoracic Growths from the Thyroid Gland" (*ibid.*); "Filaria Sanguinis Hominis" (*Johns Hopkins Bull.*, 1890); "On the Amœba Coli" (*ibid.*, 1890); "On Sensory Aphasia" (*Amer. Journ. Med. Sci.*, 1891); "On Typhoid Fever" (*Johns Hopkins Reports*, 1893 and 1894); "On Abdominal Tumours" (1894); "On Addison's Disease" (*Int. Med. Mag.*, 1896). Is also the author of several important articles in systems of medicine, and of a well-known text-book "On the Principles and Practice of Medicine." Has long occupied a leading position in Canada and the United States as a scientific physician, and has also a European reputation as one of the foremost representatives of Clinical Medicine and Pathology of the day.

HON. CHARLES ALGERNON PARSONS,

M.A. (Camb.). Engineer. M.Inst.C.E. Eminently distinguished as an inventor and engineer. By his invention of the compound steam turbine he has made it practicable to use steam economically in an engine without reciprocating parts. He has adapted the steam turbine successfully to dynamo driving and other uses, and his recent application of it to marine propulsion is a new departure of particular interest. In developing his inventions he has shown much scientific knowledge and experimental skill. Author of a number of papers on the steam turbine, its theory and its applications, in *Proc. Inst. Mech. Eng.*, 1888; *Trans. of the North-East Coast Inst. of Engineers and Shipbuilders*, 1887; Inst. of Civil Engineers, Conference, 1897; *Trans. Inst. Naval Architects*, 1887; Inst. of Marine Engineering, 1897. Has investigated experimentally the action of high-speed screw propellers (*Trans. Inst. Nav. Arch.*, April 1897); also the "Behaviour of Carbon at High Temperatures and under Great Pressures" (*Proc. Roy. Soc.*, *Phil. Mag.*, September 1893).

THOMAS PRESTON,

M.A. (Dubl.). Professor of Natural Philosophy, University College, Dublin. Fellow of the Royal University of Ireland. Inspector of Schools under the Science and Art Department. Has published works that have much advanced the study of Light and Heat. Author of treatise on "The Theory of Light" (Macmillan, 1890); and of one on "The Theory of Heat" (Macmillan, 1894); and of Memoirs "On the Motion of a Particle and the Equilibrium of a String on a Spherical Surface" (*Trans. Roy. Irish Acad.*, vol. xxix., 1889), and "On the Mass Inversion of Centrobaric Bodies" (*Proc. Roy. Dubl. Soc.*, 1887).

EDWARD WAYMOUTH REID,

M.B. (Cantab.), B.A. Professor of Physiology, University College, Dundee. Distinguished as a Physiologist, especially in inquiries relating to absorption and secretion, and to electromotive phenomena. Published the following papers on electromotive phenomena:—"On the Action of the Excised Mammalian Heart" (with Dr. Waller) (*Phil. Trans. Roy. Soc.*, 1887); "On the Process of Secretion in the Skin of the Common Eel" (*ibid.*, 1893, and *Journ. Physiol.*, 1894); "The Electromotive Properties of the Skin of the Common Eel" (*ibid.*, 1894); "Electromotive Phenomena of the Iris" (*Journ. Physiol.*, 1895). Also papers on osmose, absorption, and secretion in *Journ. Physiol.*, 1890, 1893, 1895–96.

ALEXANDER SCOTT,

M.A. (Cantab.), D.Sc. (Edin.), F.R.S.E., F.C.S. Late Assistant to the Jacksonian Professor of Experimental and Natural Philosophy. Distinguished by having paid great attention to the exact determination of atomic weights and of combining proportions by volume. Author, in conjunction with Prof. Dewar, of papers on the Vapour Densities of Potassium and Sodium; on the Atomic Weights of Manganese, Oxygen, and Silver; and on the Molecular Weights of substituted Ammonias, published in the *Proceedings of the Royal Society*. Author of papers on Vapour Densities at High Temperatures, and on the Composition of Water by Volume, the last published in the *Phil Trans.*, vol. clxxxiv. Author of a text-book entitled "Introduction to Chemical Theory" (A. and C. Black, 1891).

ALBERT CHARLES SEWARD,

M.A. (Cantab.), F.G.S. University Lecturer in Botany, Cambridge. Has made extended researches in Fossil Botany, the results of which have been published in a series of papers and works, of which the following may be specified:—That on the Wealden Flora gives, for the first time, a critical and comprehensive view of the vegetation of this important geological period, and in many respects enlarges and modifies our previous knowledge of the subject: "On *Calamites undulatus*" (*Geol. Mag.*, vol. v., 1888); "Notes on *Lomatophloios macrolepidotus*, Goldg." (*Proc. Camb. Phil. Soc.*, vol. vii., 1890); "Fossil Plants as Tests of Climate" (Sedgwick Prize Essay for 1892); "On the Genus *Myeloxylon*, Brong." (*Annals of Botany*, vol. vii., 1893); "On *Rachiopteris Williamsoni*, sp. nov., a new Fern from the Coal Measures" (*ibid.*, vol. viii., 1894); "Catalogue of the Mesozoic Plants in the Department of Geology, British Museum (Nat. Hist.)"; "The Wealden Flora, Part I., *Thallophyta* to *Pteridophyta.* Part II., Gymnospermæ" (1894-95).

WILLIAM ASHWELL SHENSTONE,

F.I.C., Senior Science Master in Clifton College. Member of Council of the Chemical Society. Distinguished for his skill as an experimenter, for his ability as a teacher, and for his zeal in the introduction of improved methods of teaching physical science as a branch of general education. Author of the following and other papers:—"Ozone from Pure Oxygen" (*Journ. Chem. Soc.*, 1887); "The Volumetric Relation of Ozone and Oxygen," "The Influence of Temperature on the Composition and Solubility of Hydrated Calcium Sulphate and Calcium Hydroxide" (*Journ. Chem. Soc.*, 1888); "Some Improved Vacuum Joints and Taps" (*ibid.*, 1890); "Platinous Chloride as a Source of Chlorine," "The Adhesion of Mercury to Glass in the presence of Halogens" (*Journ. Chem. Soc.*, 1892); "On preparing Phosphoric Anhydride free from the Lower Oxides of Phosphorus," "Studies on the Formation of Ozone from Oxygen," Part II. (*Journ. Chem. Soc.*, 1893). Also author of the article on Ozone in the current edition of Watts' Dictionary; "A Practical Introduction to Chemistry" (Rivington, 1886); "The Methods of Glass Blowing" (Rivington, 1886); Life and Work of Liebig" (Century Series, Cassell, 1895).

HENRY MARTYN TAYLOR,

Barrister-at-Law. Fellow of Trinity College, Cambridge. Formerly Tutor of Trinity College, Cambridge. Third Wrangler and Second Smith's Prizeman in 1865. Author of papers in the *Mathematical Messenger*, as follows:—Vol. iii. p. 189, "Geometrical Explanation of the Equations for the Longitude of the Node and the Inclination of the Orbit"; vol. v. p. 1, 1876, "On the Generation of Developable Surface through Two given Curves"; vol. vii. p. 22, 1877, "On Certain Series in Trigonometry"; vol. vii. p. 145, 1877, "On the Porism of the Ring of Circles touching Two Circles"; vol. xi. p. 177, "On a Six-point Circle connected with a Triangle"; vol. xiii. p. 145, "On a Cubic Surface"; vol. xvi. p. 39, "On a Geometrical Interpretation of the Algebraical Expression which, equated to Zero, represents a Curve or a Surface"; vol. xvi. p. 143, "Extension of an Inversion Property." In the *Proceedings* London Mathematical Society: Vol. v. p. 105, 1874, "Inversion, with Special Reference to the Inversion of an Anchor Ring or Torus"; vol. xiii. p. 102, "A Geometrical Theorem concerning the Division of a p-gon into n-gons (with R. C. Rowe); vol. xv. p. 122, "The Relations of the Intersections of a Circle with a Triangle"; vol. xx. p. 422, a Geometrical note "On the Developable Surface through Two Conics Inscribed (or Escribed) in Two of the Faces of a Tetrahedron." In the *Quarterly Journal of Mathematics:* Vol. xxiv. p. 55, "On the Centre of an Algebraical Curve"; vol. xxvi. p. 148, "Orthogonal Conics"; vol. xxvi. p. 214, "Orthogonal Quadrics." Writer of the article on Geometrical Conics in the last edition of "Encyclopædia Britannica," editor of "Elements of Euclid" for the Syndics of the Cambridge University Press; author of two treatises—"On Great-Circle Sailing"; "On a Method by which a Steamer's Lights might show her Course."

JAMES WIMSHURST.

Member of the Consultative Staff, Board of Trade. Qualifications: (1) Improvements in Electrical Influence Machines, which are now universally approved and adopted by Physicists; (2) an Influence Machine which gives charges of electricity, alternating from positive to negative with each rotation of the disc (in this type the glass discs, without any metal upon them, are freely self-exciting); (3) has delivered a lecture upon Influence Machines at the Royal Institution, April 27, 1888, and read papers at the Physical Society, April 17, 1891, and June 22, 1893.

THE FLOW OF WATER.

MORE than one hundred years ago, the French philosopher Coulomb caused a disc suspended by a torsion wire to oscillate in a vessel of liquid, and he thus ascertained that the resistance to various bodies under such circumstances, when the movement is a slow one, varies directly as the velocity of the motion. This law of resistance, it should be noted, is quite contrary to that of the friction between solid bodies as investigated by General Morin. Colonel Beaufoy, Froude, and others, however, found that, at higher velocities, the resistance varied more nearly as the square of the velocity. The difference of the two conditions in which the variation was directly, or, as the higher power, undoubtedly represented on the one hand the condition of water in which the mere viscosity came into play, resisting the shearing stress of the layers in passing over each other, and on the other hand the condition when the breaking up of the water into eddying motion caused the resistance to become much greater.

Prof. Osborne Reynolds, about 1883, investigated the critical velocity at which this change of state occurs, and gave calculations concerning the critical velocity, accompanied by an account of some beautiful experiments. These experiments showed the sudden breaking up at the critical velocity of the stream in a glass tube, the water in which had been flowing quite steadily until that particular velocity was reached.

Now with water flowing in a tube or channel with wetted sides the velocity is greatest in the middle, and, according to the generally accepted theory, is zero at the sides. If this be the case, it would seem that in no event can the whole body of water in the tube break up into sinuous motion; for it is evident that, although it is possible to have one of the conditions by itself, viz. the condition of lower velocity and parallel flow, it is not possible to have the other condition by itself, viz. the condition of sinuous flow. This leads irresistibly to the conclusion that at some point or other there must be a surface of separation between the two.

Such a surface of separation obviously requires special means in order to make it visible. When colouring material is introduced into water flowing under ordinary conditions, it mixes up at once throughout the whole mass. If, however, air is injected into the water, it has been recently found that, in the portion in which the sinuous state exists, the small particles of air, which appear when viewed by the eye as a sparkling mass, prevent the transmission of light and reveal on a screen, when a special lantern apparatus is employed, the actual behaviour of the flowing water. Figs. 1 and 2 show a rectangular body placed in the stream under such conditions. The lines of flow in Fig. 2 result from the use of slightly soapy water, which is used for the production of air bubbles; whereas in Fig. 1 the air is injected into perfectly clear water, and larger bubbles are consequently formed.

Now, if the above figures are examined, it will be seen that round each there is a clear border line indicating a condition differing from that in the general mass of the stream. This not only occurs with obstacles placed in a flowing stream, but in pipes as in Fig. 3. At the International Congress of Naval Architects held at the Imperial Institute last July, this mode of representing the flow of water was brought forward for the first time. It was then suggested that, in this clear border line the water was flowing in layers with parallel motion, while in the main body of the stream the flow was taking place with sinuous, or broken-up motion, and that the change of critical velocity occurred at the darker border between the two. This dark border is always more intense the higher the velocity of the flow, the width of the border becoming correspondingly reduced.

FIG. 1.—Clear water (thick sheet).

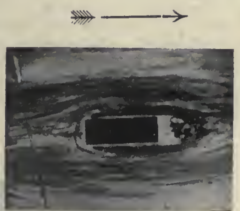


FIG. 2.—Soapy water (thick sheet).

As a good many important results turn upon this point, the subject has been pursued since that time by making a variety of experiments with bodies of varying degrees of roughness of surface, and with passages of various forms. One experiment, however, may be considered as a crucial test, which is to reduce the width of the channel itself, till it actually corresponds with the dimensions of the clear border. This has been done with the result indicated in Fig. 4, when what may be called the air method of making the flow visible entirely fails, the clear border line disappearing and the air passing through, not steadily as before, but spasmodically, while the clear border line of separation

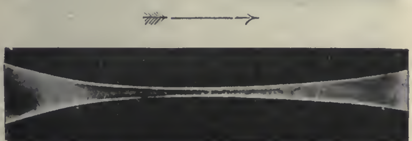

FIG. 3.—Narrow passage showing thin clear film.

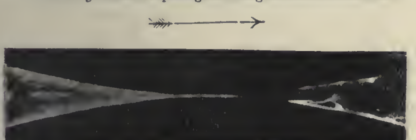

FIG. 4.—Passage still further reduced, showing failure of air method.

entirely disappears. One further step is now obvious, and that is to obtain, if possible, a sheet of water as thin as the border line itself, and examine its behaviour. The result of doing this has been brought forward in a paper read a few weeks ago at the meeting of the Naval Architects in London, when it was shown that in such a thin sheet of water stream line motion exists, thus indicating the absence of sinuous motion and the existence of the motion of parallel flow alone. Under these conditions, while it is impossible to make the motion of water visible, as before, by means of air, colour can be used, and colour bands, corresponding to the stream lines of the mathematician, can be obtained. Figs 5 and 6 indicate a comparison of these two methods to a semi-cylinder. Fig. 5. which is a case of a thick sheet, is an eddying mass of water all round, but is widest, of course, behind where the largest mass of slowly moving water exists. This case is particularly interesting, since it is a case for which the stream lines have been worked out on hydro-dynamical principles,

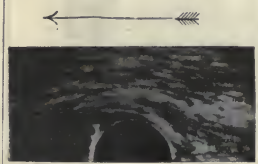

FIG. 5.—Semi-cylinder in thick sheet.

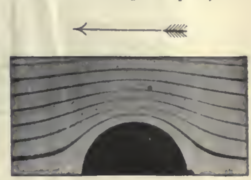

FIG. 6 – Semi-cylinder in thin sheet (test case).

and it is found, by carefully working out a test case, that for all practical purposes the results of the stream lines experimentally produced, agree with those theoretically obtained. As is well known the lines of flow for heat and electricity can be determined mathematically in the same way as those for a perfectly incompressible and frictionless fluid. Hence further verifications can be

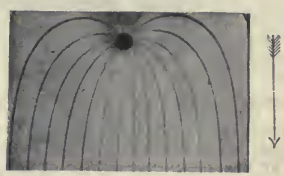

FIG. 7.—Uniform stream and "sink" in channel.

obtained by comparing the theoretical lines of force which have been worked out for electrical and magnetic problems. Fig. 7 is a case of the flow of water through a hole (called in hydro-mechanics a "sink"), and which corresponds to the flow of electricity from an electrified body into one of the wires of a wire grating (see Clerk-Maxwell's "Magnetism and Electricity," Fig. xiii., Art.

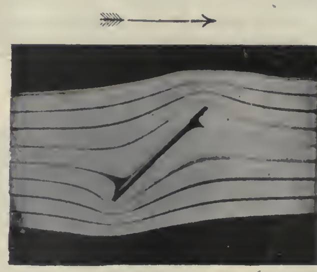

FIG. 8.—Inclined plate in thin sheet.

203, Vol. i.; third edition). A still more remarkable verification is that shown in Fig. 8, which is the case of water flowing past a plate inclined at 45 degrees. The central stream line has been predicted by Prof. Lamb to be a hypérbola, which dividing on the plate would flow round it and re-form on the other side, flowing away exactly as shown in Fig. 8, which figure can be compared with the illustration given in the treatise of Prof. Lamb.

Having thus found a way of representing stream lines by colour bands, various electrical problems, and problems connected with the flow of heat, can be solved in cases

FIG. 9.—Section of screw shaft strut (broad colour bands in thin sheet).

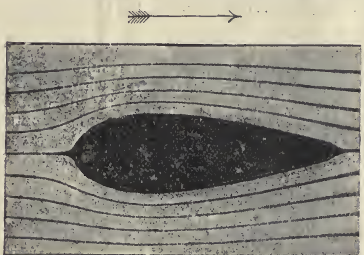

FIG. 10.—Section of screw shaft strut (narrow colour bands in thin sheet).

where it would be impossible to obtain direct mathematical solutions. It is sufficient for the present purpose to give one or two illustrations of the application of the method to problems of interest connected with the flow

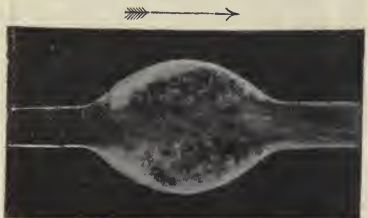

FIG. 11.—Sinuous motion in gradually enlarging and contracting channel (thick sheet).

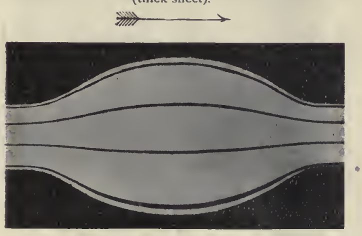

FIG. 12.—Colour bands in gradually enlarging and contracting channel (thin sheet).

of water. Thus, Figs. 9 and 10 illustrate the flow respectively in the case of broad and narrow stream bands round a section of the twin screw strut of one of Her Majesty's cruisers. This might of course be the section of a ship-shaped vessel moving through the water, and as is well known the width apart of the different stream lines would indicate the pressure and velocity in the fluid at every point. Thus stream lines can be obtained in such a case representing a process which for this form of section it would be practically impossible to do by any mathematical process. Figs. 11 and 12 illustrate the flow of water through a passage which gradually enlarges and then contracts. The former case represents the flow under ordinary conditions with the thick sheet of water; the latter case, Fig. 12, being the flow of the colour bands moving in a very thin sheet of water. One more case may be given even more remarkable than any of the foregoing, that is the case of a sudden enlargement of the section of a pipe. Fig. 13 represents the ordinary case of a thick sheet of water in which the eddies and whirls plainly indicate why it is that such a large loss of energy occurs under these conditions in a pipe; while Fig. 14 shows how a perfectly incompressible and frictionless fluid would flow under the same conditions. This is, however, actually what occurs with a thin sheet of water with suitably arranged colour bands.

FIG. 13.—Sudden enlargement (thick sheet.)

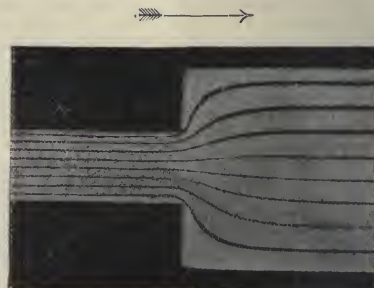

FIG. 14.—Sudden enlargement (thin sheet).

It may be well to remark that all the figures in this article are actual reproductions of photographs of flowing water, which have all been projected on a screen by means of a lantern at the two recent meetings of the Institution of Naval Architects. H. S. HELE-SHAW.

FORTHCOMING MEETING OF THE BRITISH ASSOCIATION.

THE preparations in Bristol for the meeting of the British Association on September 7 proceed apace, and local interest is now thoroughly aroused. The material for the handbook is nearly all in the hands of the editor (Dr. Bertram Rogers), and most of it in type. Among the contributors we note the names of E. J. Lowe, F.R.S. (Meteorology), C. Lloyd Morgan (Geology and Prehistoric Archæology), A. Bulleid (Glastonbury Lake Village), A. T. Martin (Roman Archæology), J. Latimer (History), J. R. Bramble (Architecture), Dr. D. S. Davies (Sanitation), J. W. White (Botany) J. M.

McCurrich (Docks and Tides), J. Holman and H. J. Spear (Economics).

It is hoped that the representation from Canada will be a feature of the meeting, and that many of those who contributed so largely to the success of the Toronto meeting will take this opportunity of paying a return visit. Committees with a view to furthering this object have been formed in Toronto under the presidency of Prof. Macallum, and in Montreal under the presidency of Prof. Bovey. It is hoped that the Mayor and the President of the Board of Trade in Toronto, the Minister of Education (Hon. G. W. Ross), the Secretary of the Royal Society of Canada (Dr. J. G. Bourinot, C.M.G.), the President of the Canadian Pacific Railway (Sir W. Van Horne, K.C.M.G.), and other distinguished guests will be present at the meeting. Among the names of those who are coming from the United States we note the names of Profs. Henry F. Osborn, J. W. Langley, H. P. Bowditch, R. A. Fessenden, R. H. Thurston, and J. Mark Baldwin. From the Continent among those of other eminent visitors are the names of Profs. A. von Kölliker, Ernest Häckel, Gustav Gilson, and Leo Errara, Dr. Paul Topinet, Prof. V. Dwelshauvers-Dery, Prof. Hugo Kronecker, and M. C. de Candolle.

Arrangements are in progress for a biological exhibit at the Clifton Zoological Gardens. Lord Llangattock has, we understand, consented to be the president of a representative honorary committee, and Dr. A. J. Harrison is chairman of the working committee of management. Tanks are being constructed, and arrangements made for an exhibit from the Marine Biological Association's station at Plymouth.

The provisional arrangements for excursions are as follows. Saturday, September 10: (1) Bath; (2) Aust Cliff, with especial reference to geology; (3) Severn Tunnel; (4) Stanton Drew, and Sutton Court, returning over Dundry Hill; (5) Cheddar, *viâ* Yatton, Wrington and Burrington Combe; (6) Avonmouth Docks, including a steamer excursion past Clevedon, Weston, the Holmes, Barry, and Cardiff; (7) Raglan Castle and Tintern Abbey; and (8) Bradford-on-Avon. Thursday, September 15: (1) the Bristol Waterworks; (2) Tortworth, by special invitation of Lord Ducie, for geologists; (3) Wells and Glastonbury, including the Lake Village; (4) Nailsea and Stroud, including Stonehouse, the Stanley Cloth Mills and Dye Works, Dudbridge, Minchinhampton, and Frocester Court; (5) Bowwood, including Avebury and Silbury; (6) Longleat and Sheerwater; (7) the Swindon Railway Works; and (8) Salisbury, Stonehenge and Amesbury. Offers of hospitality in connection with nearly all these excursions have been received and gladly accepted. It is proposed to conclude with a longer excursion, starting on Friday, September 16, to Exeter, Torquay, Dartmouth and Plymouth, returning over Dartmoor.

CITY BANQUET TO THE MEDICAL PROFESSION.

AT the Mansion House on Wednesday in last week, the Lord Mayor gave a banquet to the Presidents of the Royal College of Surgeons and Royal College of Physicians and leading members of the medical profession. This was the first occasion upon which the hospitality of the Mansion House has been extended to the medical profession as such, and a very large and distinguished company was present in response to the Lord Mayor's invitation. Lord Lansdowne, Secretary of State for War, was one of the guests, and in responding to a toast he announced that the Government proposed to make several concessions with regard to the rank of medical officers in the Army. It is proposed to form—out of the Army Medical Staff and the Medical Staff Corps—a Royal Army Medical Corps, the officers of which will bear the same military titles as other officers of the Army. These concessions have been received with great satisfaction by the medical profession, and they will doubtless lead to a marked increase in the number of candidates for the Army medical service. We give below a few extracts from some of the speeches made at the banquet.

In the course of his remarks, Lord Lansdowne spoke as follows:—

We are now about to deal with the large question in which I know the profession takes a deep interest—the question of the status and rank of the medical officers in the army. I have heard it said, Is not the title of "Doctor" or "Surgeon" a title by itself which any one might be proud to wear? But in the army rank means a great deal. It is the outward and visible sign of that authority and consideration with which the place of a man is clearly defined and designated, and it is necessary in the military profession that a man should have a proper military stamp. Let me say in half a dozen words how it is that we intend to deal with this question. We have made in former years various attempts to solve this question of titles by means of ingenious expedients, but the results have not been very satisfactory. In some cases we have, I think, invented titles which for cumbrousness and cacophony would be hard to beat. We now propose that the Army Medical Staff and the Army Medical Corps should be formed into one corps. The titles used shall be the simple, short, intelligible titles to which we are all accustomed. We propose to give the corps military titles up to and inclusive of the rank of Colonel. I have received some forcible hints that our scheme will be unsuccessful unless we proceed to the rank of General. But we in future intend to limit the rank of General to a very restricted number of officers, all of whom will be required to hold certain specific appointments carrying with them general command in the army, and they will be required to command troops, if necessary, in the field. I feel quite sure that it is not intended that any departmental officers shall be given the rank of General under this scheme. Her Majesty the Queen, whose good will towards the profession is well known, has signified her pleasure that the new corps shall be called the Royal Army Medical Corps.

The Lord Mayor, in proposing the toast of "The Medical Profession," remarked: I feel a peculiar pleasure in proposing that toast, because I think that this is the first occasion on which it has been proposed within these walls. I am delighted to welcome you here to-night in the name of the citizens of London. I welcome you for more reasons than one. In the first place I welcome you because for many generations past you have been intimately associated with the City of London. I believe that the Royal College of Physicians commenced in the City of London in 1518. The Royal College of Surgeons was intimately associated with one of our ancient City guilds—I refer to the Barber Surgeons Company. There is another company connected with your profession, also one of the livery companies, which has its residence in the City of London at the present time, and we members of the Corporation welcome you heartily as having some connection with us both in times past and at the present time.

In replying to the toast, Sir Samuel Wilks (President of the Royal College of Physicians of London) expressed the satisfaction of the profession at Lord Lansdowne's statement. Referring to the historical connection touched upon by the Lord Mayor, he said: There was a time when the two Colleges were City companies, and at that time they were under the jurisdiction of the City and of the Lord Mayor; the same, I believe, applied to the other cities of Dublin and Edinburgh. The Physicians and Surgeons existed nearly 500 years ago as distinct companies in the time of Henry VI., and at that time they were closely connected with the Corporation of London, and I believe they had to get their licence from the Lord Mayor. The Lord Mayor of that time had a supervision over the instruments of the Surgeons and also over another class of persons connected with the Surgeons whose names I will not mention, although the Lord Mayor has done so. One reads in books how often they had to fine these members of the College in sums of 6*s*. 8*d*. and 3*s*. 4*d*. for shaving polls and trimming beards on a Sunday. Subsequently came the charter of the College of Physicians which we obey at the present time, and twenty years after that came the charter given by Henry VIII. to the Surgeons. The celebrated picture by Holbein hangs in a hall close by. In that picture the King is presenting the charter to the Surgeons. On his right hand are the physicians, Dr. Chambers and Sir William Butts. Previously to this time I believe the two Colleges held an examination similar to the conjoint scheme at the present day.

Sir William MacCormac (President of the Royal College of Surgeons of England), speaking for surgery, said the members of the profession outside the army and those within its ranks were grateful for what the noble Marquis, the Secretary of State for War, had done for those who thus served their country in the Medical Department of the army. He had agreed to grant the two great wishes which have been pressed upon him—army rank and the formation of an army medical corps. Passing to the historical connection mentioned, Sir William MacCormac said: In the history of the City of London one might recall the names of many distinguished men in our profession who have served their country in the wars. The Father of English Surgery, Richard Wiseman, surgeon to King Charles I. and Sergeant-Surgeon to King Charles II., had an eventful career during the Civil War. He was taken prisoner after the Battle of Worcester, and again while practising his profession as a surgeon in the Old Bailey at the sign of the "King's Head" he was taken to the Tower, and nearly lost his own head during the Commonwealth. About the same time John Woodhall, a surgeon at St. Bartholomew's Hospital, Surgeon-General to the East India Company, also a celebrated surgeon in this old City of London, who had served both in the army and in the navy, dedicates his curious work on surgery and the duties of the surgeon's mate to the "King's most excellent Majestie" Charles I., and also to the Right Hon. Sir Morris Abbot, Lord Mayior. Woodhall speaks of himself as an ancient master of the mysterie of Barber Surgeons, an old City company which became transformed in lapse of time, let us hope improved, into the Royal College of Surgeons, while the Apothecaries, who did so much in their time for the profession of this country, and still do so, continue as one of the City companies. So there are points of contact between our profession and the City of London.

Sir William Turner (President of the General Medical Council) proposed the toast of "The Houses of Lords and Commons," coupled with the names of Lord Lister and Sir Charles Cameron, both of whom replied.

Sir George Duffey proposed "The Health of the Right Hon. the Lord Mayor." In the course of his reply the Lord Mayor said: I have inaugurated this dinner to-night in the hope but not with the assurance that my successors will follow on with it. I see no reason, looking to the facts that almost every other profession has been recognised in this hall, why the medical profession should not be included with them.

NOTES.

The first of the two annual conversaziones of the Royal Society was held yesterday evening, as we went to press.

The following fifteen candidates were selected by the Council of the Royal Society on Thursday last to be recommended for election into the Society:—Mr. H. F. Baker, Prof. E. W. Brown, Dr. A. Buchan, Mr. S. F. Harmer, Mr. A. Lister, Lieut.-General C. A. McMahon, Dr. W. Osler, the Hon. C. A. Parsons, Prof. T. Preston, Prof. E. W. Reid, Mr. A. Scott, Mr. A. C. Seward, Mr. W. A. Shenstone, Mr. H. M. Taylor, and Mr. J. Wimshurst. The certificates of these candidates are given in another part of the present number.

The annual visitation of the Board of Visitors of the Royal Observatory, Greenwich, will take place on Saturday, June 4. The Observatory will be open for inspection by invited guests at 3 o'clock.

The seventieth annual meeting of the German Association of Naturalists and Physicians will be held at Düsseldorf on September 19–24.

At last week's meeting of the Paris Academy of Sciences it was announced that the French Minister of Public Instruction had asked the Academy for an expression of opinion upon the subject of the proposed law to change the national time. The communication was referred to a committee previously appointed to consider the proposed modifications.

The following are the names of the Royal Commissioners appointed to inquire and report as to methods of treating and disposing of sewage:—The Earl of Iddesleigh (chairman), Sir Richard Thorne Thorne, K.C.B., Prof. Michael Foster, Prof. William Ramsay, Major-General Constantine Phipps Carey, Dr. James Burn Russell, Colonel Thomas Walter Harding, Mr. Thomas William Killick, and Mr. Charles Philip Cotton.

On Monday next, May 16, a special evening meeting of the Royal Geographical Society will be held in commemoration of the 400th anniversary of the discovery of the Cape route to India by Vasco Da Gama. A paper on the subject will be read by the President. H.R.H. the Prince of Wales, H.R.H. the Duke of York, and His Excellency the Portuguese Minister, Count de Soveral, have promised to be present. The anniversary meeting of the Society will be held on May 23, and the annual conversazione will be held in the Natural History Museum, South Kensington, on the evening of Thursday, June 23.

The Council of the Royal Geographical Society have awarded one of the two Royal medals to Dr. Sven Hedin for his work in Central Asia, and the other to Lieutenant E. A. Peary, United States Navy, for his explorations in Northern Greenland. The Council have also made the following awards:—The Murchison grant to Mr. H. Warington Smyth for his several journeys in Siam; the Back grant to Mr. George P. Tate for his survey work in Afghanistan, Baluchistan, especially Makran, Aden, and on the Indus; the Gill memorial to Mr. Edmund J. Garwood for his geographical work in Spitsbergen during two seasons, in company with Sir Martin Conway; the Cuthbert Peek grant to Mr. Poulett Weatherley for his exploration of the region between Lakes Mweru and Bangweolo. The following foreign geographers and travellers have been elected honorary corresponding members:—Don Marcos Jimenes de la Espada, Don Francisco Moreno, Buenos Ayres; Marquis of Rio Branco, Brazil; Dr. Thoroddsen, of Iceland; Prof. Ratzel, of Leipzig.

Several changes have have been made on the staff of the Geological Survey. The vacancy caused by the retirement of Mr. George Sharman, senior Palæontologist, has been filled by the appointment of Dr. F. L. Kitchin as Assistant Palæontologist, under Mr. E. T. Newton, F.R.S., Palæontologist. Dr. William Pollard has been appointed an Assistant Geologist in the Petrographical Department of the Survey at Jermyn Street, in the room of Prof. W. W. Watts; and Mr. C. B. Wedd has also been appointed an Assistant Geologist, to fill the vacancy caused by the resignation of Mr. C. E. De Rance. Mr. H. J. Seymour has joined the staff in Ireland as Assistant Geologist, to take charge of the petrographic work, in the room of Prof. W. J. Sollas, F.R.S.

At a recent meeting of the Gesellschaft für Erdkünde held in Berlin, Dr. Gerhard Schott of the Deutsche Seewarte gave an account of the provisional plans for the forthcoming German deep-sea expedition. The expedition was originally suggested by Prof. Chun, of Breslau, and it was at first intended to confine its labours strictly to zoological research; but the sum granted by the Imperial Parliament (15,000*l.*) is considered sufficient to allow of a comprehensive series of physical and chemical observations being undertaken as well. Soundings will be made in little-explored regions in the eastern part of the South Atlantic, on the sub-Antarctic plateau to the east of the Cape, and in the immense stretch of the Indian Ocean between the equator and 30° S. lat. Special attention will be given by the chemists to analyses of the gas-contents of the waters at different depths. The vessel, which will probably be chartered from the Hamburg-American line, is to be a steamer of at least 2000 tons, with a sea-speed of not less than 10 knots: the *personnel* of the expedition will include, besides Prof. Chun, a navigating officer, four zoologists, a botanist, an oceanographer, a chemist, a doctor, and a photographer. The expedition is to start in August, beginning work in the Faëroe-Shetland Channel, and going southward by the Canaries and Cape Verd Islands to the coast of German West Africa, where some special fishery problems are to be studied. From the Cape, the meeting-place of the hot and cold waters to the east is to be examined, and if possible an excursion made southward to Prince Edward Island. Next the waters east of Madagascar will be visited, and after touching at Zanzibar the expedition will work through the region of the Seychelle and Chagos Islands to Colombo, and thence back to Aden by the Eight-degree Channel, returning to Hamburg from Aden direct. The whole time occupied will probably be eight or nine months. We hope shortly to publish a detailed account of the final arrangements of the expedition.

THE death is announced of Prof. D. S. Kellicott, professor of zoology at Ohio State University.

THE Royal Agricultural Society has accepted the invitation to hold its country meeting in York in 1900.

PROF. JOHN MILNE has left England for a few weeks on a short tour, with the object of visiting seismological observatories in Italy, Sicily, and Germany.

THE Croonian Lectures of the Royal College of Physicians of London will be given by Dr. Sidney Martin on June 14, 16, 21 and 23. The subject is the chemical products of pathogenic bacteria considered with special reference to enteric fever.

THE Presidents of the Institute of Chemistry, Society of Chemical Industry, and Society of Public Analysts have sent out invitations for a reception to be held at the Royal Institute of Painters in Water Colours on Tuesday, May 24.

A MEETING of the Federated Institution of Mining Engineers will be held in the rooms of the Geological Society, Burlington House, on Thursday and Friday, May 19 and 20, under the presidency of Mr. A. M. Chambers.

IT is announced in the *Kew Bulletin* that Mr. J. A. Gammie, Deputy Superintendent of the Government Cinchona Plantation in Sikkim, has retired from that post, and Mr. Robert Pantling has been appointed his successor. Both Mr. Gammie and Mr. Pantling went out to Calcutta from Kew.

AT a meeting of the Essex Field Club to be held at Chingford on Saturday, May 21, Dr. H. C. Sorby, F.R.S., will lecture on "The Preparation of Marine Animals as Transparent Lantern-slides, illustrated by Characteristic Forms of the Essex Coast." The subject is one which has occupied Dr. Sorby's attention for some time, during his cruises off the coast in his yacht *Glimpse*. The preparation of marine animals as lantern-slides, so as to show not only their true general form, but also much of their internal structure, is as much a chemical as a biological problem, and different animals require very different treatment. A general account of the methods of preparing such slides was given by Dr. Sorby in a recent number of NATURE (March 31, p. 520). The company of naturalists and others interested in the subject is invited by the Essex Field Club. Cards for the meeting may be had of the Hon. Secretaries, Buckhurst Hill, Essex.

ON Saturday, May 14, the Yorkshire Naturalists' Union, of which Prof. Michael Foster is now the President, will hold a meeting at Clapham, Yorkshire, for the investigation of Ingleborough and Bowland Knotts. Special facilities have been obtained for the examination of the great Ingleborough Cave, which can be traversed for a distance of about half a mile. The cave is of little interest to the archæologist, no remains either of flint implements or bones having been found in it, but it is of surpassing interest to the physical geologist and to those who wish to study the formation of different forms of stalactites and stalagmites. An instructive leaflet containing notes on the geology and biology of the district has been prepared for the information of the members of the Union.

THE third International Congress of Applied Chemistry will be opened in Vienna on July 28, and will last until August 2, inclusive. From the *Chemical News* we learn that the subjects of the Congress are as follows: (*a*) Consultations concerning important questions in all departments of applied chemistry, and particularly of those the solution of which is a matter of public interest. (*b*) Agreement upon methods to be considered internationally valid for the analysis of such products as are valued upon the basis of their chemical composition. (*c*) Agreement upon methods to be considered internationally valid for the use of the different chemical industries. (*d*) Discussion on questions of instruction in applied chemistry, and consultations upon general affairs of chemists. And (*e*) commencement of a friendly understanding between the representatives of the different departments of applied chemistry at home and abroad. Papers to be read at the meeting should be in the hands of the General Secretary, M. F. Strohner, Vienna IV/2, Schönburgstrasse 6, not later than June 1. It is requested that no paper be longer than five pages octavo in print.

AN automatic telephone exchange system, which does away with the necessity for the staff of skilled operators at present required at exchanges, is being introduced into this country from the United States by the Direct Telephone Exchange Syndicate. Instead of ringing up the central station, requesting the attendant to put him in communication with the person to whom he wishes to speak, and waiting while the required alterations are made on the switch-board, the subscriber to an exchange worked on the automatic plan is himself able to connect his telephone with that of any other subscriber without the intervention of a third person. Each subscriber has upon the front of his instrument a circular disc pivoted at the centre, and having one-half of its circumference inscribed with figures from 0 to 9. If he wishes to communicate with another, he sets the disc so that the number of the other subscriber appears upon the dial, and he then finds his telephone in circuit with that of the person whose number he has indicated by his disc. When he has finished his conversation he simply hangs his receiver on its hook. Immediately, the switch which represents him at the exchange returns to its normal position, and communication is cut off. A third subscriber cannot get possession of the line until the first two have done with it; hence there is no possibility of interruption, and secrecy is assured. In the United States a considerable number of exchanges are in regular operation on this plan, and are stated to be proving perfectly satisfactory to their subscribers.

THE Melloni thermo-pile has of late years fallen somewhat into disuse. For the detection and measurement of small thermal changes, the bolometer of Langley, the micro-radiometer of Boys, and the extremely sensitive photo-electric cells of Minchin, have to some extent supplanted the older instrument. In a recent number of the *Zeit. Instrumentenkunde*, Prof. Heinrich Rubens shows that the capabilities of the original apparatus may be greatly increased if proper care is given to the construction, particularly by reducing the thermal capacity of the couples. Antimony and bismuth are mechanically ill-suited for the purpose; he therefore replaces them by iron and the nickel alloy "constantan," in the form of fine wires. The thermo electric "power" of an iron-constantan single couple is only about half that of antimony-bismuth, but the gain in sensitiveness, due to lessened thermal capacity, quite outmeasures this defect. Prof. Rubens has succeeded in making such a thermo-pile with twenty couples in a line of 20 mm.; the resistance is 3·5 ohms, and the E.M.F. 0·00106 of a volt per 1° C. This must be regarded as a very great advance in radiometry. It would be interesting to compare this instrument with photo-electric cells as regards their respective power of measuring stellar radiations. It should be noted that this is not the first time an iron-constantan couple has been applied to thermal investigations.

"THE collapse of a spherical shell under pressure" is a problem which has long puzzled the minds of mathematicians, and one which both engineers and geologists would be glad to see solved. An interesting series of experiments in which a hollow hemisphere of metal was made to collapse by the pressure applied on top of it by another hemisphere or plane, is described by Prof. H. Schoentjes, of Ghent, in the current *Bulletin de l'Académie royale de Belgique* (1898, No. 3). Prof. Schoentjes gives excellent photographs showing various cases of collapse in segments; triangular, quadrangular, pentagonal and hexagonal forms being all represented. The present paper forms the sequel to one published in 1890, and among the author's conclusions the following are noteworthy:—When two similar hemispheres of 10 cm. diameter were crushed together by a hydraulic press with their summits in contact, only one of the hemispheres collapsed; the cavity formed was spherical, and was moulded on the undeformed hemisphere just as if the latter hemisphere were solid. When a hemisphere of 15 cm. diameter was crushed against one of 10 cm, the smaller one penetrated nine times out of ten into the larger one; the cavity was at first spherical, but afterwards its margin became polygonal. In one case only (and the author could not succeed in repeating the experiment), both hemispheres were deformed; the larger one first penetrated the smaller, but under a force of 80 kilogrammes the edge of the cavity began to penetrate the large hemisphere. When a hemisphere was crushed by a plane the normal deformation was found to be hexagonal.

THE mathematical theory of the propagation of earthquake shocks is the subject of a somewhat interesting investigation at the hands of M. P. Rudski, an abstract of whose papers has just reached us (*Anzeiger der Akademie der Wissenschaften in Krakau*, November 1897). The author examines the consequences of the assumption made by Prof. A. Schmidt, of Stuttgart, that the wave-velocity in the interior of the earth is a function of the radius vector, which decreases as the latter increases. Under such circumstances, the rate of propagation of earthquakes along the earth's surface decreases from the epicentre outwards till a certain circle is reached, and then increases up to the antipodes of the epicentre. The position of the bounding circle in question depends on the depth of the disturbance, and M. Rudski considers it possible, from observations of earthquakes, to determine the relation between the wave-velocity and the radius vector.

A SERIES of observations of the temperature of the soil at the observatory of Catania from 1892 to 1896 has been published by Dr. Emmanuele Tringali in the *Atti dell'Accademia Gioenia di Scienze Naturali*. In addition to confirming the well-known laws according to which the diurnal and annual variations of temperature decrease and undergo retardation with increasing depth, Dr. Tringali finds that at Catania the velocity of transmission of the diurnal fluctuations is about 20 cm. for every 7½ hours, and that these fluctuations become practically unimportant at a depth of 60 cm., where they only amount to a few tenths of a degree when the atmospheric temperature changes as much as 17°.

THE summary of the Weekly Weather Report for the first quarter of this year, recently issued by the Meteorological Council, shows that in all the principal wheat-producing districts, except the north of Scotland, there is a considerable deficiency in the amount of the rainfall; while in the grazing, &c., districts a deficiency is everywhere shown. Looking at the values for the winter half-year, the excess in the north of Scotland is 3·5 inches; this is, of course, due to the tracks taken by the areas of low barometric pressure. The greatest deficiency occurs in the south of England and Channel Islands, where it amounts to 7 inches, and it exceeds 5 inches in the midland parts of England. As these values are for large districts, of course at some individual stations the deficiency is much more marked.

WE drew attention last week to the important meteorological station established by the Corporation of Southport, and we are glad to learn that the municipal authorities at many other stations are not behind that place in recognising the value of accurate meteorological observations, and of placing the stations in connection with the Meteorological Office or the Royal Meteorological Society. Among these we may specially mention the station established by the Corporation of Eastbourne, under the superintendence of Mr. R. Sheward, who has for many years published reports of the observations at that favourite sea-side resort, where every care has been taken to place the instruments in the best possible positions. Eastbourne enjoys a large amount of bright sunshine, the average annual duration being 1719 hours, while for London the average is only 1240 hours. Mr. Sheward bears witness to the value of the storm-warning telegrams issued by the Meteorological Office. He states that since the establishment of storm signals there, in 1893, no mishap has occurred to the fishing fleet, although his tables show that some serious gales have been experienced.

THE Bureau of Agriculture and Immigration of the State of Louisiana has recently issued the first volume of a treatise on the history, botany, and agriculture of the sugar-cane, and the chemistry and manufacture of its juices into sugar and other products, by Prof. W. C. Stubbs, Director of the Audubon Park Experimental Station at New Orleans. One chapter is devoted to the botanical relations of the plant, one to its anatomy and physiology, one to its modes of reproduction, and one to bacteriological notes on red cane.

THE plant yielding what is known in commerce as Ceara rubber or Maniçoba, and shipped from the Brazilian ports of Ceara, Bahia and Pernambuco, was identified at Kew eleven years ago as *Manihot Glaziovii*, Muell. Arg. Specimens of the plant were sent from Kew to our Colonies and possessions which seemed suitable for its cultivation, and the results of the attempts to introduce the Ceara rubber tree are described in the latest issues of the *Kew Bulletin* (Nos. 133–134, 1898). The following is a summary of the information thus obtained, and it furnishes another example of the valuable work done by Kew in the endeavour to increase the natural resources of British possessions: (1) The plant is readily propagated both from seeds and cuttings. Seeds are abundantly produced in almost every part of the world where the plant has been introduced. They may be gathered from plants when only three to five years old. There is therefore the great advantage that a large area could be planted within a comparatively short period. Sowing the seeds in the position where they are to grow permanently is universally adopted in Brazil. It is possible, if adopted elsewhere, this plan would greatly reduce the cost of establishing plantations. (2) The Ceara rubber plant is very hardy, a fast grower, free from insect and fungoid attacks, requires little or no attention when once established, and thrives in poor, dry and rocky soils unsuited to almost any other crop. It is evident, however, that the yield of a few trees cannot be remunerative, and only large areas can hope to make the industry a paying one. (3) It produces a good class of rubber, second only when well prepared to the best Para rubber. For this there is a steady and continuous demand. The yield per tree is apparently small, but a return is obtained earlier than from any other rubber plant. With thick planting and judicious thinning as the trees grow up, it may be possible to increase the yield hitherto recorded; while with skilful treatment the permanent trees may be tapped twice yearly, and last in a productive state for fifteen to twenty years. (4) In spite, therefore, of the apparent want of success which so far has attended experiments with Ceara rubber plants in Ceylon and other countries, the increasing importance of rubber as an article in large demand in all civilised countries at good prices, suggests a reconsideration of the merits of this interesting plant. In many of our Colonies possessing a dry climate and a poor stony soil, it is possible that large areas could be profitably occupied with Ceara rubber trees so grown as to provide annual crops for tapping.

MR. D. A. GILCHRIST, Director of the Agricultural Department of the University Extension College, Reading, has issued his fourth annual report upon the field experiments carried on during last year. Since 1894 field experiments have been made at the College, and the results have been of distinct service to agriculturists. The County Councils of Berkshire, Dorset, Hampshire and Oxfordshire co-operate with the College in this work through their Technical Instruction Committees; subsidies being granted by these bodies to the College to meet the expenses. During the season 1897 the work included the testing of manures on most of the principal farm crops, and a further development was made in the direction of carrying out field experiments of a more continuous character, such as the effect of manures, applied at the beginning of a rotation of crops, throughout the whole rotation. The results of all field experiments are of much more value in the locality in which they are carried on than elsewhere; nevertheless, Mr. Gilchrist's report gives much useful information as to the effects of various manures on different crops, under very different conditions of soil; and from this, tolerably safe general conclusions may be drawn. The Agricultural Department of the University Extension College at Reading may indeed be compared with the agricultural experiment stations of Canada and the United States, for it is performing, so far as it is able, the functions of those institutions by conducting inquiries of value to agriculturists, and acting as a reference bureau.

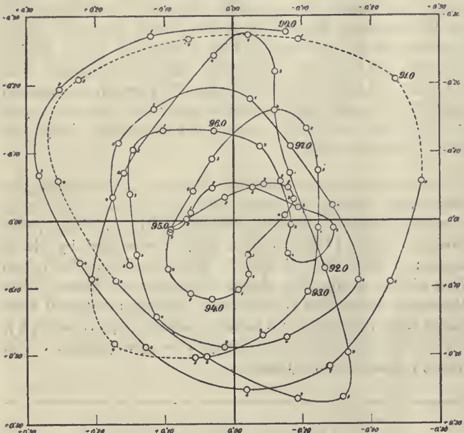
WE have received from P. K. Kozloff, member of the last Russian Tibet expedition, a very interesting contribution to the Lob-nor controversy. It is issued by the Russian Geographical Society as a pamphlet ("Lob-Nor"), and contains the Russian traveller's remarks concerning the lakes discovered by Sven Hedin, for which the Swedish explorer claims to be the true Lob-nor; while the lake Kara-koshun-kul, discovered by Prjevalsky, and described by him as the Lob-nor, would be, in Sven Hedin's opinion, but a secondary and temporary basin. P. K. Kozloff gives in his pamphlet all materials which may enable the reader to come to an independent opinion, namely, a map of the region, embodying the Russian surveys and Hedin's discovery; a copy of the Chinese map upon which Richthoffen and Hedin based their argumentation; and abstracts from Prjevalsky's, Pyevtsoff's, Bogdanovich's, Hedin's, and Kozloff's descriptions of the Lob-nor region. The map already shows to what extent Hedin's claims are admissible. The author then discusses Richthoffen's and Hedin's arguments. The Chinese map, which gives to the Lob-nor a more northern position than the position occupied by Prjevalsky's Lob-nor, Kozloff shows, is wrong, because it gives to the junction of the Tarim with the Konche daria (Airylgan) a much more northern position than was found already in 1765 by the Jesuits, and confirmed since by General Pyevtsoff. In fact, most of the positions on the Chinese map have more northern latitudes than the real ones. The lake Khas of the same map, with which Richthoffen and Hedin wanted to identify Prjevalsky's Lob-nor is, beyond any possible doubt, the lake Ghas of Prjevalsky, situated beyond the Nutsitu ridge marked on the Chinese map. As to the chain of four lakes discovered by Hedin, of which the southern only had been previously visited by Kozloff, they have been formed by the Konche daria, which, coming from the north-west, is continually shifting its bed in its lower part towards the right, *i.e.* westwards. The desert in the north of the Lob-nor has been formed through that shifting of the bed of the Konche daria, and the chain of lake-shaped enlargements of the old bed of the Konche daria, the Ilek, for which Hedin claims to be the historical Lob-nor, is nothing but a temporary formation, due to the rightward shifting of the river bed. Kozloff develops this hypothesis with much skill, and concludes that Prjevalsky's Lob-nor (the Kara-koshun-kul) must have extended much further northwards and eastwards; but the lowest part of the depression, which is occupied by this lake, always was the historical Lob-nor.

THE additions to the Zoological Society's Gardens during the past week include two Sooty Phalangers (*Trichosurus fuliginosus*, ♂ ♀) from Tasmania, presented by Mr. A. Walley; four Common Vipers (*Vipera berus*), British, presented by Mr. J. Amos; a Salvadoris Cassowary (*Casuarius salvadorii*) from New Guinea, a Glaucous Macaw (*Anodorhynchus glaucus*) from Paraguay, a Common Chamæleon (*Chamæleon vulgaris*) from North Africa, deposited; a Common Zebra (*Equus zebra*, ♀), bred in Amsterdam; six Garganey Teal (*Querquedula circia*, 3 ♂, 3 ♀), European, purchased.

OUR ASTRONOMICAL COLUMN.

THE SPECTRUM OF HYDROGEN IN NEBULÆ.—If hydrogen gas in a Geissler tube be examined spectroscopically, the brightest line observed is $H\alpha$. If, on the other hand, the lines of hydrogen in nebulæ be examined, $H\beta$ may sometimes be well seen, while $H\alpha$, the C line, can scarcely be detected. To account for this apparent change of intensity several investigations have been made, and as long ago as 1868 Lockyer and Frankland showed that the hydrogen spectrum could be reduced to the single line $H\beta$ under certain conditions of temperature and pressure. Prof. Scheiner has recently investigated the question of the luminosity of hydrogen in the nebulæ (*Astrophysical Journal*, No. 4, April 1898), and he has attempted to introduce "circumstances approximating to those under which the nebulæ emit light" to find out whether objective changes can be produced in the spectrum of hydrogen in an attenuated state, or whether the subjective weakening of the light is the determining factor, and if so to what extent. By exciting tubes filled with hydrogen in the field of a Tesla high tension transformer, the space surrounding them having a temperature of about − 200° C., Koch's investigations were confirmed that the spectrum of hydrogen did not change when the surrounding temperature was reduced as low as − 200° C. Prof. Scheiner next investigated the physiological disappearance of the $H\alpha$ line, and without entering on the procedure adopted, which is described in the journal referred to above, we will limit ourselves to the result. The absence of the $H\alpha$ line in the hydrogen spectrum is due to physiological reasons, and it is consequently not permissible to deduce from this peculiarity of the hydrogen spectrum in the nebulæ any conclusion whatever concerning the physical conditions under which the light emission of these celestial bodies takes place. Whether certain nebulæ may not prove exceptions to this rule, is to be left an open question; it is certainly not impossible that such may be the case.

THE MOVEMENT OF THE EARTH'S POLAR AXIS 1890·0–1897·5.—To the *Astr. Nachr.* (No. 3489) Prof. Albrecht contributes a short abstract of an investigation which he has just completed on the path of the earth's polar axis. In a previous number of the same journal (No. 3333) he gave the result of a similar piece of work for the period 1890·0–1895·2. The mass of material that has since accumulated has led Prof. Albrecht to reinvestigate the motion from the beginning, or, in other words, to trace the movement of the pole for the whole period 1890·0–1897·5. An examination of the resulting curve shows that from the year 1890 to 1895 a decrease in the amplitude took place, the curve towards the time of the latter year being not very far distant from the position of the mean pole. From 1895 the amplitude began to increase, but without reaching the value of that attained in the year 1890. The curve during the interval 1897·0–97·8 approached the mean pole by quite a tenth of a second more than it did during the period 1890·0–90·5. Prof. Albrecht consequently points out that since the curve does not



Movement of the north pole of the earth's axis.

repeat itself after a period of seven years, the orbit of the pole's movement cannot be represented by a term of twelve and of fourteen months period.

Comparing the observed and calculated values of $\phi-\phi_0$, he is led to infer that a part of the series of observations is more or less affected by systematic errors, the great portion being due to refraction disturbances. To remedy this in future it is pointed out that greater care must be taken to ensure equality of refraction towards the north and south by having large openings (shutters) in the observing room, and by placing the instrument central as regards the shutters. Further, mention is made of the locality of the observatory, and such positions should be chosen where the land and vegetation conditions towards the north and south do not offer great contrasts.

COMET PERRINE (MARCH 19).—The following ephemeris for this comet is continued from *Astr. Nach.*, 3488.

Berlin Midnight.

1898.		R.A. h. m. s.		Decl. ° ′		Br.
May 12	...	1 36 25	...	+54 16·3	...	0·38

During the present week the comet approaches the vicinity of the well-known great cluster in Perseus.

THE NORTHERN "DURCHMUSTERUNG."—A committee, consisting of Profs. E. C. Pickering, J. G. Hagen and M. B. Snyder, informs us (*Astrophysical Journal*, No. 4, April 1898) that a new edition of the *Durchmusterung* is being prepared by the Bonn Observatory, and will shortly be published, provided that subscriptions for a hundred copies at seventy marks each are promised. The fact that the original edition of this work is exhausted, and that the price asked was exceptionally low, should have induced many libraries and institutions to have taken this opportunity and become possessors of the work. It is stated that after May 1 of this year the price will be raised to one hundred and twenty marks, so that, if this date be adhered to, the opportunity for obtaining copies at the cheaper price has been missed.

THE ASTRONOMICAL SOCIETY OF WALES.—In this column we have several times referred to the excellent work the Astronomical Society of Wales is doing in promoting the study of astronomy and the allied sciences. The Society has just published in a new form and under somewhat new conditions the first issue of their quarterly journal, the *Cambrian Natural Observer*, which it is hoped will appear regularly. In the introduction we are told, "for some reason or other science does not seem to flourish in Wales; yet, the opportunities for the observation of natural phenomena—using these words in their broadest sense—are neither few nor unimportant." May the influence of the Society be so effective that such a statement as the above will in the next few years cease to be accurate.

SEA-BEACHES AND SANDBANKS.[1]

THIS paper is the sequel to one on "The Formation of Sand-dunes," in the *Geographical Journal*, March 1897. It embodies a research upon the processes which distribute the detritus which enters the sea at its margin, and upon the behaviour of the material distributed.

Fine mud settles through water with such extreme slowness, that wherever the bottom is disturbed by waves (say, to the edge of the continental shelf) it cannot anchor itself upon the bottom even during the slack water of the tides, so that the action of gravity is cheated. This leads to the conclusion that the transit of mud down the slope from the shore is not due to the action of gravity, but that the principal factor determining the well-known direction of mud-transport is the diminution of intensity of bottom agitation from the shallows to the depths.

The usual condition of sea-water is one of oscillation which is not quite symmetrical in amount (*i.e.* there is often a prevailing drift in one direction), and which is scarcely ever symmetrical in intensity, a short quick motion one way being balanced, as far as the movement of the water itself is concerned, by a long slow motion in the reverse direction.

The author shows how suitable oscillation on a seaward slope will set shingle travelling shoreward, and sand simultaneously travelling seaward. The condition of the transport of shingle (great intensity of motion) keeps most of it close against the shore, often in a bank or beach; while the inability of mud to settle except where the water is quiet causes it, as we have seen, to accumulate in mud flats beyond the limits of wave-action. The accumulations of sand are of greater variety, for, although the mean term in size, it possesses a greater independence of motion, or persistence, or effective inertia, than either of the extreme terms. Mud (by which is intended throughout such characteristic marine mud as the well-known "blue mud") obeys each slightest swirl of the water; it follows almost exactly the stream-lines; and it is only in the slow settlement of the mud in still water that muddy water behaves otherwise than as an emulsion. Shingle, again, is not raised to any great height from the bottom, and sinks so swiftly that it does not take a long free flight in water. Hence, when it is moving it follows almost precisely the direction of the momentary movement of the water. Sand, on the other hand, is frequently churned up to a considerable height from the bottom, and often has a long free path; but when the stream-lines of the water are suddenly deflected, whether vertically or horizontally, inertia carries the sand on, the stream-lines of the sand being deflected less than those of the water. Similarly, when the current slackens the sand flings itself forwards, as is so noticeable in the rippling of sand by

[1] By Vaughan Cornish, M.Sc. (Vict. Univ.). (Abstract of a paper read before the Royal Geographical Society on March 16, published in the *Geographical Journal*.)

waves. It is owing to its persistent motion that sea-sand accumulates in vast banks where it is flung by the sudden bending or checking of currents (*e.g.* at tidal nodes), or where it is dropped during tumultuous mixing of waters.

The wash of the waves, owing to percolation, piles up the pebbles thrown forward by the breaker, forming a bank, or ridge, or Full, and this is the action proper to the sea on a shore of shingle.

The piling up of the ridge goes on, its height and steepness increasing, until the wash can reach no higher, and the steepness of the ridge at each point is such that the assistance which gravity gives to the down-flowing surface stream counterbalances the loss of transporting power due to percolation at that level. This is the equilibrium profile or regimen of the Full. Now, the greater the volume of water flung forward by the breaker, the greater is the depth of the back-flowing surface stream, and thus for the same size of beach material the carrying power of the back-wash is more nearly equal to that of the on-wash. Consequently, in a given locality, the regimen slope of beach proper to a rough sea is not so steep as that for a quiet sea.

It is evident that the greatest amount of transport can occur when the sea acts upon the greatest quantity of shingle—that is to say, when the sea is at its highest level. The transporting power increases in a more rapid ratio than the rise of level, owing to the circumstance that most of the shingle is accumulated on the landward side of the beach, where its thickness is greatest. It follows that a wind blowing in the direction of the flood tide will have an advantage in shingle-transport over the wind which blows with the ebb; for the former, by opposing the turn of the tide, tends to increase the duration of tidal high water, and to diminish the duration of tidal low water. Thus, although the forces of currents may be equal and opposite in the two cases, the opportunities of action on shingle are greater when the wind blows with the flood tide. Again, the waves break most violently on the steep beach near high-tide mark, which further increases the effect of prolonged high water in promoting transport. The along-shore wind which is accompanied by a low barometer has a corresponding advantage of opportunity over the along-shore wind which is accompanied by a high barometer, and the wind along-shore which blows from the greater expanse of water over the wind which blows from the less.

No stony particle of less than a certain critical size can remain permanently on a beach, but is ultimately swept out to sea. This critical size is greater on a coarse-grained than on a fine-grained beach, for the regimen slope of the former is steeper, and gravity therefore gives greater assistance to the back-wash. It is well known that every particle upon the surface of a beach suffers attrition, whence the conclusion has been too hastily drawn that the grain of an isolated beach naturally becomes finer as the distance increases from the extremity where the beach is fed with detritus. Now, it is to be noted that whereas the attrition of the particles tends to lower the average size of the shingle, and hence to make the grain of the beach finer, the removal of particles of less than the critical size raises the average dimension of the shingle. Hence we may deduce the following laws of grading of beach shingle applicable to a beach fed entirely at one extremity, whence the material travels along the beach:—

Law 1.—If the material be of uniform size, the grain of the beach becomes finer as we recede from the extremity.

Law 2.—If the material be mostly fine stuff, with a small admixture of coarse stuff, then (unless the coarse stuff be very friable, and the fine stuff very durable) the grain of the beach will become coarser as we recede from the extremity, for the average size is more affected by the removal of a large number of fine grains than by the attrition of a small number of coarse grains. This increase in coarseness will continue until the beach material is brought to a uniform size, when the grading proceeds as in 1.

Law 3.—If the material be mostly coarse stuff, with a small admixture of fine stuff, then, as we recede from the extremity, the grain of the beach will become finer, for the attrition of a great number of large particles has a greater effect upon the average size of the material than the removal of a small number of fine particles.

By combining 2 and 3 we can deduce corollaries applicable to the case of a beach fed from both extremities.

Law 4.—The grain of the beach is (*ceteris paribus*) coarser where the beach is exposed to the heaviest breakers. This law follows from what has been said on the action of the back-wash, and on a "critical size" of beach material.

Law 5.—The grain of the beach is (*ceteris paribus*) coarser near the "weather" end of a promontory. Thus, if west be the weather side, and the end of a long beach is protected from the east by a headland at the eastern extremity, then both large and small pebbles will travel eastward along the beach in a westerly wind, but only the small ones are carried back from the promontory during an east wind, so that the proportion of large pebbles to small is increased as we near the promontory from the west. This is, in fact, similar to the case of the sorting of sand from shingle by unsymmetrical oscillation.

[*From a photograph by the author.*

FIG. 1.—East end of Chesil Beach.

The author considers that the chief factors which determine the observed grading of the Chesil Beach are as follows:—

(1) The beach is fed at both ends (Bridport and Chesilton).

(2) The material fed in at the west end is mostly fine, owing chiefly to the natural groynes at Golden Cap and Thorncombe.

(3) The material fed in at the east end is mostly coarse, owing to the nature of the local rock and the mode in which it is supplied to the foreshore.

(4) The main drift of water is easterly, but

(5) Of the fine shingle carried eastward from Bridport, much is brought back by waves from the east; whereas

(6) The strong outset at Chesilton removes such fine stuff as may be there supplied from Portland.

(7) The largest waves converge on Chesilton from both sides.

The formation of a beach-ridge, or Full of sand, is well seen when the sand is being brought in during off-shore winds. Sand being readily raised by upward-swirling water (which is equivalent to suction dredging), the building up of a Full of sand in front of the breaker is accompanied by the excavation of a trough, or Low, at the back of the breaker. This is roughly similar to the simultaneous excavation and elevation which produces the ridge and furrow so well known as "ripple-mark." Fine dust or mud settles too slowly, coarse shingle too quickly, to lend themselves readily to this mode of distribution by waves. A Low is dredged out in sand when the breaker-line remains stationary for a time, as *e.g.* during tidal high water. During the ebb of spring tides, a lagoon is often left between the beach and a second stretch of sand. This lagoon marks the strip where the breakers act during the period of neap tides. At low water of spring tides, the belt of sand beyond the Low is a sort of beach, the seaward face of which is where the wash of the waves acts. Beyond it, during the continuance of the spring tides the breakers commence the formation of a second Low. When the tide is up and the sea is rough, there is an outer line of breakers on the bank, which is locally called the Ball.

The connection between tidal nodes and the accumulation of sandbanks is dealt with, and the analogies with sand-dunes are pointed out.

With regard to the sandbanks which accumulate on the more sheltered side of headlands, a good example of which is the Shambles shoal, eastward of Portland Bill, it is pointed out that the materials (broken shells, &c.) which form the Shambles sandbank are not deposited in still water. The sand deposits from the mixing waters of meeting streams, an effect that is not surprising when we consider that the mixing of waters is achieved by vortices.

[*From a photograph by the author.*

FIG. 2.—Blacknor Point, Portland.

The checking and deflection of the streams is probably not nearly the whole of the mechanism by which the deposition of sand is brought about where a river meets the sea. A great part of this effect is probably due to the motions which attend the mixing of waters, a process which appears to be almost as potent a factor in the formation of sandbanks as is the mixing of airs in the production of clouds.

THE BACTERIAL CHARACTER OF CALF-LYMPH.

QUITE a flutter of excitement was produced in the ranks of the anti-vaccinators by the public announcement, made rather more than a couple of years ago, that lymph used for vaccination purposes frequently contained an immense number of bacteria, sometimes as many as two and one-half millions in a single cubic centimetre, and that amongst this vast microbial population forms were repeatedly present which, on inoculation, proved fatal to animals. A certain measure of authority was given to this communication, inasmuch as its author, Dr. Landmann, claimed to have carried out a very large number of experiments in support of his assertion; and his results were, moreover, brought before the well-known German Association of Naturalists and Physicians at one of its yearly meetings. Coupled, as Dr. Landmann's conclusions were, with the recommendation that only lymph should be used for inoculation purposes which had been officially declared germ-free—or, at any rate, devoid of pathogenic bacteria—his announcement gave such an impetus to the anti-vaccination crusade, and occasioned so much public discussion, that the Prussian Ministry felt it their duty to appoint a Commission to inquire into the character of calf-lymph. Meanwhile independent experimental inquiries were also started by various investigators, and amongst these Dr. Neidhart was able to show that Landmann's assertion that the red inflammatory margin of the pustules so frequently noticeable was directly due to the action of the bacteria present in the vaccine was not correct, inasmuch as such symptoms were produced when lymph quite free from bacteria was employed, whilst they were often absent in cases where the lymph was proved to be teeming with bacteria. The hysterical excitement caused by the circulation of Landmann's sensational statements was, however, considerably abated by the publication of the masterly report drawn up by Frosch upon the very large number of most valuable experiments undertaken in a purely scientific, uncontroversial spirit by the Prussian Committee of inquiry above referred to.

This document completely refuted Landmann's statements, and showed that the alarming conclusions arrived at by him had no real foundation in fact. Frosch further indicates, as the result of careful experiment, the best methods and most suitable precautions to be adopted in the inoculation of calves and the collection and application of the lymph, pointing out in the latter connection that local irritation from vaccination may be greatly moderated by diluting the lymph with glycerine.

These reassuring results were again independently confirmed by Kirchner, of Hanover, who, in extensive examinations of calf-lymph, found on no single occasion any pathogenic bacteria.

In the current number of the *Zeitschrift für Hygiene* the question has been again brought to the fore by the publication of elaborate experimental researches on the bacterial character of calf-lymph by Dr. Dreyer, of the Hygienic Institute of the University of Giessen.

Careful quantitative determinations of the bacterial contents of calf-lymph showed that the initial number of microbes present may vary considerably, and that in the majority of cases it is very large indeed—on one occasion reaching as many as 17½ millions in one cubic centimetre. Within twenty-four hours, however, a great diminution takes place; but this decrease does not continue at the same rapid rate. Thus, to cite one instance: a sample contained on the first day of its collection over 2½ millions of bacteria per c.c.; after five days, 112,750; after eighteen days there were still, however, 111,765 present. Some forms persist over very long periods of time; Dreyer observed bacteria after a lapse of five months, whilst Kirchner found 550 in a cubic centimetre sample over a year old.

To determine the pathogenic character of lymph-bacteria, Dreyer inoculated, subcutaneously and intraperitoneally, both mice and guinea-pigs. Out of thirty-five mice thus treated only two succumbed, one to subcutaneous and the other to intraperitoneal inoculation; in none of the other animals was any reaction perceptible. As regards the guinea-pigs, in no single instance did any result follow the intraperitoneal inoculations, whilst in nearly every subcutaneous inoculation a small and insignificant abscess was observed to form at the point of inoculation.

Not satisfied with these experiments, Dr. Dreyer experimented upon himself and inoculated his arm each time with some of the same lymph he used for the mice and guinea-pigs respectively, but in no case did any reaction worthy of record follow.

In order to determine more particularly the qualitative bacterial character of these various samples of calf-lymph, plate-cultures were also made and pure cultures obtained of different bacteria, which were subsequently inoculated both into mice and into his own arm. In two cases coccus forms proved fatal to mice, whilst in the other inoculations no symptoms of importance followed. As regards the inoculations practised upon himself with these pure cultures, nothing more significant than a slight abscess resulted, except on one occasion when an affection of the adjoining lymphatic glands was experienced.

In commenting upon these results, Dr. Dreyer states that it should be borne in mind in connection with those instances where fatal results followed the introduction of the lymph into mice, that, in the first place, the mode of inoculation obliged to be adopted was not really comparable to the simple incision made in the case of human vaccination, and that, secondly, the quantity of lymph employed relative to the size of the animal was far greater than is the case in ordinary inoculations. Moreover, the two pathogenic results which followed the inoculation of a pure culture of a coccus form do not constitute any justifiable plea for the abolition of calf-lymph vaccination. It must be remembered that the conditions of such pathogenic infection are very different from those which may be present in ordinary inoculations, should pathogenic bacteria originally be present in the lymph, for, in employing a pure cultivation of a particular micro-organism, the latter is introduced into the system in immeasurably larger numbers than would be the case were it introduced direct with the lymph.

We would, in conclusion, recommend the closing paragraph of Dr. Dreyer's memoir to the consideration of that noisy section of unreasoning obstructionists who may, even in his experiments, endeavour to find some support for their crusade against the vaccination laws: "I consider, therefore, that I may conclude from my investigations that the latter afford no support which justifies the fear that animal lymph as at present prepared can produce any serious injury to those inoculated with it."

G. C. FRANKLAND.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Junior Scientific Club held its 188th meeting at the Museum on May 4. After the Treasurer's balance-sheets had been read and carried, Mr. A. E. Tutton discoursed on the Glaciers of the Pennine Alps, illustrating his remarks by numerous lantern slides. Mr. H. E. Stapleton (St. John's) read a paper on turpentine extraction in the Southern States.—The Officers for this term are: President, Mr. W. E. Moss (Trinity). Chem. Sec., Mr. F. Soddy (Merton). Biolog. Sec., Mr. E. Gurney (New Coll.). Editor, Mr. H. E. Stapleton (St. John's). Treasurer, Mr. W. E. Blackall (Non. Coll.). Committee, Mr. W. B. Billinghurst (St. John's), Mr. C. E. A. Wilson (Ch. Ch.), Mr. F. P. Nunneley (B. N. C.), The conversazione will be held on May 24—Tuesday in Eights' Week—at 8 p.m.

CAMBRIDGE.—A University lectureship in applied mathematics will be vacant at the end of the academical year by the resignation of Mr. R. T. Glazebrook, F.R.S. Applications are to be sent to the Vice-Chancellor by May 17.

The Smith's prizes are awarded (1) to Mr. E. W. Barnes, Trinity, and (2) to Mr. W. A. Houston, St. John's.

Dr. Kanthack proposes to hold, during the Long Vacation, courses of instruction in general pathology, morbid anatomy and histology, bacteriology, and clinical pathology. The courses begin on July 8.

The University tables at Naples and Plymouth are about to be vacant. Applications for facilities for zoological research are to be sent to Prof. Newton by June 1.

Twenty-four candidates have passed the half-yearly examination in sanitary science just completed, and have received the University diploma in public health.

Twenty-eight additional freshmen, including one advanced student, were matriculated on May 5.

The University grant of 100*l.* a year for three years, made to the British School of Archæology at Athens in 1895, is to be renewed for another period of three years.

The Frank Smart studentship in botany, of the annual value of 100*l.* for two or three years, will be vacant on June 20. Candidates must be B.A.s who have taken honours in the Natural Sciences Tripos. Application is to be made to the Master of Caius College by June 11.

A combined examination for entrance scholarships and exhibitions in natural science will be held by Pembroke, Caius, King's, Jesus, Christ's, St. John's, and Emmanuel Colleges next term, beginning on November 1. A large number of major and minor scholarships and exhibitions, varying in annual value from 80*l.* to 30*l.*, will be offered. The subjects include chemistry, physics, elementary biology, physical geography, animal physiology, zoology, and botany; and candidates may offer from two to four of these. In all branches the candidates' practical work will be tested. Full particulars may be obtained from the Tutors of the respective colleges.

THE Duke of Devonshire stated in the House of Lords on Monday that, as soon as the Committee stage of the Irish Local Government Bill was disposed of, the London University Commission Bill would have a prominent place among those measures which the Government intended to pass during the remainder of the Session.

DURING the past fifteen months, says the Paris correspondent of the *Chemist and Druggist*, the sums subscribed by manufacturers and bankers in the district of Nancy for promoting the study of chemistry and physics, as applied to industry, in connection with the University of that town, have reached 400,000f. (16,000*l.*). The Lyons University has been authorised to contract a loan of 626,500f. (25,000*l.*), to be applied (1) to completing the Chemical Institute, (2) extending the laboratories of experimental and comparative medicine and physiology, (3) completing the laboratory of maritime physiology at Tamaris, Var.

THE following items concerning endowments of higher scientific education in the United States are recorded in *Science*:—The West Virginia University has established eleven fellowships yielding 300 dollars yearly and free tuition. The fellows are expected to teach one hour a week or give two hours' supervision in the laboratory. Among the eleven subjects for which the fellowships have been awarded are chemistry, physics, geology, zoology, botany, mathematics, mechanical engineering and civil engineering.—The estate of Mrs. Julia W. James, of Boston, divided by her will between the Museum of Fine Arts and the Massachusetts Institute of Technology, amounts to over 500,000 dollars.—The John Tyndall Fellowship of Columbia University for the encouragement of research in physics has been awarded to R. B. Owen, a graduate of the School of Engineering and professor of engineering in the University of Nebraska. Among the twenty-four fellowships annually awarded are the following: T. E. Hazen, botany; B. H. Owen, philosophy; J. D. Irving, geology; E. Kasner, mathematics; W. C. Kretz, astronomy; J. W. Miller, jun., mechanics; F. C. Paulmier, zoology; F. J. Pope, chemistry; C. E. Prevey, statistics; R. S. Woodworth, psychology.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, April 20.—W. Whitaker, F.R.S., President, in the chair.—Note on an ebbing and flowing well at Newton Nottage (Glamorganshire), by H. G. Madan. This well lies in a direct line drawn north and south from the church of Newton Nottage to the sea, about 80 yards south of the church and 500 yards from the sea. Sand-hills about 20 or 30 feet high lie between it and the sea. A range of carboniferous limestone cliffs runs east and west to the north of the church, while the same formation crops out in the sea at half-tide level. Between the two there is a band of Keuper conglomerate covered in one place at least by 7 feet of brown loamy clay with pebbles. At the shore-junction of conglomerate and limestone numerous springs occur, and it is in the conglomerate that the well is sunk, its bottom being 8 feet above Ordnance datum. A series of about forty observations made at intervals of an hour (and in many cases at the intermediate half-hours), during three consecutive days, enabled the author to construct a curve showing the relationship existing between the rise and fall of the tide on the coast and that of the water in the well. The result is to establish the existence of a wave in the well of the same frequency as the tidal wave, but delayed, or with an establishment of, three hours (*plus* or *minus* a few minutes). The analyses of water taken from the well at its highest and lowest show no difference, so that no sea-water enters the well directly. On the other hand, the slight brackishness of the water appears to prove the diffusion of a small amount of salt water into the well.—*Petalocrinus*, by F. A. Bather. Certain curious fan-like objects, obviously echinodermal, have for a long time been preserved in the Riks-Museum at Stockholm, but their significance was first definitely ascertained when similar fossils were found in Iowa, and brought to England by Mrs. Davidson. The latter were described by Mr. Stuart Weller in a paper entitled "*Petalocrinus mirabilis* (n. sp.), and a New American Fauna"; and the former, with fresh material obtained by Mr. Weller from various American localities, are the subject of the present communication. The Silurian crinoid genus *Petalocrinus*, Weller, is discussed, on the evidence of all the original material from Iowa and of the further material above mentioned.—On the origin of the auriferous conglomerates of the Gold Coast Colony (West Africa), by Thomas B. F. Sam.—This paper gives an account of a recent journey from Adjah Bippo to the Ankobra Junction in the Gold Coast Colony. A range of clay-slate hills is succeeded for 6 miles by flat ground in which diorite was found, and that by a lofty hill in which clay-slate dipping east occurs. The Teberibie range with reefs of conglomerate, and a second range with similar reefs were crossed. Gold-bearing alluvia are briefly described, and the gold is supposed to have come from the hills. The Adjah Bippo, Takwa, and Teberibie formations are considered to be part of a syncline. Some conclusions are drawn as to the method of formation and probable auriferous character of the rocks.

Linnean Society, April 21.—Dr. A. Günther, F.R.S., President, in the chair.—On behalf of Lieut.-Colonel Birch-Reynardson there was exhibited a portion of the trunk of an apple-tree which had been so seriously attacked by water voles (*Arvicola amphibius*) as to cause the death of the tree; and several others, it was stated, had been similarly injured. Such extensive damage from such a cause was regarded as unusual.—Mr. G. E. Barrett Hamilton exhibited a head of the common brown rat (*Mus decumanus*), showing a curious deformity arising from injury to the incisor teeth.—Prof. Douglas Campbell communicated a paper, which was demonstrated by Mr. A. Gepp, on the structure of *Dendroceros*. The chief conclusions arrived at were as follows: (1) In its apical growth and the form of the thallus, *Dendroceros* differs decidedly from other genera of the order Hepaticæ. (2) The archegonium corresponds in its structure to that of the other Anthocerotaceæ, and is intermediate in character between *Notothylus* and *Anthoceros*. (3) The antheridium is solitary, and arises, as in the others of the order, endogenously. (4) The first wall in the embryo is longitudinal, as in *Anthoceros*, but the first transverse wall determines the limits of the foot, as in *Notothylas*. (5) The origin of the archesporium is from the amphithecium as in the other genera, but it is less massive than in either of these. (6) The division of the archesporial cells into sporogenous and sterile ones is less regular than in either of the other genera, and the primary archesporial cells may be transformed directly into sporogenous ones without any further divisions. (7) In *D. Breutelii* the spores remain undivided, but in *D. crispus* (?) they germinate within the capsule and are discharged as multicellular bodies. (8) Leitgeb's statement as to the absence of stomata from the capsule was confirmed.—Mr. W. P. Pycraft read a paper on the morphology of the owls (Part 1, Pterylography). In this, the first instalment of a series of papers in which it is proposed to deal with the affinities and phylogeny of the group, the pterylographic characters were alone considered, descriptions of adults, nestlings, and embryos being given. The author remarked that, so far as the distribution of the feather-tracts is concerned, the owls resemble the *Accipitres* more nearly than any other group. The form of the external aperture of the ear seems to have been originally subject to variations, the most successful of which have become fixed by selection. In some cases there is a marked asymmetry, which may either be confined to the membranes surrounding the aperture, or may extend to the skull itself. The author considered that the facts disclosed by a study of the pterylosis might justify a slight revision and rearrangement of some of the genera.—A paper was read by Mr. J. Johnstone upon the thymus and thyroid glands in the Marsupialia. The author had investigated the neck-glands in adults of nine and pouch-specimens of seven genera, representative of the leading Marsupial families. The thymus was observed to be absent only in the Koala (*Phascolarctus*), and to persist predominantly in the region of the carotid roots.

MANCHESTER.

Literary and Philosophical Society, April 19.—Mr. J. Cosmo Melvill, President, in the chair.—The following were elected officers and members of the Council for the ensuing year:—President, J. Cosmo Melvill; Vice-Presidents, Prof. O. Reynolds, F.R.S., Prof. A. Schuster, F.R.S., Charles Bailey, and W. H. Johnson; Secretaries, R. F. Gwyther and Francis Jones; Treasurer, J. J. Ashworth; Librarian, W. E. Hoyle; other members of the Council, Prof. H. B. Dixon, F.R.S., Prof. H. Lamb, F.R.S., F. Nicholson, J. E. King, R. L. Taylor, and F. J. Faraday.—Mr. Charles Bailey exhibited some living plants of Jacquin's oxlip (*Primula elatior*), which he had gathered ten days ago in a wood at Tindon End, near Thaxted, Essex. He pointed out its peculiar distribution in England—where it is confined to an area within the triangle formed between St. Neots in Huntingdonshire, Stowmarket in Suffolk, and Bishop Stortford in Hertfordshire—and explained the botanical characters which separate it from the primrose and the cowslip. With it Mr. Bailey exhibited a flower-scape from a root which he brought some years ago from Gloddaeth, near Llandudno, which was a natural hybrid between the cowslip and the primrose, and which flowered every spring in his garden. Such hybrids generally pass for the true oxlip, and they are not infrequent in districts where both parents occur; in the neighbourhood of Manchester he had found this spurious oxlip at Ashley, at Mobberley, and in several places in Derbyshire.

EDINBURGH.

Royal Society, April 4.—Prof. Copeland, in the chair.—At the request of the Council, an address on theories concerning the structure and origin of coral reefs and islands was given by Dr. John Murray. After a brief sketch of the history of the subject, and an exposition of the insufficiency of Darwin's famous theory as an explanation of the origin of many coral reefs and islands, Dr. Murray, with the help of lantern slides, gave an account of the theory he himself supported, which was to a large extent a return to the views of Chamisso (1820). The results of recent investigations, such as Mr. Andrews' labours at Christmas Island, the extensive observations by Alexander Agassiz in the Fiji group, the boring in the island of Funafuti, and the work of the Admiralty Surveyors in the Pacific Ocean, were then referred to; and, in spite of statements to the contrary which had been going the round of newspapers, Dr. Murray concluded that all these recent discoveries tended to verify his hypothesis rather than that of Darwin.

May 2.—Dr. Munro, in the chair.—In a paper on consonant sounds, Dr. Lloyd discussed in detail the simplest group of consonantal sounds, known as the spirate fricatives, namely, *f*, *v*, *th* (both forms), *s*, *z*, *sh*, *zh*, the Scottish gutturals *ich*, *och*, and the aspirate *h*. These are all produced by the friction of the air escaping through interstices more or less narrow. They could all be whispered through a range of pitch peculiar to each, the pitch depending upon the length and shape of the resonating cavity, which at the same time determined the vowel sound associated with the consonant.—Prof. D'Arcy Thompson communicated an examination of the so-called bipolar hypothesis. Of the list of ninety forms deduced by Dr. Murray from the *Challenger* Reports in support of this hypothesis, about half were insufficiently authenticated, and a great number more were very minute and described wholly from their hard parts; of the remainder some were not really arctic or antarctic forms, and the few that seemed to present "bipolar" characteristics were remarkable in other respects. Moreover, there were no examples cited from well-marked groups, such as fishes and Crustacea. In the discussion which followed, Dr. Murray argued that the fact of bipolarity had long been recognised, Prof. D'Arcy Thompson maintaining that the data supplied by Dr. Murray were insufficient to establish its existence.—Mr. A. J. Herbertson exhibited maps showing the mean monthly and annual rainfall over the land surface of the globe. This was the first attempt to construct mean monthly rainfall charts for the whole globe. All available data had been used, and many interesting results had been obtained.

DUBLIN.

Royal Dublin Society, April 20.—Prof. W. Noel Hartley, F.R.S., in the chair.—Prof. Emerson Reynolds, F.R.S., gave a demonstration of the properties of some new silicon derivatives discovered in the chemical laboratory of Trinity College, Dublin, and showed their use in photography.—Dr. E. J. McWeeney demonstrated a special method of performing the sero-diagnostic test for typhoid fever. It consisted in causing Eberth's bacillus to grow in a hanging drop of neutral bouillon containing 10 per cent. of the serum under investigation. After a few hours at 37° C. the individuals originally present (which should be very few—one only if possible), would be found to have multiplied in such a way as to form chains of short elements devoid of motility. In twelve hours these chains had become very long and beautifully curved and contorted, occupying the whole area of the drop. This chain formation only occurred with typhoid serum. With non-typhoid serum the drop soon became filled up with actively motile separate individuals. Filament-formation he did not look upon as significant. Similar appearances had been noted by Charrin and Roger for *Pyocyaneus*, by Pfaundler for *Coli*, and by Ledoux-Lebard for pseudo-tuberculosis. Photographs of desiccated and stained hanging-drop cultures were thrown on the screen.—Dr. J. H. Clark contributed a paper on protoplasmic movements: their relation to oxygen pressure. The paper gave a detailed statement of the author's investigations on the subject, of which an abstract appeared in the *Proceedings* of the Royal Society.—Dr. T. Johnson and Miss Hensman presented a paper consisting of a list of Irish Corallinaceæ, with the distribution of the Irish species, and many additions to the list of recorded species.

PARIS.

Academy of Sciences, May 2.—M. Wolf in the chair.—On the legitimacy of the trapezium rule in the study of the resistances of dams built of masonry, by M. Maurice Lévy. A critical examination of the "trapezium" law, according to which the normal pressures exerted upon each arch are connected by a linear relation.—Researches on the state in which silicon and chromium occur in steels, by MM. A. Carnot and Goutal. From a sample of ferrosilicon, by the prolonged action of dilute sulphuric acid, the silicide $SiFe_2$ was isolated, which differs from the substance of the same composition obtained by M. Moissan in being easily attacked by warm dilute acids. From alloys containing manganese, a double silicide of manganese and iron is obtained. Starting from chrome steels, similar methods gave $Fe_3Cr_9C_7$ or $CFe_3.3C_2Cr_3$ and $Fe_9Cr_3C_5$.—Remarks on some Crustacea obtained from the six scientific voyages of the Prince of Monaco, by MM. Milne-Edwards and E. L. Bouvier. Amongst the decapod Crustaceæ only one new form was found, *Sympagurus Grimaldii*.—On ortho-benzyl-benzoic and dimethylamido-diethylamido-ortho-benzoyl-benzoic acids and some of their derivatives, by MM. A. Haller and Guyot.—On the autoplastic grafts obtained by the transplantation of large dermic strips. Their stability and the slow modifications which they undergo, by M. Ollier. The transplanted skin undergoes a progressive atrophy, losing always its original dimensions.—The return of the first periodic Tempel Comet (1867 II.) in 1898, by M. R. Gautier. A revision of the elements of this comet, rendered necessary by the varying perturbations caused by the planet Jupiter.—Relations of commensurability between the mean movements of the satellites of Saturn, by M. Jean Mascart.—Reply to a reclamation of priority of M. Marqfoy, by M. Daniel Berthelot.—On the radiations emitted by thorium and its compounds, by M. G. C. Schmidt. Thorium salts emit rays similar to those discovered by M. Becquerel for uranium salts. Quantitative comparisons of the times required to discharge an electrified plate by the rays from thorium and uranium salts showed that the latter act more powerfully. The sign of the charge in either case is without effect upon the results.—On the cycles of magnetic torsion of a steel wire, by M. G. Moreau.—A receiver for Hertzian telegraphy without wires, by M. E. Ducretet. An improvement upon a similar instrument devised by M. Popoff. A Branly tube, which undergoes sudden changes of resistance under the influence of the Hertzian waves, forms part of a delicate relay system. The whole apparatus is automatic, the message being printed in Morse character upon a strip in the usual way, the strip ceasing to unroll when the waves stop.—On the electrical conductivity of potassium permanganate, by M. G. Bredig. Remarks on the paper of M. Legrand in a recent number of the *Comptes rendus*, pointing out the prior measurements of M. Bredig and MM. Franke and Lovén.—The Perpetual Secretary remarked that the conductivity of some solutions of potassium permanganate was measured by M. Bouty as early as 1884.—Effects of solar and lunar attractions upon the atmosphere. Example of the application of formulæ, by M. A. Poincaré.—On the iodide of beryllium, by M. P. Lebeau. By the action of dry hydriodic acid gas upon beryllium carbide at 700°, the pure iodide BeI_2 is readily obtained as a crystalline sublimate. It forms colourless crystals, readily attacked by moist air, boiling between 585° and 595° C. It reacts violently with water, and with many organic substances, and from it new compounds of beryllium with sulphur, phosphorus, and cyanogen can be obtained.—On the presence of the chlorides of potassium and sodium in large proportions in the juice of grapes, and in the wines of the salt regions of Oranie, by M. Edmond Bonjean.—New reaction of tertiary alcohols and their ethers, by M. G. Denigès. The reaction employed is an acid solution of mercuric sulphate; characteristic yellow mercury compounds are formed.—Action of alkalis upon ouabaine, by M. Arnaud. An acid is formed, termed ouabaic acid, the sodium, strontium, and barium salts of which are described.—Action of bromine upon some phenols in presence of aluminium bromide, by M. F. Bodroux.—On the mono-alkyl-phosphoric ethers, by M. J. Cavalier.—Influence of diffused daylight upon the development of plants, by M. J. Wiesner.—On chocolate-coloured oats, by M. Balland. No differences in the results of analysis could be found between the brown grains and the ordinary white ones.—The bitterness of wines, by MM. F. Bordas, Joulin, and de Raczkowski. A description of the habit and mode of growth of the bacillus causing the bitterness in wine.—Pathogeny and histogenesis of cancer, a parasitic disease, by M. F. J. Bosc. The only specific element in malignant tumours is the parasitic sporozoa described in previous papers.—Softening of bone by phloroglucinol, by M. J. J. Andeer. A solution of phloroglucinol in hydrochloric acid forms a valuable histological reagent for softening bone without changing its relation to other structures.

AMSTERDAM.

Royal Academy of Sciences, March 26.—Prof. van de Sande Bakhuyzen in the chair—Prof. Franchimont and Dr. H. Umbgrove on the action of sulphuric acid of 35 to 40 per cent. at the ordinary temperature upon acid aliphatic nitramines, upon neutral ones and upon their isomers. The first mentioned (methyl-, ethyl-, propyl- and butylnitramine) very slowly yielded nitrous oxide and an alcohol, and in addition—excepting methyl nitramine—a small quantity of non-saturated carburetted hydrogen. The same result was obtained with their potassium, barium and silver derivatives. The neutral nitramines were not attacked; their isomers, however, were attacked very rapidly. Experiments were made with the isomers of propylethylnitramine, of methylethylnitramine, of dimethylnitramine, and of ethylmethylnitramine. All of them, except the last, in which again CH_3 is united with nitrogen, yielded a little ethane, besides N_2O and one or two alcohols. The authors think that through the action of sulphuric acid the acid nitramines

$$C_nH_{2n+1}NH-N\begin{matrix}\nearrow O\\ \searrow O\end{matrix}$$

slowly change into

$$C_nH_{2n+1}N=N\begin{matrix}\nearrow O\\ \searrow OH\end{matrix},$$

and that the latter, being diazonitramines, are rapidly decomposed, as well as their alkyl derivatives, the isomers of the neutral nitramines.—Dr. G. C. J. Vosmaer and Prof. C. A. Pekelharing on the reception of food by sponges. When sponges (Spongillæ and Sycones) were fed with carmine, the colouring matter was always found first in the collar cells. Metschnikoff's objection against the view, according to which the food is received into the flagellated chambers, may perhaps have arisen from the circumstance that Metschnikoff allowed the moment favourable for the inquiry to slip by. In the case of Leucosolenia just taken out of the sea-water and cut open longitudinally, the movements of the flagellated chambers were found to be most irregular, and without a trace of coordination. The authors think that the regular passage of water through sponges, in consequence of an irregular movement in the flagellated chambers, is to be explained by taking into account (1) the shape of the supplying and discharging apertures, from which it may be concluded that the collar cells counteract, like valves, the discharging of water through the supplying apertures, and (2) the shape of the discharging channels, which may serve as suction channels.—Prof. van Bemmelen made a communication on the absorptive power of colloidal silicic acid.—Prof. H. A. Lorentz on optical phenomena, depending on the electrical charge and the mass of the ions. Part I. Measurements on the Zeeman effect give the value of $\frac{l}{m}$, l being the charge and m the mass of the ions. The author remarks that some other phenomena depend on the quantity $\frac{l^2}{m}$; in particular he discusses the dispersion and the absorption coefficient of gaseous media.—Prof Korteweg presented a communication by Mr. W. A. Wijthoff, entitled "A system of operations in the space of four dimensions analogous with Hamilton's quaternions." The geometrical operations described in it are represented by biquaternions, which prove to be identical with those of Clifford for the elliptical space.

DIARY OF SOCIETIES.

THURSDAY, May 12.

Royal Society, at 4.30.—A Study of the Phyto-Plankton of the Atlantic: G. Murray, F.R.S., and V. H. Blackman.—The Electrical Response of Nerve to a Single Stimulus investigated with the Capillary Electrometer. Preliminary Communication: Prof. Gotch, F.R.S., and G. J. Burch.—Effects of Prolonged Heating on the Magnetic Properties of Iron: S. R. Roget.—On the Connection of Algebraic Functions with Automorphic Functions: E. T. Whittaker.

Royal Institution, at 3.—Heat: Lord Rayleigh.

Mathematical Society, at 8.—On the Numerical value of $\int_0^h e^{x^2} dx$: H. G. Dawson.—On the Reflection and Transmission of Electric Waves by a Metallic Grating: Prof. Lamb, F.R.S.—Notes on some Fundamental Properties of Manifolds: A. E. H. Love, F.R S.

Institution of Electrical Engineers (Society of Arts), at 8.—The Registration of Small Currents used for Electric Lighting and other Purposes: A. H. Gibbings.—A Magnetic Balance for Workshop Test of Permeability: Prof. J. A. Ewing, F.R.S.

FRIDAY, May 13.

Royal Institution, at 9.—Recent Experiments on certain of the Chemical Elements in Relation to Heat: Prof. W. A. Tilden, F.R.S.

Royal Astronomical Society, at 8.—Micrometrical Measures of the Double Stars β 883, Sirius, and Procyon: T. J. J. See.—The Relative Motion of the Components of γ Leonis: S. W. Burnham.—Vanadium in the Spectrum (C to D) of Sun-spots: Rev. A. L. Cortie.—Notes on the Zodiacal Light: Wm. Anderson.

Physical Society, at 5.—Galvanometers, Part II.: Prof. W. E. Ayrton and T. Mather.

Malacological Society, at 8.—Note on a very large Specimen of *Hippopus Hippopus*: Edgar A. Smith.—Description of New, or Imperfectly-known Species of *Nautilus* from the Inferior Oolite, contained in the British Museum (Natural History): G. C. Crick.—On the Anatomy of *Adeorbis subcarinatus* (Montagu): Martin F. Woodward.—Phylogeny of the Genera of Arionidæ: Henry A. Pilsbry.

SATURDAY, May 14.

Geologists' Association (King's Cross, G.N.R.), at 1.20.—Excursion to Ayot and Hatfield. Directors: J. Hopkinson and A. E. Salter.

Essex Field Club, at 7.—Notes on the Trees and Shrubs of Epping Forest: F. W. Elliott.

MONDAY, May 16.

Society of Arts, at 8.—Electric Traction: Prof. Carus Wilson.

Victoria Institute, at 4.30.—The Philosophy of Education: Dr. A. T. Schofield.

TUESDAY, May 17.

Zoological Society, at 8.30.—On a Small Collection of Mammals obtained by Mr. Alfred Sharpe in Nyasaland: Oldfield Thomas.—On a Collection of Lepidoptera made in British East Africa by Mr. C. S Betton: Dr. A. G. Butler —On some Earthworms from India: Miss Sophie M. Fedarb.

Royal Statistical Society, at 5.—Local Taxation in London: G. Laurence Gomme.

Royal Victoria Hall, at 8.30.—Three Months on a Coral Island: Prof. Sollas, F.R.S.

WEDNESDAY, May 18.

Society of Arts, at 8.—The Evolution of the Cycle: J. K. Starley.

Geological Society, at 8.—The Garnet-actinolite Schists on the Southern Side of the St. Gothard Pass: Prof. T. G. Bonney, F.R.S.—On the Metamorphism of a Series of Grits and Shales in Northern Anglesey: Dr. C Callaway.—On a Volcanic Series in the Malvern Hills near the Herefordshire Beacon: H D. Acland.

Royal Meteorological Society (Burlington House), at 4.30.—The Frequency of Rainy Days in the British Islands: Robert H. Scott, F.R S.—The Abnormal Weather of January, 1898: Frederick J. Brodie.

Royal Microscopical Society, at 8.—Exhibition of Aquatic Life.

THURSDAY, May 19.

Royal Institution, at 3.—Heat: Lord Rayleigh.

Chemical Society, at 8.—The Action of Formaldehyde on Amines of the Naphthalene Series: G. T. Morgan.—On the Constitution of Oleic Acid and its Derivatives. Part I.: F. G. Edmed.

SATURDAY, May 21.

Royal Institution, at 3.—Biology of Spring: J. Arthur Thomson.

Geologists' Association (Paddington Station, G.W.R.), at 1.40.—Excursion to Penn and Coleshill. Director: W. P. D. Stebbing.

Essex Field Club (at Chingford), at 7.—On the Preparation of Marine Animals as Transparent Lantern Slides: Dr. H. C. Sorby, F R.S.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—The Flora of Perthshire: Dr. F. B. White (Blackwood).—Submarine Telegraphs: C. Bright (Lockwood).—The Origin and Growth of the Moral Instinct: A. Sutherland, 2 Vols. (Longmans).—Birds in London: W. H. Hudson (Longmans).—Experimental Mechanics: G. H. Wyatt (Rivingtons).—La Famille Névropathique: C. Féré, deux edition (Paris, Alcan).—Missouri Botanical Garden, 9th Annual Report (St. Louis, Missouri).—Garden-Making: L. H. Bailey (Macmillan).—William Stokes (Masters of Medicine Series): W. Stokes (Unwin).—The Fauna of British India, including Ceylon and Burma. Birds, Vol. iv.: W. T. Blanford (Taylor).

Pamphlets.—Science and Engineering: C. Bright (Constable).—Technical Education. Application of Funds by Local Authorities (Eyre).—Mines and Quarries. General Report and Statistics for 1897. Part 1. District Statistics (Eyre).

Serials.—Strand Magazine, May (Newnes).—Science Progress, April (Scientific Press).—Chambers's Journal, May (Chambers).—Report of the Marlborough College Natural History Society, No. 46 (Marlborough).—Atlantic Monthly, May (Gay).—Quarterly Journal of the Geological Society, May (Longmans).—Observatory, May (Taylor).—Geographical Journal, May (Stanford)—Astrophysical Journal, April (Chicago)—Proceedings of the Royal Physical Society, Session 1896–97 (Edinburgh).—Monthly Weather Review, January (Washington).—Ditto, Annual Summary for 1897 (Washington).—Travaux de la Société Impériale des Naturalistes de St. Pétersbourg. AMBROISE PARÉ, SURGEON TO THE KING.

Ambroise Paré and his Times, 1510–1590. By Stephen Paget. Illustrated. (New York and London: G. P. Putnam's Sons; The Knickerbocker Press, 1897.)

ON October 1, 1889, Mr. Rickman J. Godlee delivered the introductory address in the Faculty of Medicine at University College, London. He chose for his subject a comparison of the methods of Ambroise Paré and those of a surgeon of the present time. This address, according to Mr. Paget's preface, was the moving cause of this present work. Seldom has it fallen to our lot to read a better bit of literary work, or a more stimulating biography. The author has extracted from the larger works of Malgaigue, Le Paulmier, and others the most salient points in Paré's life, and pieced them together in such a way that one has a real view of the life of the most celebrated surgeon of the sixteenth century. He has added to our literary medical store by a new translation of the "Journeys in Diverse Places," which, for faithful rendering and for the preservation of the quaint phraseology of the period, might have been done by Thomas Johnson himself, he who translated "The Works of that Famous Chirurgeon Ambrose Parey" into the vigorous and picturesque language of the earlier part of the seventeenth century. The interest to the modern general reader consists in the vivid picture of life as painted by one who saw it under every possible circumstance in the sixteenth century, and to the yet young practitioner, inasmuch as the surgery of Paré was practically the art of but yesterday until the total revolution, caused in it by the discoveries of Lister, had changed it to what it is now. Paré used to be mostly remembered at opening lectures as Hannibal was in Juvenal's time, "Ut pueris placeas et declamatio fias," and his memory was called to mind chiefly as the inventor of the ligature of arteries. Now this he did not, but only reintroduced the practice which had been restored about a century before by the German school of surgery, and lost sight of in the meanwhile. He was, however, the first to use the ligature in amputation wounds. He found out, by a scarcity of boiling oil on one occasion, that a mild application was infinitely to be preferred to that dreadfully severe one, and so set the practice of a more rational treatment of gunshot wounds. But Paré added little to the actual knowledge or practice of his art; his chief fame is due to the admirably clear writings he has left of that art as he practised it, and to the straightforward honest life he led in the midst of the most horribly cruel, licentious and debased surroundings it is possible to imagine. It is generally stated that Paré was a Protestant, and one of the very few who were spared at the St. Bartholomew massacre; but we think Mr. Paget has shown that there is good cause to believe that he was, nominally at least, a Gallican Romanist of the tolerant sort. We have selected a few extracts showing the conditions of war as Paré met with them. In the first journey, viz. to Turin, 1537, after the taking of the city, he writes:—

"We entered pell-mell into the city, and passed over the dead bodies and some not yet dead, hearing them cry under our horses' feet, and they made my heart ache to hear them. And truly I repented I had left Paris to see such a pitiful spectacle. Being come into the city, I entered into a stable, thinking to lodge my own and my man's horse, and found four dead soldiers and three propped against the wall, their features all changed, and they neither heard, saw, nor spoke, and their clothes were still smouldering where the gunpowder had burned them. As I was looking at them with pity, there came an old soldier, who asked me if there was any way to cure them. I said no. And then he went up to them and cut their throats, gently, and without ill-will toward them. Seeing this great cruelty, I told him he was a villain: he answered me, he prayed God, when he should be in such a plight he might find some one to do the same for him, that he should not linger in misery."

Again, on page 71 is an appreciation of the Spaniard of that time, which is the same that the English had, and is curiously like some of the denunciations one reads in the State papers and writings of the latter part of the reign of Elizabeth: it is as follows. After describing the departure of the Imperials from Metz, he goes on:—

"M. de Guise had their dead buried and their sick people treated. Also the enemy left behind them, in the abbey of St. Arnoul, many of their wounded soldiers, whom they could not possibly take with them. M. de Guise sent them victuals enough, and ordered me and other surgeons to go dress and physick them, which we did with a good will; and I think they would not have done the like for our men. For the Spaniard is very cruel, treacherous and inhuman, and so far enemy of all nations: which is proved by Lopez the Spaniard, and Benzo of Milan, and others who have written the history of America and the West Indies; who have had to confess that the cruelty, avarice, blasphemies and wickedness of the Spaniards have utterly estranged the poor Indians from the religion that these Spaniards professed. And all write that they are of less worth than the idolatrous Indians for their cruel treatment of these Indians."

As pointing out the immense slaughter in the battles of those times, note the account of the battle of Dreux, 1562:—

"The day after I came, I would go to the camp where the battle had been to see the dead bodies. I saw for a long league round the earth all covered. They estimated it at 25,000 men or more, and it was all done in less than two hours."

We believe that no modern battle of a like duration has produced such a loss. One more extract, and we have done; it relates to the evacuation of Havre by the English in 1563.

"When our artillery came before the walls of the town, the English within the walls killed some of our men and several pioneers who were making gabions; and, seeing they were so wounded that there was no hope of curing them, their comrades stripped them and put them living inside the gabions, which served to fill them up. When the English saw they could not withstand our attack because they were hard hit by sickness, and especially by the plague, they surrendered. The king gave them ships to return to England, very glad to be out of this plague-stricken place. The greater part of them died, and they took the plague to England, and they have not got rid of it since."

The book is well illustrated by reproductions of old prints and pictures and drawings of the places as they exist to-day. It is one of the most entrancing studies we have met with, and can be read over and over again. We heartily congratulate Mr. Paget on his work.

CAYLEY'S MATHEMATICAL PAPERS.

The Collected Mathematical Papers of Arthur Cayley, Sc.D., F.R.S. Vols. x., xi. Pp. xiv + 616; xvi + 644. (Cambridge: at the University Press, 1896.)

THIS instalment of the papers illustrates in a remarkable way Cayley's power of commenting upon and developing the work of his predecessors. The various memoirs on single and double theta-functions are, of course, based upon the results of Rosenhain, Göpel, and Kummer; and it is instructive to see how Cayley's instinct for symmetry and logical consistency has enabled him to present the theory in a compact and intelligible form. In the case of the single theta-functions, defined by their expansions in series, we have equations such as

$$\theta^2_{00}\theta_{00}(u+v)\theta_{00}(u-v)=\theta^2_{00}(u)\theta^2_{00}(v)+\theta^2_{11}(u)\theta^2_{11}(v) \quad . \quad . \quad . \quad \text{(i.)}$$

and from these it appears that any three of the squared functions $\theta^2_{gh}(u)$ are connected by a linear relation. Hence we may take the squared functions to be proportional to $A(a-x)$, $B(b-x)$, $C(c-x)$, $D(d-x)$ with x a variable, and the other quantities constant. Finally it is shown that x and u are connected by a differential equation of the form

$$du = \frac{Mdx}{\sqrt{(a-x)(b-x)(c-x)(d-x)}}.$$

Proceeding next to the double theta-functions, Cayley gives a set of 256 equations analogous to (i.); from these are derived quadric relations between the 16 functions which give, in all, 72 asyzygetic relations; it is assumed, and is fairly evident, that these are *all* the independent relations. The existence of the Kummer hexads and Göpel tetrads gives a special character to these relations. The next step is to find algebraic functions of two variables x, y and a proper number of constants which, on being substituted for the 16 theta-functions, satisfy the quadric relations identically. This Cayley succeeded in doing, apparently by a series of happy guesses; and this is his main contribution to the theory. He also shows that the two sets of variables u, v and x, y are connected by differential relations of the form

$$\sigma du+\tau dv=\tfrac{1}{2}\left(\frac{dx}{\sqrt{X}}-\frac{dy}{\sqrt{Y}}\right),\ \varpi du+\rho dv = -\tfrac{1}{2}\left(\frac{xdx}{\sqrt{X}}-\frac{ydy}{\sqrt{Y}}\right),$$

where $\varpi, \rho, \sigma, \tau$ are constants, $X=(a-x)(b-x)\ldots(f-x)$, a sextic in x, and Y is the same function of y that X is of x.

In order to complete the theory, from this point of view, it is necessary to find the connection between the constants which occur in the theta-functions as originally defined and those which are contained in the corresponding algebraical expressions. This can, in fact, be done for the single theta-functions (vol. x. p. 482); Cayley began, but did not finish the corresponding investigation for the double theta-functions (*ibid.*, pp. 563–564).

It would probably be well worth while to work out the relations of Cayley's theory to recent researches on hyperelliptic sigma-functions by Klein, Burckhardt and others. The best general view of Cayley's results is to be found in the "Memoir on the Single and Double Theta-Functions" (No. 704).

Suggested by the theta-function theory, there are several important geometrical papers, as, for example, on the 16-nodal quartic surface, and on the bitangents of a plane quartic.

The memoir "On the Schwarzian Derivative and the Polyhedral Functions" is chiefly valuable for its detailed analytical work, which is a great help to the proper appreciation of the papers of Kummer and Schwarz, especially the latter. In this connection it is proper to mention Cayley's own papers on the correspondence of homographics and rotations and on finite groups of linear substitutions (Nos. 660, 752).

Of the other papers on group-theory the most important is No. 690; this contains the "colour-diagram," and the maxim, adopted by Dyck as the motto of his "Gruppentheoretische Studien": "A group is defined by means of the laws of combinations of its symbols." This ultimate symbolical form of a group is, so to speak, its transcendental essence, which may become incarnate in an endless variety of shapes, such as sets of permutations, geometrical configurations, motions in space, and so on.

In the region of pure algebra we may notice the tenth memoir on quantics, which gives a very complete account of the binary quintic; tables for the binary sextic and ternary cubic; and a paper on the Jacobian sextic equation.

Vol. xi. contains a reprint of the articles contributed by Cayley to the "Encyclopædia Britannica." These, perhaps, will convey to the general reader some sense of his characteristic qualities as a writer; clearness, order, philosophical breadth and independence of view, combined with a studied restraint of manner which sometimes inclines to coldness. This reserve arose, probably, from an excess of sensitiveness, which made him follow an ideal of classic severity and shrink from any open expression of emotion. That he fully appreciated the æsthetic side of mathematics is clear from the well-known passage in his presidential address to the British Association, where he describes the extent and variety of modern mathematics by a metaphor of great beauty and appropriateness. But this is a rare, if not solitary exception to his usual custom; to gain a true idea of his personal charm we must appeal, not to his published work, but to the testimony of the friends who knew him well. For them the portrait prefixed to vol. xi., which shows Cayley as he was in 1885, will form a touching memorial.

Of the numerous minor papers, and of the problems and solutions contributed to the *Educational Times*, it is needless to say anything here. Diamond-dust from the lapidary's workshop, they will doubtless help to polish gems not yet extracted from the mine. G. B. M.

OUR BOOK SHELF.

An Elementary Course of Physics. Edited by Rev. J. C. P. Aldous, M.A. Pp. 862 + vi. (London: Macmillan and Co., Ltd., 1898.)

In this book an attempt is made to give a modern and practical course of natural philosophy in a compendious form, and it may be stated at once that the effort is a most successful one. It is the joint work of the editor, who is chief instructor on H.M.S. *Britannia*, Mr. W. D. Eggar, and Prof. F. R. Barrell. The editor is himself responsible for the sections dealing with mechanics, properties of matter, hydrostatics, and heat, in which the readers are provided with "a groundwork of theoretical knowledge which may enable them to understand and use the simple processes of the kinetic method, to express themselves with accuracy when necessary, and to deal with simple mechanical problems." Wave-motion, sound, and light are admirably treated by Mr. Eggar, while Prof. Barrell's contribution deals with the subjects of magnetism and electricity.

The treatment of the various subjects is most lucid and thorough, and is evidently based on an intimate acquaintance with the requirements of students. Great pains have been taken to avoid looseness of statement; and the fact that some of the sections have had the advantage of the criticisms and suggestions of Lord Kelvin, Lord Rayleigh, and others, makes it a trustworthy book of reference. Where everything is so well done it is difficult to select points for special mention, but it may be remarked that examples drawn from naval sources form a notable and valuable feature, and graphical methods of representing experimental results are largely utilised and encouraged. The generous supply of illustrations, which number nearly six hundred, and not one that fails to serve a useful purpose, enhances the value of the book, and will make it acceptable to a wider circle of readers than that comprised by students following a specified curriculum. The book is of convenient size, and is printed in very clear type; we believe it is destined to take a high place in our schools and colleges.

L'Algérie. Le Sol et les Habitants, &c. Par J. A. Battandier et L. Trabut. Pp. viii + 360. (Paris: Baillière et fils, 1898.)

This little volume is one of a class of books which is much better represented abroad than in this country—one, that is, in which a complete picture is given of a limited part of the earth's surface, under the varied aspects which make up its geography in the widest sense of the term. It is written on a scientific plan, the broad physical features of the country being taken as the basis of the whole description. In Algeria the authors distinguish three main zones, the Tell (or cultivable region), the Steppe, and the Sahara, holding that the plateaux, which some writers have made into a separate division, do not form a natural region, but fall within the Tell or the Steppe according to the amount of rain which falls. The determining factor, indeed, in the geography of the whole region, is the preponderance of the moist rain-bearing winds from the north-west, or of the parching desert winds from the south and south-east. Each of the zones is in turn described, special attention being given to their natural resources; and the fact that for over twenty years the authors have traversed the country in the prosecution of their botanical researches, enables them to speak with the accurate knowledge which can only be acquired at first hand. The inhabitants, the fauna and the geology of Algeria are also sketched in outline, so that we have in small compass a useful summary of all that is known of the country. The general conclusion arrived at is that Algeria is capable of supporting a large population, and that, in spite of the slow modification the climate has undergone since the dawn of history, cultivation will still be possible for many centuries to come.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Electric Light Wires as Telephonic Circuits.

I wish to put on record the following method of using electric lighting wires as telephonic circuits. I was requested some time ago to try to localise a fault in an electric light main, by means of a certain form of inductor used in conjunction with a telephone but not connected to the main. While using it, it occurred to me that probably the main might be used instead of a telephone wire. My first experiments were not productive of good results, as a small fraction of the Company's current passed continuously through the telephone. In October 1897, I placed $\frac{1}{3}$ microfarad condensers in my telephone circuit at each end; these stopped the current, but in no way reduced the telephonic effects. If the note given out by virtue of the rotation of the armature of the dynamo is great, it can be very greatly reduced by placing an inductively wound resistance in the circuit.

The resistance does not appear to modify the telephonic effects in any marked degree. This probably arises from the fact that the E.M.F. due to the secondary coil of the telephone transmitter is high. The experiment was successfully made over two miles of a main which was carrying the full load used in lighting the town. F. J. Jervis-Smith.

Oxford, May 16.

Sub-Oceanic Terraces and River Channels off the Coast of Spain and Portugal.

Will you allow me once more to briefly describe in advance the physical features under the Atlantic off the coast of Spain and Portugal, continuous with those opposite the coasts of the British Isles and the Bay of Biscay, already reported in your columns (Nature, March 24 and April 21)?

The great escarpment already described as descending into deep waters from the margin of the British-Continental platform is still traceable southwards along the coast of Portugal from Cape Finisterre as far at least as the mouth of the Tagus estuary, where it appears to begin to broaden out and merge into a generally rapid slope—or probably a succession of terraces. The breadth of the platform along this coast averages only 30 to 40 miles from the shore, and its margin very nearly follows the 200-fathom contour; but here the descent to the 1000-fathom contour is steep, though seldom precipitous, and is varied by numerous bays and headlands. Owing to the insufficiency of the soundings, especially off Vigo Bay, the definition of the cañons, or old river channels, is scarcely as clear as in the region further north. Still, I have been able to determine several with a great degree of certainty, such as those formerly continuous with the rivers Padron, Lima, Douro, and Tagus. There are also a few which cannot apparently be followed to their sources in the present land, such as one of special depth and precipitancy in lat. 40° 31′ N., distant about 40 miles off the coast of Portugal at Barra Nova. The continuation of these features to the Straits of Gibraltar and into the Mediterranean remains for future investigation.

20 Arundel Gardens, W., May 16. Edward Hull.

Bacteria on an Ancient Bronze Implement.

Mr. Nicholson probably refers to what is known to archæologists as "bronze cancroid."

In the last number of the *Journal* of the Royal Society of Antiquaries of Ireland, March 31, this subject is referred to under the name of "Ulcerative Disease of Bronze or 'Bronze Cancroid,'" by Dr. William Frazer.

As many readers of Nature interested in bacteria may not be able to conveniently refer to this journal, the following points brought forward by the author will be read with interest. He says, "all objects of antiquity fabricated from metallic copper, and its important alloy made by adding tin in certain proportions, are liable to be attacked by this destructive corroding affection." The "bronze disease," says Dr. Frazer, "produces a remarkable disintegrating effect on the object it attacks, and there are good reasons for considering that it possesses infective powers, spreading like a leprosy through the substance of the metal, and slowly reducing it to amorphous powder; further, there are substantial grounds for believing it capable of being conveyed from surfaces already suffering with it to those yet uninfected. So that dishonest counterfeiters of antiques now propagate it on their modern forgeries to deceive intended purchasers. This infamous act is as yet understood to be confined to Italy, where the greater part of these forgeries are made." "In genuine antiques, it unfortunately happens occasionally that the patinated surface of bronze, soon after its discovery from recent excavations, becomes affected with this distinctive bronze disease, which makes its appearance in a number of small spots of clear pale blue colour, that swell and form farinaceous elevations; in the course of time, especially when kept in a moist atmosphere, these spots enlarge, run together and multiply, gradually invading the greater part of the surface, and reducing the object to a powdery condition."

Dr. Frazer says a remedy is found in ink made from sulphate of iron and oak galls, and that scraping "risks a fresh outbreak of this infectious malady." Further on he says the chief operator in Rome is well known, and "It would appear that those skilful artists of false antiques having succeeded in counterfeiting genuine patinations, so as to deceive the most learned collectors, have subsequently gone to the length of infecting their reproductions with spots of the bronze disease. This is no mere superficial imitation which they cause, but absolute inoculation of the destructive canker itself."

In conclusion, Dr. Frazer refers to an article in the *Revue Archæologique* on the same subject by the late Count Michel Kyskiewicz, under the title, "Notes and Souvenirs of an Old Collector." W. G. S.

Dunstable.

I AM not aware of any book on the subject, but Mr. Nicholson will find scattered notices in the *Zeitschrift für Hygiene* and *Arch. für Hygiene*, also the *Journals* of the Chemical Society and Society of Chemical Industry, and *British Journal of Photography* (development of bacteria in silver gelatine films).

The best way to sterilise ancient implements is to suspend them in an oven at a temperature of 150° C.–180° C. for two hours, and let them cool in a free current of air in order to prevent deposit of moisture. This method is quite harmless to the metal, and will sterilise the most resisting spores. It presents obvious advantages over the use of antiseptic fluids.

36 Finsbury Pavement, E.C. G. LINDSAY JOHNSON.

Ebbing and Flowing Wells.

I HAVE had occasion to live for many months of several years close to a well that was sometimes affected by the tide like that at Newton Nottage (NATURE, May 12, p. 45). This was at Alibag, a few miles south of Bombay. The bed-rock is a sheet of basalt of rather uneven surface, sloping westwards at the general rate of about six feet to the nautical mile. Over this, at the spot in question, were low sand-dunes, covered with palm orchards, and full of brick wells. One of my wells was twenty or twenty-five yards from true high-water mark of spring tides, though the surf washed light objects much nearer.

In the dry weather the ebb and flow did not perceptibly affect the well; but during the monsoon the sand-dunes were saturated by the heavy rainfall, and all along their seaward foot, where the sand lay on the sheet-rock, well below high-water mark, the fresh water poured out at ebb tide. When high spring tides were coincident with heavy rain the water in this well rose a little later than the tide, and several feet higher, almost to the level of the ground around the well. Its taste was not affected. At such times the surface in the well was two feet higher than the floor of my house, which stood in a hollow of the dune, a few yards to the eastward. The house was a notorious death-trap (as might be expected); and it was in the course of endeavours to get it condemned and pulled down, that I made the observations related. As it was a Government building, the records are official; and I write from memory. But the well is probably still there; and the observations, in that case, could be verified during any monsoon.

May 13. W. F. SINCLAIR.

TECHNICAL HIGH SCHOOLS—A COMPARISON.

AT different times attempts have been made to convey to English readers interested in scientific education some idea of the facilities provided abroad, particularly in Germany and Switzerland, for the higher technical instruction. The reports of the Technical Instruction Commissioners, and of other persons who have inspected the principal foreign schools, give full particulars of the courses of study pursued in those schools, of the rapidly increasing number of students in attendance, and of the large professorial staff attached to each institution. Exact details, however, as to the magnitude of the technical high schools of Germany have not been hitherto presented in such a form, as might readily show the full importance which our German neighbours attach to the higher scientific training, as a means of advancing their commercial interests. On my return, in the autumn of 1896, from a short visit to Bavaria and Würtemberg, in company with some of my colleagues of the Technical Instruction Commission, I gave some account, in the pages of this journal, of the new electro-technical and electro-chemical institutions, recently erected in Darmstadt in connection with the polytechnic of that town. A few weeks since, I had occasion to pay a flying visit to Aachen, and there I found close to the old polytechnic, erected in 1870, an entirely new building, opened only in 1897, and devoted almost exclusively to electrical work. This school, although not so large, nor so well equipped, as the schools in Stuttgart and Darmstadt, forms a very important addition to the facilities for the higher technical instruction which previously existed in the Rhenish city. It will be seen from the accompanying illustration (Fig. 1) that this new building is a plain structure of four stories, with no pretensions to architectural effect. It is about 140 feet long, and is of a mean depth of about 90 feet, the total area covered by the building being little less than that of the science schools of South Kensington, and about half of that of the Technical Institute of the City Guilds. Yet this building is devoted almost exclusively to the teaching of one branch of applied physics.

Dr. Bosse, the well-known energetic Minister of Education for Prussia, in his dedicatory address at the opening of this school in May last, correctly expressed German opinion when he said: "Neither the technical sciences nor the technical high schools can be said to have yet reached their goal. Both stand in the midst of a restless and irresistible movement and development pressing ever forwards." This recognition on the part of the Prussian Minister of the necessity of constantly improving educational facilities so that they may keep pace with the advance of science, is characteristic of the progressive policy of Germany.

The progress I found this year in Aachen, and eighteen months ago in Stuttgart and Darmstadt, might be observed equally in other parts of Germany, showing that our German neighbours are fully as determined, that their high schools of science shall be ahead of those of other countries, as we may be resolved, that our fleet shall be equal to that of any two other nations.

It is well known to most of the readers of this journal, but must be emphasised with a view to a comparison between the provision for scientific education in Great Britain and Germany, that the polytechnics or technical high schools are institutions exclusively devoted to the teaching of science in its practical application to engineering, manufacturing and professional pursuits. They are quite distinct from the universities, which, situated in the same town or in an adjoining city, as the case may be, comprise other faculties besides science, and, although far larger and more important, belong rather to the class of institutions known in this country as University Colleges. Not far from the polytechnic at Aachen is the University of Bonn; at Munich, and within a few yards of each other, are found the university and polytechnic, and the magnificent institution at Charlottenberg is almost as near to the science laboratories of the Berlin University as is University College to the City Guilds Institute. It must also be remembered that the universities comprise schools of science of the highest grade, for each of which, as at Zürich, Strassburg and Berlin, separate buildings are provided, presided over by professors of European celebrity. In the figures I am about to quote, it will be understood, therefore, that I am dealing with a part only of the accommodation which the different German States have made for the teaching of the higher branches of science.

In order to show the relative sizes of some of the Continental institutions for instruction and research work in technical or applied science, I have obtained plans, accompanied by descriptive matter, of certain typical technical high schools, and have made squares corresponding to the areas covered by the existing buildings. In most cases the buildings erected in the early building in this country which correctly corresponds with a German polytechnic, although its courses of instruction are restricted to fewer branches of professional work. The Royal College of Science embraces a much wider range of scientific work, but, except as regards its mining department, its functions differ in many respects from those of a technical high school. University and King's Colleges may be described as imperfect and undeveloped universities, the specially technical departments of which would alone correspond to the buildings now under consideration.

Taking the areas of the sites of some of the principal foreign schools, we have the following figures arranged in order:

	Square metres
Site of the Berlin Polytechnic	82,460
,, Aachen ,, ...	21,900
,, Darmstadt ,, ...	16,150
,, Hanover ,, ...	15,294
,, Chemnitz ,, ...	12,418
,, Stuttgart ,, ...	11,189
,, London—City Guilds College ...	3,344
,, ,, Royal College of Science	1,189

Fig. 1.—Electro-technical and Mining Laboratory—Aachen.

'seventies have proved too small and ill-adapted or such practical teaching as requires the use of steam power. Separate buildings have accordingly been added for the accommodation of the engineering, chemical, and electrotechnical laboratories, for engine and boiler houses, and for other purposes. The areas of these separate buildings I have added together, and where a building consists of a front portion, and of separate wings at right angles to it, as is so frequently the case, I have taken only those parts of the site which the buildings actually cover. With a view to further accuracy I have endeavoured, where the plans enabled me to do so, to reduce the several parts of the building to a uniform height. The figures quoted may be taken, therefore, as approximately correct.

The Central Technical College of London is the only

The relative areas of these sites are shown by the squares in Fig. 2.

If we consider the buildings erected on these sites, we have the following figures representing in square metres the areas already covered:—

	Square metres
Berlin	16,500
Zürich (exclusive of observatory building) ...	15,412
Aachen (exclusive of engineering laboratory, being built)	8,255
Stuttgart	6,375
Darmstadt	6,084
Chemnitz	3,964
London—City Guilds College...	1,837
,, Royal College of Science	1,189

The accompanying squares (Fig. 3) show the relative sizes of the buildings.

I have not been able to obtain the dimensions of the building in Hanover, nor have I those of the site of the Zürich Polytechnic.

It will be seen at a glance how very inadequate is the provision in London for the higher scientific and technical teaching, as compared with what is found in even a small German town. But, as has frequently been pointed out, it is not only in the size and arrangements of the buildings devoted to science, that we in England are so far behind our German and Swiss neighbours, but also in the organisation of the instruction. In some of our best schools at home each professor has to do the work of three or four experts abroad. In a German university or polytechnic, there is a large staff of professors, each occupied with a particular section of science, in which he is specially interested, and presiding over a laboratory in which he has time and opportunity to make investigations, with the view of advancing science in some one direction. It is the combination of professorial work and the coordination of teaching that make the German university or polytechnic so powerful a machine not only for scientific training, but also for discovery and research. In London, unfortunately, we have too many separate schools, each under-staffed, and each doing much the same kind of work, and the professors are consequently required to discharge a number of duties which are wisely divided in Germany among separate specialists. The multiplication of the schools, and the overlapping of the functions of the teachers stand in the way of any organisation on broad lines of the higher scientific education in London. It appears that a much-needed extension of the Royal College of Science at South Kensington is now under consideration; and it is understood that a more ample site than was originally suggested will be provided for the new buildings on the west side of Exhibition Road, which will bring the Royal College of Science in closer proximity to the Central Technical College. This is as it should be. It is to be hoped, however, that no hasty and half measures will now be adopted. In these days of military and naval expenditure it may be well to point out that the sinews of war come not only from the tax-payers' pockets, but equally, if not to a greater extent, from our high schools of science. Advantage should be taken of the avowed intention of the Government to extend the Royal College of Science, to consider the wider but more important question of the organisation of a faculty of pure and applied science, in connection with the University of London, and of bringing together, for the advantage of the same students, the various agencies for the higher scientific training which are now scattered and separated. Any change or extension that may be now made in any one institution cannot fail to have an important influence on university teaching in London, and should be considered only in relation to the best possible arrangements for developing and improving the joint facilities which London now offers for scientific education of the highest grade.

PHILIP MAGNUS.

THE SCIENCE BUILDINGS AT SOUTH KENSINGTON.

In Nature for May 5 we printed the report of the Select Committee of the House of Commons which has recently been inquiring into the Museums of the Science and Art Department, relating to the recent proposal of the Government to build the new laboratories for the Royal College of Science on the east side of Exhibition Road. We have received for publication the following memorial recently presented to Lord Salisbury by Lord Lister, the President of the Royal Society, which has been signed by the president and officers, all the living past presidents, and many fellows of the Society, entirely endorsing the views of the Select Committee, and urging the Government to refrain from a step which is not only contrary to the policy which has been pursued for the last ten years, but which, if carried out, would make the allocation of land at South Kensington for Science and Art purposes respectively ridiculous. Nor is this all. So far as science and science teaching is concerned, we should be landed in a position far inferior to that occupied by such towns as Gratz, Chemnitz, or Aachen, not to speak of some chief cities of the Continent, Berlin, Vienna, Paris.

Memorial to the Most Honourable the Marquis of Salisbury, K.G., F.R.S., Premier and Secretary of State for Foreign Affairs.

I. Whereas in 1890 Parliament voted 100,000*l.* for the purchase of a site at South Kensington upon which to erect suitable buildings for the Science Museum of the Department of Science and Art, and for the extension of its Science Schools, in accordance with the recommendations of the Royal Commission over which the Duke of Devonshire presided in 1874, as well as of various Committees and other high scientific authorities, and of a Treasury Committee appointed in 1889.

II. And whereas when in 1891 the Government had proposed to erect an Art Gallery on the site, a Memorial, signed by the President and Officers of the Royal Society and representatives of the Universities of Oxford, Cambridge, and of many other learned bodies both in London and in the provinces, was addressed to the Most Honourable the Marquis of Salisbury, K.G., F.R.S., Premier and Secretary of State for Foreign Affairs, showing cause why the site should not thus be allocated.

III. And whereas the scheme was withdrawn, and it was stated by the late Right Honourable W. H. Smith, M.P., that "additions to the College of Science must, in any case, take the form of a separate building divided from the present building by Exhibition Road," and since then plans have been prepared on information supplied on the instructions of Her Majesty's Treasury by the professors concerned.

IV. And whereas this arrangement has been generally accepted since 1876, when the Royal Commission for the Exhibition of 1851 offered land and a building with a view of carrying out the recommendations of the Duke of Devonshire's Commission to provide the needed accommodation for Science at South Kensington.

V. And whereas it was expected that this arrangement would be carried out, when in 1890 the Government acquired the land on the West side of Exhibition Road, which was sold by the Royal Commission of the Exhibition of 1851 at one-third its market value, on the condition that buildings for Science and the Arts should be erected on it.

VI. And whereas we are informed that this arrangement is in danger of being altered by the erection of Science buildings on the East side of Exhibition Road.

We, the undersigned Fellows of the Royal Society, desire most respectfully to express to your Lordship our strong opinion that it is desirable to adhere to the policy, namely, that the needful expansion of the Science Buildings at South Kensington should be provided for on the West side of Exhibition Road, which has been acted upon and publicly acknowledged by the Government since 1890, and is in strict harmony with the recommendation of the Duke of Devonshire's Commission. We are confirmed in this opinion by the fact that the space which we understand is available for Science on the East side of Exhibition Road is but a small fraction of that which is devoted to similar purposes in many foreign towns.

(Signed)

LISTER, President of the Royal Society.
JOHN EVANS, Treasurer of the Royal Society.
M. FOSTER, Secretary of the Royal Society, Professor of Physiology, Cambridge.
ARTHUR W. RÜCKER, Secretary of the Royal Society.
E. FRANKLAND, Foreign Secretary of the Royal Society.

J. W. SWAN, President, Institution of Electrical Engineers.
C. V. BOYS, Vice-President of the Physical Society.

LIQUID HYDROGEN.

A VERY remarkable achievement, which will redound to the credit of English science, has been performed within the walls of the Royal Institution. For some time past it has been a matter of general knowledge that Prof. Dewar has been preparing for an attempt to produce liquid hydrogen on a large scale. Money has been freely subscribed for investigations to be carried on at low temperatures, and the laboratories of the Royal Institution have gradually approached more and more nearly to the likeness of an engineering workshop. Very grave difficulties had to be encountered, and success seemed long in coming; but on Tuesday, May 10, Prof. Dewar was able to inform the President of the Royal Society that on that day both hydrogen and helium had succumbed to his attack.

All this is typical of British methods. The members of a great private Institution have secured the services of a man in whose abilities they believe. They supply him freely with the sinews of war, and he justifies their confidence by achieving a success which, as far as our present knowledge goes, could only have been won by a combination of great resources and very great skill. We heartily congratulate Prof. Dewar and his supporters on this result, and on the fact that the world now possesses liquid hydrogen—so to speak—on tap.

The conditions of the experiment give some idea of the difficulties which have been overcome. Hydrogen cooled to $-205°$ C. escaped, under a pressure of 180 atmospheres, into a vacuum vessel surrounded by a space which was itself maintained at a temperature of $-200°$ C. Thus constrained it liquefied.

About 20 c.c. of the liquid were collected in another protected vessel, into which it dripped from that above described. It is transparent, colourless, with a well-defined meniscus, and apparently with a relatively high refractive index.

We sincerely hope that this great success will not be marred by a controversy as to priority, of which some symptoms have already appeared in a leading article in the *Standard* and elsewhere. The time is long past in which the liquefaction of a gas was interesting as proving that under proper conditions all substances can be liquefied. For many years nobody has had doubts on that point. We have learned to look upon the liquefaction of a gas as important, mainly because it affords a means of studying at very low temperatures not only the liquefied gas itself, but also other kinds of matter. Experiments in which momentary liquefaction is attained are chiefly interesting as showing that some approach is made to realising the condition under which more stable results may be expected. They take a much higher rank if the skilful experimenter can wrest from the substance in a transitory condition some information as to the properties which the material would have if it were reduced to the state which has been called a "static liquid." To attain these results in the case of so intractable a substance as hydrogen is an achievement of a very high order. But when this has been done it cannot be fairly contended that all the rest follows as a matter of course.

There have been discoveries in which the first step was all-important. The discovery, for instance, of the Röntgen rays opened an entirely new range of facts to scientific investigation. In other cases the root-idea had long been common property, and the merit, like that of Captain Bunsby's observation, "lays in the application of it." It has long been known that if hydrogen were ever liquefied in quantity, both cooling to a very low temperature, and a rapid expansion would play a large part in the operation. The difficulties of the experiment lay, not in understanding these principles, but in applying them, and the difficulties were so enormous that the investigator who has overcome them deserves our admiration. He has performed not only a great "tour de force," but has cleared the way to a region hitherto unexplored, to a whole series of researches which become more interesting and important as the absolute zero is more nearly approached.

It appears to us, therefore, that there is no necessity to belittle the work either of Prof. Dewar or of others who have been active in the same line of research. Cailletet and Wroblewski obtained results which, to judge from his address to the French Academy, reported in the *Times* of May 17, are regarded as inconclusive by so high an authority as M. Moissan. At the best, and assuming the liquid obtained to have been hydrogen, its existence in the liquid form was very brief. Prof. Olszewski also has published a full account of how he obtained hydrogen for a moment in a mist-like state, in which he measured some of the constants of the liquid. Yet nothing but the paucity of language could lead to the idea that this feat was the same as that which Prof. Dewar has accomplished. Had we no other evidence of the existence of water, something might be learned from the study of clouds; but nobody contends, on that ground, that a cloud is the same thing as a duck-pond. Yet the difference between the two is hardly, if at all, greater than the practical difference between hydrogen without visible form or surface, in a state of momentary or "dynamical" liquefaction, and hydrogen as a "static" liquid, with a clearly defined meniscus, boiling away quietly under conditions which enable the observer to record its appearance, to handle and to use it.

By insisting on this difference, we do not for a moment wish to question the merits of Prof. Olszewski's work. He used the means at his disposal admirably, and made measurements of the critical temperature and boiling-point of hydrogen, which, tested as they were by check experiments on oxygen and ethylene, were of great value.

Prof. Olszewski was, however, fully conscious of the difference between these results and those which Prof. Dewar has now achieved. He again and again explained with the utmost candour that he had seen no meniscus, and that he had failed to reduce hydrogen to the state of a "static liquid." He further expressed the opinion that these desiderata would not be attained until a cooling agent was discovered in the form of a gas, with a density between those of hydrogen and nitrogen. No such gas has been used by Prof. Dewar, yet hydrogen has now been seen by himself, by Lord Rayleigh and others as a well-defined liquid mass. The merits of this achievement will be in no wise diminished by a generous recognition of the researches of Olszewski, but on the other hand it would be most unfair to minimise the magnitude of Prof. Dewar's success by classing it merely as a repetition, on a larger scale, of another man's work. It is in the words of M. Moissan a "wonder of modern chemistry."

The following abstract of the paper will give further details :—

In a paper entitled "The Liquefaction of Air and Research at Low Temperatures," read before the Chemical Society, and published in the *Proceedings*, No. 158, an account is given of the history of the hydrogen problem and the result of my own experiments up to the end of the year 1895. The subject is again discussed in a Friday evening lecture on "New Researches on Liquid Air" (*Roy. Inst. Proc.*, 1896), which contains a drawing of the apparatus employed for the production of a jet of hydrogen containing liquid. It was shown that such a jet could be used to cool bodies below the temperature that could be reached by the use of liquid air, but all attempts to collect the liquid in vacuum vessels failed. No other investigator has so far improved on the results described in 1895. The type of apparatus used in these experiments worked well, so it was resolved to construct a much larger liquid air plant, and to combine with it circuits and arrangements for the liquefaction of hydrogen, which will be described in a subsequent paper. This apparatus, admirably constructed by the engineers, Messrs. Lennox, Reynolds, and Fyfe, took a year to build up, and many months have been occupied in testing and making preliminary trials. The many failures and defeats need not be detailed.

On May 10, starting with hydrogen cooled to $-205°$ C., and under a pressure of 180 atmospheres, escaping continuously from the nozzle of a coil of pipe at the rate of about 10 cubic feet to 15 cubic feet per minute, in a vacuum vessel double silvered and of special construction, all surrounded with a space kept below $-200°$ C. Liquid hydrogen commenced to drop from this vacuum vessel into another doubly isolated by being surrounded with a third vacuum vessel. In about five minutes, 20 c.c. of liquid hydrogen were collected, when the hydrogen jet froze up from the solidification of air in the pipes. The yield of liquid was about 1 per cent. of the gas. The hydrogen in the liquid condition is clear and colourless, showing no absorption spectrum, and the meniscus is as well defined as in the case of liquid air. The liquid must have a relatively high refractive index and dispersion, and the density must also be in excess of the theoretical density, viz. 0·18 to 0·12, which we deduce respectively from the atomic volume of organic compounds, and the limiting density found by Amagat for hydrogen gas under infinite compression. My old experiments on the density of hydrogen in palladium gave a value for the combined body of 0·62, and it will be interesting to find the real density of the liquid substance at its boiling-point. Not having arrangements at hand to determine the boiling-point, two experiments were made to prove the excessively low temperature of the boiling fluid. In the first place, if a long piece of glass tubing, sealed at one end and open to the air at the other, is cooled by immersing the closed end in the liquid hydrogen, the tube immediately fills, where it is cooled, with solid air. The second experiment was made with a tube containing helium.

The *Cracow Academy Bulletin* for 1896 contains a paper by Prof. Olszewski, entitled "A Research on the Liquefaction of Helium," in which he states "as far as my experiments go, helium remains a permanent gas, and apparently is much more difficult to liquefy than hydrogen." In a paper of my own in the *Proceedings* of the Chemical Society, No. 183 (1896–97), in which the separation of helium from bath gas was effected by a liquefaction method, the suggestion was made that the volatility of hydrogen and helium would probably be found close together, just like those of fluorine and oxygen. Having a specimen of helium which had been extracted from bath gas, sealed up in a bulb with a narrow tube attached, the latter was placed in liquid hydrogen, when a distinct liquid was seen to condense. From this result it would appear that there cannot be any great difference in the boiling points of helium and hydrogen.

All known gases have now been condensed into liquids which can be manipulated at their boiling points under atmospheric pressure in suitably arranged vacuum vessels. With hydrogen as a cooling agent, we shall get within 20° or 30° of the zero of absolute temperature, and its use will open up an entirely new field of scientific inquiry. Even as great a man as James Clerk Maxwell had doubts as to the possibility of ever liquefying hydrogen (see "Scientific Papers," vol. ii. p. 412). No one can predict the properties of matter near the zero of temperature. Faraday liquefied chlorine in the year 1823. Sixty years afterwards Wroblewski and Olszewski produced liquid air, and now, after a fifteen years' interval, the remaining gases, hydrogen and helium, appear as static liquids. Considering the step from the liquefaction of air to that of hydrogen is relatively as great in the thermo-dynamic sense as that from liquid chlorine to liquid air, the fact that the former result has been achieved in one-fourth the time needed to accomplish the latter, proves the greatly accelerated race of scientific progress in our time.

The efficient cultivation of this field of research depends upon combination and assistance of an exceptional kind; but in the first instance money must be available, and the members of the Royal Institution deserve my especial gratitude for their handsome donations to the conduct of this research. Unfortunately its prosecution will demand a further large expenditure.

During the whole course of the low temperature work carried out at the Royal Institution, the invaluable aid of Mr. Robert Lennox has been at my disposal; and it is not too much to say that but for his engineering skill, manipulative ability, and loyal perseverance, the present successful issue might have been indefinitely delayed. My thanks are also due to Mr. J. W. Heath for valuable assistance in the conduct of these experiments.

NOTES.

M. MARCELLIN BOULE, of Paris; Dr. W. H. Dall, of Washington (D.C.), U.S.A.; and M. A. Karpinsky, of St. Petersburg, have been elected Foreign Correspondents of the Geological Society.

PROF. MICHAEL FOSTER has been elected President of the British Association for the meeting to be held at Dover next year.

THE annual conversazione of the Society of Arts will take place at the Natural History Museum, Cromwell Road, S.W., on Wednesday, June 22. The reception will commence at 9 p.m.

A CONVERSAZIONE of the Metropolitan Counties Branch of the British Medical Association will be held in the Museum of the Royal College of Surgeons on Tuesday, June 7.

THE Prince of Wales and the Duke of York were present on Monday night at a special meeting of the Royal Geographical Society, held in commemoration of the 400th anniversary of the discovery of the Cape route to India by Vasco da Gama. The president, Sir Clements Markham, was in the chair, and the address delivered by him upon the occasion is published in another part of this issue. At Lisbon the Vasco da Gama celebrations were inaugurated on Tuesday by the firing of a salute of 101 guns by the forts and the ships anchored in the Tagus. At a meeting of the Lisbon Geographical Society, Baron von Kell, the Dutch Minister to Portugal, presented to King Charles an album and a gold wreath, as the homage of Holland to Vasco da Gama. His Majesty accepted the gift, and said that Portugal was grateful for this act of homage.

THE Judicial Committee of the Privy Council recently granted the Hon. C. A. Parsons an extension of five years for his patent, dated April 23, 1884, for "improvements in rotary motors actuated by elastic fluid pressure and applicable also as pumps." The reasons for this decision were stated on Saturday to be that Mr. Parsons had not yet been adequately remunerated for his invention.

DR. D. J. LEECH, Professor of Materia Medica and Therapeutics in the Victoria University; Prof. W. Ramsay, of University College, London; and Prof. Ira Remsen, the Professor of Chemistry at the Johns Hopkins University, Baltimore, have been elected honorary members of the Pharmaceutical Society of Great Britain.

IN the High Court of Justice on Saturday an application was made on behalf of the shareholders of the Sheffield Botanical and Horticultural Society, that the trustees might be ordered to sell its property in pursuance of resolutions passed at meetings of the members, and distribute the proceeds of the sale among the members. It was urged by the Attorney-General that the property of the Society ought not to be so divided, but ought to be given to some other institution of a like character. The judgment was, however, that the applicants were entitled to the order they asked for.

PROF. J. M. SCHAEBERLE has resigned his post as astronomer at the Lick Observatory, California.

MR. HENRY WILDE, F.R.S., has been elected an honorary member of the Institution of Electrical Engineers.

THE Boston Society of Natural History has awarded the Grand Honorary Walker Prize of one thousand dollars to Mr. Samuel Hubbard Scudder, of Cambridge, Mass., for his contributions to entomology. The prize is awarded every five years, and the four previous recipients have been Mr. Alexander Agassiz, Prof. Joseph Leidy, Prof. James Hall, and Prof. James D. Dana.

THE annual electrical exhibition was opened at New York City on May 2. The President of the United States, following the usual custom, set the machinery in motion by pressing a button at Washington. He also sent congratulatory messages, as did the Vice-President. The opening address was by Chauncey Depew, who supplemented his remarks by firing off a dynamite gun, without wires by the long-distance system of telegraphy, and by blowing up a mimic steamer in the tank by a submarine mine.

WE regret to record the death of Mr. W. C. Lucy, F.G.S., formerly of Brookthorpe, near Gloucester. For upwards of forty years Mr. Lucy was one of the most active and enthusiastic members of the Cotteswold Naturalists' Field Club. To the *Proceedings* of the Club he contributed numerous papers, including observations on the Drifts of the Severn, Avon and

Evenlode Valleys, on the Oolites and Lias of the Cotteswold Hills, &c. In 1887 he published an essay on the origin of the Cotteswold Club, with an epitome of its *Proceedings*. He died on May 11, aged seventy-five.

The *British Medical Journal* states that the Pasteur Institute at Constantinople, which recently had to close its doors owing to want of funds and the utter indifference as to its well-being shown by the Turkish Government, has been reopened. This gratifying result is due partly to the intervention of M. Boulinière, Chargé d'Affaires of the French Embassy, and partly to the action taken by the Imperial Society of Medicine, which addressed a strong protest on the subject to the Sultan. His Majesty's attention having thus been drawn to the condition of the institution, in which he had always taken the keenest interest, at once gave instructions that Dr. Nicolle should be furnished with everything that he required, and satisfactory guarantees were given that funds and all other assistance that might be needed should henceforth be abundantly supplied. It is expected that the outcome of the affair will be a considerable development of the usefulness of the Institute.

We regret to see the announcement, in the *Manchester Guardian*, of the untimely death of Dr. C. Herbert Hurst, formerly on the staff of the Zoological Department of the Owens College. Dr. Hurst was an alumnus of the Manchester Grammar School, and studied biology under Prof. Huxley with conspicuous success. After some experience as resident science master in a boys' school he entered the Owens College as a student in 1881, and in January 1883 was appointed to the post of demonstrator and assistant lecturer in zoology under the late Prof. Milnes Marshall. For eleven years he filled this office with conspicuous diligence and success, and not only earned the grateful recollection of several generations of students of the College, but also laid under obligation a much wider circle of zoologists by his share in the production of the "Text-book of Practical Zoology," which has made the names of Marshall and Hurst familiar in every biological laboratory not only in this country but in the world. In 1889 he took advantage of a prolonged leave of absence granted by the College authorities to pursue his studies at the University of Leipzig, where he carried out a valuable investigation into the life-history of the gnat *Culex*, for which he was awarded the degree of Ph.D. Latterly he had undertaken what he termed "a systematic criticism of biological theory," in the course of which he published discussions on "The Nature of Heredity," "Evolution and Heredity," "The Recapitulation Theory," and other kindred topics. In these essays certain modern views were subjected to trenchant and unsparing criticism, for Dr. Hurst was a keen controversial writer, and never hesitated to express himself clearly and forcibly even at the risk of obloquy and unpopularity. His last writings were "The Structure and Habits of Archæopteryx" and "A New Theory of Hearing." In 1895 Dr. Hurst left the Owens College to fill a similar position in the Royal College of Science, Dublin. His premature death deprives zoology of a zealous and upright worker, who was most esteemed by those who knew him best.

During the past two months the Plymouth laboratory of the Marine Biological Association has been well filled with investigators, particularly during the Easter vacation, when all the available space was in requisition. The following is a list of the gentlemen who visited the laboratory during this period, together with the subjects of their researches:—Dr. N. B. Hartman, St John's College, Cambridge (Sense-organs of Fishes), Mr. T. H. Taylor, Yorkshire College, Leeds (Polyzoa), Mr. F. W. Gamble, Owens College, Manchester (Nervous System of Polychæta), Mr. A. H. Church, Jesus College, Oxford (Algæ), Mr. E. T. Browne, University College, London (Hydroids and Medusæ), Mr. E. S. Goodrich, Merton College, Oxford (Nephridia of Polychæta), Mr. G. Brebner, University College, Bristol (Algæ), Mr. S. D. Scott, King's College, Cambridge (Excretory Organs of Tunicata), and Mr. W. I. Beaumont, Emmanuel College, Cambridge (General). Mr. Garstang's Easter class for the study of marine biology was attended by eight undergraduate students from Oxford, Cambridge, Eton, and the Yorkshire College, Leeds. Among the more recent captures of interest may be specially mentioned Mr. Browne's rediscovery in quantity of the remarkable bitentaculate Hydroid known as *Lar sabellarum*, which gives rise to the aberrant Medusa *Willia stellata*.

The Council and Parliamentary Bills Committee of the British Medical Association have drawn up a report on the Vaccination Bill now before Parliament. Referring to the clause for the extension of the age limit for infantile vaccination, the opinion is expressed that the proposal to extend the limit from three to twelve months is injudicious and would prove prejudicial in the presence of an outbreak of small-pox. In Scotland the age limit is six months; and this is the limit which is recommended. As vaccination should be practically an aseptic operation, it is suggested that some modification of the clause referring to domiciliary vaccination is needed. The home of a child may be in a slum, dirty, overcrowded, and infected; and asepsis cannot be secured in such surroundings. The proposal is therefore made that, where the house is uncleanly, it should be possible to insist on the child being taken not necessarily to a public station but to the consulting-room, either of the public vaccinator or of some private practitioner. The main defect of the Bill is considered to be the omission of all reference to re-vaccination, and the Council and Committee are of the opinion that re-vaccination should be insisted upon at the age of twelve years.

A plea for a kinematograph bureau is put forward by M. Boleslas Matuszewski, Paris, in a pamphlet of which a copy has been sent to us. His view is that a national or international bureau, directed by a responsible Government official, should be established to receive kinematographs and preserve them for their historical value.

From the *Bulletin* of the Royal Botanic Gardens, Trinidad, we learn that in the botanical department of the Agricultural Exhibition, recently held in the Colony, a new form of machine for the extraction of rubber was exhibited in action. The rubber in the space of two minutes is separated from the *latex*, or milk, of the Castilloa tree, and is then put to dry. In the space of some three hours, sheets or slabs of fine clear marketable rubber is produced, free from the usual amount of proteid and albuminoid matters which are usually found in rubber produced by the ordinary process.

An important contribution to the theory of warning colours and mimicry is made to the *Journal* of the Asiatic Society of Bengal (vol. lxvii. part 2, No. 4, 1897) by Mr. F. Finn, Deputy Superintendent of the Indian Museum. The paper is the final one of a series of four, and in it Mr. Finn gives an account of his experiments with birds other than the Babblers, to which his first paper was devoted, together with a general summary of the results and inferences. He concludes from his experiments: (1) That there is a general appetite for butterflies among insectivorous birds, even though they are rarely seen when wild to attack them. (2) That many, probably most, species dislike, if not intensely, at any rate in comparison with other butterflies, the "warningly-coloured" *Danainæ*, *Acræa violæ*, *Delias eucharis*, and *Papilio aristolochiæ*; of these the last being most distasteful, and the *Danainæ* the least so. (3)

That the mimics of these are, at any rate, relatively palatable, and that the mimicry is commonly effectual under natural conditions. (4) That each bird has separately to acquire its experience, and well remembers what it has learned. On the whole, therefore, the theory of Wallace and Bates is supported by the facts detailed in Mr. Finn's papers, so far as they deal with birds (and with the one mammal used). Prof. Poulton's suggestion that animals may be forced by hunger to eat unpalatable forms is also more than confirmed by Mr. Finn's experiments, as the unpalatable forms were commonly eaten without the stimulus of actual hunger—generally, Mr. Finn adds, without signs of dislike.

IN *Bulletin* No. 2 of the Blue Hill Meteorological Observatory, Mr. H. H. Clayton gives some very interesting examples of the diurnal changes in temperature and humidity at different heights in the free air. The observations were made by means of kites, and on two occasions these were maintained in the air during a large part of twenty-four consecutive hours. The results show that the diurnal variation of temperature was very slight or had entirely disappeared at about 2300 feet, and that the relative humidity curve at that height was exactly opposite in phase to that recorded at lower levels; the minimum humidity was recorded at night, and the maximum during the day. The records during the day show that to a certain height (which varies under different conditions) the temperature in the lowest stratum decreases with increase of altitude approximately at 1°·7 per 330 feet. Above that height the air is suddenly found warmer, and then the temperature decreases with increasing height at a somewhat lower rate. During the night there is a marked inversion of temperature between the ground and 600 to 1000 feet. Above that height the temperature decreases at a fairly uniform rate. The experiments were made under the superintendence of Mr. A. L. Rotch, the proprietor of the observatory.

THE latest contribution to the question of the age of the earth comes from Mr. J. G. Goodchild, of H.M. Geological Survey, in the form of a presidential address delivered before the Royal Physical Society of Edinburgh, and just published in the Society's *Proceedings* (Session cxxvi., 1896–97). Many geologists have attempted to estimate the length of the interval between the present time and the period when the oldest strata containing fossils were laid down; and "vague, indefinite, but unquestionably vast beyond conception" have been the conclusions. Mr. Goodchild passes in review certain changes which are known to have taken place in the past, working backwards from the Glacial Period, and estimates the time required for the formation of the rocks of the various geological periods. He concludes that ninety-three millions of years have elapsed since the commencement of the Tertiary Period, and seven hundred millions of years since the commencement of the Cambrian Period. Moreover, the beginning of life upon the earth may be as much further back from Cambrian times as Cambrian times are removed from our own, so that the total estimate assumes tremendous proportions.

IN the paper referred to in the preceding note, Mr. Goodchild confines his attention to the purely geological side of the question of the age of the earth, leaving the physicists to take up the discussion and deal with it in the light of new facts and views. He suggests in conclusion that the following points need consideration: (1) Is it certain that the whole of the downward increment of heat within the earth is due to any vestige of the earth's original heat? If not, why may not part of it be due to the conversion of the energy of motion arising from terrestrial undulation (set up mainly by luni-solar gravitational energy) into the energy of heat? (2) Is it certain that radiant energy in general differs from gravitational energy in operating only between two solid bodies? If radiant energy acts only between any two material bodies, how do we know that the radiant energy of the sun, or the heat of the earth, is being dissipated into space at anything like the rate which is generally assumed to be the case?

WE learn from the *Lancet* that the use of Röntgen rays as a means of certifying the existence of death was demonstrated at a recent meeting of the Biological Society of Paris. M. Bougarde showed three photographs of the thorax, two of them from living persons and the third from a corpse, all taken by the X-rays. In the two first the different thoracic organs and the walls of the thorax itself exhibited a hazy outline, so that their limits could not be exactly made out. This, of course, was owing to the natural movements of the parts, the pulsations of the heart and the great vessels, and the movements of the diaphragm. Even when the subjects held their breath so as to minimise movement as much as possible the outlines were still hazy, and the outline of the diaphragm was seen as a shadow varying in depth and extending over the ninth and tenth intercostal spaces. The heart and great vessels were seen to occupy the centre of the chest as a dark oval mass, the shadow of which was dense in the centre, and gradually faded away towards the periphery until the almost transparent lungs were reached. In the radiograph of the corpse, however, the appearance was quite different, for all the organs had sharp and well-defined edges.

THE *Proceedings* of the Academy of Natural Sciences of Philadelphia contains an account of the discovery of a complete volcanic crater of Mesozoic age near Pottstown, Montgomery County, Pennsylvania, by Mr. E. Goldsmith. The chief interest of the paper centres round the microscopical examination of some varieties of de-vitrified obsidian and of gabbro-phonolite. Some specimens of amygdaloid were obtained from a boring which showed remarkable fluidal texture even to the unaided eye. Basaltic columns of exceptional size were observed, the diameters of the six-sided sections measuring in some cases ten, eleven, and even fifteen feet across.

MR. E. GOLDSMITH contributes an interesting note on the petrification of fossil bones to the *Proceedings* of the Academy of Natural Sciences of Philadelphia. In digging for human remains in the deposits of the Port Kennedy limestone quarry, a fissure in the Silurian limestone on the Schuylkill River, Pennsylvania, it was found that many of the fossil bones obtained "fell to a mealy powder" when touched. Mr. Goldsmith has subjected specimens in various stages of petrifaction to analysis, and finds that the "bone meal" contains little or no calcium phosphate, but that it consists essentially of dolomite. It is supposed that the change is effected by carbon dioxide in the water retained in the fissure, the phosphoric acid being transferred and reunited with ferric oxide and alumina to form vivianite (which was found in the neighbourhood), and magnesia being taken up at the same time.

THE current number of the *Annales de l'Institut Pasteur* contains the report for the past year of the anti-rabic inoculations carried out in Paris. No less than 1521 persons underwent the treatment, which is 213 in excess of the number recorded for the year 1897. In all, eight deaths from rabies occurred, two of which, however, took place during the course of treatment and before it could have taken effect. In one case a patient was admitted in April, and underwent the inoculations, but succumbed to rabies in the middle of October. Out of the total number of patients 175 were foreigners, and of the latter Egypt contributed 2, Greece 1, the United States 1, Germany 8, Belgium 14, Switzerland 33, British India 33; whilst England, as usual, far exceeds in its contribution that of any other nation, the substantial number of 83 being sent from this country. By far the largest number of patients were admitted suffering from bites on the hands; next in order come bites on the limbs, whilst in 151 cases the injuries were inflicted on the head. The Seine Department appears to be the district where rabies is most prevalent in France, more than one-third of all the cases coming from this part of the country.

A PAMPHLET on "Science and Engineering during the Victorian Era (1837-1897)," by Mr. Charles Bright, has been published by Messrs. Archibald Constable and Co. The pamphlet is a reprint of an introduction which Mr. Bright wrote for the Victorian Era Exhibition held at Earl's Court last year.

To encourage and facilitate the use of the metric system in the United Kingdom, the *Pharmaceutical Journal* recently published a series of tables of metric equivalents of Imperial Weights and Measures, and thermometric equivalents. The tables have been found of great assistance, and they have now been reprinted in a convenient form for reference by pharmacists, chemists, and medical men.

WE have received the fourth number of the new *Journal of Applied Microscopy*, published monthly by the Bausch and Lomb Optical Company, of Rochester, N.Y. The present part is chiefly devoted to methods of imbedding and staining sections, but photo-micrography also receives its share of attention.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. W. H. Lewis; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mrs. Eyre; a Red-backed Buzzard (*Buteo erythronotus*), captured at sea, presented by Mr. Ernest Hartley; two Banded Parrakeets (*Palæornis fasciata*, ♂ ♂) from India, presented by Lady Lumsden; a Cardinal Grosbeak (*Cardinalis virginianus*) from North America, presented by Mrs. Harry Blades; two Crested Screamers (*Chauna cristata*) from Buenos Ayres, two Scaly-breasted Lorikeets (*Psittenteles chlorolepidotus*) from New South Wales, purchased; two Black-backed Geese (*Sareidiornis melanonota*) from India, two Grey-lag Geese (*Anser cinereus*), British, received in exchange.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF VARIABLE STARS.—A most useful and valuable series of variable star observations has just been published by Dr. Francesco Porro in a memoir in the *Pubblicazioni del Reale Osservatorinio Astronomico di Torino*, No. 4. The observations were made at Torino and Soperga, and extend over the years 1889-95.

COMET PERRINE (MARCH 19).—The following is a continuation of the ephemeris of Comet Perrine for the ensuing week:—

1898.	R.A. h. m. s.	Decl. ° ′	Br.
May 20	2 17 30	+55 36·6	0·30
21	22 25	43·4	
22	27 18	49·5	
23	32 6	55·0	
24	36 52	59·9	0·27
25	41 34	56 4·3	
26	46 13	8·1	
27	5 50 48	+56 11·3	

FRANCE AND INTERNATIONAL TIME.—Slowly but surely the scheme for dividing the time all over the world into an equal number of zones, differing from one another by one hour, is extending, and we hope before long that such a rational system of international time will be universally adopted. Even now there are some notable outstanding countries which as yet have not thought fit to adopt this principle. Before, however, one can say anything more in the matter, the case of Ireland must be remembered. There is no doubt that if we wish other countries to adopt a system of time zones, we should see that, at least, Great Britain, if not all British colonies, is one in the adoption of the scheme. There is absolutely no reason why Ireland should not adopt Greenwich time; but yet Dublin time is daily used, and all the while we are laughing at the prejudices of France for not instantly adopting the Greenwich meridian, which is only a matter of less than ten minutes. For Ireland there is absolutely no excuse for not coming under the new *régime*, but with France it is different. A change from mean Paris to mean Greenwich time would necessitate a great amount of work in altering their numerous publications, such as the *Connaissance de Temps* and other almanacks, to say nothing of charts, &c. Such difficulties have not, however, hindered her from adopting the international system of time zones; and although the new time she has adopted is really Greenwich time, yet the "national hour" is that "of the meridian of Paris diminished by 9m. 21s." In an interesting article (*Revue Scientifique*, May 7, 1898) on this subject, M. Bouquet de la Grye does not seem to advocate the step taken by France, and concludes that this adoption will be "contrary to the interests of our country, tradition, scientific spirit." The following list of meridians successively adopted, which is of interest, we have taken from the above-mentioned article:—

Dicéarque, of Messina, adopted the island of Rhodes, 300 B.C.

Eratosthenes chose the meridian of Alexandria, 270 B.C.

Marin de Tyr took for the origin the meridian of the islands of Fortune in the year 80 A.D.

The Arabians chose the meridian of Mecca, and also that of the column of Hercules, 800 A.D.

The Alphonsine tables assumed as their origin the meridian of Toledo, 1250 A.D.

Mercator took the Azores for the initial meridian, 1569 A.D.

The Paris Congress chose the island of Fer, 1633 A.D.

It was decided, after the example of Guillaume Delille, to place the meridian of the island of Fer 20° to the west of that of Paris, 1724 A.D.

A NEW LONG PERIOD VARIABLE.—Herren Müller and Kempf describe some observations which have led them to discover an interesting variable star of evidently long period (*Astr. Nachr.*, No. 3491). The star in question is B.D. + 30°·591, R.A. 3h. 49m. 8s., Decln. + 30° 46′·0 1900·0, and was included in their list of comparison stars for the Potsdam Photographic Durchmusterung. As soon as this star was found to vary its magnitude, observations were at once begun to determine its period. The following table shows the magnitudes, as yet, obtained.

Appearance in	Mean date.	No. of obs.	Mag.	Curve.	Mag. curve.
1887–88	1888 March 10	4	6·36	6·31	+0·05
1888–89	Nov. 24	16	6·29	6·31	−0·02
1889–90	1890 Jan. 11	14	6·33	6·31	+0·02
1890–91	Dec. 12	16	6·30	6·31	−0·01
1891–92	—	—	—	—	—
1892–93	—	—	—	—	—
1893–94	1894 Feb. 22	5	6·44	6·46	−0·02
1894–95	1895 March 6	9	6·60	6·59	+0·01
1895–96	1896 Jan. 19	41	6·69	6·70	−0·01
1896–97	Dec. 21	28	6·82	6·81	+0·01
1897–98	1897 Dec. 1	26	6·92	6·93	−0·01

The fourth column gives the observed magnitudes of the variable, the fifth the magnitudes as obtained by drawing a curve through the points when plotted with the time as abscissæ and the magnitudes as ordinates; and, lastly, the sixth denotes the differences between the two latter. A glance at the curve shows that the star from 1887 to the middle of 1891 retained its original brightness, namely 6·31 mag. It began then to dim off, and from the beginning of 1894 it has decreased 0·01 magnitudes monthly, or a little over one-tenth of a magnitude in a year. This new variable is said to be of a yellowish-white colour. With the help of the 30-inch Pulkova refractor Herr Renz has examined the star for duplicity, but could not detect a second body. Probably the spectroscope may tell us more about the constitution of this interesting variable: it is hoped that both spectroscopic and photometric observations will be made to unravel the mystery of such a long period variable as this appears to be.

THE ROYAL SOCIETY'S CONVERSAZIONE.

THE first soirée this year was held on the 11th inst. It was numerously attended, and a large number of objects had been brought together. We have not space to refer to all the exhibits.

Prof. Hele-Shaw exhibited experiments on the flow of water. We have already given an account of some of these (p. 34). Prof. Hele-Shaw also showed instruments for describing cycloidal curves and envelopes. By means of the instrument exhibited, two surfaces of cardboard or paper are made to revolve so that imaginary pitch circles on each roll upon one another. This is effected by employing auxiliary circles within or without the pitch circles, the auxiliary circles being made to move at the same velocity by passing between two pairs of equal wheels, each wheel being connected by an axle with the corresponding wheel for the other auxiliary circle. By a further combination of wheels the actual centres of rotation are dispensed with, only virtual centres being used. Hence it is possible to draw with a small instrument cycloidal or involute curves for circles of any radius, however large, and to find envelopes or centrodes under any conditions of fixed or varying radii. A simple practical application is that to the teeth of wheels, examples of which were exhibited.

Mr. J. Mackenzie Davidson exhibited Röntgen ray apparatus for localisation purposes.

Mr. T. Andrews, F.R.S., exhibited (1) micrographic illustrations of deterioration in steel rails. These high power investigations of old rails, which have worn well, afford an indication of the microscopic structure and composition best adapted to ensure endurance and safety in rail service. (2) Micro-crystalline structure of iron. The micrographs indicate the existence of a primary and secondary crystalline formation in large masses of iron which have been slowly cooled.

Mr. C Orme Bastian showed an electric current meter acting by electrolysis. The height of a column of liquid (sulphuric acid and water) contained in a glass tube is caused to decrease by electro-decomposition, and this decrease in height is utilised to indicate the quantity of current (in ampère hours) that has passed through the meter in any given time. Assuming the voltage of the supply to be constant, a perfectly accurate measure of the electric energy, which has passed through the meter, is recorded by means of a scale in front of the above-mentioned tube, which can be calibrated in Board of Trade or other units. A hole in a rubber plug at the top of the tube allows the gases resulting from the electro-decomposition of the liquid to pass away into the atmosphere, through the gauze tray and holes in the top of the meter case. Paraffin on the surface of the fluid prevents atmospheric evaporation. The instrument starts registering with an infinitely small current; it is accurate at all temperatures and at all loads; its accuracy is unaffected by temporary excess currents; and it is not capable of being affected by outside disturbing influences.

Dr. Leonard Hill and Mr. Harold Barnard showed simple forms of sphygmo-manometers.

Admiral Sir W. J. L. Wharton, K.C.B., F.R.S., and Prof. J. W. Judd, C.B., F.R.S., exhibited, on behalf of the Coral-Reef Committee of the Royal Society, charts, sections and specimens, illustrating some of the results of the investigations carried on in the atoll of Funafuti (Ellice Group), South Pacific.

Prof. Poulton, F R.S., showed insects captured in Canada and some adjacent States during a visit in connection with the meeting of the British Association in 1897. The insects in this collection are not of any special interest on account of rarity, but they serve to convey an impression of the general characteristics of this section of the fauna by which the traveller is surrounded as he proceeds, at the time of the year indicated in the labels, across the American Continent on a line not far distant from the Canadian southern boundary. The general similarity of the Lepidoptera to those of Europe is remarkable. Attention is directed to the geographical data on the small printed labels. The cases are arranged so that the left hand represents the westernmost locality (Vancouver Island), the right hand the easternmost (Quebec).

Dr. H. Gadow, F.R.S., and Mr. W. F. Blandford exhibited a series of models, illustrating the composition of vertebræ in the various groups of vertebrata.

Prof. T. Rupert Jones, F.R.S., and Mr. J. Ballot showed a series of large stone implements, collected by Sidney Ryan, Esq., from the tin-bearing gravels of the River Embabaan, in Swaziland, South Africa.

Mr. Alan A. Campbell Swinton exhibited (1) experiments upon the circulation of the residual gaseous matter in Crookes' tubes. Radiometer mill wheels are employed to detect the direction and velocity of the gaseous streams, and the experiments indicate that in very highly exhausted tubes of the focus type, in addition to the well-known negative stream from the kathode, discovered by Crookes, there exists also a positively electrified stream from the anode, which travels in the opposite direction to the kathode stream, and is exterior to the latter. Mill wheels of various forms and of both non-conducting and conducting material show these effects. (2) Röntgen ray camera, showing the position, dimensions and form of the source of the X-rays in a Crookes' tube. (3) Kathode ray lamps. The kathode rays from two concave kathodes placed opposite to one another and supplied with an alternating electric current of about 20,000 volts pressure, are focussed upon a button of refractory material, which is thus raised to a very high temperature and becomes brilliantly incandescent. The efficiency in terms of the amount of light produced for a given quantity of energy supplied to the lamp, appears to be much superior to that obtained in ordinary incandescent electric lamps, and under suitable conditions may even exceed that of the arc.

Mr. J. Wimshurst showed improved apparatus for holding, and for the excitement of Röntgen ray tubes; Mr. Killingworth Hedges, specimens of copper rapidly deposited at high current densities; and Prof. J. P. O'Reilly, a set of fourteen original coloured drawings of the principal cromlechs existing in the vicinity of Dublin. The drawings being plans and sections to scale, tend to show that the cromlechs in question were oriented truly: (*a*) either as regards their side walls (Druid's Glen) (Shankell), or (*b*) present in their arrangement indications, which point to bearings either N. by S. and E. by W., or to the points of the summer and winter solstices; or, as the case of the Glen Druid Cromlech, an inclination of the cap stone marking the altitude of the winter sun at the solstice (14° approx.), and consequently tending to prove that the cromlechs were designed, amongst other uses, to allow of astronomical observations being made with a view to the determination of fixed periods of the year or commencements of seasons.

The Rev. Walter Sidgreaves, S.J., showed the spectrum of Mira (*o* Ceti) compared with the spectra of other stars of Secchi's third type; and Mr. K. J. Tarrant, photographs of electrical discharges.

Mr. W. Ellis, F.R.S., showed smoothed curves of sun-spot frequency (Wolf), compared with corresponding curves showing the variation in diurnal range of the magnetic elements of declination and horizontal force from observations made at the Royal Observatory, Greenwich. A graphical representation of the periodical variation in frequency of sun-spots, and of the amplitude of the diurnal magnetic movement. The average length of the period is about eleven years, subject, however, to a variation of one or two years or more, which the sun-spot and the magnetic curves alike exhibit. There is also a corresponding variation in intensity at the different epochs of maximum effect.

Mr. R. B. Roxby had on view specimens of "Naturographs" (prints produced by Dr. Selle's process of photography in natural colours).

Mr. C. V. Boys, F.R.S., showed phase reversal and silver zone plates made by Mr. R. W. Wood, of the University of Wisconsin. These plates are made with 230 zones. In consequence of the great number, their equivalence to a lens in image-making is very complete. Some are printed on bichromated gelatine. These are stated to be "phase reversal," *i e.* the thickness is such that alternate zones are in opposite phases, so the whole surface is operative. Two of these, of about 70 and 13 cms. focus, are mounted as a telescope, and show a magnified image of incandescent electric lamps. Others are photographed upon metallic silver by coating a deposited film on glass with bichromated gelatine, exposing, washing, exposing to iodine, dissolving with "hypo," and finally washing off the remaining gelatine when the lines acted upon by light are left as bright silver, the rest being transparent glass. One is elliptical, with axes in the ratio of $\sqrt{2}:1$. If this is placed on the hypothenuse of a right-angled prism with Canada balsam, it will give images due to the difference of phase between the light totally reflected and that metallically reflected on alternate zones.

Three photographs, taken with some of the plates, were exhibited.

Dr. Armstrong, F.R.S., exhibited coloured photographs of Yellowstone Park, U.S.A., by Mr. F. Jay Haynes, of St. Paul, Minn.; Mr. A. E. Tutton, an interference dilatometer of increased sensitiveness; and Mr. Edwin Edser, apparatus exhibiting peculiarities of interference fringes when formed between silvered surfaces. When interference bands similar to Newton's rings are formed with monochromatic light between two partially silvered surfaces, the appearance presented is that of narrow sharply defined bright bands separated by broad dark intervals. When the light used consists of two different wave-lengths (such as that from a Bunsen burner into which some salt of sodium has been introduced) the interference bands become alternately double and single as the distance between the silvered surfaces is increased. This principle has been used by MM. Fabry and Perot to confirm Michelson's results as to the homogeneity or otherwise of spectral lines incapable of resolution by spectroscopic methods.

Mr. Edwin Edser and Mr. C. P. Butler showed a simple interference method of calibrating a spectrometer. Two pieces of plate glass, each thinly silvered on one surface, are placed with these surfaces parallel and very nearly in contact. This arrangement is placed immediately in front of the collimator slit of a spectrometer. A ray of slightly convergent white light being directed on the slit through the air film between the silvered surfaces, the resulting spectrum consists of bright bands separated by dark intervals. If the wave-lengths corresponding to any two interference bands be known, that corresponding to any other band can be calculated or determined graphically with great accuracy. It is proposed to use such a system of interference bands as a reference spectrum, to facilitate the reduction of prismatic spectra in terms of wave-lengths.

Prof. W. C. Roberts-Austen, C.B., F.R.S., exhibited apparatus to illustrate M. Daniel Berthelot's interference method of measuring high temperatures. One of the beams of light in an interference apparatus traverses a heated porcelain tube, and the other beam traverses a tube of equal length containing rarefied air. When interference takes place it indicates that the air in the two tubes is equally rarefied, and therefore the temperature of the heated tube can be calculated from the pressure of the air in the other tube. The interference apparatus employed is that exhibited by Messrs. Edser and Stansfield at the conversazione last year. Prof. Roberts-Austen also showed a complete installation of apparatus for the microphotography of metals.

Mr. A. Stansfield exhibited (1) experiments of showing an exception to the law of Magnus; (2) a method of demonstrating the existence of an allotropic change in iron. An electric current may be generated by heating unequally a circuit composed of a single metal, if very steep temperature gradients are maintained in the wire of which it is composed. The Thomson E.M.F. must therefore be abnormal under these conditions. Experiments were arranged to demonstrate this in the case of platinum and other metals, and to show readily the allotropic change which takes place in iron at about 800° C.

Dr. Alexander Muirhead and Prof. Oliver Lodge, F.R.S., showed improvements in Hertz-wave space-telegraphy; Prof. Ewing, F.R.S., a magnetic balance for permeability tests of iron; Mr. J. E. Stead, specimen and photographs illustrating the crystalline structure of iron and steel; and Mr. Joseph Goold, experiments in relation to resonance.

An exhibit by the Hon. C. A. Parsons consisted of (1) one of the earlier Parsons steam turbines of three-horse power driving a dynamo; speed of working, 12,000 revolutions per minute; (2) photographs of the *Turbinia*; (3) screw propeller cavitating the water, the atmospheric pressure being removed from the surface by an air-pump. A small screw propeller is driven by an electric motor at a speed of 1000 revolutions per minute within a tank in the form of a hollow oval ring, around which the water flows under the action of the propeller, the conditions of flow resembling closely those in the case of an ordinary screw propeller driving a ship. The illumination is effected by a beam from an electric lamp reflected from a mirror attached to and rotating with the screw shaft, and again reflected on to the propeller by a concave fixed reflector. The propeller thus illuminated appears stationary, and the cavities in the water formed by and around the blades can be clearly seen or photographed. To facilitate the formation of cavities, and to reproduce the conditions of very fast ships at convenient speeds for observation, the whole of the atmospheric pressure is removed from the upper surface of the water by an air-pump. The pressure then remaining to hold the water together is that due to the head of water above the screw, plus capillarity. The relation holding between the model and screws on fast ships, with the same slip ratio, when cavities are formed appears to be—lineal speed of blade varies as the square root of the total pressure holding the water together.

Prof. W. A. Herdman, F.R.S., and Prof. R. Boyce, exhibited healthy and unhealthy green oysters, showing the causes of the coloration, and the connection between oysters and disease.

The Marine Biological Association had an exhibit showing the adaptations of marine animals to their environment, illustrated by living examples of the higher Crustacea.

The Joint Permanent Eclipse Committee and Eclipse Commission of the British Astronomical Association showed photographic and other observations made in India at the total solar eclipse of 1898, January 22.

Prof. Sherrington, F.R.S., exhibited specimens of sensorial organs, illustrated by the microscope.

Sir Richard T. Thorne, F.R.S., and Dr. Copeman had an exhibit illustrating the bacteriology of calf vaccine lymph.

Mr. Horace Seymour, Deputy Master of the Mint, exhibited a case of medals bronzed by Japanese methods. Various solutions are employed by the Japanese for this purpose, but "rokusho," or verdigris, is the main constituent of most of them. The medals shown are the result of experiments made in the Mint with a view to reproduce Japanese effects.

Dr. Russell, F.R.S., showed pictures taken on photographic plates by vapours from certain metals and certain organic bodies.

Sir David Salomons, Bart., exhibited the pseudoscope for producing stereoscopic effects by means of a single picture.

Prof. Unwin, F.R.S., exhibited apparatus for indentation tests of metals. The relative hardness is measured by the indentation per ton per inch of knife edge.

Dr. MacMunn showed microscopic preparations illustrating the structure of the digestive gland of Mollusca and Decapod Crustacea.

Electrical recording apparatus was shown by Prof. H. L. Callendar, F.R.S.

Mr. C. T. R. Wilson demonstrated production of cloud by the action of ultra-violet light. When the light from an arc lamp is brought by means of a quartz lens to a focus within a vessel containing moist, dust-free air, a bluish fog gradually develops along the path of the light. The effect is entirely prevented if the ultra-violet rays be cut off by interposing a sheet of glass or mica, no cloud or rain resulting under these conditions even when supersaturation is brought about by sudden expansion. Possibly the small particles which give rise to the blue of the sky are produced by the ultra-violet rays of sunlight absorbed in the upper layers of our atmosphere.

Prof. Oliver Lodge, F.R.S., exhibited improvements in magnetic space-telegraphy. The discharge of a condenser or Leyden round a large wire coil sets up an alternating magnetic field, which excites induced currents in another distant condenser-circuit tuned to the same frequency, causing the second Leyden either to overflow into a coherer, or to disturb a Rutherford detector or a telephone so as to give a signal.

The detector shown was a special series of small free coils and granular microphones, each coil in a permanent magnetic field and so connected to the microphone of the next that a very feeble alternating current in the first of the series is able to make a telephone in the last emit a loud sound, or, through a Langdon-Davies relay, to ring an electric bell and work a Morse sounder. A tone-telephone was also shown, which acts as a highly syntonised "call."

The magnetic vibrations in the sending current can be maintained in various ways, but the way shown is a device due to Dr. Pupin, with a vibrating string and battery contact. A signalling key enables the ordinary Morse alphabet to be sent without any connecting wire, and independently of obstacles. It may be regarded as, in some respects, a modification and improvement of the induction method of telegraphy inaugurated by Mr. Willoughby Smith and practised by Mr. Preece; but, with suitable circuits, the tuning must be nearly exact to evoke much response, and with enough copper in each circuit there is no assignable limit of distance.

Prof. A. Barr and Prof. W. Stroud exhibited range-finders.

THE PRESENT POSITION OF SOME CELL PROBLEMS.

DURING the last two decades or so a new branch of science has been quietly, but rapidly, working its way from a position of comparative obscurity to one of considerable importance. This new-comer has been designated Cytology, and it embraces as its province that department of knowledge which centres around the cell, whether this body be regarded from its structural or from its functional aspect. And cytology, which is still a young offshoot both from botany and zoology, possesses one strongly marked advantage, viz. that of providing a common ground on which the botanist and the zoologist may still meet to discuss questions of equal interest to each. For in dealing with the cell we are approaching facts and phenomena which are essentially shared or exhibited by animals and plants alike, and, indeed, the measure of their relative importance can be gauged by the degree in which they reappear in each of the two great divisions of organic life; although in most other respects the animals and plants have followed widely diverging paths of development.

The cell was long ago recognised as the structural unit of an organism, but the relations of its various parts to one another were overlooked or misunderstood, and we are still far from arriving at a satisfactory solution of the difficulties which each investigator meets when attacking the problems presented by any special case; nevertheless, some general facts have been discovered which serve as landmarks to guide future exploration.

In all but the very lowest forms of life, and in some others which are probably degenerate, we recognise clearly enough that the protoplasm of an organism contains one or more nuclei within its substance. Commonly, though by no means invariably, each nucleus is associated with a definite mass of protoplasm which is segregated, more or less strictly, from the rest by means of membranous partitions. These partitions are not, however, necessarily always present. Some animals, and many of the lower plants, possess a protoplasm in which are distributed large numbers of nuclei, which thus appear to lie embedded in a common matrix. Instances of this are seen in *Vaucheria* and in the embryonic stages of *Peripatus*. But although the nuclei are thus scattered, there is a considerable body of evidence to show that their respective spheres of influence are tolerably clearly defined, just as are those of different countries, even when these are not delimited by obvious boundaries like rivers or mountain ranges.

On the other hand, just as there are roads and traffic between two neighbouring countries, so it has been shown by several observers that even where the "cells" are separated by walls from each other, the adjacent protoplasms are often connected by fine threads of the living substance which traverse the intervening cell walls. The phenomenon seems to have been occasionally seen without apparently its importance being realised, but Tangl clearly demonstrated it for plant cells (Endosperm) almost twenty years ago. Since that time the investigations of Gardiner, Kienitz-Gerloff, and others have shown that what were once thought to be merely isolated cases may possibly turn out to form rather the rule than the exception. There can be but little doubt that the improved uranium-osmium method of Kolossow, which has recently been employed with considerable success by Gardiner, will materially extend our knowledge in this direction, and will confirm what most of us have for a long time held, that the difference between such a plant as *Caulerpa* and the ordinary multicellular forms is rather one of degree, the result of specialisation, than one of kind. Thus during the germination of some algæ, certain of the *Fucaceæ* for example, the embryo exists for a considerable time in a multinucleate condition, the cell walls only appearing at a later stage. The same is also seen during the development of the endosperm in a flowering plant, and still more strikingly during the germination of the spore of *Isoëtes* or of *Selaginella*. The occurrence of a stage in the development of many plant tissues, during which the constituent cells are sliding past each other in adjacent rows, is seen to furnish no real argument for a protoplasmic discontinuity at this period, when it is remembered that not only are the walls still soft, but that they actually contain a nitrogenous body which is almost certainly protoplasm in their substance. On the animal side also evidence is not lacking to show that in some of the higher forms, at least in the earlier stages, protoplasmic continuity is of frequent occurrence; and it also obtains, according to Schuberg and others, between the cells of some tissues in the adult animal.

Nevertheless, the want of such a continuity in nerves, *e.g.* in the ganglionic cells, suffices to show that it is unsafe to generalise on *à priori* grounds too freely, for it is in nerves, perhaps more than in most other tissues, that a direct continuity might have been expected. And it is the more necessary to emphasise the lesson derived from a study of the histology of nervous tissues, inasmuch as a continuity of protoplasm has been generally assumed to exist in the tissues of motile organs of plants, on purely physiological grounds, although it may not have been demonstrated histologically.

The *rôle* played by the nucleus in influencing or in determining the mode of special activity manifested by its attendant protoplasm is one of great interest, and a great deal of light has been thrown upon it within recent years. Haberlandt and others have clearly shown that in cases where metabolism was more active in one region of the cell than in another, the nucleus commonly migrates to this locality. Beautiful examples of this may be observed during the thickening of the walls so frequently met with in the protective layer of seeds or fruits. Thus if the development of the seed of the common night-shade (*Solanum Dulcamara*) be followed, it will be seen that in the young stages of the large cells which ultimately give rise to the hard shell of the seed, the nucleus occupies a central position. Later on, the nucleus becomes lodged in close proximity to the inner wall of the cell, and this then begins to thicken. This deposition of thickening substances spreads to the lower (or inner) parts of the lateral walls; whilst their outer portions, as well as the whole of the external wall, which is remote from the nucleus, remains thin. Again, it has been observed by Istvanffi that when the hypha of a fungus is about to branch, the nucleus is discoverable at a spot just beneath which the outgrowth is about to arise.

The well-known and highly characteristic appearance of the large nuclei met with in tissues the cells of which are in an active state of division, is all evidence of the important influence of these bodies over the process. So also is the fact that those cells which are the last to lose the faculty of resuming an embryonic condition (*i.e.* of giving rise to fresh tissues) retain these nuclear peculiarities longest. This point is well brought out in a study of the cells of a growing root, for it is easily seen that those which form the layer known as the pericycle keep the primitive appearance of their nuclei the longest, and it is in this layer that the new structures, the lateral roots, when they occur do actually originate. Again, when new structures are about to be formed from tissues already adult, or even senescent, the first obvious sign of the new impulse is detected in a change in the nuclei of the cells, a change which depends as much on chemical as on physical differences. In cells which are secreting, whether belonging to animals or to plants, the nuclei are observed to pass through a remarkable series of changes, which may even result in the temporary differentiation of the peculiar so-called *chromatic* elements, resembling if indeed not identical with those appearing during nuclear division. Much the same is to be seen in the huge nuclei often present in the "foot cells" in an animal testis, around which the young immature spermatozoids cluster in groups, apparently deriving from the chemical activity of these cells the nourishment requisite for the completion of their development.

Even more conclusive evidence as to the close relation between the metabolism of the external protoplasm (conveniently distinguished as *cytoplasm*) and the nucleus is furnished by the different behaviour of nucleated and non-nucleated fragments of protoplasm respectively. It is quite possible, by taking appropriate measures, to vivisect a single cell, so that one portion shall contain a nucleus and the other not. The former half commonly regenerates itself, and if derived from a plant cell, forms around itself a new cell wall; on the other hand, the non-nucleated fragment sooner or later perishes, although it may continue for a time to exhibit normal vital functions. Usually, however, it is able neither to secrete on its surface a membrane, nor to engage on constructive metabolism.

But interesting and suggestive as are the relations which can be discerned between the cytoplasm and the nuclei of cells in a condition of comparative repose, they are almost eclipsed by the wonderful series of changes which recur with surprising uniformity each time the nucleus and the cell divides. Nor is it always easy correctly to estimate the relative importance of the various structural elements which are involved or concerned in the process.

Of late years we have heard a great deal about a minute particle which is present, sometimes in the nucleus, oftener in the external cytoplasm, and which is by many assumed to play the part of a directive agent in the matter of nuclear division. This body, known as the Centrosome, was first brought into prominence by the researches of Van Beneden on the developing eggs of *Ascaris*, and it has since been recognised in an enormous number of animals, and also in the cells of some plants.

The centrosome is frequently a body of extraordinary minuteness, and it is most easily recognised during certain stages of nuclear division, on account of the central position which it occupies with respect to the radiations which accompany the process.

It has, however, been identified in many cells which are in a state of repose, as a minute particle which may or may not be surrounded by differentiated zones of specialised protoplasm, though it is certain that in many cases this appearance is due merely to a diffraction-phenomenon. Furthermore, it is not unfrequently observed that its division precedes any change in the nucleus, and that when the division of this latter body is approaching, the two daughter centrosomes diverge from each other, each situated in a definite protoplasmic mass and forming one of the two poles of the spindle structure which arises during the process of karyokinesis.[1] Sometimes, indeed, this spindle structure is seen to be spun out, as it were, between the two centrosomes at the moment of their separation, and to grow as they move further apart. Even more important, perhaps, than these observations was the statement made by Fol, that during the process of fertilisation both the male and female cells contributed a distinct centrosome, each of which then divided, and the half of the one then fused with the corresponding half of the other, a proceeding to which he gave the name of the Quadrille of the Centrosomes. This statement, which was supported by precisely similar statements on the part of Guignard for plants, as well as by other zoologists, has, however, proved to be due to misinterpreted or mistaken observation. It is quite certain that at present there is no really authenticated example of such a proceeding occurring either in plants or in animals, although a glance at many modern text-books testifies to the hold which these erroneous accounts have taken on receptive minds.

In the enthusiasm to which the first discovery of the centrosome, and its subsequent identification in so many kinds of cells, gave birth, it has not always perhaps been sufficiently remembered that *post hoc* by no means necessarily implies *propter hoc*; and that neither its reappearance at the period of karyokinetic activity, nor yet its observed persistence through the resting stage in some cells, are of themselves sufficient to establish its claims to be regarded as the *primary directive agent* in bringing about a nuclear division. Supposing, however, that it could be shown to be really possessed of all the occult powers which have been claimed for it by its numerous devotees, the main result would be to remove to an immeasurably greater distance all chance of penetrating more deeply into the mysteries of cell life. For its very minuteness renders it almost immune from the critical gaze of the curious.

Possibly some light may be thrown on the method of action (if indeed it really possesses any at all) of this enigmatical body, by a consideration of some of the cases in which it cannot be said to exist at all. For some years past it has been known (and the number of examples has been recently multiplied) that in certain plants the nuclear division is not inaugurated by the appearance of two diverging centrosomes, which could occupy a definite position with regard to the radiations at this time visible in the protoplasm. On the contrary, radiations start out from many centres in the cell, and run in various directions, though with a general tendency towards the nucleus. Later on these numerous centres become, so to speak, polarised, and commonly come together at two principal points occupying opposite ends of the cell. Thus a final condition of affairs is reached, resembling the more regular arrangement obtained by the centrosome mechanism (Figs. 1 and 2). What starts these radiations in the first instance? It is difficult to imagine them to be otherwise than due to a chemical change in the protoplasm, or of some of its included substances, and this view is strengthened by the observations made by Hertwig and others on the stimulating and modifying action of drugs, such as quinine or strychnine. Morgan, by merely altering the salinity of the sea-water, was able to produce centrosomes and radiations at will, and the irregularity in number and size which they displayed was just such as might have been expected, on the hypothesis here advanced.

These observations—and many similar ones could be cited—go to show that the impulse to division, which some have tried to identify exclusively with the centrosome, is more probably dependent on the condition of the protoplasm as a whole. It is quite probable that, as in so many other cases, the stimulus may be at bottom a chemical one, connected with the elaboration of some substance producing the disturbances which result in the formation of the machinery for cell division. It is even possible that the substance may, in the more specialised cells, or in those of rapidly dividing tissues, be aggregated into a mass which assumes the manifold appearance that one finds in the centrosomes, centrospheres, and so on. From what we know of protoplasm it would hardly be surprising if this were so. Carbohydrate can be stored as starch, to be again lost to sight as sugar, &c.; why not the substance which may be supposed to be capable of reacting with the rest of the protoplasm in the

Fig 1

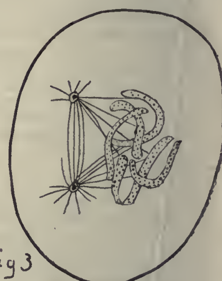

Fig 3

Fig. 2

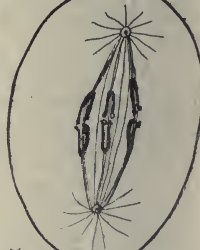

Fig. 4

production of the karyokinetic phenomena? But this is a very different thing from considering the centrosome as a sort of autocrat presiding over the destinies of the cell, as its more enthusiastic supporters have claimed. It would not even be necessarily a *permanent structure* inaugurating the cell changes, but would represent a substance, which might merely be formed *ad hoc*, and which, after the period of activity, might either lose its identity—sinking to the general level of the substances contained in the protoplasm—or if present, in sufficient quantity, over and above what proved to be needed for a given occasion, it might remain as a formed substance to be used up later.

There is a large body of evidence to show that, when present, it is intimately associated with the processes of nuclear division, though whether in an active or passive connection it is difficult, perhaps impossible, to say. Certainly, taking the most favourable view as to its autocratic powers, it can effect nothing unless the protoplasm be ready to receive it. The centrosome of a spermatozoid introduced into a ripe egg may become the centre of a system of radiations, but none are produced if the ovum happens to be immature. And on the whole, especially in view

[1] A word used to signify nuclear division, introduced by Schleicher; it is equivalent to the term *Mitosis*, employed by Flemming.

of the behaviour of those cells in which no centrosomes have been discovered in spite of infinite toil having been spent on the attempt to prove their existence, it seems more probable that they are not to be regarded as morphological structures ranking with nuclei or plastids, but at most as consisting of matter which may be condensed to a granular form, or which may be present or be manufactured in a state diffused through the protoplasm. Indeed this matter may perhaps not be inappropriately compared with zymogens, which, when suitably acted upon, liberate substances capable of exerting an influence altogether incommensurable with their amount on materials within the scope of their power. But no one would probably go so far as to elevate a lump of zymogen, if it could be shown to exist in a given cell or tissue, to the rank of a cell organ, any more than most people regard the elaborated spindle fibres as representing anything but a specialised phase of protoplasmic structure, at most temporarily differentiated from the rest of the cell substance, and destined, sooner or later, to be re-absorbed into it, although the remains of some spindles persist long after the cells in which they were formed (*de novo*) have completed their division.

Having briefly glanced at the centrosome, we may pass on to consider some of the more important peculiarities connected with the actual process of division of the nucleus. And, first, we will consider the mode of the formation and division of those remarkable structures—the chromosomes. During its resting state, a nucleus presents a granular or spongy appearance, and is commonly seen to contain one or more refractive bodies—the nucleoli. As the stages of approaching division are passed through, a substance (which can be identified also in the resting state), known as the chromatin, begins to assume a growing importance. This substance, which consists largely of nucleic acid, aggregates along more or less definite tracts of the colourless and less stainable matrix (linin) within the nucleus, and finally nearly all the linin is used to provide a substratum in which the chromatin is embedded. This linin scaffolding assumes the appearance of a much convoluted thread or threads, and, owing to the predominance of the chromatin, its existence is easily (and often) overlooked. The thread then shortens and thickens, and eventually breaks transversely into a definite number of segments constant for the particular species. Meantime the well-known *spindle* is formed, and the chromosomes become arrayed around it (Figs. 2, 4). They are now seen to split longitudinally, and finally the two halves separate, passing to opposite ends of the spindle, where they help to reconstitute the daughter-nuclei which arise in this way. Now, since the original chromatin-containing thread appears to be symmetrical about its long axis, it is clear that there exists no obvious grounds for assuming that the two groups of chromosomes, which have ultimately arisen as the result of a longitudinal fission of this thread, represent anything but the reflected images of each other; and indeed there is a great deal which strongly suggests that the significance of the complicated stages passed through, lies in the ensuring of a qualitatively equal distribution of material to each of the two daughter cells; *quantitative* equality is also secured far more accurately than would probably be the case if each chromosome divided transversely instead of longitudinally.

The reappearance of a definite number of chromosomes, as well as *à priori* considerations, based on the relations which on good grounds believed to obtain between the chromosomes and the existence of hereditary qualities in an organism, have led many investigators to believe that they are the *same* chromosomes which constantly reappear at each karyokinetic period; although, in the majority of instances, they cannot be recognised in the intervening state of rest between the successive divisions. This view is, perhaps, hardly sufficiently warranted by the facts, and some of its warmest supporters have been obliged to take refuge in expressions such as a "physiological persistence"; a sort of persistence which may be entertained as a pious opinion, but which, when one tries to rigorously define it, proves as elusive as metaphors usually are.

But the chief interest which centres in the chromosomes depends on the remarkable part played by these bodies in connection with the reproductive processes. Since every act of fertilisation consists essentially in the union of two cells and of their contained nuclei, it is clear that the resulting nucleus will possess twice as many chromosomes as that in each of the cells which have fused together. And if this is repeated in consecutive generations it is obvious that the chromosomes, increasing in geometrical progression, will soon become too numerous to be contained within the limits of any one nucleus. Hence the necessity of a reduction in their number at some period between each act of fertilisation. This reduction regularly occurs, and always happens at a definite period in the history of the organism, although the exact epoch may differ considerably in different groups of plants or animals.

A considerable discussion has arisen as to the exact significance to be attached to the process, over and above the bare fact of the halving of the number of the chromosomes. Some have tried to show that variation, so characteristic of animals and plants, is ensured by the distribution of entire chromosomes between the two daughter-nuclei; others have seen in it a return to an "embryonic condition" which renders the act of fertilisation a necessary antecedent to further development; others, including Strasburger, whilst recognising that it is preparatory to fertilisation, and that it indirectly promotes variation by rendering the fusion with another cell possible, regard it as the expression of a return to an ancestral condition which prevailed before fertilisation by the union of two individuals had come into existence. Of the explanations here mentioned the first is the most consistent, or at least is, at first sight, less obviously contradicted by facts than the rest. But, nevertheless, it will be seen that it does not by any means embrace all the well worked-out cases, and therefore cannot be considered as of general application. It will, however, be specially considered here, because it is so often brought forward as a most important argument in support of Weismann's theory of Heredity.

Weismann, as is well known, regarded the hereditary qualities of an individual as closely bound up with certain cellular structures, and he has identified these with the minute particles of chromatin which in the aggregate go to form a chromosome. Each chromosome is conceived of as possessing the material substrata for all the specific characters of the organism, but the arrangement or constitution of these is slightly different in the different chromosomes. The actual course of development, followed by the organism as a whole, depends on the degree in which one or other group of characters becomes predominant, or on the result of a compromise between them.

Clearly, therefore, whilst an organism which had lost half its chromosomes could not be expected to exhibit as many possibilities of variation as one which retained its full number (if development were possible at all under such circumstances), by the elimination of the half, and subsequent replacement of them by corresponding (but slightly differing) chromosomes from another individual, the chances of new variation would certainly, if we accept the premises, be greatly increased.

These views have been worked out in great detail, and they have received quite a remarkable confirmation as the result of the researches of Rückert, Häcker, vom Rath, and others. But, whilst recognising the great interest attaching to the results obtained by these investigations, it is at present quite impossible to regard them as affording more than a local confirmation of Weismann's theories, simply because, although they may possibly bear this interpretation, there are (as already indicated) other cases which even Procrustes himself could not fit into the same bed.

As regards the general character of the "reduction divisions," there naturally exists a certain amount of variety in detail; but in the following summary an attempt will be made to present the more salient and fundamental features of the process. If one takes as an example a higher animal, the reduction divisions are seen to be closely related with the formation of the actual sexual cells—ova and spermatozoa; up to the penultimate divisions the line of cell generations have possessed nuclei with a definite number of chromosomes, which we will designate as $2n$. Then follows a long period of repose and of growth, and when the nuclei of these cells emerge from their quiescent condition, the number of their contained chromosomes is seen not to be $2n$, but only n. That is to say that a numerical reduction has, somehow, been accomplished in the resting period. There is no question here of any chromosomes having been *eliminated*; nothing has been expelled (so far as can be seen) from the nucleus, but there has been a rearrangement. It has been suggested, and the view is stoutly maintained by Häcker and others, that the reduction here is only *apparent*, and that what has really occurred is that the original thread has only, so to speak, broken transversely at every other joint, leaving two chromosomes attached end to end. Each apparent chromosome then would be really double. Be this as it may, these chromosomes behave essentially like those of other preceding cells as regards their fission, dividing longitudinally, as before. But the process is here very complicated, and it is only as the result of very many and careful researches that this fact has been definitely ascertained. Quite apart from the altered (reduced) numbers of the actual chromosomes present, the course of their development deviates so widely from the normal type of karyokinesis in whatever the animal or plant one may happen to be investigating, that it has been designated by Flemming as the Heterotype[1] division.

It has already been stated that some writers hold that no true reduction has occurred at this period, and by them (Häcker, Rückert, &c.), it is termed a *pseudo-reduction*, for they consider that in the next, and rapidly following, division the real reduction occurs. In the latter division it is believed, in the cases investigated, which belong chiefly to the Arthropoda, that a real *qualitative* reduction occurs by the splitting transversely of each of the pseudo-chromosomes, and by the distribution of the halves thus produced to the two daughter-nuclei. In other words, the two genuine chromosomes which remain united as a pseudo-chromosome during the heterotype karyokinesis, now separate from each other, and thus each daughter-nucleus receives half the number of original entire chromosomes, and consequently comes to contain slightly different sets of hereditary potentialities. However this may be for Arthropoda, in which the process is by no means easy to follow, it is certain, as the researches of Meves, conducted under the auspices of Flemming, clearly prove, that such a sorting of chromosomes does not occur during the development of the sexual cells of Salamander, but that the second (and last), like the heterotype division preceding it, passes through a longitudinal-fission stage. And it is equally certain that the same is true, at least, for the higher plants. Ischikawa's recent results with *Allium*, which seem to point to a contrary conclusion, can hardly be admitted as evidence one way or another, since, judging from his own account of the process, he seems to have misunderstood the stages with which he was dealing. And in any case, the existence of numerous exactly worked-out examples in which a transverse fission certainly does not occur, obviously disposes of any attempt to make it serve as the basis for a general theory of the mechanism by which variation may be supposed to be secured.

In spite of all the efforts which have been made, we are still without a certain clue to the meaning of the reduction. Unquestionably Weismann's view, which has been supported by Häcker and others, offers the most attractive solution of the puzzle; but, as has been pointed out, it clearly will not explain the facts in all cases. Others believe the essential feature to lie in the sudden reduction in the amount of chromatin consequent on two so rapidly consecutive divisions But the divisions do not invariably succeed each other with no intervening period of rest. Strasburger has suggested that it represents a return to an ancestral pre-fertilisation state, and it is possible that there may be found to be some probability for this. But against it is to be set the question why organisms with different numbers of chromosomes in their nuclei always halve that number, whatever it may happen to be, and do not all come to possess a common number of reduced, and consequently of duplicated chromosomes, for even closely related forms often differ widely in this respect. However we explain it, it seems clear that no theory which depends on the continued permanence of chromosomes can be admitted. Each one of the reduced number cannot be compounded of two original ones, as such, but must be a new structure; else it is obvious that we have no real reduction at all, but only a series of pseudo-reductions—a view which would soon land us into an impossible position. But if the chromosomes are not really permanent structures, then the whole process of the two divisions of which we are speaking, resolves itself into a mechanism which, whilst providing for a halving, provides equally for an accurate distribution of the halved substance between the two final daughter-nuclei. And although the acceptance of such a view of the matter would involve a modification of those opinions shared by many as to the nature of the architectural configuration of the hereditary substance, in accordance with which discrete particles of it are commonly assumed to be associated with definite hereditary qualities, still the alternative hypothesis by no means negatives the possibility of regarding heredity as the outcome of the constitution of some such substance taken as a whole. The qualities of the organism would depend on the structure of the material basis, just as the structure of a crystal—to use an old illustration—depends on the ultimate configuration of the constituent molecules. An analogy of this sort is perhaps not worth much—it is a comparison of a relatively simple with an infinitely complex case—but still we are more likely to make a definite advance by arguing, even imperfectly, from things of which we know something, than by abandoning ourselves to phantasies which are intangible, and consequently incontestible.

During the course of a nuclear division, there are few phenomena which are more striking than the genesis and mode of operation of that extraordinary structure known as the achromatic spindle. This body provides the framework for the whole process, as well as the machinery by which it is effected. It originates in many different ways, and exhibits various degrees of perfection in different organisms; but the ultimate result attained is much the same in all.

Two extreme types of its modes of origin may be briefly outlined. In the less perfect form, as the period of nuclear division is about to commence, radiations are seen to start out in the protoplasm. Sometimes these are connected with the nucleus itself, but more often they seem to be focussed in groups on many of the granules with which, at this stage, the protoplasm is filled. But there is no sort of order in their arrangement. Later on it is seen, however, that the lines become gradually and with increasing rapidity focussed to two opposite spots in the cell, and then the normal spindle is fully formed. It is idle here to speak of the existence of centrosomes as initiating a process which thus begins so irregularly, and the assumption that they are really secretly existent all the time, and by their hidden activity cause the astral radiations to converge to the two poles, suggests if not a *petitio principii*, at least a revelation derived from some source from which mere mundane minds are debarred.

In the more perfectly formed mechanism, the spindle originates from a definite mass of protoplasm which is intimately related to centrosomes, and consequently it only is formed in this manner when these structures are actually present.

It appears to be, so to speak, spun out between the diverging centrosomes, and either to pass into a groove in the nucleus, or to rope up towards itself the chromosomes which by this time are differentiating. But whatever be the manner of its origin, when it is fully formed it provides a structure upon which the chromosomes are arrayed, and upon which, after the separation of the two halves into which they severally split, the daughter chromosomes travel to the respective poles. In many cases additional fibres can be distinguished which have become attached to these retreating bodies, and thus, by contracting, drag them towards the two ends of the spindle.

The advantage, mechanically speaking, of two poles to which all the achromatic fibres running between them converge, is clearly recognised during the changing conditions of stress and strain which occur during the course of a karyokinesis, and it serves to throw some light on certain phenomena which have attracted less attention than they seem to deserve.

Hitherto the poles have been treated of here as though they were only marked by the convergence of the nuclear spindle fibres; but, over and above these, there are numerous other fibres which radiate into the cell protoplasm, and which may even reach the cell wall. Now, it is a significant fact that these radiations are most apparent during the first formation of the spindle and during the end phases of division, *i.e.* whilst the daughter chromosomes are being pulled up to the poles. Often, as in germinating spores of *Pellia* (a liverwort), they entirely die away in the interval separating these two stages. The whole appearance strongly suggests that the function of these radiations, differentiated out of the cytoplasm, is to steady the poles, and thus render the achromatic framework a rigid one. Indeed without some such arrangement it is difficult, if one watches the process going on, to imagine how the necessary stability would be secured.

When the chromosomes have reached their respective

[1] The chief differences which distinguish the heterotype from other divisions lies in (α) the long period of growth preparation; (β) the relatively early appearance of longitudinal fission in the chromatic thread; (γ) the frequent separation of the halves thus formed at this early stage, and their subsequent approximation to one another of the halves in a variety of ways, *before* they become grouped on the spindle; (δ) the curious and very characteristic appearance of the mature chromosomes on the spindle, sometimes taking that of closed rings, with (commonly) local equatorial thickening, or the chromosome at this stage may, in some forms, assume the form of four spheres, loosely held together, constituting the *vierer gruppe* of the German authors.

destinations, and whilst they are gradually forming into the daughter-nuclei, a curious change usually occurs at the equator of the spindle in the fibres which still stretch across the intervening space between the two poles. The threads become more numerous and present over the area mentioned a thickening of their substance, and by the fusion of the swellings a cell wall, dividing the original cell into two halves, may be formed. And whilst this is happening, there is evidence to show that the fibres themselves, which become strongly arched, are in a state of compression and thus the young wall is stretched to its utmost extent. The plane of equilibrium within the spindle depends on the shape of the cell; and thus at first, and whilst still plastic, one can predict what position it will

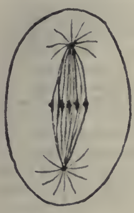

Fig. 5

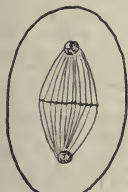

Fig. 6

Fig. 7

take up as regards the existing boundaries of the cell. Indeed the resemblance of such a nascent wall to a soap film has struck more than one investigator, and has been worked out in some detail by Wildemann.

The general relation of cell division to mechanical conditions is well illustrated during the development of pollen cells. In the monocotyledons the original pollen-mother-cell gives rise to the pollen grains by two succeeding divisions with an interval of rest between them. The first karyokinesis is followed by a partitioning of the cell, which is thus divided into two symmetrical halves, often hemispheres. When the latter finally divide, they also are symmetrically partitioned, though this, of course, can (and usually does) happen by means of walls which are not similarly orientated in both of the two first formed cells. In Dicotyledons, on the other hand, in which also there are two successive bipartitions of the nucleus, the appearance of the cell walls is deferred until the full number (four) of nuclei has been produced. And, just as might have been expected, the way in which the actual partitioning takes place is consequently modified. If spherical, as is commonly the case, the quadrinucleated cell is simultaneously divided into four tetrahedral cells by walls converging to the centre at an angle of 60°.

It would be difficult to find an example which more strongly witnesses to the influence of the form of the cell as governing

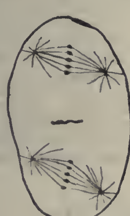

Fig. 8

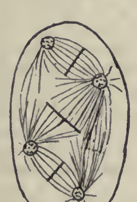

Fig. 9

the disposition of the walls which partition it, than is furnished by the spore formation of a common liverwort, *Fegatella conica*. And as it also illustrates some other points touched upon in the preceding pages, this paper may be fitly brought to a close by a description of the more salient peculiarities attendant on the process. The spore-mother-cell, which ultimately gives rise to four spores, is shaped like an oval box flattened above and below. When its nucleus divides (Fig. 5), the two daughter-nuclei lie in the line of its major axis, and a rudimentary cell wall begins to be formed at the equator of the spindle (Fig. 6), after the fashion already indicated above. But, unlike most structures of this kind, it does not extend to the peripheral walls owing, apparently, to the relatively small size of the spindle. As the two daughter-nuclei pass into the resting condition, the spindle fibres die away, and an interesting change comes over the character of the uncompleted division-wall. It ceases to be stretched out, and becomes somewhat crumpled and obviously thicker, whilst its area correspondingly diminishes (Fig. 7).

Then, after a time, the two daughter-nuclei again divide (Fig. 8), and after this division, resulting in the production of four nuclei, preparations for the real partitioning of the cell begins. Whatever position they may have previously occupied, the nuclei now take up that shown in Figs. 9 and 11; and they are apparently compelled to do so by the action of the radiations, which extend from each one of them into the surrounding cytoplasm. Whilst they are settling down to their final positions, the original cell-plate, above spoken of, is caused to rotate through an angle of 90°, so that it now is parallel with, instead of at right angles to, the major axis of the elliptical cell. Its motion is clearly seen to be the result of a directive action on the part of the highly developed systems of radiating fibres, and when it has turned round it is seen to have lost its thick crumpled appearance, and to have become thin and tense. As soon as it has ceased to cut across the line of protoplasm between the nuclei belonging to opposite pairs, the radiations are seen to arrange themselves into a spindle form, just like that formed between the daughter-nuclei of each pair, a fact of considerable theoretical importance in the elucidation of the genesis of spindle structures generally. In the equators of these two newly differentiated spindles, as in each of the two normal ones, cell-plates are formed, four in all, and they become attached in pairs to the ends of the primary plate, now lying longitudinally in the cell (see Figs. 9 and 10), and thus the partition of the space is completed (Fig. 11). A point of special interest in

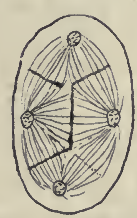

Fig 10

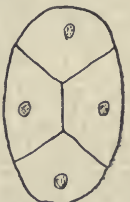

Fig. 11

this case of *Fegatella* lies in the remarkable fact that we here meet with two perfectly different conditions of cell division, and that the transition from the one to the other can be followed in every stage. Theoretical requirements are here demonstrably satisfied in a manner such as we can seldom hope to equal in our attempts to solve the many problems with which cytology has to deal.

J. B. FARMER.

VASCO DA GAMA.[1]

WE are assembled this evening to commemorate one of the greatest events in the history of the world—the discovery of the ocean route to India by the Portuguese. Vasco da Gama completed the mighty enterprise on the day when the ghâts of India were sighted from the deck of his ship just four hundred years ago to-morrow. The credit of this discovery is due to the Portuguese people, to their constancy and heroic perseverance, even more than to the skill and ability of their leaders; and I think that many of the illustrious navigators of Portugal are equal in merit, and should be equal in renown. We contemplate the perseverance of this people and the continuity of their work during a century and a half of mighty effort, rather than a single stroke of genius. Yet it is right that Vasco da Gama, who forged the last link, should have the first place which Camoens has assigned to him, *primus inter pares*.

Prince Henry gave the first impetus, and during a quarter of a century he created a school of seamen who rounded Cape Bojador in 1435, Cape Blanco in 1443, Cape Verde in 1445, and

1 Address delivered before the Royal Geographical Society, on May 16, by the President.

reached the Gambia in 1454. All this was done in the lifetime of the Prince Navigator. At his death the work was continued, with almost equal zeal, by the kings—his nephews—Alfonso the African, Joaõ the Perfect Prince, Manoel the Fortunate. Portugal was indeed fortunate in her sovereigns of the house of Avis, fit guides and leaders of the little hero nation, as Schlegel calls her. The ships of Alfonso reached Sierra Leone in 1462, made a colony at Lamina, on the coast of Guinea, crossed the equator, and sailed as far south as Cape St. Catherine. His son, "O Principe perfeito," sent Diogo de Azambuja to found the castle at Lamina, and Diogo Cam to push southward, until at length the Congo was reached.

The *padraos* were intended to be eternal monuments of Portuguese achievement. They were stone pillars with an inscription, and the arms of Portugal carved upon them—the well-known "cinco chagas," with the orle of the seven castles of Algarve. Each explorer was to plant one on a conspicuous point at his furthest point. The "padraos" were named after saints. That of Santo Agostinho (once planted in 13° 27′ 15″ S., south of Benguela) is now in the museum of the Geographical Society at Lisbon, as well as that once on Cabo Negro, in 15° 40′ 30″ S. Two of these "padraos" were on the arms granted to Diogo Cam, the discoverer of the Congo.

It was the ambition of each successive Portuguese voyager to plant a national monument beyond the furthest point reached by his predecessor. None had been so zealous in this glorious work as the family of Diaz, whose first sailor scions were trained in the school of Prince Henry. Joaõ Diaz rounded Cape Bojador, Dinis Diaz first reached Cape Verde, and Bartholomew Diaz was destined to complete the maritime fame of his family by being the first to round the southernmost point of Africa, planting "padraos" as he proceeded. In 1487, Bartholomew Diaz passed the Table mountain undiscerned amidst the stormy waves, rounded Cape Agulhas, the southernmost point of Africa, and reached the Great Fish river, which he named after his companion, Joaõ Infanta. It was with great reluctance that the gallant Diaz, complying with the urgent entreaties of his crew, shaped a course homewards; and then it was that he first sighted the cape, which received from him the name of Cabo Tormentoso, and which the King changed to the Cape of Good Hope. Covilham, exploring southwards from Egypt, had discovered the whole east coast of Africa as far as Sofala, and had sent a full report from Cairo to King Joaõ. So that there was nothing left to discover, except the bit of African coast from the Great Fish river to Sofala.

The goal was well in sight. The eastern side of Africa had been reached by Diaz, and was known through the report of Covilham. Thence the next explorer would stretch across to the shores of India. King Joaõ prepared for the final and crowning expedition by the building of two suitable ships, which were commenced under the superintendence of Bartholomew Diaz, the ablest and most successful Portuguese explorer of that age. But in 1495 the king died, and the great work remained to be achieved in the reign of his successor, King Manoel ("O Fortunado"), who was at the head of Portuguese affairs for the next fifty-six years. He continued the equipment of the expedition, which had been commenced by his predecessor.

Then it was that Da Gama appeared on the scene. Camoens introduces him—

> "Vasco da Gama, valiant capitayne,
> For deiring do the noblest volunteer;
> Of notable courage and of noble strain,
> Whom smiles of constant fortune love to cheer."

The Da Gamas came of an ancient, valiant, and loyal house, their ancestors having fought by the side of Alfonso III. in the conquest of Algarve from the Moors, and by the side of Alfonso V., "the Brave," at the battle of Salado. Estevan da Gama, their father, was chief magistrate of Sines; and here Vasco and his brothers were born. The little town of Sines is situated in a bay, about half-way between Lisbon and Cape St. Vincent. To the west are the blue waves of the Atlantic, but to landward an undulating sandy plain extends for several leagues. On the north side of the bay there is a granite ridge running out into the sea, and on the top of the cliff there is a small church built by Vasco da Gama towards the end of his life.

The four sons of Estevan da Gama appear to have been born and brought up at Sines; but I believe that little or nothing is known of them before the date of the great expedition. The two ships had been built, the *Sam Gabriel* of 120 and the *Sam Rafael* of 100 tons; another vessel was purchased from a Lagos pilot named Berrio, and named after him; and a provision-ship of 200 tons was also got ready. Then it was that Vasco da Gama was selected by King Manoel to command the expedition. He was not more than twenty-eight years of age. His eldest brother, Paulo, was equally fitted for the post, and he insisted upon accompanying and serving under Vasco, in command of the second ship. They both looked upon Nicholas Coelho, who was captain of the *Berrio*, as their brother.

Paulo da Gama was one of the kindest and most lovable of men, and his presence in the fleet was an influence for good. The best trait in the character of Vasco was his love for and devotion to his elder brother.

All things were prepared for the great enterprise, and the ships were ready in the Tagus. The beautiful church of Belem was not then built on the beach of Restrello, but Vasco da Gama passed the night before his departure in prayer in a little chapel which had been erected there by Prince Henry. He embarked next morning, and the expedition sailed on Saturday, July 8, 1497; there were about 160 souls all told. Six *padraos* were taken out, to be set up on prominent headlands, but not one of them is now known to exist. The fleet was accompanied by the great navigator, Bartholomew Diaz, as far as the Cape Verde Islands. He was going out in a fast caravel, to take up his command of the new Portuguese settlement of Lamina, on the coast of Guinea.

In December the expedition reached the "Rio do Infante," the furthest point of Bartholomew Diaz on the eastern side of Africa, and entered upon new ground. There was a mutiny at this critical time. The men feared to proceed further, and wanted to return, according to Correa, who adds that Vasco da Gama put the master and pilot in irons for giving the same advice, and threw all their instruments overboard. His brother Paulo induced his crew to obey orders by argument and persuasion, and interceded for Vasco's prisoners. This mutiny is not mentioned in the "Roteiro."

The first experience of the explorers on entering the previously unknown ocean was the force of the current, so strong that they feared it might frustrate their plans, until a fresh stern wind sprang up, which enabled them to overcome it. This Agulhas current was first scientifically investigated by Major Rennell in 1777.

Vasco da Gama passed the coast, which was named by him "Natal," on Christmas Day, and was well received by the natives of Delagoa Bay. He was at Quillimane in January 1498; at Mozambique in March; and he reached Melinde on April 15. There was a terrible outbreak of scurvy off Mozambique, and again on the way home; and then it was that Paulo da Gama proved the guardian spirit of the expedition, giving up all his own private stores for the use of the sick, ministering to them, and warding off despondency by his words of encouragement and by his example.

The King of Melinde supplied the Portuguese with an Indian pilot, a native of Gujarat, and on April 24 the voyage was commenced across the Indian Ocean, from the east coast of Africa to Malabar. Before starting, Vasco da Gama, with the hearty concurrence of the King of Melinde, set up one of the *padraos*, with the escutcheon of the *Quinas* carved on one side, and a shield bearing a sphere on the other. Beneath was King Manoel's name. It was placed on a hill above the town.

A voyage of twenty-three days brought the adventurous discoverers in sight of the mountains above Malabar—an event which Camoens thus relates:

> "Pale shone the wave beneath the golden beam,
> Blue o'er the silver flood Malabria's mountains gleam;
> The sailors on the maintop's airy round
> 'Land! Land!' aloud with waving hands resound.
> Aloud the pilot of Melinda cries,
> 'Behold, O Chief, the shores of India rise!'
> Elate the joyful crew on tiptoe trod,
> And every breast with swelling raptures glowed.
> Prone on his manly knees the hero fell;
> 'Oh, bounteous Heaven!' he cries, and spreads his hands
> To bounteous Heaven, while boundless joy commands
> No further word to flow."

Then the immortal poet, in words of fire, declares how this mighty deed was done, and by what kind of men:

> "*Not* those who ever lean on ancient strain,
> Imping on noble trunk a barren chain;
> *Not* those reclining on the golden beds,
> Where Moscow's zebelin downy softness spreads;

> *Not* with the novel viands exquisite;
> *Not* with the languid wanton promenade;
> *Not* with the pleasures varied infinite,
> Which generous souls effeminate, degrade;
> *Not* with the never conquer'd appetite,
> By fortune pamper'd as by fortune made.
> *But* by the doughty arm and sword that chase
> Honour which man may proudly hail his own;
> In weary vigil, in the steely case,
> 'Mid wrothsome winds and bitter billows thrown,
> Suffering the frigid rigours in th' embrace
> Of South, and regions lorn and lere, and lone,
> Swallowing the tainted rations scanty dole,
> Salted with toil of body, moil of soul.
> Thus honour'd hardness shall the heart prevail,
> To scoff at honours, and vile gold disdain.
> Whoso shall rule his life by reasons light,
> Which feeble passion ne'er hath power to hide,
> Shall rise (as rise he ought) to *honour true*.
> Maugre his will that ne'er hath stooped to sue."

And thus was the Portuguese empire in India founded by two of Portugal's noblest sons, Vasco and Paulo da Gama. Time will not allow us to linger with them on the coast of Malabar. On March 20, 1499, they cleared the Cape, and returned to Lisbon on September 18. But Paulo da Gama had died at Terceira, in the Azores. Equal to Vasco in heroism and constancy, Paulo excelled him in the more Christian virtues, and was, as I have already said, the guardian spirit of the voyage. When Vasco is remembered, Paulo da Gama should never be forgotten. They are equal in merit, and both equally deserve to have their memories honoured by their country, and by the civilised world.

True to the spirit of perseverance and energy which had led the Portuguese to this crowning success, a large fleet was despatched to India in the year after the return of Vasco da Gama, and in each succeeding year. Vasco da Gama commanded the fourth voyage in 1502, and on his return he was created Count of Vidigueira. Then followed the brilliant achievements of Alfonso d'Albuquerque, who occupied Goa, Ormuz, and Malacca, and established Portuguese power in India on a solid foundation. It was to last unchallenged for eighty years, when the disaster of El Kasr-el Kebir brought on what the Portuguese called the sixty-years captivity.

For twenty years Vasco da Gama was unemployed, living at a house in Evora, the walls of which were painted with figures of Indian animals and plants, and hence the street in which it stood is still called "Rua das Casas Pintadas." Here he brought up a family of six sons; but in 1524 he was called from his retirement to rule over Portuguese India. He went out with a large fleet, surrounded by all the pomp and circumstance of a viceroy, and he died at Cochin, on the scene of his discoveries, on Christmas Day 1524, aged 55.

Vasco da Gama is described as a man of middle stature, rather stout, and of a florid complexion. The portrait, which belonged to Count Lavradio, is given by Lord Stanley of Alderley, in his translation of the account of Da Gama's voyages in the "Lendas da India," of Correa. It is a copy of the portrait in the Museu das Bellas Artes at Lisbon, a photograph from which is given in Ravenstein's "Roteiro." It represents a handsome man, aged about fifty, with a white beard and severe expression, wearing a furred robe, and the cross of the order of Christ hanging from a chain round his neck. *His crest* was a girthed doe trippant, or. *Arms*—chequy of fifteen, or and gules; two bars argent; over all an escutcheon with the *quinas* of Portugal.

Luis Camoens, the great epic poet, is said to have been born in the year that Da Gama died; and Lord Stanley says, I think truly, that the name Vasco da Gama has left in history is due largely to the great genius of Camoens. "The discovery of India," says Schlegel, "the greatest event of modern times, could only be worthily celebrated by one who had himself passed a portion of his life in those regions. A warrior could only thus have written."

"At the proudest moment of that brief but glorious period of Portugal's greatness, one great national song broke forth, like the dying note of the fabled swan, a dirge for the departing hero-nation. The remembrance of her departed glory is enshrined in this immortal work, created by the divine genius of her national poet to immortalise her fame. The exquisite bloom and grace of the diction of Camoens are unparalleled among modern writers." [1]

The most learned and accomplished English traveller of modern times, the late Sir Richard Burton, devoted twenty years of his life to the study and translation of the "Lusiads of Camoens." He declared that he felt a glow of pleasure at having undertaken it—at having lived so long in contact with so noble a spirit as that of his master. He also took pride in the ambition of familiarising his fellow-countrymen with a workman and a work not readily to be rivalled in the region of literature. No single publication extant gives so full and general a portrait of Camoens, his life and his work, as that of Sir Richard Burton, and his translation is undoubtedly the most faithful and the best in our language. The Hakluyt Society, of which I have the honour to be President, has also laboured to make the achievement of Vasco da Gama better known in this country. In 1869 we brought out the "Lendas" by Gaspar Correa, translated and edited by Lord Stanley of Alderley; and this year, with a view to celebrating the present commemoration, we have published the "Roteiro" of the first voyage, which has been ably translated and edited by Mr. Ravenstein.

After the sixty years of captivity came to an end, Portugal rose like a phœnix from its ashes. The old alliance with England was renewed. It was commenced when the founder of the house of Avis, the great King Joaõ of Good Memory married that English princess, who bore him five noble sons, including Prince Henry the Navigator. Since 1640, the year of liberation, English and Portuguese have fought side by side on many a battle-field for freedom, we have formed alliances, and now our royal houses are nearly related. There are many reasons why England should feel warm sympathy for Portugal in the commemoration of the mighty deeds of her sons. The nation of heroic memories has a glorious history to be proud of; and by the commemoration of the discovery of India by Vasco da Gama, we hope that those memories will impress themselves even more strongly than ever on the minds of her sons, leading them on to an honourable and prosperous future. We wish health and happiness to his faithful Majesty, and success and prosperity to our old and tried ally, the noble Portuguese nation.

[1] Schlegel.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—A proposal to establish a final honour school of agricultural science, the examination in which was to be partly of a practical character, with the condition that the candidates must have obtained honours or passed the preliminary examinations in natural science, was rejected by Congregation on Tuesday.

CAMBRIDGE.—Mr. H. Yule Oldham, of King's College, has been appointed Reader in Geography for five years from Midsummer 1898. Mr. A. C. Seward, of St. John's College, has been reappointed University Lecturer in Botany.

The grace for the recognition as a public hostel of St. Edmund's House, established as a place of general education for candidates for the Roman Catholic priesthood, has been rejected by 471 votes to 218.

MRS. ELIZABETH H. BATES, of Port Chester, N.Y., has left, by her will, property valued at 135,000 dollars to the University of Michigan.

A COURSE of six lectures on electric traction, by Prof. Schwartz and Dr. D. K. Morris, was commenced on Tuesday evening at the South-West London Polytechnic, Manresa Road, Chelsea, and will be continued on succeeding Tuesdays.

THE Town Council of the county borough of West Ham have made the following appointments on the teaching staff of the new Municipal Technical Institute: Head of the Chemical department, Dr. Harold A. Auden, of the Owens College, Manchester; Lecturer in Mechanical Engineering, Mr. John Duncan, of University College, Nottingham.

THE fifth annual report of the Technical Education Board, presented to the London County Council on Tuesday, is a document of fifty foolscap pages. It includes a general account of the work of the Board, showing the lines on which the work has been organised, and giving a survey of the provision for technical education which now exists in the metropolis. Several maps are appended at the end of the report, which give a general idea of the character and locality of the various institutions in which technical and scientific education is provided. During the year covered by the report, the Board has continued its policy of attempting primarily to coordinate and develop the provision for technical education made by the various public institutions of the metropolis. In the secondary schools the Board's regulations have lead to a great increase in the number of teachers of science and of domestic economy, while facilities for teaching practical chemistry and practical physics have been provided in the majority of boys' schools, some of which possess first-class physical laboratories and workshops. At the same time, the School Board has done much to equip its upper standard schools with laboratories and appliances for the practical teaching of science. To the polytechnics and the established schools of art, and to many secondary schools, the Board has made annual or maintenance grants. Provision has also been made in two polytechnics for courses of practical work for elementary teachers, and special classes of somewhat similar type have been provided at the cost of the Board in connection with University College, King's College. and Bedford College. Day classes in particular branches of science and technology are, in addition, conducted at some of the polytechnics. The Board contemplates making provision for developing commercial education, and is considering how to advance the interests of electro-chemistry, electro-metallurgy, and other subjects. The "Monotechnic" schools for particular subjects are also engaging its serious attention. When the Board commenced its work in 1893, there were only six polytechnics at work in London; there are now eleven. Last year the Board contributed a sum of 28,129*l*. to these institutions. During the year a total of 117,744*l*. 12*s*. 11*d*. was expended by the Board, leaving a balance in hand of 41,144*l*. 14*s*. The aggregate expenditure and liabilities for the year ended March 31, 1898, may be stated in round figures to be 150,000*l*., but this amount cannot be precisely estimated until all the claims for attendance grants are received. The Board estimates that during the year 1898-99 170,000*l*. will be required for the Council to meet the increased expenditure (possibly amounting to 184,175*l*.) necessitated by the development of the work of the Board.

The Chancellor, Lord Herschell, presided over the annual celebration of the University of London, at the presentation of degrees last week. After congratulating the winners of distinctions he referred to the University of London Bill in the following words:—They were all aware that the Government had introduced a Bill which was to effect a reorganisation of the University, and that Bill had already passed one of the Houses of Parliament. The Government had announced their intention to bring the subject to a discussion and, if possible, to a solution in the House of Commons. On this question there were certain facts which were beyond dispute which it was necessary that they should take into account in estimating the situation as it stood to-day. In the first place there was a very strong public opinion—he might say conviction—that the University work of London needed some fresh organisation. There was also, he believed, a preponderating public opinion that those needs should be supplied, not by the creation side by side of the existing University of another University in London, but by the organisation of that existing University. But when they got beyond this they came no doubt into the region of controversy. There was, however, a further proposition about which they might be quite agreed, and that was this. If there was some further University provision to be made in London, and if it was to be accomplished by the reorganisation of the University of London, it would be utterly impossible to frame any scheme or to produce any solution of the question which would satisfy everybody. There were two points on which there seemed to be some misapprehension. He referred first to the position taken by some that the existing charter gave to the graduates a right which would be infringed if any measure were passed dealing with the University or its reorganisation except with their sanction and consent. That view he held to be quite erroneous. It was quite true that in the existing charter a provision was to be found that no new charter could be applied for by the Senate if Convocation vetoed the proceedings. It was, however, to be observed that the right was given by the charter to Convocation and not to the graduates otherwise than by or through Convocation. The Senate remained the executive of the University, and it was from the Senate that the petition for a new charter must come. Thus it was merely a domestic provision regulating the rights of the Senate and Convocation as between themselves. But since the charter was granted a most important change had taken place. Parliament was not content that the Government of the day should have power to advise Her Majesty to grant a charter to a new University or a new charter to the old University, and consequently every new charter had to be placed upon the table of Parliament; and Parliament had a distinct right of intervention with reference to the grant or refusal of a new charter. It was, therefore, a false attitude to say that the members of that University were in a position to dictate to Parliament what change should take place when it had come to the conclusion that some change was necessary in the public interest. It was Parliament alone which could finally determine such a question.

SOCIETIES AND ACADEMIES.

London.

Royal Society, May 12.—"A Study of the Phyto-Plankton of the Atlantic." By George Murray, F.R.S., Keeper of Botany, British Museum, and V. H. Blackman, B.A., F.L.S., Hutchinson Student, St. John's College, Cambridge, and Assistant, Department of Botany, British Museum.

The authors record their observations on a year's work in collecting phyto-plankton along a track from the Channel to Panama carried out by Captains Milner and Rudge, and also during one voyage to Brazil by Captain Tindall. They also give the results of their own observations on living material at sea. The material was obtained by the pumping method.

One of the objects of their work was to determine, if possible, the nature of the Coccospheres and Rhabdospheres. They describe the minute structure of the calcareous plates or coccoliths and rhabdoliths, and record the existence in the Coccospheres of a single central green chromatophore, separating into two on the division of the cell. They regard Coccosphæraceæ as a group of Unicellular Algæ, and they define the group, the limits of the genera and species. The Coccospheres and Rhabdospheres from the surface are compared with those of the deep-sea deposits and their identity established. They are also compared with geological coccoliths and rhabdoliths from various beds, and many objects regarded by geologists as true coccoliths and rhabdoliths are rejected. A large number of new Peridiniaceæ were discovered and are formally described and figured. No specific diagnoses of marine Peridiniaceæ have previously been published, authors of species having depended on figures, and, at most, a few words of description. It is hoped that the present systematic treatment of the subject will conduce to greater order in the group. The authors record the occurrence of all the forms in seven tabular statements, one for each collecting voyage.

Observations of the diatoms and Cyanophyceæ are also made, and are briefly treated.

A study was also made of the species of Pyrocystis, of which they describe a new one. The facts they record tend, in their opinion, to confirm the view originally expressed of it by Dr. John Murray, its describer, that it is an unicellular alga, doubts having been entertained of the accuracy of this opinion by several biologists.

Zoological Society, May 3.—Prof. Howes, F.R.S., in the chair.—Sir Harry Johnston, K.C.B., made remarks on the larger mammals of Tunisia, and selected for special mention the lion, leopard, cheetah, wild cat, Caracal lynx, hyæna, jackal, Fennec and common foxes, genet, ichneumon, porcupine, Barbary wild sheep, Addax antelope, hartebeest, and three gazelles. He mentioned the possibility of the leucoryx penetrating into Southern Tunisia, and noted the importation into Tunis from Morocco of a baboon (*Cynocephalus hamadryas?*), which was brought there by natives of Morocco. He also commented on the representations of the African elephant as a Tunisian animal in the Roman mosaics.—A communication was read from Prof. Robert Collett containing descriptions of three species of pigeons and two species of parrots from Northern Australia, of which the following were characterised as new: *Petrophassa rufipennis*, *Ptilopus* (*Leucotreron*) *alligator*, and *Psephotus dissimilis*.—A communication was read from Mr. W. T. Blanford, F.R.S., stating his reasons for regarding *Lepus oiostolus* Hodgs. and *L. pallipes* Hodgs. as identical, suggesting that the hare identified with *L. oiostolus* by Büchner was *L. hypsileius* Blanford, and showing that *Macacus rhesus villosus* True was identical with *M. assamensis* McClelland.—A communication was read from Dr. F. A. Dixey, Mr. Malcolm Burr, and the Rev. O. Pickard Cambridge, F.R.S., on the insects and arachnida collected in Socotra by Mr. E. N. Bennett, who had visited that island in 1896 and 1897 in company with the late Mr. Theodore Bent. It was pointed out that though the Socotran lepidoptera showed, as might have been expected, strongly marked African affinities, some of them, by their relation to forms belonging to West Africa and South Africa and the Mascarene group, suggested the conclusion that remains of a more primitive fauna still survived in Socotra.—A communication was read from Miss E. M. Sharpe on a collection of lepidoptera from San Domingo. This was accompanied by field-notes by the collector, Dr. Cuthbert Christy. Ninety-one species were enumerated, of which one—*Telegonus christyi*—was described as new.—A second communication from Miss Sharpe contained a list of lepidoptera lately collected by Mrs. Lort Phillips in Somaliland. Two new species of *Lycænidæ* were described, viz. *Tarucus louisæ* and *Spindacis waggæ*.

Geological Society, May 4.—W. Whitaker, F.R.S., President, in the chair.—The carboniferous limestone of the country around Llandudno, by G. H. Morton. At Llandudno the precipitous Great Orme's Head presents fine sections of the carboniferous limestone and its subdivisions referred to, and may be easily examined in a continuous series of cliffs, ridges, and quarries. The entire succession is, however, not perfect, for the highest beds of the "Upper Grey Limestone" have been denuded, and at the Little Orme's Head the subdivision is altogether absent. Copper-lodes on the Great Orme's Head appear to have been worked by the Romans, and again in recent years until abandoned fully thirty years ago. Some of the lodes are faults, but little can be ascertained about them now, and only two or three are faults with any appreciable amount of dislocation. It is to the undulation of the limestone that the ever-varying dip of the beds is attributed. Numerous fossils occur in the "Upper Grey Limestone," and a few are peculiar to the subdivision and the locality, but of these only a single specimen of each has been found.—The dolomitisation of the carboniferous limestone is remarkable, and almost peculiar to that around Llandudno, though it also occurs at Penmon in Anglesey. The "Lower Brown Limestone" has been almost entirely converted into dolomite, and portions of the overlying subdivisions. The filling of the faults has often been changed into dolomite, and the alteration of the limestone has generally been very capricious: the author's opinion being that the change took place after the dislocation of the strata in post-Triassic times.—The graptolite-fauna of the Skiddaw Slates, by Miss G. L. Elles. This paper deals, not only with the collections of the author, but with the Dover Collection and others preserved in the Woodwardian Museum, with the collections of Prof. H. A. Nicholson, Mr. Postlethwaite, and that of the Keswick Museum of Natural History. An account of the literature, both stratigraphical and palæontological, of the Skiddaw Slates is given, followed by a list of all the graptolites known from the beds. This list comprises twenty-two genera and fifty-nine species.

Entomological Society, May 4.—Mr. G. H. Verrall, Vice-President, in the chair.—Colonel Yerbury exhibited a series of Diptera collected at Hyères during March and April 1898, and including *Brachypalpus valgus*, Panz., *Callicera fagesii*, Guér., and a species of *Platystoma* which appeared to be undescribed.—Mr. Barrett showed aberrant forms of British species of Lepidoptera from Gloucestershire and Warwickshire.—Mr. Waterhouse exhibited two burnished golden beetles, *Anoplognathus aureus* from Queensland, and *Plusiotis resplendens* from Panama, which he stated to be interesting examples of a similar result being attained by a process of natural selection in two species of the same family in widely separated localities. Many members of the family had a slight tendency to show metallic colours. It would be interesting to ascertain whether there were any similarity in their surroundings in the two countries which would make this golden appearance an advantage, or whether it might be considered a "warning colour." Allied species, however, appeared to be edible.—Mr. Walker exhibited specimens of the rare *Philonthus fuscus*, Grav., found in a *Cossus*-eaten poplar in Chatham Dockyard at the end of April.—Mr. R. McLachlan communicated a paper on "Neuroptera-Planipennia belonging to the families Osmylidæ, Hemerobiidæ and Chrysopidæ, taken by the Rev. A. E. Eaton in Algeria."

PARIS.

Academy of Sciences, May 9.—M. Wolf in the chair.—Method for detecting and estimating small amounts of carbon monoxide in air in presence of traces of hydrocarbons, by M. Armand Gautier. The method described in previous papers on the same subject at 60° C. (the action of carbon monoxide upon iodic anhydrides) is here further developed. It is shown that the iodine set free can be determined with great exactness by passing the gases over copper at 100° C.; the loss of weight of the iodic anhydride, and the amounts of carbon dioxide and water produced can also be accurately estimated. Test analyses of known gas-mixtures containing 1 part per 1000, and 1 part per 10,000 respectively, gave very satisfactory results: samples of Paris air taken at different times gave from 0·0 to 0·9 parts CO per million, while the air of the laboratory contained as much as 12·3 parts per million.—On the losses of ammonia which accompany the manufacture of farm manure, by M. P. P. Déherain. The results of the experiments are given in the form of three rules to be followed by the farmer, the chief point being that in presence of an excess of carbonic acid the losses of ammonia are much reduced.—Researches on the progressive development of the grape, by MM. Aimé Girard and Lindet. A series of proximate analyses of the pulp, skins and stones of the grape at various stages in its development.—The modifications undergone by strips of skin in autoplastic grafting, and the conditions which favour their growth in area, by M. Ollier.—On a mode of obtaining cultures and homogeneous emulsions of the human tuberculosis bacillus in a liquid medium, and on a mobile variety of this bacillus, by M. S. Arloing. Minute details are given of the methods of preparing homogeneous liquid cultures and emulsions of the tubercle bacillus. The immobility of this bacillus is not absolutely characteristic, as has hitherto been supposed.—Simple explanation of some celestial phenomena by the kathode rays, by M. H. Deslandres. A recognition of priority of M. Goldstein in his work on kathode rays, and a discussion of the application of this to the solar chromosphere and comets.—On the magnification of the discs of the sun and moon on the horizon, by M. D. Eginitis. The observations of the author show that none of the suggestions hitherto put forward to explain the increase in size of the sun and moon when low down in the horizon are sufficient. They may contribute to the phenomenon to a small extent, but the principal cause is still unknown.—On the explicit determination of differential equations of the second order at fixed critical points, by M. Paul Painlevé.—On the general theory of the characteristics of partial differential equations, by M. E. Goursat.—On total differential equations, by M. Alf. Guldberg.—On the evaporation of iron at the ordinary temperature, by M. H. Pellat. The effect previously shown to be produced upon a sensitised plate is shown to be due to a vapour given off by the iron, and not to any radiations of the nature of uranium rays.—On the kathode rays, by M. P. Villard.—Strengthening the X-rays, by M. Virgilio Machado. The tubular portion of the bulb is wrapped round with metal foil, or with an insulated spiral of copper wire.—The effect of diffusion in developing baths, by M. Adrien Guébhard.—On the limits of inflammability of carbon monoxide, by MM. H. Le Chatelier and Boudouard. Under ordinary conditions gas mixtures containing between 16 and 75 per cent. of carbonic oxide are inflammable. The effects of the size of tube, temperature, and pressure of gas were also studied.—On a boro-carbide of beryllium, by M. P. Lebeau. The substance $C_4B_6Be_6$ is produced by heating an intimate mixture of glucina and boron in a carbon boat at the temperature of the electric furnace.—On some halogen salts of lead, by M. V. Thomas. Treatment with nitrogen peroxide distinguishes between mixtures of lead chloride and iodide, and a true chloro-iodide, only the latter giving the corresponding oxychlorides.—Note on the micro-structure of the alloys of iron and nickel, by M. F. Osmond. The study of the micro-structure of these alloys confirms the classification into three groups based upon their mechanical properties.—Thermal data relating to ethyl-malonic acid. Comparison with its isomers glutaric and methyl-succinic acids, by M. G. Massol.—Formation of furfurol by cellulose and some of its derivatives, by M. Léo Vignon.—Preliminary note on the geographical distribution and evolution of the *Peripatæ*, by M. E. L. Bouvier. The specimens studied were collected in Africa by the late M. Thollon, in whose memory the one new species is named *Peripatus Tholloni*. This species is intermediate between the American forms and those of the Cape.—On the organisation of the *Pleurotomariæ*, by MM. E. L.

Bouvier and H. Fischer.—On the structure and evolution of the protoplasm of the Mucorinaceæ, by M. L. Matruchot.—On the resistance of seeds to immersion in water, by M. Henri Coupin. Seeds differ greatly in their resistance to water, some living about the same time whether the water be renewed or not, others dying much sooner in the latter case.—Contributions to the knowledge of volcanic rocks in the French Alps, by MM. W. Kilian and P. Termier.—On a quaternary tufa recognised at Montigny, near Vernon, by M. Gustave F. Dollfus.—On the land-slip of Saint-Pierre-de-Livron, and the infiltration of layers of tufa, by M. E. A. Martel.—Embryological notes on the migration of spinal ganglia, by M. A. Cannieu.—Contribution to the study of the albumenoid materials contained in cereal and leguminous flours, by M. E. Fleurent.—On the periods of treatment of black rot in the south-east of France.—A local magnetic pole in Europe, note by M. Mascart. M. Leïst, of Moscow, has discovered at Kotchétovka, a village in the province of Koursk, a local magnetic pole where the magnetic needle stands vertically. A distance of 20 metres from this spot suffices to change the angle of dip by 1°.—Earthquake of May 6, 1898, communicated by M. Lœwy.

St. Louis.

Academy of Science, April 18.—Mr. Carl Kinsley read a paper on series dynamo electric machines. He showed, by the results of tests of machines, that the relations between electromotive force, current, and speed can be represented by a surface. This is easily done, since for widely different currents, and for both dynamos and motors, the total induced electromotive force is strictly proportional to the speed when the current is constant. He stated that Frölich's empirical equation can be used to represent large portions of this surface, as suggested by Prof. F. E. Nipher. It was stated that the way in which a series motor will operate from a series generator can be predetermined; and, for cases reported, it was shown that computed results, throughout the complete range of working conditions, gave an average agreement with observed results to within 0·05 per cent. The method explained in the paper enables an engineer to design such a power transmission circuit accurately from shop tests of the machinery, and to operate the series motor at constant speed under all loads. It was shown that the resistance of the generator does not vary with the speed. This makes it possible to use a small series generator as a speed indicator, and so obtain instantaneous values of engine speeds from the voltmeter or ammeter readings, if the resistance of the outside circuit is kept constant. The practicability of this method of determining engine speeds was fully shown by the results reported in the paper.—Prof. J. H. Kinealy made some informal remarks on the ventilation of schools, and by means of a number of stereopticon views showed the different methods adopted for supplying the air required to the different rooms of school-houses.

DIARY OF SOCIETIES.

THURSDAY, May 19.

Royal Institution, at 3.—Heat: Lord Rayleigh.
Chemical Society, at 8.—The Action of Formaldehyde on Amines of the Naphthalene Series: G. T. Morgan.—On the Constitution of Oleic Acid and its Derivatives. Part I.: F. G. Edmed.

FRIDAY, May 20.

THURSDAY, MAY 26, 1898.

MODERN PHYSIOLOGY FROM THE CHEMICAL STANDPOINT.

Text-book of Physiology. Edited by E. A. Schäfer, LL.D., F.R.S. Vol. i. (Edinburgh and London: Young J. Pentland, 1898.)

UNDOUBTEDLY, as the editor remarks in his preface to the above work, there has been a great desire on the part of teachers of physiology in this country to obtain a complete text-book on their subject, written in English, somewhat similar to the classical Handbuch of Hermann. Prof. Schäfer, with the aid of some of the best-known physiologists in Britain at the present day, has succeeded in bringing out a work which, if one may judge from the first volume, is destined to supply more or less completely the want that has been so long felt. It is a text-book essentially intended for advanced students; and although all the parts are not treated with like fulness, still the fact remains undoubted that at present no text-book in English is so complete as this one. The first volume deals practically entirely with the subject from the chemical standpoint. The first two chapters, by Halliburton, on the chemical constituents of the body and food, and on the chemistry of the tissues and organs respectively, are praiseworthy in so far as they give a fairly full account of the subjects with which they deal. But, seeing that these chapters must contain from their very nature many of the points to be discussed afterwards under special chapters, it would have been better, perhaps, had they been slightly shorter and more interestingly written. Then, again, a number of errors have crept in that ought not to have appeared. For example, the statement that the sugars are designated according to the number of carbon atoms they contain is hardly correct, as one may see by taking one of the examples given in the book. Rhamnose, although it contains six carbon atoms, is not a hexose but a pentose, viz. a methyl-pentose $CH_3(CHOH)_4COH$. They are designated not by the number of carbon atoms they contain, but by the number of oxygen atoms they possess. Here and there careless methods of expression are used, especially in the case of the sugars. Levulose is a ketone of sorbite as well as mannite. The note at the foot of p. 6 is slightly vague in meaning. Of course, as the writer says, the letters *d*, *l*, *i* do not refer to the rotatory power of the sugars, but to their genetic relationship to a fixed aldo-hexose. The letters only agree with the rotatory power in the case of the natural aldo-hexoses. Small points here and there are vaguely expressed. There is absolutely no doubt that vitellin is not a globulin, but a nucleo-albumin. The statement that Kossel has described four nucleic acids corresponding to four separate nuclein bases is hardly correct. He merely surmised that there might be a nucleic acid furnishing on decomposition a single definite alloxur base, and he based this supposition upon his investigation of the nucleic acid obtained from the nuclein of the thymus gland, which he at first termed adenylic acid because he imagined that adenin only was obtained from its decomposition. This, of course, has been shown by Kossel himself to be incorrect. Up to the present no such nucleic acids have been prepared. Again, it is more than doubtful whether any genetic relationship exists between hæmatogen and hæmoglobin, as Bunge thought. The way in which the iron is bound in the former is absolutely different from that in the case of the latter. Again, there are points of the greatest interest that might have been put in a more interesting fashion; for example, the extremely important relationship between chitin and chondrin. The classification of the proteids which is given is not a particularly good one. There are too many repetitions, and the divisions into which the author has classed the different members are so scattered that it is difficult to grasp the subject at all well. There are many other points that would have been the better for a little fuller description, *e.g.* carnic acid (Siegfried) and the paired acids of glycuronic acid.

These articles have entailed undoubtedly a great deal of labour, and contain much that is interesting and difficult elsewhere to obtain, but they are hardly intended for students.

The part dealing with hæmoglobin and the principal products of its decomposition, by Gamgee, is exceedingly well written. It suffers, however, from its more or less one-sided character. Some of the more recent work—as, for example, the acids obtained from hæmatin—by Küster has been wholly disregarded. Through it all, however, the reader can easily perceive that it is a subject with which the writer is familiar.

The section on the blood, by Schäfer, is very well written.

The effect of acids on the reaction of the blood of herbivora might have been more clearly explained.

The proteids of the tissues in herbivora do not break down to furnish ammonia to neutralise the acid introduced, and hence the alkali of the blood is taken up with the result that mineral acids act as poisons in such a case.

The equation given on p. 157, showing the action of disodic phosphate in the transmission of CO_2 in the blood, is incorrect. It ought to be

$$Na_2HPO_4 + H_2CO_3 = NaH_2PO_4 + NaHCO_3.$$

Some reference might have been made to the important work done before Hürthle on the cholesterin esters in the blood; and it would also have been better if Nasse's work contradicting that done by Lépine on the absence of the glycolytic action of the blood in diabetes had been mentioned, as it is so important.

The recent work of Hammarsten on the coagulation of the blood might have been more fully referred to, as it was so carefully done, and the results obtained were so important. Many of the important points in Hammarsten's paper are referred to, but the source is not always acknowledged.

Diffusion, osmosis and filtration are treated of by Waymouth Reid in a very interesting chapter. This subject has been so much worked at in Germany within recent years, that the author would have no difficulty in gathering together and weaving into an interesting whole a number of facts scattered through the *Zeitschrift für physikalische Chemie* and Pfeffer's new text-book.

The chapter on the production and absorption of lymph, by Starling, is short but good, and gives a succinct account of our present-day knowledge of this very interesting subject.

The next chapter, by Moore, on the chemistry of the digestive processes, must have entailed a large amount of labour, as the literature is overwhelming. It might have benefited by curtailment, and by the omission of such words as "flocky," "unsolvable," and some others. The mass of unproved details with which Kühne deluged physiology has been largely made use of. Those who wish to be able to criticise this work of Kühne might with advantage look up the original papers by Kühne and Chittenden and Neumeister. They will then perceive that a number of bodies there referred to depend for their separate and definite existence upon very insufficient data. The physiological chemist of a later date will smile when he reads of anti-albumid, anti-albumate, anti-albumose, and so on. A lot of details given in this paper might have been, perhaps, with advantage omitted, as after all they are only of use to those working at the subject, and later on will be merely of historical interest. Paijkull's work on the mucin of bile requires to be repeated. It is by no means certain that the mucin is a nucleo-proteid. This chapter, however, gives as good an account of the subject as any one could desire. It has been kept well up to date, including as it does such recent work as that of Nuttall and Thierfelder.

The chapter, by Langley, on the salivary glands is an excellent one, distinguished alike by its clearness and suggestiveness as well as its succinctness.

The mechanism of the secretion of gastric, pancreatic, and intestinal juices is discussed in an interesting way by Edkins, as is also the section on the secretion of bile, by Noël Paton.

The important chapter on the chemistry of the urine has been entrusted to Hopkins, who has succeeded, in the space at his disposal, in giving a most excellent account of the subject. Here, of course, an author must exercise the gift of selection, as, in order to be complete, one would require to give another Huppert and Thomas' Handbuch. It ought to have been noted that the Krüger and Wulff method for estimation of the nuclein bases and uric acid is not a trustworthy one, as other nitrogen-holding bodies are precipitated. The inorganic constituents of the urine have received but scant attention.

The chapters on the secretion of urine and on that of milk, by Starling and Schäfer respectively, are clearly written; as is also that on the secretion and absorption of the skin, by Waymouth Reid.

The chapter on the chemistry of respiration, by Pembrey, is a good one; as are also those on animal heat, by the same author, and on metabolism, by Schäfer.

It is a pity that in such a book as this there is not only a necessary repetition, but also a tendency to omission of certain facts because they fall under two headings. An example of this may be given. The relationship between leucocytosis and the excretion of uric acid and nuclein bases is referred to in the section dealing with the chemistry of the urine, and also in that on metabolism. The result has been that in neither is there a proper description of Horbaczewski's experiments, nor are the conclusions which Horbaczewski arrived at clearly defined.

The work of Sandmeyer, on the effect of giving pancreas by the stomach to dogs that have had their pancreas removed, has not been referred to. This volume closes with an exceedingly interesting account of the internal secretions of the ductless glands and their effects upon metabolism. As one would expect from the writer of this article, the supra-renal extracts have received a good deal of attention, a little of which might have been bestowed on the thyroid therapy.

The points which have been drawn attention to in this review as perhaps admitting of improvement are few in number. The book stands as a monument of industry care and thought on the part of the editor and his coadjutors. It is, without doubt, the best book that we at present possess in English on the subjects dealt with in the first volume of what will prove to be a text-book of the greatest advantage to all interested in the subject of physiology. Before the value of such a book can be accurately appraised, it must be read carefully and intelligently, and compared with the original papers from which all such books must be built up. Those working at a special department of the subject may think that there might have been some additions or omissions; but one must remember that the subject is such a huge one, and the mass of literature to be consulted so immense, that after all such a complete text-book for the scientific worker must always remain mainly as a stepping-stone between the ordinary smaller text-book and the original papers. It is the conscientious perusal of the latter that must always remain, if the slowest, still the surest way to gain a knowledge of that most fascinating subject, physiology. T. H. MILROY.

VEGETABLE ORGANOGRAPHY.

Organographie der Pflanzen. By Dr. K. Goebel. Part i. With 130 figures in the text. Pp. ix + 232. (Jena: Gustav Fischer, 1898.)

IT is difficult to realise that this book is the work of the same author who wrote the now classical text-book of morphology. Later publications of Dr. Goebel's have been largely occupied with biological subjects, and he appears in the book before us to have abandoned the morphologist's standpoint, and assumed a physiological or, perhaps more correctly, a biological position. In making this change he admits that phyllogenetic speculations are, without doubt, more attractive than the investigation of the illusive causes, external or internal, which determine modifications of form; yet for him the recognition of the factors which bring about the unsymmetrical form of a leaf is of more importance than the construction of insubstantial theories of phyllogenetic development.

In the introduction the author further insists on the insufficiency of morphology, and quotes from Herbert Spencer to emphasise the fact that function and form are mutually interdependent. In the strict study of morphology the functions have been treated as something extraneous, and as having nothing at all to do with the characteristics of the organs.

The latter part of the introduction is devoted to a discussion of the two rival hypotheses as to the formation of the organs of plants, *e.g.* the theory of the differentiation of indifferent rudiments and that of the metamorphosis of rudiments materially differing from one another. Dr. Goebel shows a strong bias in favour of the latter. Thus he says a foliage leaf is not a foliage leaf in the later stages of its development only, but the material constitution of its rudiment determines its development. Internal or external influences may, however, direct this development along other lines. To illustrate this point of view he describes the metamorphosis of the rudiment of a foliage leaf of a maple into a scale-leaf. But it must be confessed that although his arguments and illustrations are interesting, he fails to convince the reader that there are less difficulties in the way of the theory of metamorphosis, involving as it does some form of evolution in ontogeny, than are presented to the theory of differentiation, which in this case appears to be based on epigenesis. The indisputably indifferent nature of the cells forming the archesporial tissues and those in other positions in leaves, which are able to give rise to adventitious buds, are arguments in favour of the indifferent nature of all the leaf-cells, even in comparatively late stages of development. That no absolute material difference exists between the rudiments of different categories of organs is rendered probable by the absence of any definite demarcation between stem and leaf, as is shown by the example of Utricularia, which Dr. Goebel himself has investigated. Indeed in this direction Dr. Goebel goes further than the majority in maintaining that the vegetative body of Lemna is composed of branching leaves, and is not a leafless stem.

The purely morphological view, without regard to the functions of the organs considered, may often lead to misconception, and Dr. Goebel takes hairs as an example of this possibility. Thus according to him no sensible man would call a fern sporangium a "trichome"; for one cannot believe that either in the life-history of the individual, or of the race, that a sporangium arose by the metamorphosis of a hair. And yet the belief, which Dr. Goebel himself seems to share, that a stamen is a metamorphosed foliage leaf appears to rest on similar grounds, especially when viewed in the light of Bower's researches on spore-producing members.

Of great interest are those sections of the book dealing with the symmetry of organs and with the effect of light on dorsi-ventrality. The author finds that *Selaginella sanguinolenta* possesses leaves of two kinds, and is dorsiventral when subject to bright illumination; while if it is exposed to feeble light, it possesses leaves of one kind only and is radially symmetrical. The arrangement which is induced by the situation of the individual of this species, occurs normally on different parts of the same individual of other species. In these the individual is radially symmetrical in the lower portions of the stem, while the upper parts are anisophyllous. Furthermore, Dr. Goebel has been able to cause *S. helvetica*, which is normally anisophyllous, to considerably lessen the contrast between the two kinds of leaves by simple etiolation. Thus it appears that in some the adaptation is ontogenetic in its nature, and is brought about by the actual circumstances of the individual; in others it is inherited, and not materially affected by the immediate surroundings, although probably brought about by the relations of a succession of individuals to light.

In the succeeding section, on the difference between the structures of organs in the adult and early stages of development, there is much of interest. *Polysiphonia Benderi*, one of the most remarkable examples of this difference, has been already described by Dr. Goebel. In this alga the first stage resembles the adult in possessing a cylindrical thallus. This gives rise to one or more flat structures, which apply themselves to the surface of other algæ, and which are wholly different from both the first and final stages in appearance. Only before the formation of the reproductive organs are the adult cylindrical branches developed.

Passing on to the development of the higher plants, perhaps every one will not agree with the author in his view that the simpler form of the primary leaves of seedlings is due to an arrest of development. The existence of a more complicated form in some primary leaves than in those of the adult stages, must make one hesitate before accepting the theory of arrested development in every case, and may suggest that a similar reason for the difference between the leaves of the seedling and those of the adult exists both when the former are more simple and when they are more complex than those of the latter.

The section on vegetable teratology may be noted, as in it Dr. Goebel gives his support to Beyrinck's extension of Sachs' hypothesis, that the difference in form of plant organs is due to a difference of substance, and that changes in form are referable to alterations in the nutrition of the parts involved. Beyrinck's view is that galls are caused by such an alteration in the nutrition of the part in response to the stimulation by the gall-producing animal.

The last part of the book is devoted to a discussion of the influence of correlation and external stimuli on the form of plants. It is not behind the earlier parts in interest and wealth of example. Among the more important matters touched upon in this part are Lindemuth's experiments on the production of seeds in bulbous plants, Sachs' investigations on the relation of flower-production to light, and Lothelier's observations on the conversion of the spinous leaves of Ulex into flattened forms, in a moist atmosphere. Dr. Goebel doubts that this modification of spines due to moisture is of frequent occurrence, and believes that Lothelier observed isolated examples.

With confidence Dr. Goebel's book may be recommended to all who are interested in theoretical botany. It is full of suggestion and novelty, and its occasionally dogmatic style in no way lessens its tendency to arouse interest and discussion.

H. H. D.

A GREAT NORTH ROAD.

A Northern Highway of the Tzar. By Aubyn Trevor-Battye. Pp. xiv + 256. (London: Archibald Constable and Co., 1898.)

MR. TREVOR-BATTYE gives in this book a very interesting account of his journey home from Kolguev, an island in the Arctic Ocean, on which he was for some time ice-bound.

The journey was undertaken in October, a time known in Northern Russia as the Rasputnya season. Mr. Trevor-Battye describes the season as follows :—

"Rasputnya, as I have been since informed, means, literally, 'the separation of the roads,' but by some process of thought has now come to be the term for a fifth season, for the time which lies between autumn and winter; in short, for the month of October. It means in Northern Russia that the first frosts have thawed and the first snows melted; that the rivers are blocked with streams of broken ice, the morasses like a quagmire, the tracks, where any advance has been attempted upon old forest bog, a mixture of treacle and glue. Finally, it means, as I have said before, that no one dreams of trying to move until the country is sound and hard under the settled frost. During the whole of October the Government postal service is stopped, labour contracts are off, and the keepers of the stages are entirely freed from their usual obligation to supply the traveller with horses and sleighs."

Undertaking a journey at such a time seemed an act of madness, but it certainly was the means of getting an insight into the character of the North Russian peasant, and of seeing a side of it which might not have been revealed under ordinary circumstances. Their kindly good nature is striking, and throughout the journey, although at first objections were raised and the impossibility of accomplishing the various stages of the journey put forward, still some one was always found willing to supply horses and sleighs, and to accompany the travellers.

After crossing from Kolguev to the mainland, Mr. Trevor-Battye, together with his camp-man Thomas Hyland, and his old spaniel "Sailor," made their way across country to the small village of Askino, on the river Pechora. They were assisted in getting there by the Samoyeds, inhabitants of the *tundra* in the west. Askino is practically the only place where the Russians speak Samoyed, and where there is any apparent intercourse between the two races. At their next destination, Ust Tsilma, also on the Pechora, and which they reached by boat, the condition was quite changed; for on inquiry not one person could be found who spoke Samoyed, although the two places were only about 180 miles apart.

From Ust Tsilma the journey was continued overland, from *stantsyia* to *stantsyia*, which are log buildings put up by the Government at variable distances apart, and in charge of a *yamshstchik* (driver), who is bound to supply horses and conveyances to any travellers on production of a printed permission. The difficulties of getting conveyances, owing to Rasputnya, and the descriptions of the numerous adventures, especially those connected with crossing the ice-blocked rivers, are of great interest. Archangel was eventually reached, and the travellers considered their difficulties over. The sleigh drive to Vologda, a distance of about 700 miles, was accomplished without any difficulty, as the track was good. Having reached Vologda, the journey home was continued by rail.

The book gives us a good insight into the peasant life. The houses, or rather huts, occupied by the peasants are simple in the extreme, and consist generally of two rooms. In a prominent position in the front room there is always an *ikon*, before which lamps or candles are lighted. Attention is also drawn to the oven or *paitch*, which forms such a feature in these small buildings; and we are told that a characteristic proceeding of a *yamshstchik* on entering a house, "is to cross himself many times before the *ikon*, and the next to climb up to the oven top, from which simmering pulpit he holds forth on the events of the day."

Except for some references to birds and fishes, natural science does not form the same feature in the present book that it did in Mr. Trevor-Battye's previous one, "Ice-bound on Kolguev." This, however, is to be expected, for the journey had to be made with all possible speed. The book is written in a very instructive and pleasing style, and the map and illustrations by the author add much interest to it.

OUR BOOK SHELF.

Vorlesungen über Bacterien. Von Dr. Alfred Fischer, A.O. Professor der Botanik in Leipzig. Pp. 186. (Jena: Gustav Fischer, 1897.)

It is sometimes alleged that bacteriology has suffered, as a pure science, from its association with medicine, since its pathological side has become disproportionately developed. This statement is certainly no longer justified, for the applications of the science to agricultural and manufacturing industries have been found almost as important to the farmer, the dairyman, and the chemist as they have been to the pathologist. Prof. Fischer's book is one which fills a distinct gap in bacteriological literature. Himself a botanist, he treats the subject from a broad and general standpoint. Without neglecting the pathogenic organisms he deals with them only, as it were, incidentally, and the book presents an admirable and judicial summary of the present state of knowledge of bacteriology in its widest and truest sense. It forms a valuable introduction to the subject from whatever point of view it is to be studied, since it affords a solid groundwork upon which more technical and special knowledge may afterwards be built.

The earlier chapters deal with morphology and with the intimate structure of bacteria—matters upon which Prof. Fischer's well-known researches on "plasmolysis" render him well qualified to speak. In the chapters on specificity and classification he shows himself no advocate of the extreme views on pleomorphism which have been advanced by some. In his remarks on classification he insists, with much justice, that strictly morphological characters must form the basis of generic distinctions, and that this matter lies within the province of the botanist alone. The classification which he proposes is a reasonable one, based largely on the character and distribution of the cilia, and the nature of the spores. The mode of life, and physiological properties of bacteria are next described, the chemistry of aërobiosis and anaërobiosis being fully dealt with; and two chapters are then devoted to the influence of physical and chemical agents, especially in relation to the problems of disinfection. The most fascinating part of the book will, however, be found in the sections devoted to the circulation of nitrogen and of carbonic acid in nature. The assimilation of free nitrogen by bacteria in the soil and in the nodules of Leguminosæ, and the decomposition and nitrification of proteids are set forth by the author with admirable clearness, and the same may be said of the various processes of fermentation with which he also deals. The last three chapters are devoted to pathogenic bacteria, and contain a short account of some of the more important species and their mode of action, with a sketch on serum-therapeutics and immunity. The writer is throughout thoroughly impartial and judicial, and shows a healthy scepticism as regards theories unsupported by adequate fact. There can be no doubt that a translation into English of this admirable book would be of great assistance to all those students of bacteriology who are unable to read it in the original.

Lehrbuch der Entwicklungsgeschichte des Menschen. Von Dr. J. Kollmann, o.ö. Professor der Anatomie in Basel. Pp. xii + 658. (Jena: Gustav Fischer, 1898.)

THIS work appears to approach in method the ideal of an elementary text-book of science, since it gives a sound and well-balanced *résumé* of its subject to date, with references to authorities sufficient to place the student in direct touch with original description of detail. The pages of the book never pall, and in treatment and mode of expression it is one of the least "German" of German text-books with which we are familiar. It is illustrated by 386 excellent processed drawings, many of which are coloured, and where original these are very good and such as are likely to become popular. The investigations of His, of course, come in for a full share of recognition, and good use has been made of those of Keibel, Mall, Röse, Toldt, and others among recent workers. The book is divided into five leading sections. An introduction of sixteen pages is followed by portions dealing with the earlier stages of development ("Progenie" and "Blastogenie"), treated as far as is necessary comparatively. The fœtal membranes and progressive development of the human fœtus next come in for consideration; but the bulk of the work (405 pages) is of necessity devoted to a description of the development of systems and organs, and there is appended a twenty-page dissertation on heredity. Not the least pleasing feature of the book is its consummately artistic plan. Illustrations never obtrude themselves upon the margin nor overpower the text. In the placing of the figures, choice of their colour and descriptive letterpress, there are evidences of the bestowal of great care and forethought and of painstaking consideration of detail, which are alone a strong recommendation of the work. It is carefully written and non-pedantic, and should be deservedly popular.

Missouri Botanical Garden. Ninth Annual Report. Pp. 160. (St. Louis, Missouri: published by the Board of Trustees, 1898.)

ADMINISTRATIVE details occupy but a small part of this report, the chief contents being a collection of scientific papers and notes on interesting plants, illustrated by several half-tone plates. The results of the studies of the American Lemnaceæ occurring north of Mexico, by various botanists, are brought together by Mr. C. H. Thompson, and are combined with his own researches into a revision of the order. Mr. H. C. Irish contributes to the report a revision of the genus Capsicum, with especial reference to garden varieties. Mr. J. N. Rose describes five species of agaves which flowered in the Washington Botanic Garden in 1897, and were identified by him. One of these (*A. Washingtonensis*) appears to have been hitherto undescribed. Among the notes, Mr. William Trelease, the Director of the Gardens, records some interesting observations on Yuccas. He points out that *Yucca gigantea* is distinct from *Y. gloriosa* and *Y. Guatemalensis*—its nearest allies—and gives a figure of an Azorean specimen which is a good example of the species. With reference to the extent of the pollination of Yuccas by the Yucca moth, Mr. Trelease has now obtained information which proves the moth to be "the active agent in the pollination of Yuccas from Florida northward as far as fruit is set as a result of *Pronuba* activity, westward as far as southern California, and into the mountains of northern Mexico to the south."

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Liquefaction of Hydrogen.

YOUR last issue contains a report of Prof. Dewar's remarkable achievement in the liquefaction of hydrogen and helium. In his account of it, which you quote, Prof. Dewar describes the apparatus employed as an enlarged plant of the same type as that used in his hydrogen-jet experiments discussed in his paper before the Chemical Society of December 19, 1895 (see *Proceedings*, No. 158), and in his lecture at the Royal Institution (see *Proceedings*, 1896), and illustrated in a figure printed with this lecture. An examination of that illustrative figure and of the description shows that the type of apparatus used involves an entirely new departure as compared with the methods of all who had liquefied air before 1895, including Prof. Dewar himself. The new self-intensive method then and now employed is a combination of the following four points: *a long tube conveying compressed gas, expansion of the compressed gas through a nozzle or throttle-valve, direct return of all the expanded gas over the tube of compressed gas, good interchange of temperatures between the compressed and expanded gas.* The new method embodying the above combination will be found fully described and illustrated in my patent, No. 10,165, 1895 (May 23). What is equally important historically: in November 1894, more than twelve months before Prof. Dewar first showed this new method in action, liquefying air, I had called, with an introduction, on his chief assistant, Mr. R. N. Lennox, at the Royal Institution, had there explained to him this self-intensive method, and had proposed it as a means of obtaining intensely low temperatures. By employing this method I was afterwards the first in this country to liquefy air and oxygen without employing other refrigerants. Since then, at the Royal Institution, where alone sufficient means are available for the prosecution of these researches, the same method has bridged over the space, impassable by former methods, between the temperature of liquid air and that of liquid hydrogen and helium, thus proving itself a new and valuable scientific instrument.

Under these circumstances I think that Prof. Dewar, seeing he was aware of the facts at the time of his account, ought not to have been content with eulogising the services of his assistant Mr. Lennox, but should also have given me credit for the invention of the method which has procured him so great a success. Although he has been easily able to find in old patents the separate elements which go to make up the new method—this can be done for any new invention—he has nowhere found, before the date of my communication to Mr. Lennox, that combination of the four points given above which is absolutely necessary to his apparatus for liquefying hydrogen.

The facts referred to above are stated and discussed in greater detail in a paper, to be printed shortly, which was read by me before the Society of Chemical Industry at Burlington House on the 2nd inst., with illustrative diagrams, and in letters by me to *Engineering* for April 15 and May 6. W. HAMPSON.

Concerning the Thermodynamic Correction for an Air-Thermometer.

IT is common in works on thermodynamics to give a formula for the thermodynamic correction applicable to an air-thermometer; the following is substantially the usual proof.

Accepting the current theory of the Joule-Thomson experiments, we may show that

$$t\frac{dv}{dt} - v = k\frac{\delta t}{\delta p},$$

where k is the specific heat at constant pressure measured dynamically. From this we obtain

$$t\frac{dv}{dt} = v + k\frac{\delta t}{\delta p}$$

and

$$t = \left(v + k\frac{\delta t}{\delta p}\right) \div \frac{dv}{dt}.$$

Thus t is seen to consist of two terms; the second term

$k\frac{\delta t}{\delta p} \div \frac{dv}{dt}$ is the smaller of the two, and we proceed to find its value. We have as a first approximation to the behaviour of gases,

$$pv = C(1 + \alpha T),$$

where T is the temperature centigrade on a gas-thermometer.

We therefore have, as approximate equations,

$$v = \frac{C}{p}\left(1 + \alpha T\right),$$

$$\frac{dv}{dT} = \frac{C\alpha}{p}.$$

We may further assume that $\frac{dv}{dt} = \frac{dv}{dT}$, since the degrees are practically equal on the two scales.

We therefore obtain, approximately,

$$v = \frac{C}{p}\left(1 + \alpha T\right),$$

$$\frac{dv}{dt} = \frac{C\alpha}{p}.$$

Using these approximate values, we have

$$k\frac{\delta t}{\delta p} \div \frac{dv}{dt} = \frac{kp}{C\alpha}\frac{\delta t}{\delta p}$$

$$= \frac{k}{C\alpha}\frac{\delta t}{\delta \log p},$$

and the equation for t becomes

$$t = v \div \frac{dv}{dt} + \frac{k}{C\alpha}\frac{\delta t}{\delta \log p}.$$

If now, further, we use the approximate values of v and $\frac{dv}{dt}$ in the term $v \div \frac{dv}{dt}$, we shall obtain

$$t = \frac{1}{\alpha} + T + \frac{k}{C\alpha}\frac{\delta t}{\delta \log p}.$$

This is the formula usually given.

This method of working appears to me to be incorrect, for the following reason:—

In the equation

$$t = \left(v + k\frac{\delta t}{\delta p}\right) \div \frac{dv}{dt}$$

there are two terms on the right-hand side, one of which, $k\frac{\delta t}{\delta p} \div \frac{dv}{dt}$, is small compared with the other. We may therefore neglect it as a first approximation, and we then obtain $\frac{v}{t}$ = function of p, in accordance with the laws of a perfect gas. If we wish to proceed to a closer approximation, we may use the perfect-gas laws as sufficiently good in the term $k\frac{\delta t}{\delta p} \div \frac{dv}{dt}$, because that is a small term, and the departure of the actual gas from the perfect gaseous laws will consequently in this term introduce only errors which depend on the squares of small quantities. But we are not at liberty to use the perfect gas laws in the remaining term $v \div \frac{dv}{dt}$, because it is *not* a small quantity, and we have therefore no guarantee that the use of such an approximation will not introduce errors of the first order of small quantities—that is to say, comparable with the term $k\frac{\delta t}{\delta p} \div \frac{dv}{dt}$ itself. With such errors introduced, the second approximation would not necessarily be better than the first.

The mistake in principle, which I have indicated, appears to be widespread, since it has crept into several of our well-known text-books. Thus the discussions given in Tait's "Heat" (pp. 338–339), in Baynes' "Thermodynamics" (pp. 126–127), and in Maxwell's "Heat" (pp. 211–214), all appear to me infected by this source of error. It is true that in these discussions the mistake is introduced more subtly, and is covered with a mass of symbols; whereas in the faulty investigation given above, I have purposely made the paralogism as glaring as possible. But *in substance* the mistake occurs in each of the discussions above named. JOHN ROSE-INNES.

Printer's Ink and Photographic Plates.

IN a paper on the action exerted by certain metals and other substances on a photographic plate, by Dr. W. J. Russell (*Proc. R.S.*, vol. lxi. p. 424), the author mentions that the *Westminster Gazette* is printed with an ink which readily acts on a photographic plate. The printed paper in some experiments is placed in contact with the photographic plate, in the dark, and after being left in contact for some time, in the dark, the plate is developed, and the printed letters come out clearly. Dr. Russell mentions the names of several periodicals the print of which acts on a sensitive plate. To these the following example of the same phenomenon may be added: a photographic plate wrapped up in an advertisement sheet of *Modern Society* on development showed the printed characters very clearly, the words reading from left to right, not being reversed, so that the action must have taken place through the thickness of the paper. This sample of the action of printer's ink on a photographic plate (the property of Mr. W. B. Croft) has been in the excellent physical laboratory museum at Winchester since 1892. The print is good and clear, and probably one of the earliest observed instances of the action of printer's ink on a photographic plate in the dark, in which the physical conditions were known and recorded. F. J. JERVIS-SMITH.

Oxford, May 16.

Heavy Rainfalls.

I THINK it worthy of record that at a place called Nedunkeni, in the Northern Province of Ceylon, the rainfall on December 15–16, 1897 (24 hours), was 31·76 inches. The average annual rainfall of this place was 64·70, but in 1897 the amount totalled 121·85 inches.

The heaviest recorded rainfalls (as given in the "Encyclop. Britt.") are at Joyeuse, France, 31·17 inches in 22 hours; at Genoa, 30·00 inches in 26 hours; at Gibraltar, 33·00 inches in 26 hours; on the hills above Bombay, 24 inches in one night; and on the Khasia Hills, India, 30·00 inches on each of five successive days.

The rainfall in Ceylon, referred to above, is therefore notable. The greatest annual rainfall occurs, as is well known, on the Khasia Hills, with 600 inches. The wettest station in Ceylon is Padupola, in the Central Province, with 230·85 inches (mean of 26 years), the rainfall for last year being 243·07 inches. C. DRIEBERG.

School of Agriculture, Colombo, Ceylon.

Hermaphroditism in the Apodidæ.

I AM not sure but that the tone of Prof. Lankester's demand, in NATURE of May 12, that I should "at once" withdraw my "assertions," or confirm them by "some evidence," would not have justified my ignoring it altogether. For those of your readers, however, who may be interested in this subject, may I say that I *have* produced "some evidence" (*Ann. and Mag. Nat. History*, xvii., 1896, plates xi. and xii.), and no counter evidence whatever has yet been forthcoming to shake my faith in the justness of my conclusions. HENRY BERNARD.

Streatham, May 17.

MAGNETISM AND SUN-SPOTS.

WHEN Sir Edward Sabine was preparing his paper[1] "On Periodical Laws discoverable in the mean effects of the larger Magnetic Disturbances—No. ii.," in which he discussed the magnetic observations made at the temporarily established Colonial observatories at Toronto and Hobarton, he found that there existed at these places, in the years 1843 to 1848, a progressive increase in amount both of magnetic disturbance and in extent of diurnal range of the declination magnet, the values of diurnal range for the year 1843 having become in 1848 increased by some 40 per cent., the Toronto values for these years being 8'·90 and 12'·11 respectively, and the Hobarton values 7'·66 and 10'·63. This was an altogether unlooked-for result, one that engaged his special attention, such increase of value from year to year

[1] Read before the Royal Society, May 6, 1852.

in two quarters of the globe so widely separated as Toronto and Hobarton presumably indicating not simply a local effect, but one rather of cosmical character. He pointed out that as the sun must be recognised as at least the primary cause of all magnetic variations that conform to a law of local hours, as does the solar diurnal range, it seems not unreasonable to suppose that in the case of other magnetic variations we should look, in the first instance, to any periodical variation by which the sun is affected, to ascertain whether any coincidence of period or epoch is traceable. And he draws attention to the circumstance that, according to Schwabe's then recently-published table of frequency of solar spots, a minimum in number of spots occurred in 1843 and a maximum in 1848, with progressive increase in the intermediate years similar to that of the diurnal magnetic range during the same interval as shown by the Toronto and Hobarton observations. This led Sabine to infer the probable existence of a periodical variation in magnetism similar to that—one of about ten years—which Schwabe had detected in sun-spots from observations extending over a period of twenty-five years.

In the meantime another worker had been busy with the same subject. In *Poggendorff's Annalen* for December 1851 there appeared the well-known paper by Dr. Lamont, "on the ten-yearly period," in which he gave the following values of diurnal range of the declination magnet as observed at Munich.

1841 = 7′·82	1846 = 8′·81
1842 = 7·08	1847 = 9·55
1843 = 7·15	1848 = 11·15
1844 = 6·61	1849 = 10·64
1845 = 8·13	1850 = 10·44

Lamont considered that these numbers indicated a periodical variation, and from them he found by graphical construction that a minimum apparently occurred in 1843 and a maximum in 1848. He further discussed such older magnetic observations as were found to be available, and came to the following conclusion, which it may be interesting to give in his own words. "Die grösse der Declinations-Variationen hat eine zehnjährige Periode, so zwar, dass sie mit regelmässigen Uebergange fünf Jahre im Zunehmen, und fünf Jahre im Abnehmen begriffen ist."

Sabine became acquainted with Lamont's paper whilst writing his own, and quotes Lamont's figures from 1843 to 1848, showing how the Munich results confirmed those of Toronto and Hobarton. It would seem that Lamont and Sabine each independently suspected the existence of a periodical variation in diurnal magnetic range, which Lamont appears to have first distinctly formulated in the words quoted; whilst it was to Sabine that the suggestion that the periodical variation was one apparently concurrent with that of sun-spots was due. Lamont considered the variation to be so real that in any theory of the diurnal movement it could not be disregarded. Sabine more cautiously wrote: "As the physical agency by which the phenomena are produced is in both cases unknown to us, our only resource for distinguishing between accidental coincidence and causal connection seems to be *perseverance in observation*, until either the inferences from a possibly too limited induction are disproved, or until a more extensive induction has sufficed to establish the existence of a connection, although its precise nature may still be imperfectly understood." In a postscript to Sabine's paper (dated May 24, 1852) he gives a table of mean diurnal range of declination for Toronto and Hobarton from 1841 to 1851, which clearly shows, as do the Munich numbers, the minimum of 1843 and the maximum of 1848; and in 1856 he showed that at Toronto, from 1844 to 1848, there was a progressive increase in the amount of magnetic disturbance in all three elements of declination and horizontal and vertical force.

Considering that the periodical variation of diurnal range was found to exist in regions of the earth so far apart as Toronto, Hobarton and Munich, the results at the three places being distinctly corroborative, and, further, the circumstance that it appeared to be closely in accord with the established solar-spot variation, it seems to be matter for reflection as to how it happened that in some quarters the agreement between the magnetic and solar variations was thought to be only of apparent or accidental nature. Sir George Airy, in his paper[1] "On the Diurnal Inequalities of Terrestrial Magnetism," had occasion to give therein a list of the days of greater magnetic disturbance at Greenwich in the years 1841 to 1857, and he incidentally remarks that "there is no appearance of decennial cycle in their recurrence." But this is not surprising, for although magnetic disturbance does cluster about the epochs of maximum of sun-spots, it is on occasions by no means closely confined thereto, though nearly or quite absent at epochs of minimum of sun-spots. Thus the periodical variation, as regards the disturbance element, although existing, is not so distinctly traceable unless longer periods are examined, accompanying sun-spot maxima as disturbance does in a somewhat loose fashion as compared with the more regular increase and decrease of diurnal magnetic range with variation of sun-spot frequency. The behaviour of magnetic disturbance in this respect is indeed a matter that I am yet hoping to investigate more exactly.

Then, again, Lamont appears to have adopted for the diurnal magnetic range the difference between the positions of the magnet at 8h. in the morning and 1h. in the afternoon, as being the times of the greatest easterly and westerly deviation respectively. It is true that the positions of the magnet at these hours would not be likely to represent the extreme positions at Munich throughout the year, especially as regards the easterly deviation; still the diurnal range resulting from the employment of such fixed hours approximates in such degree to the true range for Munich, as very well serves clearly to bring out the decennial variation, of which indeed the good agreement between Lamont's and Sabine's results is of itself further proof, since the latter do depend on observations extending through the twenty-four hours of the day. From whatever cause, however, there were those in earlier days who doubted the existence of any real relation between magnetic and solar variations. The so-called decennial period, it may be here mentioned, seems to be more nearly an eleven-year period, this being about the mean value, although it is variable in length to the extent of several years.

When, in the year 1875, I was transferred at the Royal Observatory from the Astronomical to the Magnetical and Meteorological Department, I had then paid no particular attention to this question, and had an open mind thereon. But the daily examination of the photographic records after a time convinced me that change was in progress in the character of the records from year to year, such as even in this simple daily inspection of the records could not be well overlooked; and acting involuntarily on Sabine's principle of perseverance in observation, I came to the conclusion that it would be well to endeavour further to investigate the facts of observation, especially as the long series of Greenwich observations, made throughout on the same general plan and with instruments of the same kind, furnished so excellent an opportunity for applying an independent test of the reality or otherwise of the relation supposed to exist, which the late Dr. Wolf, of Zürich, had already done so much to establish. My first paper appeared in the *Philosophical Transactions* for the year 1880, and deals with the Greenwich observations from 1841 to 1877. This I have recently supplemented by a second paper, read before the Royal Society on March 10 of the

[1] Read before the Royal Society, April 23, 1863.

present year, which appears in the *Proceedings* of the Society. The results here employed extend from 1841 to 1896, a period of fifty-six years. The addition of the more recent observations is especially interesting as contrasting in some respects with the earlier portion, the

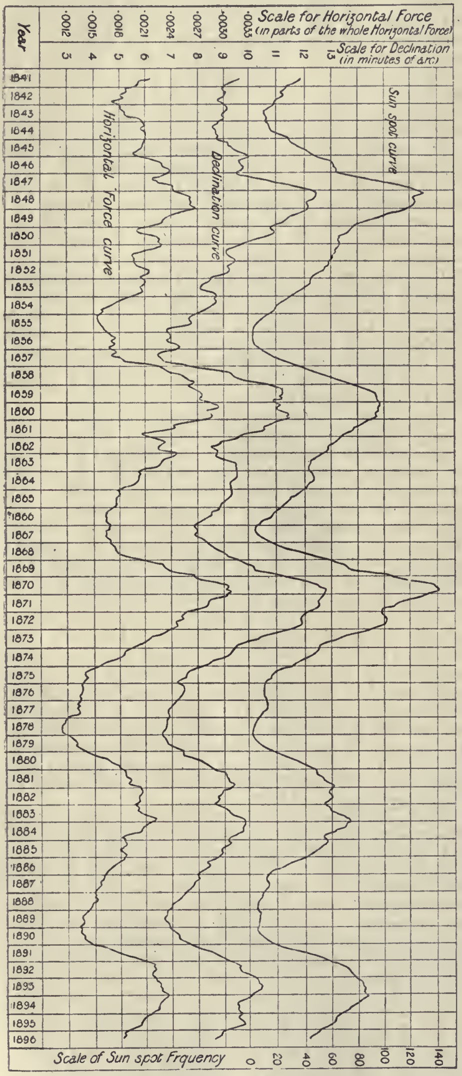

Fig. 1.—Smoothed curves of sun-spot frequency (Wolf), compared with corresponding curves showing the variation in diurnal range of the magnetic elements of declination and horizontal force from observations made at the Royal Observatory, Greenwich.

whole forming one continuous chain of evidence that much strengthens the argument for relation between the two classes of phenomena. The records of horizontal magnetic force, as well as those of declination, are employed. From 1841 to 1847 the results depend on eye observations made at intervals of two hours. In 1848 and afterwards, they depend on hourly tabulations from the photographic records. The mean diurnal range in each month is taken to represent (relatively to other months) the magnetic energy of the month. By the mean diurnal range of declination or horizontal force is to be understood the difference between the least and the greatest of the mean hourly values in each month.

In any graphical representation of unexplained phenomena it is important to give ready reference to the numerical data employed. Consequently in both papers complete tables of the elements used are either included, or indication given where such collected results can be found. The numbers for declination are in minutes of arc, those for horizontal force are in parts of the force, taken as unity. There being in the numbers a strongly marked annual period (the summer values being greater than those for winter), numbers that shall be free of annual inequality have (as explained in the paper) been prepared and used to construct the middle and lower curves of the diagram of collected curves. For sun-spot frequency the numbers published for so many years by Dr. Wolf, and since his death continued by his successor, Prof. Wolfer, have been employed. It is impossible to value too highly work of this kind, carried on for so many years on one fixed plan; such steady adherence to a definite method having many advantages. The monthly sun-spot numbers show considerable irregularities which Wolf smoothed by a process similar to that employed to free the magnetic numbers from the annual inequality, the resulting numbers being used for the upper curve of the diagram.

The collected curves show striking points of interest. The epochs of the extreme points of the curves are given in the following table:—

Table of Epochs of Magnetic and Sun-spot Minima and Maxima.

Reference No.	Phase.	Magnetic epochs.			Sun-spot epoch.	Excess above sun-spot epoch.		
		Declination.	Horizontal force.	Mean magnetic.		Declination.	Horizontal force.	Mean magnetic.
						y.	y.	y.
1	Minimum ...	1844·3	1842·9	1843·60	1843·5	+0·8	−0·6	+0·10
2	Maximum ...	1848·1	1849·0	1848·55	1848·1	0·0	+0·9	+0·45
3	Minimum ...	1857·2	1855·1	1856·15	1856·0	+1·2	−0·9	+0·15
4	Maximum ...	1860·6	1860·2	1860·40	1860·1	+0·5	+0·1	+0·30
5	Minimum ...	1867·5	1867·6	1867·55	1867·2	+0·3	+0·4	+0·35
6	Maximum ...	1870·8	1870·9	1870·85	1870·6	+0·2	+0·3	+0·25
7	Minimum ...	1879·0	1878·7	1878·85	1879·0	0·0	−0·3	−0·15
8	Maximum ...	1884·0	1883·8	1883·90	1884·0	0·0	−0·2	−0·10
9	Minimum ...	1889·5	1890·0	1889·75	1890·2	−0·7	−0·2	−0·45
10	Maximum ...	1893·5	1894·0	1893·75	1894·0	−0·5	0·0	−0·25
	Mean excess (five epochs of minimum)					+0·32	−0·32	0·00
	Mean excess (five epochs of maximum)					+0·04	+0·22	+0·13
	General mean excess					+0·18	−0·05	+0·06

The intervals between the successive mean magnetic epochs and the corresponding sun-spot epochs run, it will be seen, closely together. And if instead of successive intervals we take successive periods, as from No. 1 to No. 3, No. 2 to 4, &c., of the table, we have—

Length of Magnetic Period.

1–3	2–4	3–5	4–6	5–7	6–8	7–9	8–10
y.	y.	y.	y.	y.	y.	y.	y.
12·55	11·85	11·40	10·45	11·30	13·05	10·90	9·85

Length of Sun-spot Period.

y.	y.	y.	y.	y.	y.	y.	y.
12·50	12·00	11·20	10·50	11·80	13·40	11·20	10·00

Nos. 1 to 3, 3 to 5, &c., represent intervals between successive minimum epochs, and Nos. 2 to 4, 4 to 6, &c., intervals between successive maximum epochs. These are shown graphically in the annexed figure.

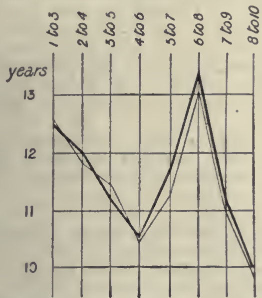

FIG. 2.—Length of sun-spot and magnetic periods compared. The thick line shows the variation in length of successive sun-spot periods, and the thin line that between successive magnetic periods. Odd numbers indicate periods from minimum to minimum, and even numbers periods from maximum to maximum.

Examining further the collected curves, it is seen that the several maximum points have at different epochs very different degrees of intensity. Arranged in order of intensity these are as follows:—

Order of Epochs.

Sun-spot curve	1870	1848	1860	1894	1884
Declination curve ...	1870	1848	1860	1894	1884
Horizontal force curve...	1870	1860	1848	1894	1884

The agreement is complete, excepting that in horizontal force the epochs 1848 and 1860 are transposed, although otherwise falling in with the order of the other curves.

The paper goes on to point out that—considering how the irregularities in the length of the sun-spot and magnetic periods, and also the order of epochs as regards elevation or depression of the maximum points of the curves, so entirely synchronise, and, further, the usually sharp rise from minimum to maximum and the more gradual fall again to minimum, a characteristic of all three curves—"there would appear to be no escape from the conclusion that such close correspondence, both in period and activity, indicates a more or less direct relation between the two phenomena, or otherwise the existence of some common cause producing both." Reference is also made to the question of the supposed lagging of the magnetic epoch, as referred to the sun-spot epoch, which the results presented do not appear much to confirm.

The paper concludes with an inquiry as to how far the practice of including in the Greenwich tabulation of magnetic elements all days (except those of extreme disturbance) may have affected the results presented, for which purpose diurnal ranges were deduced for the years 1889 to 1896 from five selected quiet days in each month —days free from magnetic disturbance—with result that the diurnal ranges so found show the same variation with sun-spots as do the diurnal ranges of the ordinary tabulation. WILLIAM ELLIS.

MONOGRAPHS OF THE UNITED STATES GEOLOGICAL SURVEY.

THE GLACIAL LAKE AGASSIZ.[1]

ONCE upon a time in North America the continental ice-sheet attained an area of about four million square miles, while its maximum thickness, in the central portion, was probably from one to two miles. It extended from the Atlantic to the Pacific, and from the northern United States to the Arctic Sea. During the closing stage of this glaciation there existed an immense lake, whose area is estimated to have been about 110,000 square miles; a lake which extended 700 miles in length, and attained a width of 250 miles. Its maximum depth was 700 feet above the present level of Lake Winnipeg.

That the idea of the former existence of this great lake is no romance of modern days, no "glacial nightmare," is indicated by the fact that so long ago as 1823 the traces of it were recognised by Keating. Not, however, until 1879 was its present name applied to it in honour of Louis Agassiz.

Placed almost in the centre of North America, and occupying what is now part of the plain of the Red River and Lake Winnipeg, together with the Lake of the Woods and other smaller sheets of water, it lay for the most part in territory now Canadian, but a fifth part occurring within the United States. In the southern region, however, its ancient shore-lines have been more exactly explored. A very large part of its area in Canada, besides a considerable tract within its limits in northern Minnesota, is covered by forest, which makes it impracticable to trace there the beach-ridges and deltas, usually but a few feet high, the low escarpments of erosion, which range from 10 to 30 feet, and the other evidences of this lake, which in the prairie region could far more readily and definitely be followed.

It was evident that the scientific study of this interesting region should not be restricted by national geographical circumstances, and it is pleasing to note that arrangements were made between Director Powell (of the U.S. Geological Survey) and Director Selwyn (of the Canadian Survey), that the work of mapping the shores of Lake Agassiz should be continued by Mr. Upham through the prairie region of south-western Manitoba. Altogether this work comprises the results of field-observations carried on during six years.

Over the greater part of the old lacustrine area there is boulder clay from 100 to 300 feet thick. A series of terminal moraines marks the stages of retreat of the ice-sheet. For a while the lake gradually increased in size northwards, finding an outlet to the south in the "glacial" River Warren, whose channel was cut to a depth of 90 feet, and whose course is now occupied by Lakes Traverse and Big Stone and by the Minnesota River. As the ice-front retreated the lake was eventually drained by the natural slope of the land to the north-east, excepting in those areas which now form the lakes of Manitoba.

The steady uplifting of the area of Lake Agassiz, resulting from the unburdening of the land by the recession of the ice-sheet, gave to its beaches a northward ascent, and caused the several shores of its southern part to become double or multiple as they are traced northward.

The author gives a full and particular account of the beaches formed at different stages in the history of the lake, and discusses various earth-movements, some of which were independent of glaciation.

His work is by no means devoid of practical value. A chapter is devoted to artesian and common wells, and to the distribution and origin of certain saline waters; and another chapter is given to the agricultural and material resources of the area.

THE FLORA OF THE AMBOY CLAYS.[1]

This work, which was very nearly finished in 1890, by the late Dr. Newberry, was placed in the hands of Mr. Hollick in 1892. His task has not been unattended with difficulty, but he has carefully indicated his necessary alterations and additions.

The Amboy Clays take their name from Perth Amboy

[1] By Warren Upham. ("Monographs of the U.S. Geological Survey," vol. xxv. Pp. xxiv + 658; 38 maps, and 35 other illustrations.)

[1] By John Strong Newberry. Edited by Arthur Hollick. ("Monographs of the U.S. Geological Survey," vol. xxvi. Pp. x + 137, with 58 plates.)

and South Amboy in New Jersey, where they form the local base of the Cretaceous group. The clays constitute an important item in the mineral resources of the State. The mollusca found in the Amboy Clays prove them to be of estuarine origin. Compared with European strata it seems probable that they may be regarded as Upper Cretaceous.

156 species of plants are described, and these include 8 ferns, 17 conifers, and 5 cycads, in addition to the many dicotyledonous angiosperms, and a few doubtful forms. No palms are recorded.

Geology of the Denver Basin in Colorado.[1]

In this work the authors describe an area of about one thousand square miles, in the centre of which stands the city of Denver in Colorado. Topographically the area itself forms a kind of basin, but geologically it has been found that the rocks of the Cretaceous system, which occur over a large part of the country, constitute a well-defined syncline which is named the Denver Basin.

The mountain range on the west comprises a crystalline complex of pre-Cambrian rocks, flanked by highly inclined rocks of the age of the Jura-Trias, and these are succeeded with apparent though deceptive conformity by Cretaceous deposits which assume a fairly horizontal position beneath Denver, and are uptilted slightly on the east so as to form the before-mentioned basin.

It is held that considerable portions of the crystalline nucleus of the Rocky Mountains constituted an archipelago of large islands in the Palæozoic seas. Within the area now described no outcrops of Lower Palæozoic rocks are found, but there is good reason to believe that they underlie the later sediments, and are concealed along the Archæan borders by the overlapping Mesozoic and later deposits.

The movements that took place at various intervals subsequently to the early Palæozoic times are briefly indicated. They are complex, and have variously affected the character and distribution of the strata. The present relations of the Jura-Trias and Cretaceous to the crystalline nucleus are not due to a simple vertical upward movement of that core: the structure has rather been produced by tangential compression, the effect of which was to produce a structure somewhat analogous to a vertical upthrust, but as a result of a horizontally rather than of a vertically acting force.

The strata referred to the Trias consist, curiously enough, of brilliant red conglomerates, sandstones and shales, with thin limestones and gypsums in the upper part. They are known as the Wyoming formation, and are overlaid by a series of freshwater marls—the Morrison formation—grouped as Jurassic. This group is also known as the Atlantosaurus clays, from its abundant reptilian remains.

The geology of these and of the succeeding Cretaceous, Tertiary and Pleistocene formations, is exhaustively treated, and there is a full account of the igneous rocks. In the chapter on Economic Geology, coal, fire-clays and other clays, building-stones, and artesian wells are dealt with. The coal occurs in the Laramie formation of the Cretaceous. A final chapter is devoted to Palæontology, including some account of the Cretaceous plants, by F. H. Knowlton; and of the Jurassic, Cretaceous, and Tertiary vertebrates, by Prof. O. C. Marsh.

The work is well illustrated with maps, sections and pictorial plates. The "spherical sundering in basalt" is well shown in Plate xiv. Among other plates we have restorations of the Jurassic *Brontosaurus*, *Stegosaurus*, *Camptosaurus*, *Laosaurus*, and *Ceratosaurus*; of Cretaceous Birds and Dinosaurs; of the Tertiary Mammals, *Brontops* and *Entelodon*; and of the Quaternary *Mastodon*.

The Marquette Iron-bearing District of Michigan.[1]

The Marquette district occupies an area extending from Marquette on Lake Superior westwards to Michigamme, a distance of rather less than forty miles, and with a breadth of from one to over six miles. From the western part of the main area two arms project for several miles, one known as the Republic trough and one as the Western trough. The district is the oldest important iron-producing area of the Lake Superior region.

The rocks comprise three series, separated by unconformities. These are the Basement Complex or Archæan, the Lower Marquette, and the Upper Marquette; the two latter constituting the Algonkian of the district, and perhaps equivalent to Huronian. The Marquette series is mainly sedimentary, although among the strata are included large masses of igneous rocks. The succession of the series is somewhat obscured by irregularities of deposition, and by inter-Marquette erosion. After the Upper Marquette series was deposited the district was folded, faulted and fractured in a complex fashion, with resultant profound metamorphism.

The greater iron-ore deposits occur in the Negaunee formation, which is from 1000 to 1500 feet thick, and occurs in the Lower Marquette series. Petrographically the formation comprises sideritic slate, ferruginous slate, ferruginous chert, jaspilite, and iron-ore. The ferruginous chert and jaspilite are frequently brecciated. The iron-ores resulted from the concentration of the iron-oxides through the agency of downward percolating waters. These concentration-bodies usually occur upon impervious basements in pitching troughs.

The various features connected with this iron-producing region are all worked out in great detail, and the memoir is beautifully illustrated with coloured plates of banded and brecciated rocks, and various pictorial views and sections.

H. B. W.

[1] By C. R. Van Hise and W. S. Bayley, including a chapter on the Republic Trough, by H. Lloyd Smith. ("Monographs of the U.S. Geological Survey," vol. xxviii. Pp. xxvii + 608; 35 plates, and 27 other illustrations, together with large folio atlas of maps.)

ANTHROPOLOGY IN MADRAS.

When recently on furlough in England, I was greatly interested in hunting up the facilities for the study of anthropology in London, and in the scheme for the establishment of a bureau of ethnology for the British Empire. And it has been suggested to me that it may interest those concerned in the development of anthropological research to know what is being done, in a mild way, in a remote possession of the Empire, the Madras Presidency, viz. the southern portion of the Indian peninsula. I add this geographical explanation, inasmuch as a friendly critic, in a recent review of my work, got hopelessly mixed between Madras and Bengal, reminding me of the story of the Viceroy-elect, who was overheard murmuring to himself, "Bombay in the west, Calcutta in the east, Madras in the south." Wide as is the area, and numerous as are the tribes, castes, and races included within my limited beat of 150,000 square miles, I have set myself the task, which must perforce occupy many years, of carrying out a detailed anthropological survey. This survey was, with the approval of the Madras Government, inaugurated in 1894. In that year, equipped with a set of anthropometric instruments obtained on loan from the Asiatic Society of Bengal, I commenced an investigation of the hill-tribes of the Nīlgiris, the Todas, Kotas, and Badagas, bringing down on myself the unofficial criticism that "anthropological research at high altitudes is eminently indicated when the thermometer registers 100° in Madras." From this modest beginning have resulted: (1) investigation of the various classes which inhabit the city of Madras, during my residence at headquarters; (2) periodical tours to various parts of the Presidency, with a view to the study of the more important tribes and classes; (3) the publication of bulletins, wherein the results of my work are embodied; (4) the establishment of an anthropological laboratory (Fig. 1), equipped with the apparatus necessary for carrying out anthropometric research; apparatus for testing sight, hearing, vital capacity, handgrip, &c.; a small series of Hindu, Muhammadan, Burmese and Sinhalese skulls; and an anthropomorphic series, still in a very early stage of development, but including the finger-print impressions of an Orang-utan; (5) a collection of photographs of native types, arranged in albums; (6) a series of lantern-slides for lecture purposes.

A museum, such as that of Madras, the visitors to which sign their names in Tamil, Telugu, Kanarese, Malayalam, Nāgari, Hindustani, Mahrāti, Guzarāti, Bengāli, Burmese, Sinhalese, and Chinese, lends itself to the requirements of the anthropologist, as it is resorted to by very large numbers of the poorer classes, who, in return for a small fee, are ofttimes willing to lend their bodies for the purposes of anthropometry. And, nearly every morning, I am to be seen measuring Hindus or Muhammadans, amid an admiring crowd of native visitors (the females dressed in gaudy English piece-goods), in the surrounding corridor. Quite recently, when I was engaged in an inquiry into the Eurasian or half-breed community, the booking for places was almost as keen as on the occasion of a first night at the Lyceum, and the Sepoys of a native infantry regiment, quartered in Madras, entered heartily into the spirit of what they called the "Mujeum gymnashtik shparts," cheering the possessor of the biggest handgrip, and chaffing those who came to grief over the spirometer. Anthropological research in the city of Madras, where the native community has become accustomed to the European, and discovered that, if his ways are peculiar, he is at any rate harmless, is all plain sailing. But, in the jungles and places remote from civilisation, one has to deal with simple-minded folk, unfamiliar with the eccentricities of the investigator, and suspicious of his motives. Well do I remember a native remarking at a pearl-fishery camp, "Mr. Thurston is a pleasant man, and it is a great pity he is so mad." The fact indicating insanity being that I used to sit outside my tent in the sun, at mid-day in the month of April, examining oyster after oyster in connection with the pearl-producing area.

The essential ingredients of a successful campaign in the wilds are tact, patience, 4-anna pieces, cheap cheerots, and, as a final resource, raw whiskey or brandy. The Paniyan women of the Wynaad, when I appeared in their midst, ran away, believing that I was going to have the finest specimens among them stuffed for the museum. Oh, that this were possible! The difficult problem of obtaining models from the living subject would then be disposed of. The Muppas of Malabar mistook me for a recruiting sergeant, bent on enlisting the strongest of them to fight against the Moplahs. An Irula of the Nīlgiris, who was "wanted" for some ancient offence relating to a forest elephant, refused to be measured on the plea that the height-measuring standard was the gallows. A mischievous rumour found credence among the Irulas that I had in my train a wizard Kurumba, who would bewitch their women and compel me to abduct them. The Malaiālis of the Shevaroys got it into their heads that I was about to annex their lands on behalf of the Crown, and transport them to the penal settlement in the Andaman islands; and one of them informed me that he would rather have his throat cut than be measured. On one occasion I casually photographed a group of Badagas in their bazaar, and, on the following day, a deputation waited on me with a petition to the effect that "we, the undersigned, beg to submit that your honour made 'botos' of us, and have paid us nothing. We, therefore, beg you to do this act of common justice." The deputation was made happy with a *pour boire*. Would that official deputations could be disposed of as easily!

Despite the trifling obstacles at the outset, confidence was eventually established with the various tribes just referred to, though not without a good deal of palavering and mild bribery, and a sufficient number of individuals for statistical purposes were investigated.

The main objects, which are systematically kept in sight during my wanderings, are:—

(1) To record at least the essential measurements of men, and (when they will permit) women.

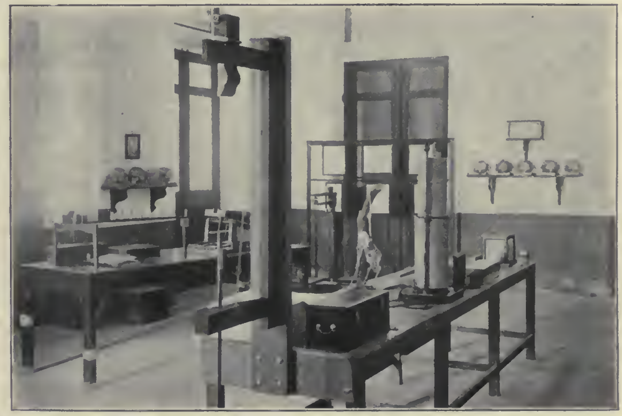

FIG. 1.—Anthropological Laboratory.

(2) To study the characteristics of external anatomy.

(3) To record "manners and customs," tattoo-marks, clothing, personal adornment, &c.

(4) To take photographs of typical individuals, dwelling-huts, &c.

(5) To acquire by purchase "specimens" illustrating clothing, jewellery, musical instruments, games, &c.

As a general rule the traveller, who makes collections in any branch of science, hands them over, as a gift or by purchase, to some national or provincial museum, and honours are divided; the museum securing the collection, and the collector being immortalised on a label or in a monograph. Possibly, with luck, a new species, or even genus, is named after him, and his reputation is enhanced in the family circle. Looking recently, on a depressing November day such as we in the East know not, at a collection of sponges which to the casual visitor possess no special attraction, exhibited in or by my name at the British Museum (Natural History), I recalled to mind the many pleasant hours spent in a dug-out (canoe) on the coral reefs, an attack by a saw-fish, and a severe sun-head. And the museum, whose destinies I have steered since 1885, teems with happy memories of camp and jungle life; for, by the fortune of circumstances, it falls within my province not only to make collections, but to preside over their arrangement for exhibition. And the advantages of this dual function are self-evident: a tour concluded, the work of museum arrangement commences; and here one is met with an obvious difficulty at the outset. For two systems of arrangement are possible, each with much to be said both for and against it, and a selection of one or the other has to be made; for the material collected, and available space will not, as a rule, suffice for both. Either the collections may be arranged according to the nature of the exhibit, *e.g.* models of boats, sacrificial utensils, musical instruments, games, images, &c.; or each tribe or community may be represented in its various aspects, animal and social, in a single case or in adjacent cases. For myself, I give the preference to the latter system, mainly on the score of convenience and finality of arrangement. Very effective, I remember, in one of my galleries, were some life-size photographic transparencies of Andamanese heads, presented by Mr. Portman to the ethnological section of the Indian Museum, Calcutta, when I was in temporary charge thereof some years ago. So, too, were the models of the Andamanese, executed, if my memory serves me rightly, by a Bengāli modeller. But the utility of most models, which I have seen, is marred by the want of care in representing the colour of the skin, and in decorating the model with the proper jewellery, which, in many cases, is absolutely characteristic of a particular tribe.

Writing elsewhere, I said: "The more remote and unknown the race or tribe, the more valuable is the evidence afforded by the study of its institutions, from the probability of their being less mixed with those of European origin." Tribes which, only a few years ago, were living in a wild state, clad in a cool and simple garb of forest leaves, buried away in the depths of the jungle, and living, like pigs and bears, on roots, honey, and other forest produce, have now come under the domesticating, and sometimes detrimental influence of contact with Europeans, with a resulting modification of their conditions of life, morality, and even language. The Paniyans of the Wynaad and the Irulas, who inhabit the slopes of the Nīlgiris, now work regularly for daily wage on planters' estates; and I was lately shocked by seeing a Toda boy studying for the third standard, instead of tending the buffaloes of his "mand." Ample proof can be adduced in support of the fact that European influence, import-trade with other countries, and the struggle for existence, are bringing about a rapid change (sad from an ethnographic standpoint) among the natives of Southern India, both tame and wild. It has recently been said that "there will be plenty of money and people available for anthropological research when there are no more aborigines"; and it behoves our museums in Great Britain and its dependencies to waste no time in completing their anthropological collections.

I gathered from observation when in London (1) that man as a social and intellectual being is illustrated with the unavoidable want of proportion, when no systematic scheme for the regular expansion of the collections is at work at the British Museum, Bloomsbury; (2) that it is under contemplation to illustrate man and the varieties of the human family from a purely animal point of view at the British Museum (Natural History), South Kensington; (3) that skulls must be sought for at the Royal College of Surgeons, Lincoln's Inn Fields; (4) that lectures and anthropological literature are available to members at the Anthropological Institute, Hanover Square. To this must be added (5) Mr. Galton's laboratory. Surely a great want of centralisation, such as might well be remedied, is indicated here. And as I wandered, both in and out of the London season, through the deserted galleries of the Imperial Institute, I could not refrain from speculating whether, with a radical change of policy for good, this much-discussed building could not be converted into our great National Museum of Ethnology, where man shall be represented fully and in every aspect, and where those interested in ethnological research could find under one roof a skilled staff to appeal to in their amateur difficulties, collections, literature, lectures, and anthropological laboratory. For the great mass of visitors to popular museums, who come under the heading of sightseers, it is of primary importance that the exhibits should be attractive. And I feel convinced that, were an ethnological museum up to the high standard of the British Museum (Natural History) established, it would, when its reputation became known, be, like Madame Tussaud's, widely resorted to by the general public, and that, by an admixture of free and paying days, and by the charge of a small fee for examination in the laboratory, it might be made to a certain extent self-supporting, and not entail a great burthen of expenditure on the State. EDGAR THURSTON.

Madras Government Museum.

NOTES.

WE are glad to notice that the Queen's birthday honours include the name of Dr. John Murray, F.R.S., of *Challenger* renown, who has been appointed a Knight Commander of the Order of the Bath (K.C.B.).

THE Chemical Society's banquet to Lord Playfair and six other past presidents who have completed fifty years' fellowship of the Society, is to be held at the Hôtel Métropole on Thursday, June 9.

THE death is announced of M. Souillart, professor of astronomy in the University of Lille, and correspondant in the Section of Astronomy of the Paris Academy of Sciences.

THE Department of Science and Art has received information that the fifth International Congress of Hydrology, Climatology, and Geology will be opened at Liége on September 25.

THE eighty-first annual meeting of the Sociéte helvétique des sciences naturelles will be held at Berne on August 1–3. This will be the sixth occasion upon which Berne has been the meeting-place of the Society. The reception will take place in the great hall of the Museum on the evening of Sunday, July 31. On the following day there will be a general meeting, a banquet, and a fête, and the sections will meet for the consideration of papers on August 2. The sections and their presidents are as follows:—Mathematics, astronomy and physics, MM. Graf, Huber, Sidler; chemistry, MM. de Kostanecki, Friedheim; botany, M. L. Fischer; zoology, M. Th. Studer; anthropology, M. Th. Studer; geology, mineralogy, petrography and palæontology, M. A. Baltzer; physical geography (comprising geodesy and meteorology), M. E. Brückner; anatomy and physiology, MM. Strasser and Kronecker; medical clinics, MM. Kocher, Müller, Sahli; hygiene and bacteriology, MM. Girard, Tavel; pharmacy and alimentation, M. Tschirch; veterinary science, M. Berdez; agriculture and sylviculture, M. Coaz.

AT the Royal Institution on Thursday, June 2, Dr. Edward E. Klein delivers the first of two lectures on "Modern Methods and their Achievements in Bacteriology," and on Saturday, June 4, Dr. Richard Caton begins a course of two lectures on "The Temples and Ritual of Asklepios at Epidaurus and Athens." The Friday evening discourse on June 3 is by Prof. W. M. Flinders Petrie, on "The Development of the Tomb in Egypt"; that on June 10 is by Lord Rayleigh, whose subject is "Some Experiments with the Telephone."

As the result of a bacteriological examination, Dr. Haffkine has reported that the recent sudden outbreak in Calcutta was due to true bubonic plague. A long and detailed statement of the facts referring to the outbreak, and the measures taken by the Government of Bengal to prevent its spread, is given in the *Pioneer Mail* of May 6. As a preventive measure, inoculation with the prophylactic virus prepared by Dr. Haffkine is recommended. It has been found that inoculation by this material prevents from 80 to 90 per cent. of deaths from plague, and reduces the plague from an epidemic form to the position of a sporadic disease. Surgeon-General Harvey was deputed by the Government of India last month to Bombay specially to examine the results of Dr. Haffkine's methods, and his report is stated to be generally favourable to the system of inoculation. The Government of Bengal have therefore decided to exempt from liability to segregation all families which have been entirely inoculated prior to the occurrence of any case of plague among them. Inoculation is not to be forced on the people, but if a member of a completely inoculated family is attacked by the plague, neither he nor his family will be liable to removal to a segregation camp.

At the anniversary meeting of the Royal Geographical Society on Monday, the medals were presented as already announced (p. 38). In the course of his address, the President said that a very sympathetic reply had been received from the Prime Minister's private secretary to the appeal on behalf of a Government Antarctic expedition. A German expedition was being organised on a liberal scale, and funds were being collected throughout Germany for the purpose. Moreover there was reason to hope that the Norwegian Government might send out an expedition also, perhaps under the leadership of Dr. Nansen, to carry out exploration mainly on land. Meanwhile the Belgian expedition, under M. de Gerlache, had been actively engaged, and the expedition, liberally supported by Sir George Newnes, under Mr. Borchgrevink, was in an advanced state of preparation. After a brief reference to Mr. Jackson's account of the Jackson-Harmsworth expedition, to Lieutenant Peary's labours, and to those of Captain Sverdrup, Colonel Fielden, Mr. Pearson, Mr. Arnold Pike, and Sir Martin Conway, the President said that German and Swedish expeditions were in progress for Spitsbergen and Franz Josef Land. Germany was setting an admirable example in scientific exploration. Besides the Antarctic expedition referred to, the German Government had made a grant of 15,000*l.* for oceanic research, especially in the Atlantic and Indian oceans. In the North Atlantic much good work was done under the joint co-operation of the Swedish, Norwegian, German, and British Governments. He hoped that during the coming summer authentic and satisfactory information concerning the hazardous balloon expedition undertaken by M. Andrée would be received.

Mr. Borchgrevink has given to a representative of Reuter's Agency some details of the arrangements for the Antarctic expedition which will shortly leave for Australia and South Victoria Land. He said that his ship, the *Southern Cross*, has been designed by the builder of the *Fram*, and has 10 feet of solid oak at her bows, and at her weakest point is 32 inches in thickness. Over all she is sheathed with 3 inches of American greenheart—a wood which never splits, and is very hard and slippery. The *Southern Cross* will fly the British flag, and will leave London in July. A pack of sixty-five Siberian sledge-dogs will be taken, and a number of sledges for the inland journey on the South Victorian continent. The object of the expedition is to explore South Victoria Land, and to investigate the seas and islands between there and Australia. Mr. Borchgrevink is taking with him stores for three years and a supply of carrier-pigeons.

Information of the death of Mr. Edward Wilson, F.G.S., who for the past fourteen years has been Curator of the Bristol Museum, has been received from Mr. F. W. Knocker, Sub-Curator of the Museum. Having a good general knowledge of zoology and botany, and an extensive acquaintance with geology, Mr. Wilson was admirably fitted for his position. His efforts to enrich the Museum were zealous and untiring, and he was engaged during the last month of his life in procuring a large collection of mammalian remains and some worked flints from the cavern-deposits of Uphill, near Weston-super-Mare. He had likewise arranged in the Museum a special students' collection of minerals, rocks and fossils, of which he prepared a separate catalogue, in addition to his numerous issues of the "Guide to the Bristol Museum." For many years prior to his removal to Bristol, Mr. Wilson had been a science teacher at Nottingham, and he was there led to pay particular attention to the Permian and Triassic strata, the Rhætic beds and the Lias, to our knowledge of which he made considerable additions in papers dating from 1868. In 1885 he published an important article on the Marlstone of Leicestershire as a source of iron. Later on he devoted himself more especially to the study of the Liassic Gasteropoda, on which subject he had become our chief authority. He was joint-author, with Mr. W. H. Hudleston, F.R.S., of a Catalogue of British Gasteropoda, 1892. More recently he has laboured in company with Mr. S. S. Buckman at the palæontology of Dundry Hill. A new Liassic Gasteropod was named *Wilsonia* in honour of Mr. Wilson, by Mr. Hudleston, and the Council of the Geological Society awarded to him in 1888 the Murchison Geological Fund. He died after a short illness on May 21, at the early age of forty-nine, and his loss will be widely felt by his many friends. All acquainted with him entertained the highest regard for his gentle unassuming character, as well as for his able and painstaking researches.

The report of the Committee appointed by the Society of Arts to consider the causes of the deterioration of paper is printed in the current number (May 20) of the Society's *Journal*, and is here summarised. At the outset, the report points out that during the present century the paper-making industry has undergone many revolutionary changes. As an industry it has grown considerably, and to meet the requirements of the enormously increased production a quantity of new fibrous raw materials have been introduced and have taken their place in due course as indispensable staples. The more important of these, so far as concerns this country, are esparto, in the period 1860–70; "mechanical wood" or ground wood pulp, in 1870–80; the wood celluloses, in the period 1880–90. These substances differ in chemical composition from the celluloses obtained from cotton, flax and hemp, which were the exclusive staple raw materials for paper making up to this century; and although they are efficient substitutes in most respects, it must be admitted that time has not yet been able to pronounce a judgment upon the relative permanence of the papers made from them. There is more than a suspicion that many of them are very inferior in this important respect, and it has been the main purpose of the work of the Committee to sift the evidence upon which such suspicions have been engendered.

The Committee referred to above have examined a number of books as evidence of "deterioration of paper"; some submitted by librarians in a condition of complete disintegration; some of their own selection exhibiting various grades of deterioration of the paper of which they are composed. They conclude on the evidence before them as follows:—As to the two tendencies to deterioration of papers these are marked (1) by disintegration, (2) by discoloration. They are independent effects, but may be concurrent. They are notably so in papers containing mechanical wood pulp. Actual disintegration has been brought to light in papers of all grades; from those of the best quality as regards the fibrous materials of which they are composed, *i.e.* rag papers; also of course in those of lowest quality, *i.e.* containing mechanical wood pulp in large proportions. It is generally the result of chemical change of the fibres themselves. As to the causes determining such changes: in the case of the rag papers examined the effects appear to be due to acid bodies; the disintegration may be generally referred to acidity. In the case of mechanical wood pulp the effects are traceable to oxidation pure and simple; the disintegration is accompanied by a basic or alkaline reaction of the paper. Discoloration may be said also to affect all papers more or less, and without discussing minutely the chemistry of the changes, the evidence obtained certainly warrants the general conclusion that discoloration of ordinary cellulose papers (as distinguished from those containing mechanical wood pulp) under usual conditions of storage is proportional to the amount of rosin which they contain, or more generally to the rosin and the conditions employed for fixing it in the ordinary process of engine-sizing. The Committee have been desirous of bringing their investigations to a practical conclusion in specific terms, viz. by the suggestion of standards of quality. They limit their specific findings to the following, viz. (1) normal standard of quality for book papers required for publications of permanent value. For such papers they specify as follows:—Fibres: not less than 70 per cent. of fibres of the cotton, flax, and hemp class. Sizing: not more than 2 per cent. rosin, and finished with the normal acidity of pure alum. Loading: not more than 10 per cent. total mineral matter (ash).

The Röntgen Society has appointed a Committee to inquire into the alleged injuries produced by exposure to Röntgen radiation. In order to obtain accurate information, the committee has prepared a set of questions framed with a view of determining the cause or causes of the injuries received.

A note in *Comptes rendus* (May 9) states that M. Mascart has received information that Prof. Leist has found at Kotchétovka, in the province of Kursk (Russia) a local magnetic pole; that is to say, a point where a dipping needle stands vertical. It is necessary to move twenty metres from this point to change the direction of the needle by 1°. The declination needle sets itself indifferently in any direction in the spot where this magnetic anomaly occurs.

M. Vincent stated at a meeting of the Academy of Medicine, held on May 10 (says the *Lancet*), that he has found that French soldiers are on an average a hundred times more subject to typhoid fever than native soldiers—a singular observation, because this disease is in general serious when it attacks Arabs. The comparative exemption of the Arabs depends, in his opinion, neither on a previous attack nor on a slow acclimatisation consequent on residence in towns, but on a natural immunity comparable to the immunity of negroes against yellow fever, or of Algerian sheep against anthrax.

The U.S. Weather Bureau has published in its *Bulletin* No. 21, an abstract of a report on solar and terrestrial magnetism in their relations to meteorology, by Prof. F. H. Bigelow, who has during the last six years devoted much time to the study of the fundamental principles of this important subject. It is stated in the introductory text that he is of opinion that the atmospheric conditions which culminate in the storms traversing the United States are in part dependent upon the solar energy that reaches the earth in the form of magnetic force, and that there are synchronous fluctuations in the pressures and temperatures of the north-western regions of the American continent in the neighbourhood of the magnetic pole. Prof. W. L. Moore, the chief of the Weather Bureau, is of opinion that while at this stage of the investigation the sequence of cause and effect is not shown with sufficient definiteness to justify the weather forecaster in attempting to apply these theories in predicting marked atmospheric disturbances, the paper will lead to discussion and result in further additions to our knowledge of magnetic science.

Petermann's Mittheilungen publishes a new map of the central highlands of northern German East Africa. Much new matter is introduced by the addition of the surveys made by Premier-Lieut. Werther on the so-called Irangi expedition during 1896 and 1897; the map itself is drawn by Dr. B. Hassenstein. A paper describing the main features of the country traversed by the expedition is appended by Lieut. Werther.

Prof. A. Supan contributes a careful analysis of the reports and statistics of trade in China for the year 1896 to *Petermann's Mittheilungen*. The results lead him to expect immense developments from the construction of railways, even within the next decade, and he believes the establishment of Germany at Kiaou-tschou will mark the beginning of a new era in the trade of that country.

We have received the index to the first ten volumes of the *Mittheilungen von Forschungsreisenden und Gelehrten aus den Deutschen Schutzgebieten*. The index, which covers the years 1888 to 1897, is arranged under six separate headings, four of which are subdivided according to the different colonies. Dr. von Danckelman is the editor.

The *Verhandlungen des naturhistorischen Vereins der preussischen Rheinlande* contains a long paper, by Herr R. Hundt, on the petrography and palæontology of the middle Devonian rocks of south-west Prussia. The geology of the *Lenneschiefer* beds is discussed in detail, and a comparison with the Calceola beds of the Eifel is based on the distribution of fossils of Calceola and Stringocephalus. A map of the region is appended.

A recently issued part of the *Proceedings* of the U.S. National Museum (vol. xx., No. 1134) contains an important contribution to our knowledge of the ornithology of the Philippine Islands, by Messrs. Worcester and Bourns. The first portion of this memoir consists of a complete list of the 526 birds as yet known to inhabit the various islands of the Philippine archipelago and of those of the adjoining group of Palawan in a tabular form, and shows their occurrence or absence in thirty-seven islands of the two series. Taking this list as a text, Mr. Worcester proceeds in the second portion to discuss the very interesting problems presented by the distribution of the birds in these islands. Each island is taken in order, a list of its known birds is given, and its relationships, as thus shown, are worked out. Mr. Worcester comes to the conclusion that Mr. Everett's view (*Proc. Zool. Soc.*, 1889) that Palawan and its satellites belong ornithologically to Borneo, and not to the Philippines, is amply confirmed by recent evidence. Turning to the Philippines proper, the author shows that the five "sub-provinces" into which Dr. Steere, in 1894, proposed to divide the Philippine area are not maintainable. Nor is Mr. Worcester better satisfied with Dr. Steere's deduction that each genus of Philippine birds is represented by a single species only in each island. The contrary is manifestly the case in many instances. The memoir is illustrated by a map and numerous diagrams, and is worthy of careful study by all who are interested in laws of geographical distribution.

One of the most important services performed by the Agricultural Experiment Stations found in almost every one of the United States, is the instruction of the farmer and the fruit-grower in the life-history of the animal and vegetable foes which destroy or injure his crops, and in the mode of combating them.

From the Cornell University Experiment Station, located at Ithaca, N.Y., we have received *Bulletin* No. 145, devoted to two important diseases of the pear, the "leaf-spot" (*Septoria piricola*), and the "leaf-blight" (*Entomosporium maculatum*), by Mr. B. M. Duggar, admirably illustrated; and from that for the University of Wisconsin *Bulletin* No. 65, on a bacterial rot of cabbage and allied plants (*Bacillus campestris*), by Mr. H. L. Russell, also well illustrated. These bulletins and the annual reports are sent free to all residents in the State on request. From the Michigan State Station we have also received *Bulletins* Nos. 151-153, containing a very large amount of practical information on the growth of vegetables and fruits suitable for cultivation in that State.

IN a recent article (March 17, p. 464) on the resources of the West India Islands, reference was made to the necessity for supplementing the staple products by the introduction of a variety of cultural industries which would increase the wealth of these Colonies. The obvious way to lead to such developments is to establish a department of economic botany, for the purpose of carrying out systematic experiments concerned with agricultural cultivation, wherever necessary, and to extend the equipment of existing botanic gardens so that proper attention can be given to the introduction of new plants. Mr. J. H. Hart, the Director of the Royal Botanic Gardens at Trinidad, in a lecture reprinted in the *Bulletin* of the Gardens, shows that many at present minor industries might be developed with profit in the Colony. He points out that Trinidad could grow enough mahogany and cedar to supply the markets of Great Britain, and if the island was simply a mahogany and cedar forest, it would be one of the richest of our colonial possessions. Yet no one plants cedar trees in the island, and no one plants mahogany. Jamaica exports logwood to the value of 300,000*l*. annually, but Trinidad, where logwood of the very finest quality can be grown, sends none to market. Rubber trees grow well in the Island, the trees in the Botanic Gardens yielding from four to six pounds of rubber per tree per annum, but they are not cultivated to any extent outside the Gardens. In addition to these potential crops, Mr. Hart enumerates fifty other products which could be successfully grown in Trinidad. His lecture shows the valuable assistance which botanic gardens are able to give to cultivators; and we are glad to see that the botanical department under his direction is to be extended, land having now been allotted for the purpose of establishing a section for economic and scientific work. The extension encourages the hope that the reproach, that "Trinidad has the wealth of the Straits Settlements going to waste," will soon be removed.

THE fifth and sixth Reports on the Yorkshire Carboniferous Flora, by Mr. Robert Kidston, are reprinted from the *Transactions* of the Yorkshire Naturalists' Union.

THE third edition of Mr. W. T. Lynn's little book on "Remarkable Eclipses" has just been issued by Mr. Edward Stanford. The book has been brought up to date by mention of the total solar eclipses of August 1896, and January last.

A SECOND edition of "Applied Bacteriology," by Messrs. T. H. Pearmain and C. G. Moor, has just been published by Messrs. Baillière, Tindall, and Cox. Several parts of the book have been enlarged and improved, and the whole has undergone revision. A short account of the bacteriology of sewage has been added. The volume provides students, medical officers of health, analysts and sanitarians with a good general survey of the science of bacteriology.

THE second part of Mr. W. P. Hiern's "Catalogue of the African Plants collected by Dr. Friedrich Welwitsch in 1853-61," comprising the natural orders of Dicotyledons from Combretaceæ to Rubiaceæ, has just been published by the Trustees of the British Museum (Natural History). Another publication which has just been issued from the Museum is a list of the types and figured specimens of fossil Cephalopoda in the collection, prepared by Mr. G. C. Crick.

THREE papers of interest to anthropologists appear in the *Proceedings* of the Royal Society of Tasmania (1897). One contains the results of measurements of the crania of Tasmanian aboriginals now in the Hobart Museum, compared with measurements of the skulls of Europeans, by Dr. A. H. Clarke and Mr. W. E. Harper. The authors do not attempt to draw conclusions as to the origin of the Tasmanian aboriginals, nor to define their characteristics; but the measurements of the skulls of an extinct race constitute a work of value to anthropologists. The two other anthropological papers in the *Proceedings* are by Mr. J. B. Walker; they contain a number of interesting notes on the Tasmanian aborigines, extracted from the journals of his father.

THE Rev. Prof. G. Henslow has in preparation a volume entitled "Medical Works of the Fourteenth Century," consisting of transcripts with notes from four MS. volumes contemporary with the works of Wiclif and Chaucer. These transcripts will furnish illustrations of the crude and quaint conceptions of the value of plants as drugs prevailing in the Middle Ages. The volume will also contain an alphabetical list of upwards of 700 medical and other plants mentioned in works of the fourteenth century, compiled and identified with their modern English and Latin equivalent names.

PROF. T. W. RICHARDS, of Harvard, whose name is already identified with the accurate determination of atomic weights, has recently published the results of a redetermination of the atomic weights of nickel and cobalt. The close approach to equality in the atomic weights of these elements has always given a special interest to any such redetermination, and this interest has been increased in recent times by the suggestion that the two elements are ordinarily associated with a third new element—"gnomium," which is not separated from them in the usual course of analysis. The evidence on which this suggestion was based by Krüss and Schmidt was subsequently rebutted by the work of Winkler; yet Winkler's own determinations of the atomic weight of cobalt by two different methods gave results which differed by 1 part in 200, viz. 59·82 and 59·52. Still later determinations by Hempel and Thiele, by three methods, gave respectively 58·99, 58·78 and 58·91. The method employed by Prof. Richards consisted in the preparation of the bromides of nickel and cobalt, and their analysis by means of pure silver nitrate. The greatest precautions were taken in order to obtain pure anhydrous materials, and the same methods of manipulation employed as in the previous case of the determination of the atomic weight of magnesium. The fourteen experiments with nickel bromide agree remarkably, the extreme differences being just over 1 part in 1000. Thirteen experiments with cobalt bromide show an equally good agreement. The numbers given finally are for nickel 58·69 and cobalt 58·99 (O = 16). Prof. Richards, anticipating the criticism that his determinations are based on a single method, remarks that a series of carefully conducted determinations by a single reliable method have especial value in the case of nickel and cobalt, where hitherto accuracy has been sought by varying the methods rather than by securing constancy in the results attainable by any one of them. Prof. Richards concludes that discrepancies among previous determinations of the atomic weights of nickel and cobalt afford no evidence of the existence of the hypothetical gnomium, nor do his own observations in any way indicate the existence of such an element.

THE additions to the Zoological Society's Gardens during the past week include a Guinea Baboon (*Cynocephalus sphinx*, ♂) from West Africa, presented by Captain H. de la Cour Travers; a Vervet Monkey (*Cercopithecus lalandii*, ♂) from South Africa, presented by Mr. C. J. Barratt; a Common Raccoon (*Procyon lotor*) from North America, presented by Mr. A. D. Jenkins; a Reindeer (*Rangifer tarandus*, ♂) from Newfoundland, presented by the Hon. M. A. Bourke, H.M.S. *Cordelia*; a Common Guillemot (*Lomvia troile*), British, presented by Mr. Ernest Horne; a Seven-banded Snake (*Tropidonotus septemvittatus*) from North America, presented by Mr. James Meldrum; a Barbary Ape (*Macacus innus*, ♂) from North Africa, a Red-River Hog (*Potamochœrus penicillatus*) from West Africa, a Beccaris Cassowary (*Casuarius beccarii*) from New Guinea, two Orange-winged Amazons (*Chrysotis amazonica*), two Blue-fronted Amazons (*Chrysotis æstiva*) from South America, deposited; a Leucoryx Antelope (*Oryx leucoryx*, ♂) from North Africa, purchased; a Red-winged Parrakeet (*Ptisles erythropterus*, ♀), a Long-billed Butcher-Crow (*Barita destructor*) from Australia, received in exchange; two Japanese Deer (*Cervus sika*, ♂ ♀), three Shaw's Gerbilles (*Gerbillus shawi*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE :—

June 3. 6h. 34m. to 9h. 25m. Transit of Jupiter's Sat. III.
4. 8h. Eastern elongation of Saturn's Sat. Japetus.
4. 8h. 10m. to 9h 11m. Occultation of A Ophiuchi (mag. 4·7) by the moon.
4. 15h. 43m. to 16h. 34m. Occultation of B.A.C. 5909 (mag. 6·2) by the moon.
5. 10h. 15m. to 11h. 22m. Occultation of λ Sagittarii (mag. 3·1) by the moon.
9. 11h. 31m. to 12h. 23m. Occultation of B.A.C. 7804 (mag. 6·1) by the moon.
9. Saturn. Outer minor axis of outer ring, 18″·62.
10. 10h. 23m. to 13h. 16m. Transit of Jupiter's Sat. III.
12. 19h. Neptune in conjunction with the sun.
15. Venus. Illuminated portion of disc 0·853.
15. Mars. ,, ,, ,, 0·919.
15. Jupiter. Polar diameter, 34″·8.
15. Saturn. ,, ,, 17″·0.
17. 9h. 45m. to 11h. 23m. Transit of Jupiter's Sat. IV.
18. 10h. 59m. Minimum of β Persei (Algol).
23. 5h. Inferior conjunction of Saturn's Sat. Japetus.
29. Saturn. Outer minor axis of outer ring, 18″·33.

The transit of Jupiter's fourth satellite on June 17 is the only one visible during 1898.

BLURRING ABERRATION IN THE TELESCOPE. — Some time ago we referred in this journal (December 30, 1897, p. 200) to a communication by Prof. Schæberle which pointed out that the optical image of a celestial object, formed in the focus of a reflecting telescope of great angular aperture, is possessed of errors of definition which arise from a cause hitherto unrecognised by mathematical and practical opticians. The main results of this paper briefly summed up are as follows:—First, that the focal plans of a curved reflecting surface for parallel rays impinging thereon is situated upon the axis, half-way between the centre of curvature and the reflecting surface itself; and, second, that the plane of the image formed by each small patch of the converging surface tends to lie at right angles to the path of the focussed rays, so that the images formed from every minute portion of the reflecting surface, while their centres may coincide on the axis of the telescope, all tilt from the focal plane directly as the extreme of aperture is approached, or as the focal point is shifted from the axis. In the *Transactions* of the Astronomical and Physical Society of Toronto for 1897, Mr. J. R. Collins, in referring to Prof. Schæberle's paper, points out that it is possible to so proportion the curvatures of the reflecting surfaces of the Gregorian form of reflecting telescope (where the image is formed by the large reflector in front of the small concave mirror, and the light is thrown back to a focus on the axis through an opening in the centre of the large reflector to the eye-piece), as to completely correct the tilt and want of uniformity of dimensions of the components of the compound image, that it may reach the front of the eye-piece entirely freed from these defects. It may be remarked that the tilting of the image not only occurs in the case of the reflector, but in that of the refractor also, the effect in the latter case being twice as great as that in the former. In fact, the Schæberle aberration is a defect that exists in all forms or combinations of lenses, and must, therefore, be taken into account if we wish to attain maximum efficiency in definition.

PHOTOGRAPHY BY THE AURORA BOREALIS.—Mr. J. E. Turner, writing in *The Amateur Photographer* for May 6, describes a unique photograph which he has obtained. It seems that on April 15 Gourock was visited by a very vivid display of the aurora borealis, which lasted from 10 to midnight. The moon having set at 9.13 p.m. and not rising again until 4.5 a.m. the next morning, he thought it might be possible to get a photograph merely by the light of the aurora borealis, and he consequently exposed a plate towards the northern horizon, giving an exposure of only two minutes with f/8 and a Paget xxxxx. plate. The negative, when developed with a very weak pyro and ammonia developer for about one hour, came out well and showed clearly the nearest land that was three miles distant, together with the houses, which were clearly defined, besides numerous trees in the foreground. The photograph is reproduced in the above-named journal. It is not mentioned whether an impress of the aurora itself was obtained, but only the statement: "the stars also nearest the zenith are faintly seen, the light from the aurora, of course, obscuring them."

MR. TEBBUTT'S OBSERVATORY.—The Report of Mr. Tebbutt's Observatory at Windsor, New South Wales, for the year 1897, shows that the number of observations made is up to the standard of former years. The 8-inch equatorial was employed for observing occultations of stars by the moon, 134 phases being noted, and numerous minor planets. Perrine's comet was also diligently watched for several weeks, and many variable stars and phenomena of Jupiter's satellites observed. The meteorological observations have been as usual regularly made. Seven years' meteorological observations are now in hand, and will be soon published; and when this is completed, there will be a period of thirty-five years of published data which will be invaluable for investigating the local climate. In consequence of recent local legislation, Mr. Tebbutt writes: "A notice was sent to the Minister of Public Instruction on October 11 last, that it was intended at the close of the year to discontinue the meteorological department, and the hope was expressed that the Government would see fit to continue the work at its own expense. A reply was received stating that the work would be continued . . . at the Hawkesbury Agricultural College, about four miles west of the Observatory." Such an arrangement as this was evidently very satisfactory, for it would have been a crime to have suddenly broken the continuity of what must be valuable data for investigating the climatic conditions of New South Wales. "After due inquiry," as Mr. Tebbutt further states, "at the close of the year, it turned out, however, that provision had not been made for continuing the Windsor meteorological work in all its departments. It is proposed to continue at this observatory observations of the daily rainfall by the two gauges, and to secure the monthly maximum and minimum air temperatures." We hope that the Government will not be long in seeing that due attention must be paid to the question of meteorology in New South Wales, and that, after private enterprise has carried on the work for so many years, it becomes a duty to see that a breach in the continuity of the observations is not made through lack of funds.

SOME NEW STUDIES IN KATHODE AND RÖNTGEN RADIATIONS.[1]

THE researches of Crookes, Lenard, and Röntgen have given to man a new eye; they have, perhaps, also given to nature a new light; they have certainly given to science more than one new problem. A vacuum tube may appear but a simple piece of apparatus; but were we acquainted in their entirety with the secrets that it contains, we should know much at present utterly unknown, not only as regards electrical action, but also in reference to the fundamental constitution of matter, and the

[1] Abstract of Friday evening discourse delivered at the Royal Institution on February 4, by Alan A. Campbell Swinton.

true mechanism of energy. It is, in fact, for the reason that within the Crookes' radiant matter tube it is possible to deal, not as in every-day life with aggregates of matter, but perhaps individually with single molecules and single atoms floating apart in space, that so much attention is at present being devoted to this particular branch of physics.

Every one is now acquainted with what has become the quite ordinary phenomenon of the kathode rays. These excite luminescence in the glass upon which they fall, and cast a sharp shadow of any obstacle interposed in their path. When the tube is suitably placed in a magnetic field the shadow rotates and becomes at the same time smaller, the magnetic field having thus the property of concentrating the rays, and at the same time giving them a twist. This concentration of the kathode rays by means of a magnetic field, which has been studied by Birkeland and by Fleming, can be employed to show the intensely heating effect and erosive properties of the rays. Indeed, by suspending a tube over one pole of a straight electro-magnet, and thus concentrating the rays to a point, it is possible by moving the tube or the magnet to actually engrave on the interior surface of the glass a figure of any desired form.

The more ordinary method of producing a concentrated kathode discharge is by employing as kathode a spherical aluminium cup, from the concave side of which the rays are given off normally to the surface. By employing two such cups, connected to the two secondary terminals of an induction coil supplied with alternating electric current, and giving at the secondary terminals a pressure of about 20,000 volts, the intense heating effect of the kathode rays can readily be shown by allowing them to fall upon a small fragment of quicklime. In this manner a brilliant and beautiful light is produced, and it is not at all improbable that it may eventually be found possible to obtain in this way, commercially and practically, high voltage electric lamps of much higher efficiency than the ordinary incandescent filament lamps, and possibly even rivalling arc lamps. In both these latter it is necessary that the incandescent substance should be a fairly good electrical conductor; whereas in the kathode ray lamp there is no such limitation, and consequently there is a much wider range of available refractory substances. It is also quite conceivable that in the future an electric furnace of this nature may be found of service in some of the more delicate of chemical investigations, where it is necessary to obtain in isolated substances exceedingly high temperatures. Indeed, already, Crookes and Moissan have employed this means for turning into graphite the surface of diamonds.

It is now becoming more and more generally believed that Sir William Crookes' original theory as to the nature of these kathode rays is correct. According to this theory they consist of material particles of residual gas, which, being similarly electrified by contact with the kathode, are violently repelled by the latter. This has been the view held for a long time by most English physicists, and the chief point of difference now appears to be whether these material particles are single atoms, single molecules, or larger aggregations of matter. This theory is supported by the erosive action of the rays, which are found after a short time to bore straight and very minute holes right through the block of quicklime in the kathode ray lamp. A model, consisting of a gilded pith ball suspended between two metal plates connected to a Wimshurst machine, may be used to roughly illustrate what is supposed to occur. The ball obtains an electrical charge from whichever plate it starts in contact with, and is violently repelled into contact with the other plate, and so on backwards and forwards. In a Crookes' tube, however, the velocity of the negative stream is undoubtedly much higher than that of the positive stream. This may be connected with the fact that the positive discharge is much more dispersive than the negative. Indeed, a tube while in action appears to be filled almost entirely with positively electrified atoms, while it is only behind the kathode and in the kathode stream itself that any negatively electrified atoms are to be found. It is, however, possible to show experimentally that something, at any rate, producing the same effect as a positive stream does exist at very high exhaustions. For this purpose a radiometer tube, as shown in Fig. 1, containing a small mill wheel with mica vanes, similar to those employed by Crookes, may be used. The wheel is mounted upon a sliding carrier, so that it can be moved bodily either out into the centre of the tube, when the kathode stream impinges directly upon the vanes, or back into an annex, when the vanes are quite outside the kathode line of fire. In the former position, as discovered by Crookes, the wheel rotates with great rapidity in a direction indicating an atomic stream from the kathode to the anode. In the latter position, with sufficiently high exhaustion, the wheel is found by the author always to rotate in an opposite direction, indicating a returning stream of atoms from the anode to the kathode, the anode stream passing outside of the kathode stream. As suggested by Prof. G. F. Fitzgerald, some action of this nature will perhaps explain the curious effects obtained by the author, and already noticed in NATURE for April 15, 1897, from which it appears that both the convergent and divergent cones of kathode rays in a focus tube are usually hollow, it seeming likely that if the supply of atoms to the active kathode surface is from all round the edge of the latter, the atoms may be all shot off again from the kathode in the form of a hollow cone, before they get further than a certain distance towards the centre.

Birkeland has shown that if a thin kathode stream, obtained by passing the rays from a flat kathode disc through a narrow slit in a piece of platinum serving as the anode, is deflected by a suitable magnetic field, it is split up into bundles of rays; and if allowed to fall upon the glass walls of the tube, it gives fluor-

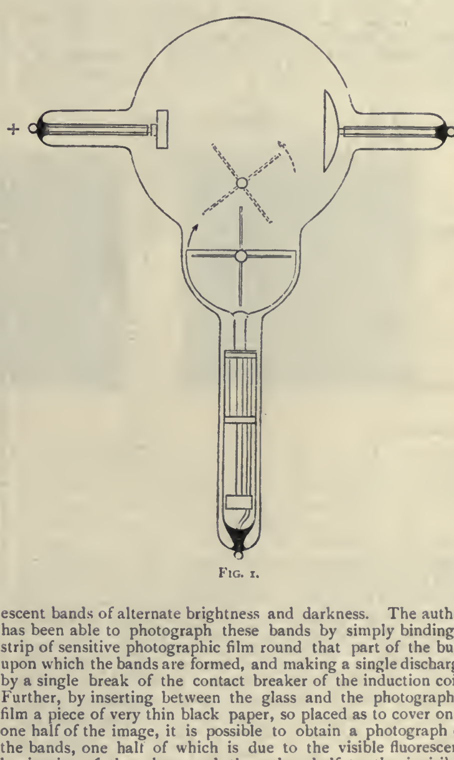

Fig. 1.

escent bands of alternate brightness and darkness. The author has been able to photograph these bands by simply binding a strip of sensitive photographic film round that part of the bulb upon which the bands are formed, and making a single discharge by a single break of the contact breaker of the induction coil. Further, by inserting between the glass and the photographic film a piece of very thin black paper, so placed as to cover only one half of the image, it is possible to obtain a photograph of the bands, one half of which is due to the visible fluorescent luminosity of the glass, and the other half to the invisible Röntgen rays. Photographs produced in this manner show that the Röntgen rays are also under these conditions given off in bands, which are co-terminous with the fluorescent bands, though photographically fainter than the latter. It is important to note that in the Röntgen ray photograph the greatest effect is always produced by the least deflected of the kathode-ray streams; that is to say, by that stream which is presumably travelling at the greatest velocity. Here we have a probable explanation of the existence of the bands, which are most likely due to the atoms of the kathode rays having from the first different velocities imparted to them, due to the oscillatory character of the induction coil discharge, and from their gathering into groups travelling at different velocities, on the well-known principle that occasions the traffic in the street to form knots of maxima and minima, owing to the faster vehicles catching up the slower, and being impeded by them.

Passing on to the production of X-rays in tubes of the ordinary focus type, it is found that the particular material employed for the anti-kathode surface considerably affects the production of the Röntgen rays. This is a subject that was first investigated by Prof. Sylvanus Thompson, who found that the best absorbents were the best emitters of the Röntgen rays; in other words, that the best materials for the anti-kathode were metals of the highest atomic weight. If, as seems probable, the Röntgen rays are produced by the sudden removal of velocity from the kathode ray atoms by collision with the anti-kathode, this is in accordance with what would be expected, as substances of high atomic weight would obviously be the most efficient by reason of the greater inertia of their atoms. The author has made numerous experiments with various metals for the anti-kathode, comparing them in a tube in which the anti-kathode, made half of one metal and half of another, was movable. By jerking the tube, either half could be brought opposite the kathode, and put into use; so that under exactly similar conditions it was possible to accurately compare the efficiency of the two substances. Of available substances, platinum was found to be much the best.

The usual method adopted for varying the resistance of a Röntgen ray tube, and thus modifying the character of the

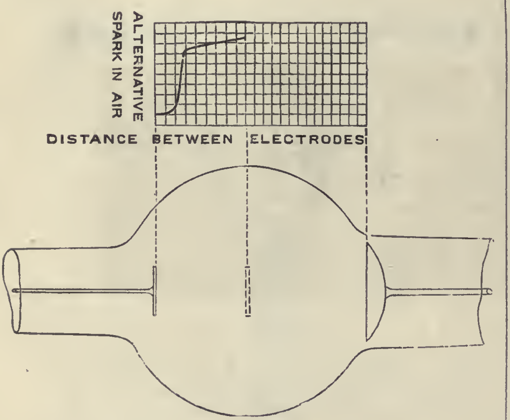

FIG. 2

Röntgen rays it produces, so as to obtain the exact penetrative quality that is desired, is by varying the vacuum. The higher the exhaustion the greater is the resistance in the passage of the discharge, the greater appears to be the velocity of the kathode stream, and the more penetrative are the Röntgen rays. This variation of the vacuum is usually effected by heating the tube, which has the effect of driving out into the interior molecules of the residual gas condensed or occluded upon the glass. Apart from this, however, it is suggested that very possibly the temperature of the contents of the tube and the consequent kinetic energy of the molecules, which is greater the higher the temperature, may in itself assist the passage of the discharge. The author has found other means of varying the resistance of the tube, and altering the character of the Röntgen rays that it generates, which do not depend upon either the degree of exhaustion or upon the temperature. According to one method the tube is fitted with two or more kathodes of different sizes, but all focussing upon the same anti-kathode. With such a tube it is found that the smaller the kathode the greater is the E.M.F. required to cause the electric discharge to pass through the tube, and the more penetrative are the Röntgen rays generated. Another method of effecting regulation consists in making the anti-kathode, which is also the anode, movable, and altering the distance between it and the kathode. Still another, in making the kathode movable, and altering its position relative to the glass walls of the tube. Some of the author's experiments in these directions have already been described in NATURE for April 29 and May 27, 1897. He has, however, now further studied the cause of these effects by means of a tube in which the positions of both anode and kathode can be altered independently by means of a magnetic adjustment. Fig. 2 shows a portion of this tube, and above it is drawn a curve representing, in terms of the alternative spark in air, the difference of potential required to cause a discharge to pass through the tube with varying positions of the anode. In the diagram the abscissæ represent the distance between anode (which also formed the anti-kathode) and the kathode, divided in tenths of an inch, while the ordinates represent also in tenths of an inch the length of the alternative sparks in air between two brass balls ¾ inch in diameter. Starting with the anode in its furthest position from the kathode, and moving it gradually towards the latter, it will be observed that at first there is a slight gradual increase in the length of the alternative spark. Then for the next small movement there is a very sudden increase, and after that a further gradual increase till the point marked in dotted lines is reached, which denotes the limit of travel that the anode was allowed. Similarly, Fig. 3 represents the effect of moving the kathode in the same tube, the anode being stationary in the position shown. Here, as will be seen, the less the distance between the kathode and anode the less is the length of the alternative spark. This distance in this case

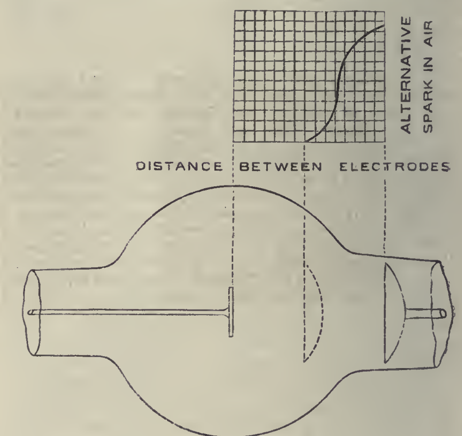

FIG. 3.

does not appear to be the determining factor, as it is more than counterbalanced by the more important factor of the position of the kathode relatively to the glass walls of the tube. Starting with the kathode as far away as possible from the anode, and moving it towards the latter, there is a gradual decrease in the length of the alternative spark to commence with, then a further, much more rapid decrease, as the kathode emerges from the annex, and a still further, but less sudden decrease, as the kathode is moved away from the glass walls out into the bulb. Now as to the effect upon the Röntgen rays, as it has been before remarked, the greater the resistance of the tube and the greater the E.M.F. necessary to cause a discharge to pass, the greater is the velocity of the atoms that form the kathode stream, and the more penetrative are the Röntgen rays produced. Further, so far as the movable kathode is concerned, the supply of atoms appears to be of great importance. If penetrative Röntgen rays are desired, the access of atoms to the kathode must be restricted. If only a few atoms can get to the kathode, these are projected at great velocity; if there is too ready access, the atoms crowd in upon the kathode, and the electrical charge of the latter is unable to throw them off with much speed. It is possible to restrict the supply of atoms to the kathode either by bringing the latter back into a recess or annex, as in the tube just shown, or by using a tube in which both kathode and anti-kathode are fixed, but in which there is a movable conical glass shield which can be brought up from behind the kathode so as to impede the access of the atoms which, as we have seen, come in round the edges of the kathode, to any desired extent. This tube regulates just as did the adjustable kathode tube.

In order to produce sharply-defined Röntgen photographs, it is of course of the utmost importance that the rays should be given off from a very small area. The sharpness of definition varies considerably with different tubes, and a ready means of judging as to their quality in this respect is very useful.

The best and most accurate method is by means of pin-hole photography. Seeing that the Röntgen rays are not refracted, photography with a lens is, of course, out of the question; but with a pin-hole, very accurate and distinct images can be obtained. It is only necessary to place a sheet of lead, pierced by a pin-hole, near the tube, and then to examine the rays coming through the hole with a fluorescent screen, placed some way behind the lead sheet, in order to see exactly the size and shape of the active area of the anti-kathode; or, instead of the screen, a photographic plate may be employed and the effect recorded. Fig. 4 shows three pin-hole photographs of the anti-kathode taken in this way, giving the effect produced with three different distances between the kathode and anti-kathode. The largest figure is produced with the greatest distance, and *vice versâ*. It will be observed that, owing to the anti-kathode being placed obliquely to the kathode, the figures are all oblique, though somewhat imperfect, conic sections; further, that when the distance between kathode and anti-kathode is great, we have a section of the divergent cone giving a hollow ring with a central spot. The ring gets smaller and smaller, and finally disappears as the distance between the electrodes is reduced, and the focus approaches the anti-kathode. It will also be noticed that where in the ring portion of the figures the kathode rays strike most normally—that is to say, at one of the two points of greatest curvature of each ellipse—the Röntgen rays are produced more actively than in the remaining portion where the kathode rays impinge on the anti-kathode more on the slant.

FIG. 4.

By some it is imagined that because the Röntgen rays are so very penetrating, therefore they are of the nature of an invisible light of great intensity, which, though not affecting the human retina, acts upon photographic plates very powerfully. This is quite erroneous, and, as a matter of fact, the photographic effect of Röntgen rays is relatively very feeble. The author has investigated this by exposing two photographic plates, respectively, to a very powerfully excited Röntgen-ray tube, screened by black paper to remove the visible luminosity, and to the light of a single standard candle. By adjusting the distances and exposures so as to obtain a precisely equal effect in both cases, he has found that the photographic power of the particular Röntgen-ray tube investigated was about one-sixtieth of one standard candle.

With regard to the true nature of the Röntgen rays, there have been many theories. There is the original suggestion of Röntgen himself, that they may possibly consist of longitudinal waves in the ether. Others have thought that they were possibly ether streams or vortices. There is a theory that they consist of moving material particles similar to the kathode rays. There is the more generally received doctrine, that they are simply exceedingly short transverse ether waves, similar in all respects to the waves of light, only so much shorter than the most ultra-violet waves hitherto known that they pass between the molecules of matter, and are consequently neither refracted nor easily absorbed or reflected by any media. Lastly, there is the theory, first suggested to the writer early in 1896 by Prof. George Forbes, and recently independently enunciated and elaborated by Sir George Stokes, which imagines them to be frequently but irregularly repeated, isolated, and independent disturbances or pulses of the ether, each pulse being similar, perhaps, to a single wave of light, and consisting of a single transverse wave or ripple, but the pulses following one another in no regular order, or at any regular frequency, as do the trains of vibration of ordinary light.

Then, again, there is the question of the mechanism by means of which the Röntgen rays are produced. They are generated by the impact of the kathode stream upon the anti-kathode, and it is now becoming more and more certain that the kathode stream consists of negatively charged atoms travelling at enormous velocity. If we accept this view, there are obviously several methods by which we may imagine the Röntgen rays being generated by the impact of the travelling atoms upon the anti-kathode. Each kathode-ray atom carries a negative charge, while the anti-kathode is positively charged, so that when the two come into contact an electrical discharge will take place between them. An electrical oscillation will thus take place in the atom just as in the brass balls of a Hertz oscillator, and transverse electromagnetic waves will be propagated through the ether in all available directions. As the electrostatic capacity of the atom must be exceedingly small, the periodicity of oscillation and the wave frequently will be enormous, while at the same time the oscillation will probably die out with sufficient rapidity to admit of only one or two complete periods. At the same time the greater the difference of potential between atom and anti-kathode at the moment of impact the greater will be the amplitude of oscillation, and the more vigorous and far-reaching the etheric disturbances.

Or we may imagine a more purely mechanical origin for the Röntgen rays. It is believed that the velocity of the kathode rays is enormous, being, as recently measured by J. J. Thomson, over 10,000 kilometres per second; and though Lodge, in his well-known endeavours to detect a movement of the ether by dragging a material body through it obtained only negative results, of course he could not possibly obtain any velocity at all comparable to this. Assuming that at the velocity of the kathode-ray atoms these do appreciably drag the ether with them, there may be some other effect produced, analogous to the atmospheric effect that is noted as the crack of a whip or a clap of the hands, as each atom hits the anti-kathode and rebounds.

Since this paper was written, the author's attention has been called to Prof. J. J. Thomson's suggestion in the *Philosophical Magazine* for February, that the Rontgen rays consist of very thin and intense electromagnetic pulses produced in the ether by the sudden stoppage by the anti-kathode of the electrified particles of the kathode stream.

Or, again, it is conceivable that the phenomenon is merely one of heating, and that the kathode stream atoms are, by impact with the anti-cathode, raised to such an enormous temperature, that they give off for a short space of time super-ultra-violet light. Taking a velocity for the atoms of 10^9 centimetres per second, as found by J. J. Thomson to be the minimum velocity of the kathode stream, and calculating the temperature to which a nitrogen atom would be raised if, when travelling at this speed, it were instantly brought to rest and the whole of its energy converted into heat in the atom itself, we have the result that the rise in temperature is no less than the stupendous figure of approximately 50,000,000,000 degrees Centigrade. This is upon the assumption that the specific heat remains constant; but allowing for this, and even allowing for the merest fraction of the energy being converted into heat in the atom itself, there is obviously an ample margin to admit of a temperature being actually obtained enormously transcending anything of which man has any knowledge. Perhaps it may be objected that it is only when we come to deal with aggregations of atoms that we can speak of heat, and that a hot atom is a physical absurdity. If, however, we look upon heat as a rhythmic dance of the atoms, perhaps we may also contemplate the possibility of a single atom executing a *pas seul*, and giving pulses to the ether at each of its movements. In any case, this difficulty disappears if we imagine the travelling particles each to consist of an aggregation of atoms. The fact that substances of high atomic weight form the most efficient anti-kathodes, lends force to the suggestion that the Röntgen rays are produced in some way by the sudden removal of velocity from the atoms that form the kathode stream, owing to the collision of these latter with the comparatively stationary atoms of which the anti-kathode is composed; while the effect observed with the pin-hole photographs of the anti-kathode, in which, as has been seen, the kathode rays that strike the anti-kathode most normally are the most effective in producing Röntgen rays, is also in accordance with this view. At the same time, the fact that in Röntgen ray photographs of Birkeland's kathode ray spectrum it is always the least deflected ray that produced the greatest photographic action, goes to show that the higher the velocity of the kathode ray atoms the more effective these latter are in generating the Röntgen rays.

More than two years have now elapsed since the date of Röntgen's discovery, and nearly twenty years since the commencement of the researches of Crookes. Here, as always, we find that "Art is long, opportunity fleeting, experiment uncertain, judgment difficult." Thus wrote the Greek Hippocrates some twenty-three centuries ago, and time has not impaired the truth of the ancient aphorism.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The Junior Scientific Club met at the Museum on Wednesday, May 18. After private business, Rev. G. D. Allen exhibited his collection of European Cicindelidæ and Carabidæ. Mr. N. V. Sidgwick (Ch. Ch.) read a paper on "Tautomerism," which gave rise to a short discussion, and Dr. Gustav Mann gave an account of Miss L. Huie's further researches on changes produced in Drosera by feeding. The foods recently investigated include peptone, milk, globulin, and urea. The results previously obtained with egg albumin are confirmed by the three former foods, with important modifications. Urea acts as a poison.

CAMBRIDGE.—On June 15, honorary degrees are to be conferred on General Ferrero (Italian Ambassador), the Master of the Rolls, Mr. Leonard Courtney, Mr. James Bryce, Prof. Dicey, Sir Edward Poynter, Sir William Turner, F.R.S., the Master of Balliol, Mr. F. C. Penrose, F.R.S., Prof. S. R. Gardiner, Sir Henry Irving, and Mr. Charles Booth, author of the valuable inquiry into East-end life and poverty.

The honorary degree of M.A. is to be conferred also on Dr. Arthur Willey, Balfour student, for his excellent researches on *Nautilus*.

The General Board of Studies recommend the establishment of a University Lectureship in Chemical Physiology, but in view of the present state of the University finances the post will be without stipend from the Chest.

Dr. Joseph Griffiths has been appointed to the new Readership in Surgery, which takes the place of the suspended Professorship.

THE Report of the Council of the City and Guilds of London Institute upon the work of the Institute during last year has just been published. Before referring in detail to the several branches of the Institute's work, the Council point out that the percentage of expenditure on the teaching staff is 61·9 per cent. at the Central Technical College, and 58·2 per cent. at the Finsbury Technical College, while the average of fourteen University Colleges is 64·9 per cent. The comparison relieves the Council of any suspicion of excessive expenditure. The Research Fellowship at the Central Technical College, founded by the Leathersellers' Company during the mastership of Dr. W. H. Perkin, F.R.S., was awarded at the commencement of the summer term, with the sanction of the Company, to Mr. W. S. Gilles and Mr. F. F. Renwick, who were together engaged in investigating the oxidation products of the so-called artificial camphor. Dr. Williamson, the holder of the Salters' Company's Fellowship, has continued his investigations at the College on the actual composition of the wheat grain grown on Sir John B. Lawes's experimental farm at Rothamsted, and that of the Royal Agricultural Society at Woburn. A number of other investigations have been carried out in the engineering, physics, and chemical laboratories, and the results in many cases have been published in the technical and scientific journals. Prof. Ayrton rightly points out that the assignment of space for an electro-chemical laboratory merits attention in consequence of the rapidly growing importance of the electro-chemical industry. It is certainly time that a well-equipped laboratory was established to provide facilities for investigations in electro-chemistry.

SCIENTIFIC SERIALS.

American Journal of Science, April.—On the temperature coefficients of certain seasoned hard steel magnets, by Arthur Durward. The author examined the temperature coefficients of a large number of stout magnets seasoned according to the method of Barus and Strouhal. If the temperatures are plotted as abscissæ, and the percentage losses of magnetic moment as ordinates, the curves obtained show a slight concavity upwards in most cases, which implies that the loss of moment becomes accelerated at the higher temperatures. Some specimens show an anomalous behaviour, which can be traced to local softening of the steel, and a temperature coefficient considerably augmented in consequence.—The skull of Amphictis, by E. S. Riggs. Describes an almost complete skull in the Princeton collection from the phosphorites. It is unusually small, the length from the incisors to the condyles being ·074 m. The cranium is well expanded, showing a large and well-convoluted brain. The nasals are narrow and slender as in the civets. The genus forms a connecting link between the Mustelidæ and the Vineridæ, and supports Schlosser's theory as to their common origin.—New form of make and break, by C. T. Knipp. The ordinary form of make and break for a seconds pendulum consists of a platinum tip brushing through a mercury drop. This is subject to oxidation and other troubles. The author uses a simple spring device which is always in order, and gives a sharply defined tick for transmission. A T-shaped lever of thin sheet brass is attached to the pendulum. As it swings, each end alternately comes into contact with a fine steel spring. In the middle position, the springs are both in contact, and the circuit is established and transmits the signal.—Rhodolite, a new variety of garnet, by W. E. Hidden. During the past fifteen years there has been found from time to time, over a very limited area in western North Carolina, a variety of garnet called rose garnet. It is distinguished by the variety of its tints, by its transparency, and by its freedom from inclusions and other imperfections. Its specific gravity is 3·838. The ratio of MgO to FeO is almost exactly 2 : 1. The detailed formula is $2Mg_3Al_2(SiO_4)_3.Fe_3Al_2(SiO_4)_3$.

Bulletin of the American Mathematical Society, April.—The February meeting, in accordance with the rule lately set up by the Society, was an all-day one. This arrangement gives opportunity for not only scientific, but also social intercourse. There was a good attendance of members, and many papers were read.—The theorems of oscillation of Sturm and Klein (first paper), by Prof. Bôcher. The author states that Sturm's work (*Liouville's Journal*, 1836) has been regarded by some writers as not sufficiently rigorous, and that other methods must be substituted for his; for instance, the method of successive approximations recently employed by Picard for establishing some of the theorems. Prof. Bôcher considers that Sturm's work can be made perfectly rigorous without serious trouble and with no real modification of method. This is what he proposes to do in the present paper; in a subsequent paper he hopes to discuss the cases in which certain functions are discontinuous either within or at an extremity of the intervals within which they are considered. The paper was read at the December meeting, and within its limits appears to be a thorough discussion of the matter.—Another paper read at the December meeting is by C. L. Bouton, on some examples of differential invariants. It is founded on Lie's methods. The invariants are those occurring in projective transformations, and the treatment for the plane is given in full; the method for the corresponding solid problem is sketched in, and the results given. In the author's opinion all the invariants are new.—Papers read at the February meeting are on an extension of Sylow's theorem, by Dr. G. A. Miller.—Note on the tetrahedroid, by Dr. J. L. Hutchinson. The writer points out the connection between a certain quartic surface, discussed by him in the *Annals of Mathematics* (vol. ii. p. 158), and the above-named surface.—Note on integrating factors, by P. Sarel.—Early history of Galois' theory of equations, by Prof. J. Pierpont. This is a very interesting bibliographical paper, which treats of (1) Galois' relations to Lagrange, and (2) how Galois' algebraic theories became public. Galois' estimate of his discoveries is thus stated: "J'ai fait des recherches qui arrêteront bien des savants dans les leurs."—Reviews follow of Love's theoretical mechanics, of Schell's tortuous curves, and of Page's differential equations.—There are a few slight notes, and the useful list of mathematical publications.

Wiedemann's Annalen der Physik und Chemie, No. 3.—Conductivities of electrolytes, by F. Kohlrausch, L. Holborn, and H. Diesselhorst. The authors point out that the modern advances in the measurement of temperatures and resistances have made it necessary to redetermine the conductivities of electrolytes in terms of the units now adopted. As standard electrolytes they take solutions of sulphuric acid of density 1·223, magnesium sulphate of density 1·190, and sodium chloride saturated at 18°. The resistance of 1 cc. as a cube is 0·7398, 0·04922, and 0·21605 in the three cases, which represent the maximum conductivities of those salts at the temperature mentioned.—The foundations of the electric unit of resistance, by W. Jaeger and K. Kahle. The authors describe the methods adopted in the Physikalisch-Technische Reichsanstalt for purifying the mercury and calibrating the tubes of standard resistances. The tubes must be filled in a vacuum. The resistances show a secular diminution of about 0·00003 ohms in five years.—Absorption and emission of steam and carbonic acid in the infra-red spectrum, by H. Rubens and E. Aschkinass. The infra-red rays separated out by five successive reflections at fluospar surfaces are absorbed by carbonic acid and water vapour in thick layers. Their wave-length is about $24\,\mu$. Their absorption by the atmosphere accounts for their absence in the solar spectrum.—On the transparency of some liquids for rays of great wave-length, by the same authors. Water shows considerable absorption, but benzol is more transparent even than silver chloride.—On light nodes in a kathode ray bundle under the influence of a magnetic field, by E. Wiedemann and A. Wehnelt. When the lines of force are parallel to the axis of the tube, the kathode rays are twisted into a bundle having successive nodes. The phenomenon is completely in accordance with the projected-particle theory of kathode rays.—Visibility of Röntgen rays, by E. Dorn. Proves that the light effects seen are not due to an accommodation-strain or to electrical discharges in the neighbourhood of the observer's head.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 5.—"Observations on the Action of Anæsthetics on Vegetable and Animal Protoplasm." By J. B. Farmer, M.A., and A. D. Waller, M.D., F.R.S. Received March 9.

The object of the investigation was to observe simultaneously and comparatively the effects of certain anæsthetics (carbon dioxide, ether, and chloroform) upon vegetable and upon animal protoplasm.

Two gas chambers in series, through which anæsthetic and other vapours can be passed, contain: the first, a leaf of *Elodea Canadensis* under the microscope (× 300); the second, a sciatic nerve of *Rana temporaria* connected with an inductorium and galvanometer (or upon occasion a galvanograph).

The actual movements of chlorophyll bodies in a cell of the leaf were observed and measured by one observer, while the other took readings of the galvanometric deflections in response to excitation of the nerve. To establish comparison between the two classes of effects we took as measures:—the number of chlorophyll bodies that crossed a cobweb in the eye-piece during each successive minute, and the magnitude of galvanometric deflections at intervals of one minute, before, during, and after the action of the vapour. The number of bodies passing per minute gives measure of the rate of movement in the vegetable protoplasm, while the magnitude of successive galvanometric deflections gives measure of the mobility of the animal protoplasm.

The results obtained from a study of *Chara*, *Elodea*, and plasmodium of *Badhamia* were quite consistent, but owing to the greater ease in making a quantitative determination, *Elodea* was used for the more exact comparative experiments.

The action of carbon dioxide was to produce an initial slight acceleration, followed speedily by a complete cessation of movement. On disconnecting the CO_2 apparatus and aspirating air through the chamber the protoplasm, after the lapse of two or three minutes, began to show signs of recovery. Fitful movements of the granules first occurred, and then they soon resumed their processional motion around the cell; at first very slowly. The movement rapidly became accelerated and considerably exceeded the normal rate. This acceleration was not of long duration, and was followed by a slowing down to the ordinary speed.

The results of experiments with chloroform and ether were also given.

May 12.—"On the Connection of Algebraic Functions with Automorphic Functions." By E. T. Whittaker, B.A., Fellow of Trinity College, Cambridge. Communicated by Prof. A. R. Forsyth, Sc.D., F.R.S.

If u and z are variables connected by an algebraic equation, they are, in general, multiform functions of each other; the multiformity can be represented by a Riemann surface, to each point of which corresponds a pair of values of u and z.

Poincaré and Klein have proved that a variable t exists, of which u and z are uniform automorphic functions; the existence-theorem, however, does not connect t analytically with u and z. When the genus (*genre*, *Geschlecht*) of the algebraic relation is zero or unity, t can be found by known methods; the automorphic functions required are rational functions, and doubly periodic functions, in the two cases respectively. But no class of automorphic functions with simply connected fundamental polygons has been known hitherto, which is applicable to the uniformisation of algebraic functions whose genus is greater than unity.

The present memoir discusses a new class of groups of projective substitutions, such that the functions rational on a Riemann surface of any genus can be expressed as uniform automorphic functions of a group of this class. Groups are first considered which can be generated by a number of real substitutions of period two, whose double points are not on the real axis, and whose product in a definite order is the identical substitution. A method is given for dividing the plane into curvilinear polygons corresponding to such a group; these polygons are simply-connected, and cover completely the half of the plane which is above the real axis. Sub-groups of these groups are found, whose genus is greater than unity, and which are appropriate for the uniformisation of any algebraic curves.

The sides of the polygons, into which the half-plane is divided, are formed of arcs of circles orthogonal to the real axis.

The analytical connection between the variables of the algebraic form and the uniformising variables is given by a differential equation of the third order. A certain number of the constants in this equation have to be determined by the condition that the group of substitutions associated with the equation leaves unchanged a certain circle. When any arbitrary values are given to these constants the solution of the differential equation is termed a quasi-uniformising variable. The properties of quasi-uniformising variables, and their relation to the uniformising variable, are discussed in the last section of the paper.

Physical Society, May 13.—Mr. Shelford Bidwell, President, in the chair.—A paper by Prof. W. E. Ayrton and Mr. T. Mather, on galvanometers, was read by Prof. Ayrton. It is a sequel to *Proc. Physical Soc.*, vol. x. p. 393, and to *Phil. Mag.*, vol. xxx. p. 58. The authors suggest that in future the comparative sensitiveness of galvanometers should be expressed in terms of the number of millimetre scale-divisions per micro-ampere, when the observed image or "spot" is one metre from the mirror. Unit angular deflection is therefore 1/2000 of a radian. Further, for the periodic time, *i.e.* the time between two transits of the "spot" across some fixed point on the scale, in the *same* direction, the standard should be ten seconds. It is also proposed to reduce the factor of sensitiveness, as regards resistance, to the common basis of one ohm. The assumption is that, for a given galvanometer, the deflection per micro-ampere is proportional to the 2/5 power of the resistance of the windings. Tables accompanying the paper give complete data for a large number of galvanometers constructed during the past ten years, and it is possible to trace the improvements in sensitiveness throughout that time. The most sensitive galvanometers are the oscillographs, they have very short periods; the moving parts are small, the controlling fields very strong. They are designed to indicate the character of rapidly-varying currents. An oscillograph, as improved by Mr. Duddell, was exhibited; its period is 0·0001 sec., and its factor of sensitiveness, according to the authors' classification, is greater than any yet obtained. A distinction is drawn as to the use of the term "dead-beat." Maxwell applies it to galvanometers in which the motion is "aperiodic," *i.e.* to those in which the suspended system, before coming to rest, passes only *once* through the position of equilibrium. This meaning is retained; it is not to be confused with "quick-moving" or "short-period." A pendulum illustrating these distinctions was exhibited. As regards insulation of galvanometers and shunt-boxes, the authors now apply the "guard-wire" principle of Mr. W. A. Price. The instrument to be insulated is enclosed in a metal case provided with a terminal, to which one end of the windings is connected. The second end of the windings passes out through an ebonite bush-piece. This arrangement is said to nullify leakage and to prevent electro-static disturbance of the suspended system. In the second section of the paper, the authors calculate the limiting sensitiveness of galvanometers of the "Thomson" type. The investigation is based upon Prof. Schuster's B.A., 1894, paper; it takes into account the period of the suspended system, and the specific magnetisation of the needle. Lastly, the authors discuss the relative merits of long and short periods, *i.e.* the best "control," for galvanometers intended to indicate zero points in potentiometer operations. They conclude that if the control can be readily altered, and if the sensitiveness can be adjusted for the test, then, for rapidity of working, the "control" should be so adjusted that the sensitiveness is approximately two or three times greater than is absolutely needed for the desired accuracy. Prof. Threlfall thought the authors' method of comparing galvanometers very misleading. The results obtained in their comparison of the oscillograph (3,310,000), and the suspended-coil galvanometer (27) might be regarded as the *reductio ad absurdum* of the proposed system. The absurdity arose from the dissimilarity of the two instruments. Moreover, the proposed system ignored the fact that sensitiveness may be obtained by optical as well as by electro-magnetic means. Optical sensitiveness, owing to its greater stability, was to be preferred to electro-magnetic sensitiveness. The fundamental problem in the construction of galvanometers is an optical one; it is necessary to decide the mass and dimensions of the suspended parts so as to ensure (1) optical accuracy, and (2) electro-magnetic sensitiveness. Thus, to some extent, the weight of the mirror determines the thickness of the suspension. As an instance of what might be done by optical methods Prof. Threlfall referred to work done by himself and Mr. Brearley. (*Phil. Mag.*, 1896), in which it was possible to measure to $1{\cdot}48 \times 10^{-13}$ amperes, and, with special refinements, to 3×10^{-14} amperes. He had found that the best diameter for glass mirrors was 1·1 cms., with a weight just under 0·5 grammes. These were used with a scale at 276 cms., read by a microscope to 0·04 m.m. The course of the light was: lamp, large lens, small scale, mirror, eye-piece. The period was 25 secs., and the resistance 50,000 ohms. Even better results could be obtained by using mirrors of quartz or of blood-stone. Quartz is incomparably to be preferred to glass. Such figures indicated what could be done by optical sensitiveness, the sensitiveness that the authors ignored. It was pointed out by Prof. Threlfall that the controlling field for galvanometers of the "Thomson" type should be straight and uniform. This was best secured by using two magnets, one above and one below the needles. Prof. Perry said the authors had not asserted that a galvanometer with higher figure of merit, according to their classification, was *superior* to another of lower figure. It must be agreed that the figure they obtain is a very valuable datum for the comparison of instruments designed for similar purposes; for instance, in classifying those used by Prof. Threlfall. Mr. Duddell was to be congratulated on the extreme sensitiveness and small period of his oscillograph. Prof. Ayrton, referring to Prof. Threlfall's *reductio ad absurdum*, admitted that the criticism would carry some conviction if the two instruments were of different kinds; if, for instance, one possessed a suspended needle and the other a suspended coil. But the argument failed, because both instruments were of the suspended-coil type. In one of them Mr. Duddell had developed the advantages to be gained by reducing the air-gap. To form an opinion of electro-magnetic improvements in galvanometers it was necessary to reduce the results of all instruments to some system of classification. There was no objection, after that, to adding a good mirror, and reading by a good microscope.—The President proposed votes of thanks to the authors, and the meeting adjourned until May 27.

Chemical Society, May 5.—Prof. Dewar, President, in the chair.—The following papers were read:—The action of hydrogen peroxide on carbohydrates in the presence of iron, by C. F. Cross, E. J. Bevan, and C. Smith. The authors show that the presence of iron salts is necessary to cause the oxidation of hexoses and cane-sugar by hydrogen peroxide; the hydrogen peroxide causes a constitutional change in the hexose molecule yielding products containing the group C(OH) : C(OH). Dicarboxylic acids are produced as the result of secondary reactions.—Note on the oxidation of certain acids in presence of iron, by H. J. H. Fenton.—Properties and relationships of dihydroxytartaric acid. Part ii. Metallic salts, by H. J. H. Fenton. The salts of dihydroxytartaric acid with the alkali metals are now described.—The affinity-constants of dihydroxymaleic, dihydroxyfumaric, dihydroxytartaric and tartronic acids, by S. Skinner. On comparing the affinity constants of maleic, malonic, succinic, fumaric, tartaric, dihydroxymaleic, dihydroxyfumaric, dihydroxytartaric and tartronic acids, it appears that the affinity constant increases on introducing hydroxyl groups, and is greater for the lower members of the series of dibasic acids; the unsaturated acids have larger affinity constants than their saturated isologues.—Note on the enolic and ketonic forms of ethylic acetoacetate, by R. S. Morrell and J. M. Crofts.—The resolution of tetrahydropapaverine into its optically active components, by W. J. Pope and S. J. Peachey. The constitution which Goldschmeidt has attributed to papaverine indicates that tetrahydropapaverine has the constitution

$$\begin{array}{llllll} (OMe)C.CH : & C.CH_2. & CH. & CH_2. & CH : & CH.C(OMe) \\ \quad\quad \| & | & | & & | & \quad \| \\ (OMe)C.CH : & C.CH_2. & NH & & CH : & CH.C(OMe) \end{array}$$

The authors confirm Goldschmeidt's constitution for papaverine by showing that the tetrahydro-derivative is racemic, and have isolated the dextro- and lævo-isomerides by means of their salts with dextrobromocamphorsulphonic acid.—Molecular weights of permanganates, perchlorates, and periodates in solution, by J. M. Crofts. Molecular weight determinations of permanganates, perchlorates and periodates in fused Glauber's salt indicates that these salts have the molecular composition $M'MnO_4$, $M'ClO_4$ and $M'IO_4$.—The action of chlorine on pyridine, by W. J. Sell and F. W. Dootson. Amongst other products an addition compound of pyridine and chlorine is formed during the action of the latter upon the former.—The oxidation of paranitrotoluenesulphonic acid to dinitrostilbenedisulphonic acid and to paranitrobenzaldehydorthosulphonic acid, by R. Herz and W. H. Bentley.—Determination of molecular weights: modification of Landsberger's boiling-point method, by J. Walker and J. S. Lumsden.

Royal Microscopical Society, April 20.—Mr. E. M. Nelson, President, in the chair.—Mr. Rousselet exhibited and described a metal lamp chimney made by Mr. Pillischer, and having two openings to carry white and tinted glass.—The President exhibited and described a new monochromatic light screen trough of American invention.—Mr. H. G. Madan read a paper "On some organic substances of high refractivity available for mounting specimens for examination under the microscope." Mr. White asked if these media were suitable for histological work. Mr. Madan said piperine and quinodine had been found harmless, monobromonaphthaline and phenylthiocarbimide were not likely to injure even delicate tissues, but he thought the mixture of metacinnamene and phenylthiocarbimide approached most nearly to balsam in permanency and neutrality. Dr. Dallinger said he had specimens mounted in nearly every medium which had been mentioned, but at the present time only one of these slides was in good condition; nevertheless, it was most important that such media should be available. The President referred to a table of coefficients which he had worked out to show the comparison of the refractive indices and dispersive powers of these new media with those of some well-known glasses.—Mr. Morland exhibited about three dozen slides of diatoms.—Mr. J. J. Vezey read a short note by Mr. E. B. Stringer, supplementary to his paper on photomicrography which was read at the meeting of the Society in December last.

Mathematical Society, May 12.—Prof. Elliott, F.R.S., President, in the chair.—Mr. A. E. H. Love, F.R.S., gave an account of some fundamental properties of manifolds.—Lieut.-Colonel Cunningham, R.E., communicated a description of "the 77 squares puzzle," by Major Turton, R.E., and exhibited a cardboard specimen of the puzzle. He also reported that the *complete* factorisation of the numbers $N = 3^n + 1$, where $n = 6\nu + 3$, had now been effected by the joint work of Mr. C. E. Bickmore and himself for the following values of n (51, 57, 69, 75, 81, 93 in part, 99, 105), thus *completing* the factorisation of these numbers up to $n = 105$ (except 93 in part), those from $n = 3$ to 45, 63, 87 being previously known. These numbers include several high primes of 9, 10, 11 figures.—The President communicated a paper, by Mr. H. G. Dawson, on the numerical values of $\int_0^h e^{x^2}dx$; and one by Prof. H. Lamb, F.R.S., on the reflection and transmission of electric waves by a metallic grating. Impromptu remarks were made by the President (in connection with the figure of Pascal's theorem) and by Mr. F. S. Macaulay.

Zoological Society, May 17.—W. T. Blanford, F.R.S., Vice-President, in the chair.—Mr. Oldfield Thomas read a paper on a small collection of Mammals from Nyasaland that had been presented to the British Museum by Mr. Alfred Sharpe, C.B. Sixteen species were enumerated, mostly from North Nyasaland. Among them was a new antelope from Urori, coloured like *Cephalophus æquatorialis*, but with horns in the female, as in *C. monticola*.—A communication was read from Dr. A. G. Butler on a collection of Lepidoptera lately made in British East Africa by Mr. C. S. Betton. It contained examples of 123 species of butterflies and of 111 species of moths. Among the moths were forms which were referred to five new genera, viz. *Bettonia*, *Aclonophlebia*, *Trotonotus*, *Hameopis*, *Lembopteris*, and *Metaculasta*. Besides these new genera thirty new species were characterised in this paper.—Mr. F. E. Beddard, F.R.S., communicated a paper by Miss Sophie M. Fedarb on some earthworms from India. Four species were treated of in this paper, of which the following three were described as new:—*Perichæta cupulifera*, *P. crescentica*, and *Dichogaster parvus*.—Mr. W. E. de Winton described a new rodent of the family Anomaluridæ from the Benito River, French Congo, which was referred to a new genus *Aëthurus*, differing from both *Anomalurus* and *Idiurus* in not having any expanded flying-membranes, but resembling the former in the formation of the tail, and being more like the latter in the form of the skull. The species, proposed to be named *Aëthurus glirinus* was of the same size as *Anomalurus batesi*, grey in colour, with a black bushy tail and a thickening of the skin of the lower leg, in which are set jet-black, club-shaped hairs forming anklets.—A communication was read from Mr. Stanley S. Flower, in which he pointed out that the gecko from Penang described by Stoliczka as *Cyrtodactylus affinis* and that described by himself under the name of *Gonatodes penangensis* were identical, and that the proper appellation of the species would be *Gonatodes affinis*.

Royal Meteorological Society, May 19.—F. C. Bayard, President, in the chair.—Mr. R. H. Scott, F.R.S., read a paper on the frequency of rainy days in the British Islands. He had taken the number of rainy days in each month at forty stations for the twenty years 1876-95, and then divided that number by the total number of days in the month, and so ascertained the resulting percentage. The greatest excess of frequency is always on the extreme north and west coasts. June is the month with the least number of rainy days, but in July the summer maximum of rain occurs, bringing the well-known Lammas floods. In October the weather becomes decidedly showery, and the distribution begins to assume its winter type. November is the month with the greatest frequency of rainy days.—Mr. F. J. Brodie read a paper on the abnormal weather of January last, which was one of the most remarkable winter months on record. The month was singularly dry, with an absence of snow or sleet—a somewhat unusual feature in January even for any individual station, but far more remarkable as applying to the country as a whole. The special feature, however, was the striking absence of severe frost, the frequent prevalence of unusually mild weather, and as a result the abnormal warmth of the month, especially in the more northern parts of the kingdom. The mean temperature was generally over the whole country about 5° above the average, while at many places situated in the more northern parts of the kingdom it was more than 6° above the average. The atmospheric pressure throughout the month was also very high, the mean being from two to three tenths of an inch above the average.

CAMBRIDGE.

Philosophical Society, May 2.—Mr. F. Darwin, President, in the chair.—On the theory of order, by Mr. E. T. Dixon. All the theorems of non-metrical (projective) geometry depend solely on the conception of "order" so defined as to be independent of the idea of "before or after," which belongs only to time. It follows from this definition that no "order" can be ascribed to less than four units in any uniform group: and this is why less than four points have no "projective relation" or an harmonic ratio. The paper further discusses the way in which numbers (or coordinates) may be assigned to the units of a group for purposes of analysis, with or without a system of "unique" lines having already been determined.—On the representation of a function, by Mr. H. F. Baker.—On the total eclipse of the sun, January 22, 1898, by Mr. H. F. Newall. A general account was given of the observations made during the recent eclipse, and photographs were exhibited, showing: (1) the general appearance of the corona; (2) the spectrum of the sun's limb as photographed with prismatic cameras by Sir Norman Lockyer's party, and by Mr. Evershed; (3) the spectrum of the sun's limb as photographed with a slit spectroscope.—Captain E. H. Hills, R.E., exhibited and described the photographs obtained by him of the spectrum of the corona, and also the two series of photographs of the spectrum of the sun's limb at the beginning and end of totality.

PARIS.

Academy of Sciences, May 16.—M. Wolf in the chair.—The Secretary announced to the Academy the loss it had sustained by the death of M. Souillart, Correspondant in the Section of Astronomy.—On the impossibility of certain series of groups of points on an algebraic surface, by M. Émile Picard.—On some causes of uncertainty in the exact estimation of carbonic acid and of water vapour, diluted with large volumes of air or inert gases, by M. Armand Gautier. It is shown that potash, even when spread over long columns of glass beads, is incapable of removing the last traces of carbon dioxide from air. This, however, is readily accomplished by the use of a U-tube containing moistened baryta. The increase of weight of a phosphoric anhydride tube after passing through it large volumes of air dried over sulphuric acid was also determined, the amount being of the order of 0·4 mgr. for 100 litres of air. An attempt was made to estimate the maximum amount of sulphuric acid vapour carried away by 100 litres of air, and the conclusion drawn that at ordinary temperatures the vapour pressure of sulphuric acid in air must be less than one twenty-millionth.—On an absolute actinometer, by M. A. Crova. The instrument described is a modification of those proposed by M. Knut-Angström and M. Chwolson, consisting of a thin disc of pure copper, suitably protected from accidental radiations, and placed normally to the sun's rays, the temperature being measured by the resistance of a thin constantin wire.—Agglutination of the bacillus of true tuberculosis, by M. S. Arloing. Certain serums have the power of causing the bacilli of true human tuberculosis to cohere. An attempt will be made to see whether this property can be applied to the diagnosis of tuberculosis in man, analogous to the method now used for typhoid fever.—On the development of the disturbance function, by M. Adrien Féraud.—On the quadratic and rational correspondence of two plane figures, and on a remarkable substitution, by M. Ernest

Duporcq.—On the Hamiltonian groups, by M. G. A. Miller.—On the liquefaction of hydrogen and of helium, by M. James Dewar (see NATURE, p. 55.) On a Crookes' tube which can be revivified by osmosis, by M. P. Villard. A platinum tube is fixed to one end of the glass part of a Crookes' tube. When after repeated use the resistance of the tube becomes too high, the platinum tube is heated with a Bunsen burner, the hydrogen of the flame penetrates the tube, and in two or three seconds the tube is fit for use again.—On a property of fluorescent screens, by M. P. Villard. If an object is placed between the Crookes' tube and the screen, the latter illuminated for some time, and then the object removed, it is found that those parts of the screen previously protected by the interposed object are more luminous than the others.—On the molecular weights of the easily liquefiable gases, by M. Daniel Berthelot. Starting with the theorem that the molecular weights of gases are proportional to their limiting densities when the pressure is infinitely small, from the experiments of M. Leduc, the true density ratios of oxygen, carbon droxide, nitrous oxide, hydrochloric acid, acetylene, phosphoretted hydrogen, and sulphur dioxide are determined, the precision being, in the opinion of the author, equal to that obtained by the best chemical methods.—On the preparation and properties of anhydrous beryllium fluoride, and the oxyfluoride of beryllium, by M. P. Lebeau. The product obtained by drying in air the substance given by the solution of beryllium hydrate in hydrofluoric acid is an oxyfluoride, $5BeF_2.2BeO$, and the anhydrous fluoride cannot be obtained in this way. The latter, however, can be obtained in the pure state if the drying be conducted in a stream of gaseous hydrogen fluoride.—On a method of preparing potassium carbonyl-ferrocyanide synthetically, by M. J. A. Muller. Potassium ferrocyanide, heating in closed vessels with carbonic oxide at 130°, gives in less than forty-eight hours 90 per cent. of the theoretical yield of $K_3Fe(CN)_5CO$.—On a new unsaturated tertiary alcohol, dimethylheptenol, by M. Ph. Barbier.—Ethanepyrocatechol and its derivatives, by M. Ch. Moureu.—On the presence of the common eel in the open sea, by M. Léon Vaillant. The eel was found in the stomach of a sperm whale, and is of interest in furnishing an undoubted proof that the eel descends to the sea.—On the development of *Alpheus minor*, by M. H. Coutière.—Origin of the structure of lenticels, by M. Henri Devaux. The observations given show that the lenticel is a small region continually accommodating itself to the conditions of external moisture.—On the origin of the thallus of the Cutleriaceæ, by M. C. Sauvageau.—On the *Septoria graminum*, destroying the leaves of wheat, by M. L. Mangin.—Insertion of the base of the nerve fibre on the limiting margin of an adult nerve axis, in the form of a continuous epithelial sheet, by M. J. Renaut.—Some micro-organisms of soured wines, by MM. F. Bordas, Joulin and de Raczkowski.—Some periscopic glasses, by M. Ostwalt.—Variations in the pressure and horizontal components of the wind governed by the moon. Discussion of the formulæ: generation of depressions, by M. A. Poincaré.—Earthquakes of May 6, 1898, documents by M. Jullien of Chambéry, M. Guerby of Annecy, M. André of Saint-Genis-Laval, and M. Soret of Geneva, communicated by M. Mascart.

DIARY OF SOCIETIES.

THURSDAY, May 26.

Royal Society, at 4.30.—On the Cytological Features of Fertilisation and Related Phenomena in *Pinus silvestris L.*: V. H. Blackman.—The Skeleton and Classification of the Calcareous Sponges: G. P. Bidder.—On Surfusion in Metals and Alloys: Prof. Roberts-Austen, F.R.S.—Note on the Complete Scheme of Electrodynamic Equations of a Moving Material Medium, and on Electrostriction: Dr. J. Larmor, F.R.S.—Aluminium as an Electrode in Cells for Direct and Alternate Currents: E. Wilson.—Contributions to the Study of "Flicker": T. C. Porter.—On the Kathode Fall in Gases: Dr. Capstick.

Royal Institution, at 3.—Heat: Lord Rayleigh.

Institution of Electrical Engineers, at 8.—The Design of Electric Railway Motors for Rapid Acceleration: Prof. Charles A. Carus-Wilson.

FRIDAY, May 27.

Royal Institution, at 9.—Sir Stamford Raffles and the Malay States: Lieut.-General the Hon. Sir Andrew Clarke.

Physical Society, at 5.—A Simple Interference Method of Reducing Prismatic Spectra: Mr. Edser and Mr. Butler.—Some further Experiments on the Circulation of the Residual Gaseous Matter in Crookes' Tubes Campbell Swinton.

SATURDAY, May 28.

Royal Institution, at 3.—The Biology of Spring: J. Arthur Thomson.

Geologists' Association (Liverpool Street Station, G.E.R.), at 11 45.—Long Excursion to Aldeburgh and Westleton. Directors: W. Whitaker, F.R.S., F. W. Harmer, and E. P. Ridley.

WEDNESDAY, June 1.

Entomological Society, at 8.—The Lepidoptera Heterocera of China and Japan: J. H. Leech.—The Moths of the Lesser Antilles; Sir Geo. F. Hampson, Bart.

THURSDAY, June 2.

Royal Institution, at 3.—Modern Methods and their Achievements in Bacteriology: Dr. E. E. Klein.

Linnean Society, at 8.—Notes on some Lories: Prof. St. George Mivart, F.R.S.—A Revision of the Genus Symblepharis: E. J. Salmon.—On the Food of the Uropoda: Surgeon-Captain H. A. Cummins.

Chemical Society, at 8.—The Action of Ether on Organic Acids and on Carbohydrates in Presence of Hydrogen Bromide: H. J. H. Fenton and Mildred Gostling.

FRIDAY, June 3.

Royal Institution, at 9.—The Development of the Tomb in Egypt: Prof. W. M. Flinders Petrie.

Geologists' Association, at 8.—Fossil Sharks and Skates, with special reference to those of the Eocene Period: A. Smith Woodward.

SATURDAY, June 4.

Royal Institution, at 3.—The Temples and Ritual of Asklepios at Epidaurus and Athens: Dr. R. Caton.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

Books.—Electro-Dynamics: Prof. C. A. Carus-Wilson (Longmans).—Bulletin of Miscellaneous Information, 1897 (Darling).—The Scientific Memoirs of Thomas Henry Huxley, edited by Profs. M. Foster and E. Ray Lankester, Vol. 1 (Macmillan).—Creation Records discovered in Egypt: G. St. Clair (Nutt).—Catalogue of the African Plants collected by Dr. F. Welwitsch in 1853–61: W. P. Hiern, Part 2 (British Museum).—List of the Types and Figured Specimens of Fossil Cephalopoda in the British Museum (Natural History): G. C. Crick (British Museum).—Elements of Descriptive Astronomy: Prof. H. A. Howe (Philip).—Manual Training: Woodwork: G. Ricks (Macmillan).—A Simplified Euclid Book I.: W. W. Cheriton (Rivingtons).—Syllabus der Pflanzenfamilien: Dr. A. Engler, Zweite, umgearbeitete Ausgabe (Berlin, Borntraeger).—Die Vegetation der Erde, II. Grundzüge der Pflanzenverbreitung in der Karpethen: F. Pax, I. Band (Leipzig, Engelmann).

Pamphlets.—Per la Storia della Meteorologia in Italia: P. G. Boffito (Torino).—Essai sur la Théorie des Machines Electriques a Influence: Prof. V. Schaffers (Paris, Gauthier-Villars).—Versuch einer Darstellung der Empfindungen: W. Przibram (Wien, Hölder).

Serials.—Journal of the Chemical Society, May (Gurney).—Zoologist, May (West).—Himmel und Erde, Mai (Berlin).—History of Mankind: F. Ratzel, translated, Part 26 (Macmillan).—Bulletin de l'Académie Royale des Sciences, &c., de Belgique, 1898, No. 4 (Bruxelles).—Memoirs and Proceedings of the Manchester Literary and Philosophical Society, Vol. 42, Part 2 (Manchester).—L'Anthropologie, Tome ix. No. 2 (Paris).—Monthly Weather Review, February, (Washington).

THURSDAY, JUNE 2, 1898.

SYSTEMATIC BACTERIOLOGY.

System der Bakterien. Handbuch der Morphologie, Entwickelungsgeschichte und Systematik der Bakterien. Allgemeiner Theil. By W. Migula. Vol. i. Pp. 368; 6 plates. (Jena: Gustav Fischer, 1897.)

APPLIED or technical bacteriology in recent years has developed so rapidly, that in the rush after new discoveries the study of systematic bacteriology has been almost entirely neglected. With the introduction of Koch's methods the separation of bacteria was made an easy matter, and when it became evident that a large number of pathological lesions are caused by micro-organisms, bacteriology was introduced into the medical laboratories, and undoubtedly the pathological bacteriologist has greatly advanced our knowledge of the action of bacteria in health and in disease. Until Pasteur appeared, those lowly organisms had been unobtrusively studied in botanical laboratories, but the discoveries of this immortal genius revealed to all how great a share the bacteria have in the preservation of health and the causation of disease, in the sorrows and pleasures of life. Discovery after discovery in the causation of disease has led to triumph after triumph in prevention and cure; the study of fermentation has led to the perfection of important industries, and even now an appeal is made to the bacteria to keep our surroundings in a good sanitary condition. Bacteriology was so keenly studied by medical men that at one time there was almost a danger lest all micro-organisms were regarded as our foes, and yet their friendly acts greatly outweigh the harm that they do to us. Now, however, this is fully recognised, and just as at one time disease-producing bacteria were searched for, so at present the tendency is to seek after useful micro-organisms and to sing their praises. In this country, as usual, we are slow to encourage the study of applied bacteriology; in our midst it is yet fighting its way into medicine, and there is still an appalling ignorance of bacteriology even amongst the youngest physicians and surgeons; the British brewers are just beginning to see what Denmark and Germany saw years ago, and in agriculture we pin our faith on lectures and feeble examinations instead of opening research laboratories for the study of bacteriology as applied to the dairy and the soil. However, the records of other countries show us what practical bacteriology has achieved in a short time.

The never-ceasing discovery of new bacterial forms by men who have no knowledge or sympathy with systematic botany has led to serious confusion, especially in medical circles. It is their practice to describe an organism, at once to give it a name, often derived from the lesion it produces, and to claim for it a specific place in nature, without attempting to define its proper position in a systematic classification. The confusion about the choleraic vibrio is not yet entirely cleared away; thirty and more varieties have been described as different species, and now in the case of the diphtheria bacillus the number of pseudo-forms increases rapidly. The medical bacteriologist is too much influenced by simple staining reactions, and morphological appearances or biological and chemical phenomena, and he distinguishes species by most inadequate tests. It is therefore a matter of congratulation to be able to welcome two works on bacteriology, founded upon botanical principles, such as Prof. Migula and Prof. A. Fischer have offered. Here we shall speak only of Prof. Migula's "System of Bacteriology."

The author begins with a concise critical account of the historical development of systematic bacteriology from Leeuwenhoek to our present time. It must be a relief to many that Prof. Migula considers it almost useless waste of thought to ponder over the question whether bacteria are plants or animals; since they must be placed somewhere, we may without hesitation classify them among the plants, not because they possess a vegetable nature, but because their nearest living allies are found among the plants. The different systems proposed by Cohn, Zopf, Flügge, de Bary, Hüppe, Eisenberg, Miquel, Fischer and others are discussed and criticised. A classification on the principle of fructification is impossible, because we cannot honestly accept the existence of arthrospores, and thus there is no *fundamentum divisionis*; nor can we classify bacteria according to their chemical, physical and physiological properties, as proposed by Eisenberg. Prof. Migula justly repudiates the extraordinary artificial and unnatural system of Miquel, which was founded upon the constancy of physiological properties. As it is a habit of medical bacteriologists, even at the present time, to distinguish species or varieties on such a principle, which has also been ably criticised by Prof. Marshall Ward, we advise them to glance at pp. 42 and 43, which should convince them of their error. Prof. Migula's system is as follows:—

BACTERIA.

Family I.—Coccaceæ.

Species 1. Streptococcus = division in one plane.
2. Micrococcus = division in two planes.[1]
3. Sarcina = division in three planes.
4. Planococcus = division in two planes; flagella.
5. Planosarcina = division in three planes; flagella.

Family II.—Bacteriaceæ.

Species 1. Bacterium = no flagella.
2. Bacillus = completely surrounded by flagella.
3. Pseudomonas = polar flagella.

Family III.—Spirillaceæ.

Species 1. Spirosoma = no flagella; rigid.
2. Microspira = 1, or 2–3 polar flagella; rigid.
3. Spirillum = 5–20 polar flagella; rigid.
4. Spirochæte = no flagella; flexible.

Family IV.—Chlamydobacteriaceæ.

Species 1. Streptothrix.
2. Cladothrix.
3. Crenothrix.
4. Phragmidiothrix.
5. Thiothrix.

Family V.—Beggiatoaceæ.

Species Beggiatoa.

The morphology of the bacterial cell is carefully described, and considerable attention is paid to the cell-membrane, which, according to Prof. Migula, is directly

1 It is pleasing to note that the term "staphylococcus" does not occur this system.

continuous with the flagella where they exist. The latter cannot be traced into the substance proper of the cell, a statement which the writer of this review, from his own studies, especially on the bacillus of tetanus, is not prepared to accept. The question whether bacteria possess a nucleus is discussed at length, and the author concludes that true nuclei have not been detected, and it is improbable that they exist. All the granules or structures hitherto described as nuclei, cannot possibly be regarded as such; this is clearly shown by Fischer's researches on bacterial plasmolysis. In studying the minute details of the bacterial cell, Prof. Migula rightly insists upon the absolute necessity of starting from the normal living micro-organism. Extremely interesting is the masterly discussion of the nature of the granules and vacuoles observed in the substance of the bacterial cell, of the origin of polar staining and segmentation. In this section the subject of plasmolysis is carefully considered. The granules so frequently observed he regards as the rudimentary nucleus of the bacterial cell, but he frankly admits that this view is based entirely on personal opinion. One of the best portions of the book is the section on the flagella, which recently have been diligently studied also by Fischer, who has proved that these fascinating structures are the motor-organs of the mobile micro-organisms, and who has attempted to classify the bacteria according to the arrangement and distribution of their flagella. Prof. Migula concludes that all flagellate schizophytes, excepting Spirochæta and Beggiatoa, are bacteria, and that different species belonging to the same family can be distinguished by their flagella; and herein all who have experience of flagella staining will agree with him: the number of flagella, their mode of insertion, and their shape and curves—all these points must be noted.

The growth and division of the bacterial cell is described with eloquent fulness. The mode of division is a generic character in the coccaceæ; it is constant, and a coccus dividing in one plane by no manner of means can be made to divide in two or three planes. But, furthermore, it is a fundamental distinctive feature between the coccaceæ and the other bacteria; for the latter divide only in one plane, and the division is always preceded by an elongation of the cell in a direction at right angles to the plane of division. Until recently it was stated that cocci are as long as they are broad, and that by such measurements they can be distinguished from the bacteria; but Prof. Migula insists that we must abandon this unsatisfactory distinction in favour of the one just enunciated. The bacteriaceæ always divide at right angles to their long axes, and we must therefore take exception to the statements, recently made in certain quarters, that the diphtheria bacillus divides parallel to its long axis. Of the branching of streptococcus chains he gives two satisfactory explanations: (1) occasionally in a long chain a coccus becomes twisted so that its plane of division is turned in a different direction; (2) a few links in the chain die, and are overgrown by the survivors. This branching therefore does not signify a mycelial ancestry. After division has taken place, the organisms may be arranged as diplo-cocci, strepto-cocci, tetra-cocci, or as sarcinæ; but it is absurd to use the terms diplo- and tetracoccus as generic ones, for many organisms belonging to different genera may present all these forms. The chapter on spore formation occupies fifty-three pages, and is a masterly account of the subject, from which a few points may be quoted. The so-called arthrospores cannot be distinguished from ordinary vegetative cells, and cannot therefore be regarded as spores, so that the endospore is the only recognised spore. Physiological properties, such as resistance against heat, desiccation, or antiseptics cannot decide the nature of a spore; the only true criterion is germination, a process differing in essence and in principle from ordinary vegetative proliferation by division. The formation and structure of the spore are described with a wealth of detail which omits no important fact. Broadly speaking, germination may occur in three ways: (*a*) the membrane of the spore remains unruptured, either persisting as the membrane of the young bacterium, or being dissolved during the process of germination; (*b*) the spore-membrane is ruptured at one or other pole, allowing the young bacterium to glide out; or (*c*) it is ruptured equatorially; but in each case there are numerous minor variations and deviations from the type, depending partly upon the conditions under which the germination is observed. A nucleus so far has not been demonstrated in the spore, although recently Hegler claimed to have done this. We must fully agree with Prof. Migula when he expresses the opinion that so long as we are ignorant of the natural conditions of bacterial growth, we are not in a position to use the faculty of spore formation for the purpose of systematic classification, for many bacteria which at present are described as asporogenous under more natural conditions than the gelatine or agar-agar tubes can supply, may actually form spores.

Everybody will turn with interest to the chapter on Pleomorphism and Variability, which opens with a historical account of the views held since Nägeli's time. Nägeli in almost unpardonable and unintelligible manner ignored all morphological and physiological characters of the bacteria, and became the master of the reckless apostles of pleomorphism. Their creed led the philosophic Buchner into the almost amusing error of proclaiming the identity of the hay bacillus and the anthrax bacillus, and caused the illustrious Billroth to blunder with his *Coccobacteria septica*. Prof. Migula insists that species must be determined by identity in development and growth and constancy of morphological characters; but as yet our microscopes are not perfect enough to detect the minutest morphological differences, and therefore for the present, in many cases, we must fall back upon biological characters. Varieties are by no means constant, and widely different forms may constitute a species. It is impossible here to discuss the question more fully; those who take an interest in such matters must consult the original.

In the last 100 pages the biological characters of the bacteria are discussed; the different nutrient media and the methods of cultivation; the formation of pigments (which are subdivided according to their solubility in water and alcohol); the products of fermentation and of metabolic activity, and the pathogenetic properties of the bacteria. To the medical bacteriologist the chapter on infective micro-organisms is an important one. For practical purposes it is proper to distinguish between pathogenetic and non-pathogenetic organisms, but this distinction cannot be recognised in systematic bacteriology. Prof. Migula invites the botanist to follow the methods of the medical bacteriologist in the study of bacterial diseases of plants, which he regrets in most cases has been undertaken in a slipshod and careless manner. He gives a number of plant diseases, said to be due to bacteria, to expose the manner in which the subject hitherto has been approached. Anaerobiosis and phosphorescence, the thio-bacteria and ferruginous bacteria form the subjects of the next few chapters, and then we come to an interesting and concise account of the nitro-bacteria; the volume is concluded by two short chapters on the influence of heat and light on bacterial growth.

We may disagree with the author here or there, but we, and especially the medical bacteriologists, must welcome the appearance of this work. The volume is the result of Prof. Migula's own labours and studies pursued for many years with true German industry, and this enhances its value considerably. It is well written, and the language is not particularly difficult; the literary references at the end of each chapter are excellent. It is impossible to read the book without regretting that the second volume has not yet appeared. Six plates accompany the text, but, by an oversight, plates iv. and v. have been placed and numbered in wrong order, and must be transposed. A. A. KANTHACK.

THE PHYSICAL PROPERTIES OF CRYSTALS.

Die fundamentalen physikalischen Eigenschaften der Krystalle in elementarer Darstellung von Dr Woldemar Voigt, o.ö. Professor der Physik an der Universität Göttingen. (Leipzig: Veit and Co., 1898.)

PROF. VOIGT is well known for his researches into the physical properties of crystals. Not only is the mathematical theory of large parts of the subject due to him, but the experiments on which the theory is built were largely made by himself and Prof. Riecke, and many of the instruments used were invented or improved by him. His latest contribution to the science is a little book, half-way between a popular exposition and a technical treatise. Last year Prof. Voigt lectured at Göttingen on crystals to teachers in the upper classes of secondary schools, and these lectures form the basis of the book before us.

Prof. Voigt is a mathematician, and though the mathematics is here reduced to a minimum, he assumes a knowledge of the elements which his hearers doubtless possessed. A command not of facts and formulæ, but of mathematical and physical ideas and terms is required for a satisfactory study of the book. In particular, some familiarity with the use and transformation of coordinates is essential. In England, where the knowledge of elementary mathematics is widely spread, this little volume ought to find many readers, and a good translation is to be desired.

We have before us no mere text-book, but a book with an idea and a plan. Round the idea the facts are grouped, and one is carried on naturally from one set of properties to another. After a preliminary chapter on the symmetry of crystal forms, the leading idea is developed in the second chapter. Prof. Voigt points out that, in investigating the relation between cause and effect, it is allowable to treat not only effects but causes as states of matter. For instance, electric phenomena produced by heat may be regarded as the relation between the temperature and the electrical state of a body. Temperature is determined by a scalar quantity, and the electrical state of any particle by a vector. This vector is, moreover, a so-called polar vector, *i.e.* one, like a translation, whose components change sign when the sense of all the coordinate axes is changed, in contradistinction to a so-called axial vector, whose components retain their signs. Temperature involving no direction, the direction of the vector can only be determined by the crystalline structure, and we should expect such a relation to be possible in acentric crystals possessing one single polar axis of symmetry, such as tourmaline. In fact, the pyro-electric properties of tourmaline have been known for 200 years.

Besides scalars and vectors there is a third kind of quantity, by which a state of tension or dilatation is characterised. It is determined by a magnitude and a straight line, undetermined in sense. Prof. Voigt calls such a quantity a *tensor*, and three mutually perpendicular tensors a *tensor-tripel*, giving in the preface his reasons for the adoption of a new term, and pointing out that in doing so he is merely extending the use of the word in quaternions. By means of these three kinds of quantities and their mutual relations, he is able to classify, in the manner indicated, the different phenomena. In every case we have two effects due to the same cause, and the primary effect is taken to represent the cause in its relation to the secondary effect. Each chapter after the second exhibits such a relation. We have an example of the relation between a scalar and a tensor-tripel in that between temperature and deformation, between a vector and a tensor-tripel in piëzo-electricity, and numerous examples of two vectors; elasticity is treated as a relation between two tensor-tripels.

The method gives more than a mere classification, as the example shows. It enables us to say *à priori* whether a given body, isotropic or crystalline, is capable of exhibiting certain phenomena. In general the phenomena which are *à priori* possible, are *à posteriori* known to exist. In one case, however, referred to in Chapter iii., a set of phenomena represented by the relation between a scalar and an axial vector, theoretically possible in a large class of crystals, has never been observed, and it remains open to question whether the failure to observe pyromagnetic phenomena is due to an unknown point of theory or to unsuspected difficulties of observation.

In the chapter on the symmetry of crystals, Prof. Voigt takes three typical forms—Iceland spar (rhombohedron), tourmaline, and quartz—and he derives the two latter from the former by the simple process of joining together two "half rhombohedra." In spite of three excellent figures, the explanation would not be comprehensible without previous knowledge of the way in which the rhombohedra are to be divided. Even the simplest crystal forms are hard to understand without a model, and one could wish, in addition to the figures, for diagrams of models to be made in folded paper.

One purely external fact may be noted about the book: unlike most foreign publications, it can be bought neatly bound in buckram.

W. H. AND G. CHISHOLM YOUNG.

MODERN DEVELOPMENT OF THE ATOMIC THEORY.

The Arrangement of Atoms in Space. By J. H. Van 't Hoff. Second revised and enlarged edition, with a preface by Johannes Wislicenus, &c.; translated and edited by Arnold Eiloart. Pp. xi + 211. (London: Longmans, Green, and Co., 1898.)

THE history of the development of that department of science which it is now usual to call stereo-chemistry is extremely interesting. While it shows that great results often spring from small beginnings, it also shows that although genius may discern in apparently trivial phenomena the basis of very far-reaching ideas, it requires the united efforts of a large number of workers both to extend the applications of the idea and to render its foundation firm and secure. In 1848 Pasteur discovered that racemic acid, itself possessing no action on a ray of polarised light, is resolvable into two acids, each of which rotates the plane of polarisation in equal but opposite directions, and that this property of optical activity is associated with hemihedrism in the crystalline form. Not till more than a quarter of a century later, namely in September 1874, did Van 't Hoff give to the world his ideas on the representation of chemical structure in space. Two months afterwards similar views were put forward by Le Bel. So far as it obtained any notice at all, the new theory was received chiefly with ridicule. It is now accepted by the whole chemical world.

Nearly all the difficulties attending the new doctrine were cleared away in Van 't Hoff's "Dix Années dans l'histoire d'une théorie" (1887), and since that time a new chemical literature has sprung up devoted to the exposition of the doctrine and its application to the large number of examples now known. This little book will be useful to students looking at the subject from the theoretical point of view. And perhaps it supplies all that is really desirable, inasmuch as it provides freely references to the original papers of the numerous chemists who have worked experimentally upon the subject; and so, perhaps, the lack of detail as to methods is less likely to be felt. Dr. Eiloart, the translator of the volume, is known as an investigator of stereo-chemical problems, and he has published a useful "Guide to Stereo-chemistry," based on lectures delivered by him a few years ago in the Cornell University. The translation may be therefore trusted to represent accurately the views and intention of the author. The worst that can be said is that the exposition is in some places rather scanty, as, for example, in all that relates to the supposed configuration of the nitrogen atom, no alternative views being considered. There is an interesting appendix, containing a note by Prof. A. Werner, of Zürich, on the application of stereo-chemical ideas to the isomerism of metallic compounds, more especially to the plato-ammines and cobalt-ammines. The configuration of the groups MA_6, in which M is the metal and A the group NH_3 or some negative radicle, is represented by a regular octahedron, the metal occupying the centre, and the groups having their places at the solid angles. This accounts for the existence of two isomeric forms of these compounds, but the reader is left to find out for himself in what manner the ionisable radicles which enter into the composition of the salts are attached to this octahedral arrangement. It is interesting to find that the possibility of applying stereo-chemical ideas to elements other than carbon and nitrogen is at last beginning to be recognised by chemists. W. A. T.

OUR BOOK SHELF.

The Linacre Reports. Vol. iii. 1895–1897. Edited by E. Ray Lankester, M.A. (London: Adlard.)

THIS volume contains eighteen papers published by Prof. Lankester and his staff at Oxford since the summer of 1895, together with the reports of the teaching in the department over which he presides, and a list of the zoological additions to the Museum during the past two years.

As a record of work done in the laboratory at Oxford it compares favourably with the two volumes which preceded it, and proves that the energy and perseverance in research of the Oxford zoologists still form one of the most gratifying features of the science schools of that University. Although one-half of the papers in the volume deal with the morphology of segmented worms, the others treat of animals in widely separated classes, showing that under the guiding influence of Prof. Lankester the school is not likely to suffer from the spirit of hasty generalisation on the one hand, nor from the evils of narrow-minded specialisation on the other.

Two papers by Mr. Goodrich on the Cœlom theory and on the homologies of the Annelid prostomium can be compared with Prof. Benham's papers on certain Earthworms. The former may be taken as admirable examples of biological reasoning and clear statements of views, the latter as examples of laborious and valuable investigations of anatomical details. Prof. Lankester may be heartily congratulated upon this further proof of the stimulating influence of his teaching, and upon the skill and zeal of his friends and pupils at Oxford.

S. J. H.

Anatomia Vegetale. By Dr. F. Tognini. Pp. 274 (Milan: U. Hoepli, 1897.)

Fisiologia Vegetale. By Dr. L. Montemartini. Pp. 230. (Milan: U. Hoepli, 1898.)

THESE two handy little manuals are both apparently largely based on the "Lehrbuch der Botanik" by Strasburger, Noll, Schenck and Schimper. The vegetable anatomy, by the late Dr. Tognini, is a good account of the leading features of the science. More attention is devoted in it to the histology of plants than to their gross anatomy. The small size of the book necessitates a sketchy treatment of the subject, and the descriptions in several instances are meagre. Thus the structure and arrangement of the bast is dismissed in a few words, while scarcely anything at all is said of the changes which take place in the sieve-plates. However, much accurate information is contained in the book, and a great deal of the results of recent investigations are included in it. The illustrations are good and numerous; they are to a large extent either drawn specially for the work, or are taken from Briosi and Tognini's work on *Cannabis sativa*.

Dr. Montemartini has succeeded in getting a large quantity of sound information into his short treatise on "Plant Physiology," and he has made it more useful by citing the chief literature of each subject in a list at the end of each chapter. It is curious to note that he quotes the ringing experiment, as used by Hales, to demonstrate the ascent of water in the wood. In the "Vegetable Statics," however, this experiment is described to prove that there is no great downward motion of water in the bark. With regard to the problem of the ascent of water in trees, Dr. Montemartini accepts the hypothesis which maintains that the sap is drawn up in a tensile state. In each section the principal facts are well described, and the book is well up to date. The section on growth is perhaps the best in the book, and contains a short account of the author's own researches. The last section in the book is on reproduction, and too short to be of much use.

Glass Blowing and Working. By Thomas Bolas. Pp. 212. (London: Dawbarn and Ward, Ltd.)

CONSIDERING the practical importance of glass-blowing, not only in physical and chemical laboratories but in many manufactures, it is remarkable that so few works have been written on the subject. English students are practically restricted to Mr. Shenstone's well-known little book, and the chapters in Prof. Threlfall's "Laboratory Arts." The present work, which is based upon a course of lectures given by the author in connection with the Technical Education Committee of the Middlesex County Council, is quite distinct in character from either of these, and in some respects, perhaps, is less suitable for a beginner. The opening chapters are devoted to glass-working tools, the most important of which, of course, are the blowpipe and the bellows. The remarks on these are practical and lucid, the author showing that the ideal blowpipe and bellows differ considerably from those usually found in chemical and physical laboratories. The chapter on minor tools and appliances is very full, although many of the instruments described are but rarely used by professional glass-blowers. The chapters on glass manipulation contain nothing essentially new, the only points which seem somewhat unorthodox to one accustomed to the German style of glass-blowing being the method of making the inside seals in "traps," and the use of lead glass. The author is a strong advocate of the use of the latter, and indeed regards the blackening in a reducing flame as a positive advantage to the beginner, as compelling him to work with a flame in which the combustion is complete. The latter part of the book gives instructions for making small decorative articles at the blowpipe, with notes on the preparation of enamels and coloured glasses. Many useful recipes are given throughout the book, mostly published for the first time, of which the various inks for etching and printing on glass may be specially mentioned. If only as a collection of practical hints, the book is certain to be found on the shelves of all amateurs in this fascinating art.

Experimental Mechanics. By G. H. Wyatt, B.Sc., A.R.C.S. Handbooks of Practical Science, No iii. Pp. 54. (London: Rivingtons, 1898.)

A NUMBER of simple experiments in mechanics, most of them quantitative, are described in this book. The experiments are capable of being performed by pupils who can understand the descriptions of them, and they will train the hand, mind and eye to work together.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Notes on the Bugonia-Superstitions.—The Occurrence of *Eristalis Tenax* in India.

IN consequence of a notice published by Baron C. R. Osten-Sacken in NATURE (vol. xlix., p. 198, December 28, 1893), requesting the public for information about the folk-lore of the Oxen-born bees, I made to him several communications, most of which were incorporated in his subsequent works: namely, "On the Oxen-born Bees of the Ancients" (Heidelberg, 1894), and "Additional Notes in Explanation of the Bugonia-Lore," &c. (*ibid.*, 1895).[1] Continuing since in the researches, I have collected the following notes, which I trust you will allow me a space to publish, inasmuch as the latter work (p. 4) contains the author's indication that he shall thereby conclude his publications on this subject:—

(1) *The Occurrence of the Bees in a Skull.*—Besides the two instances of this incident quoted in "O. B." (pp. 64, 3) from Herodotus and from Patterson, we find another case in Purchas's "Pilgrimes." 1624, Part III., l. iii. p. 627, where Geo. Berkeley, the English merchant (*c.* 1605), narrates from his personal observations that Livonia was then so much devastated by the Russians that, her woods were "strowed with bones of the dead carcases, and himselfe did once in one of those woods, eate Honey out of a man's skull wherein a swarm of bees were, and bred as it hanged on a Tree."

(2) *Chinese Lores in Relation to the Bugonia.*—Mr. G. B. Buckton, in his "Natural History of *Eristalis tenax*," 1895, p. 79, gathering from "O. B.", includes Japan and China among the countries that "have been all more or less affected by this strange idea." Should a reader infer from this passage that the Japanese and the Chinese ever dreamt of the breeding of honey-bees from bovine carcases, gross must be his blunder. He can find in "O. B." a reproduction of my clear statements of the absence from those nations of this belief (p. 20), and of the early Japanese discrimination established between bees and drone-flies (p. 33).

However, the exposition of Mr. Buckton could excellently apply to the case of the Chinese, provided the term "Bugonia-superstition" be used in such an extensive sense as to cover all allied beliefs derivable from the confusions of bees and drone-flies. As the result of my research for three years past, I can now enumerate altogether three instances of such beliefs from Chinese source: firstly, a notice of a literatus in the beginning of the seventeenth century, who apparently mistook some *Eristalis* for honey-bees (see NATURE, vol. l. p. 30, May 10, 1894); secondly, an inveterate fallacy current among the renowned naturalists in China, that the bees use human urine for manufacturing honey[2] ("O. B.," p. 19; "A. N.," pp. 17, 19–20); and thirdly, a passage which I have lately found in "Koo-kin-tu-shu-tseih-ching" (Peking, 1726, Sec. IV., tom. lxviii, "Ki-i-pu-wei kau," i. fol. 2, *b.*), and reads thus:—"Should a hen's egg turn into bees or wasps, it would portend the town where it happens to become totally evacuated in subsequent time."

Here I may add that, although the Chinese were singularly free from the barren speculations on the artificial breeding of honey-bees from dead oxen, yet they did not escape the invasion of another enterprising illusion, which might have rivalled the Bugonia-craze in its absurdity. It is described by Chang Hwa (232–300 A.D.) in his "Poh-wuh-chi" (tom. iv. f. 7, *a*, Jap. ed., 1683):—"Tear the Turtle (*Trionyx*) into pieces about as large as stones used in the game of Ki (a sort of chess); mix them well with the juice of the Chih-hien (the red variety of *Amaranthus mangostanus*), and bury them underground in a thick envelope made of the Imperata-grass; thus, after ten days, you will find each piece of flesh changed into a turtle." Another book, named "Pi-ya Kwang-yau," is said to relate: "If a carapace of the turtle be wrapped with the Amaranth and placed

[1] For brevity's sake I shall use in this article the abbreviations "O. B." and "A. N." respectively for these works.

[2] So, Li Shi-Chin, one of the greatest naturalists China has ever produced, praises the Bees in a similar tone to Samson's riddle by saying: "Out of the fetor came forth deity; and out of the decay came forth mystery" ("Pan-tsau-Kang-muh," 1578, *sub.*, "Mih-fang")

on damp ground, it turns into another turtle: now there are men who use to divide into pieces the turtle's flesh, and by adding to them the Amaranth-juice, change them after ten days to turtles as minute as young silkworms, which they throw in ponds under the name of 'Seedling-Turtles' (*Chung Pieh*)" ("Yuen-kien-lui-han," 1701, tom. cdxli., art. "Pieh").[1] These preposterous schemes of multiplying by gemmiparone process one of the dainties dearest to the Celestial's palate, were doubtless an outcome of erroneous observations, whereby those credulous folks mistook for newly hatched turtles some insects of a turtle-like configuration with the habit of thronging about the putrid animal substances.[2]

(3) *Japanese Lores concerning Eristalis tenax.*—"In regard to the composition of honey and the confusion of the honey-bee with *E. tenax* [*cf.* (2) *supra.*], the Japanese nation was far in advance of its neighbours" ("A. N.," p. 19). Only single instance somewhat analogous to the old western stories of the Wasp and Hornet generated from dead horses, I have recited in NATURE, *ubi supra*, from a Japanese work. This is the belief in the "Horse-Hair Wasp," so-called from the popular notion of an ichneumon-fly whose ovipositors resemble horse-hairs, that it is a metamorphosis of the latter;[3] while, as Baron Osten-Sacken aptly expounds, the alleged Horse-born Wasp and Horse-born Hornet are both the issues of the ancients' confusion of *Helophilus* and *Gastrophilus*, with the hymenopters in question ("O. B.," pp. 53–55).

"The occurrence of *E. tenax* of Japan is of very long standing . . . the people did not confound it with the bee" ("O. B.," p. 33, note; *cf.* "A. N.," pp. 20–22). This Japanese immunity from the taint of such a widespread superstition, appears to be mainly due to their early ignorance of the bee-keeping.[4] Although Japan is not destitute of the indigenous bees (*cf.* Kaibara, "Yamato Hongô," 1708, tom. xiv. fol. 13), the comparative paucity in the old Japanese literature of the allusions to honey and bees, and a definite register in the national history of a failure in introducing them from Corea in 643 A.D. ("Nihongi," lib. xxiv.), together with the striking absence from the Japanese language of any native name of honey,[5] are sufficient to preclude any ideas of the original familiarity of the Japanese with apiary.

This primitive ignorance of the honey-keeping certainly gave great impulse to the early establishment by the Japanese of the demarcation between the bee and the drone-fly; which latter dipteron they have properly grouped with its allies, such as *Tabanus*, *Helophilus*, and *Gastrophilus*, under the general onomatope "Abu," which corresponds with "Mang," the Chinese appellation after their humming sounds—from the former, no doubt, descends the modern Japanese name of *E. tenax*, "Bun-bun" (*cf.* "O. B.," p. 20).

That the Japanese were early acquainted with the rat-tailed larva of *E. tenax*, is evinced in a cyclopædia compiled in 1713, wherein the imago and the larvæ of the fly are figured and described distinctly ("A. D.," p. 20). In an old vernacular leechcraft, the so-called "Long-tailed Dung-Worm" (*Onaga-Kusomushi*), the larva of the fly, was prescribed as an invaluable cure for rickets (*Kan*) (Terashima, as quoted in foot-note 4). Baron Osten-Sacken already gave from my communication to him a popular rhyme said to be efficacious in keeping this larva away from out-houses ("A. D.," p. 21). In some provincial versions of the rhyme, the larva is called "Kamisake-mushi" or "Kamisake-jorô" (*i.e.* Worm-or-Strumpet who avoids the [Shintoist] Gods).[1] "Eibian," a Japanese antiquary, understands this cursing poem to have been composed by a zealous Shintoist, who might have directed it against the Buddha Sâkyamuni, whom it represents by the loathsome larva, and whose birth took place on the day named in it (Yamazaki, "Seiji Hyakudan," 1841, chapter xli). This remark points at the remote antiquity of the Japanese acquaintance with the *ver à queue de rat*; for, according to it, the verses must have sprung in an epoch when the native and Indian creeds were yet contending greatly in Japan.

(4) *The Mithraic Association of the Bees with the Lion and the Oxen.*—Dr. Ernest Krause, in his article, "Die mythologische Periode der Entwickelungsgeschichte," in "Kosmos," Jahr. IV., B. viii. p. 350, Leipzig, 1880, ascribes the triple association of these creatures to the amalgamation of the Christian legend with the classic stories. Nevertheless, the fact that these *trio* were long in existence in Persia, before the introduction of Christianity into classic regions, is evident from the ancient cultus of Mithras, in which one who was initiated into the mystic grade of Lion had to "wash his hands with honey collected by bees who are Oxen-begotten" (Thomas Taylor, "Select Works of Porphyry," 1823, p. 181); added to which, on an ancient cylinder of recent discovery, those persons presiding on the Leontic rites, are said to be represented in the tunics and stoles covered with the design of honey-comb (F. Lajard, "Recherches sur les Cultes publics et les Mystères de Mithra," 1867, 2*e* Section, p. 240, *seqq.*).

(5) *Astronomical and Elemental Explanations of the Bugonia Myth.*—In his "A. N.," pp. 12–13, Baron Osten-Sacken names the three methods of treatments of this myth by the commentators on the classic passages that concern it. To those three, I may add as the fourth the following explanation by A. de Gubernatis, who endeavours to treat the myth astronomically: "According to Porphyrios, the moon (Selênê) was also called a bee (Melissa). Selênê was represented drawn by two white horses or two cows; the horn of these cows seems to correspond to the sting of the bee. The souls of the dead were supposed to come down from the moon upon the earth in the forms of bees. Porphyrios adds that as the moon is the culminating point of the constellation of the bull, it is believed that bees are born in the bull's carcase. Dionysos (the moon), after having been torn to pieces in the form of a bull, was born again, according to those who were initiated in the Dionysian mysteries, in the form of a bee; hence the name of Bougenês, given to Dionysos (moon). . . Sometimes, instead of the lunar bull, we find the solar lion" ("Zoological Mythology," vol ii. p. 217, London, 1872). The fifth method, as it might be, seeks in the Bugonia an "elemental" myth, as we find it in F. Lajard's work, quoted above. According to this authority, the Ox and the Lion appear to have symbolised in the creed of ancient Persians what the Chinese have designated respectively with the terms of "Yin" ("negativeness") and "Yang" ("positiveness") (*cf.* my letter in NATURE, vol. li. p. 32, November 8, 1894); and the Mithraic association of the Leontic grade with honey (compare last paragraph) is solvable by the reason that honey contains an essence extremely combustible (extremely "positive" in Chinese philosophy), which is wax (p. 242). It is highly probable that the association of the bees with the oxen existed in the same cultus of Mithras (*cf.* Taylor, *l.c.*), as we can adduce it from the Persian cosmogony, which states that, the First Bull, the first of all beings created by Armuzd, having been slain by the jealous Ahriman, his soul, the Ized Goschorum, issued from his left shoulder, and after collecting the sperm of the terrestrial bull, carried it to moon, where it became the germ of all creatures (see Lajard, p. 49; *cf.* the Dionysian story in (4) *supra*).

(6) *Bugonia-Superstitions in India.*—Once I communicated

[1] Perhaps "Hwin-nan-wan-pih-shuh," attributed to Liu Ngan (*c.* 179–122 B.C.), is the oldest work extant which mentions this sympathetic power on the turtle of the "Hien," which name comprises, besides all species of *Amaranthus*, the Purslane (*Portulaca oleracea*). Some authors who take for "Hien" the latter plant singly, tries to explain a passage in the "Book of Changes," where occurs the "Hien" with the *Phytolacca* (for the latter see my letter in NATURE, vol. liv. p. 343, August 13, 1896) as the types of diabolical plants, by conceiving as devilish the remarkable resistance to desiccation of the Purslane as well as its alleged influence on dead turtles (Chang Urh-Ki, "Hau-ngan-hien-hwa," tome i; Wu-Ki-Shun, "Shih-wohming-shih-tu-kau," ed. Ono, tome iii. fol. 19, *b*). It is a curious contingency that the word "Amaranth" is derived from Greek words—α, privative, and μαραινω, to wither (Loudon, "Encyclopædia of Plants," 1880, p. 787). Also there is a Chinese belief in a visceral disease called "parasitic turtle" (*Pieh-hia*), said to originate in eating turtle-flesh with the Hien ("Yuen-kien-lui-han," *l.c.*; Chang Urh-Ki, *ut supra*), which error has probably arisen from their confusion of some parasitic flat worms with turtles.

[2] Cf. Pliny, H. N., xi. 20: "Sicut asinorum scarabaeos mutante natura ex aliis quaedam in alia." In Chinese glossaries there are names of many beetles founded on the resemblance to the turtle. Certain aquatic Heteroptera (*e.g. Belostoma indica*) that are perhaps the origin of the "Seedling-Turtle" story, are called in Japanese "Tagame," or "turtle in rice-field" (Terashima, "Wakan Sansai-dzue, 1713, tome liii.).

[3] For the assimilation of the ichneumon-flies with the wasps, cf. Pliny, xi. 24: "Vespae quae ichneumone vocantur." "Ma-fang" (literally, horse-wasp) occurs in Chinese; here, however, the epithet "horse" signifies "large" (cf. Kaibara, *op. cit.*, tome ix. fol. 10, *b*).

[4] Even in the sixteenth century the domestication of the bees must have been unknown, at least in some western provinces: for the fact is particularly called attention to in the narration of a Japanese ambassador sent to Rome by a prince in Kyûshû: "Non hanno in quei paesi Api, ne in consequenza il nobilissimo frutto del mele . . ." ("Breve Ragguaglio dell' Isola del Giapone, Roma, 1582, Brit. Mus., 10,055. a. 1, fol. 2, *a*).

[5] Only word ever used in Japan for honey is "Mitsu" (or "Michi" in its obsolete form), bore a modification of Chinese "Mih," and that for the honey-bee is "Mitsu-bachi," composed of the heterogeneous words "Wamyô Shô," written in the tenth century, tomes xvi. and xix.).

[1] So a rustic version runs: "Since long ago auspicious is the eighth of the fourth moon; on this day punishment of worms that hate gods is their doom."

to Baron Osten-Sacken my suggestion of the possibility of finding some traces of these superstitions from an Indian source; but it met his negative remark in "A. N.," *sub fin*, chiefly grounded on the alleged lack till that time of any report firm enough for the inclusion of *E. tenax*, among the Indian fauna. In a work of N. Müller, however, we have lately found described an old silver vase made in India, which has engraved thereon Kamadeva (the Love) in the act of producing Totma (the Force). It represents the infant god riding on his quiver,[1] from which a lion is issuing forth, while the quiver rests on the back of a bee, and, as is well known, a chain of bees forms the string to the god's bow. Another mythical picture of Totma described by the same author is a lion producing out of his mouth a swarm of bees and a cow ("Glauben, Wissen, und Kunst der alten Hindus," Manzig, 1822, B.I., S. 553, *seqq.*; with Tab. I., Fig. 11 and 12). From these figures we are perhaps right in believing that the Hindus were not totally unaffected with the Bugonia-myth; and if it be so, how anciently the myth existed in India? This is the question which I should solicit assistance from any of your readers to elucidate.[2]

(7) *The Occurrence of Eristalis tenax in India.*—To supplement the last paragraph, it will be interesting to introduce here the following letter from Mr. E E. Austen, of the British Museum (Natural History), which I owe to his kindness:—

"November 16, 1897.

"*Eristalis tenax, L.* has never been recorded (at any rate, under its own name) from India. However, in a collection of Diptera from India belonging to the Bombay Natural History Society, and at present in my hands for determination, are four specimens which, in my opinion, undoubtedly belong to this species. I have not time just now to make minute examination, but so far as I can see these specimens agree perfectly with the normal European form. If there are any differences, I do not think that they can possibly be of *specific value.* Of the four specimens in question one is unlabelled; the other three are labelled respectively—'N. W. P.' (North-West Province), 'Himalayas,' and 'Musourie.' I may add that the Bombay Natural History Society's collection also contains five specimens (not labelled with precise localities) of *E. pertinax, L.*—a species which closely resembles *E. tenax*, and has identical habits. In England, at any rate, it is often the more abundant of the two.

(Signed) "E. E. AUSTEN."

In a Buddhist cyclopædia in Chinese (Tau-ngan's "Fah-yuen-chu-lin," completed 668 A.D., ed. 1827, tom. xxviii. fol. 12-13), there is a quotation from an Avadâna Sûtra, giving account of how Ananda found in a pond near Râdjagriha, which receives all sewerage of that city, a huge worm several tens of feet long, and without limbs, amusing itself among refuses, rolling, raising, and lowering The question as for the cause of so unpleasant an animal, the Buddha answers by tracing it to a long past æon, when an avaricious abbot cursed good monks with very unwholesome words, which effected the malefactor's transmigration to such a disgusting life. Here, the worm in ordures is described too briefly, but its figures, except the exaggerated size, forcibly put me in mind of a similar account of the "Long-tailed Dung-Worm" by a Japanese author (see "A. N.," p. 21); which leads to the view that the Indians took early notice of the rat-tailed larva of some *Eristalis.*

(8) *Stingless Bees besides Eristalis tenax.*—From the instances I shall give presently it will be evident that the readers must take precaution against the hasty identifications with the *Eristalis* of all so-called "stingless bees." Thus, Prof. A. Merx, of Jena, suggests the possible identity with *E. tenax* of certain stingless bees in Abyssinia, which J. Ludolf records in his "Historia Æthiopica," 1681, lib. 1, chap. 13 ("O. B.," p. 67). But it is too evident from the following words that the identity is not true:—"De hoc accipiunt Habessini Mel agreste. . . . Quia verò aculeo carent, la tenebrâ se tuentur; sub terrâ enim favos condunt, angustissimo introitu, quem viso homine quinque vel sex implent capitula sua solo æqualia ponentes, tam solerter, ut acutissimos oculos fallant." Two manners of the "stingless bees" in the Western Hemisphere are respectively described by Fernandez d'Oviedo (1478–1557) and H. Schmirdel (*c.* 1534–54): both agree in building their nests inside of trees, where they make white excellent honey (Ramusio, "Navigationi e Viaggi," Venetia, 1606, fol. 51, A; Purchas, "Pilgrimes," Part III., l. vii., chap. 4). One who reads Astley's "Collection" (1745, vol. ii. p. 355), might naturally be struck with the thought that there *E. tenax* is meant by a "Drone-Bee" that "frequents the villages [in the western coast of South Guinea] . . . but yields no honey"; on examination, however, of the original of this passage, we confirm other insect is meant thereby, as the statement has this qualification:—"[They] hurt nobody unless provoked, and then their sting causes great and dangerous inflammations" (J. Barbot's "Description of Guinea," in Churchill's "Collection," 1732, vol. i. p. 116).

KUMAGUSU MINAKATA.

7 Effie Road, Walham Green, S.W.

P.S.—It may be not amiss to note here that the Spanish Benedictine, Benito Feyjoo, in his "Théatro Critico Universal" (Madrid, 1734, tom. iv. p. 198), devotes a chapter to the Bugonia, where he refers to Sperling's failure to find any bees from dead oxen while serious pestilence was prevailing among cattle in Würtemberg (see "O. B.," p. 61). He continues: "Doctor Don Joseph Ortiz Barroso, the learned physician in the city of Utrera, experienced the same failure on two several occasions of similar epidemic that visited the territory of Sevilla. The latter observations conflict with the solution which F. Sachs seeked to apply to the case of Sperling's failure, by attributing it to the too cold climate of Würtemberg for the bees; for the same failures were experienced in Andalusia, which is a quite warm country; while such coldest countries in the north as Russia, Podolia, &c., have great abundance of the bees, causing very cheap sale of honey and wax in those parts."

K. M.

[1] In this connection it is significant that "the Italian 'carcasso' means quiver, because it is encircled and kept together with iron rings or ribs, which resemble the ribs of a human carcase" (Webster's Dictionary).

[2] About four years ago, when I followed to the British Museum my master in Mantranism, Mr. Hôryû Toki, that Yogâtchârya informed the late Sir (then Mr.) Augustus Franks of the remarkable coincidences that exist between the characters of the Brahmamist "Kamadeva" (the Hindu Eros) and of the Mantranist's "Aizen Myôwô" (the bright king who soaks mankind with love). One conspicuous figure of the latter is his crown of a lion's head (see Butsuzô Dzui," n. e., 1886, tome ii. fol. 20, *a*), whence it is very probable that some vestiges of the Leontogenes occur in the "Aizen-kyô," a Buddhist sûtra devoted to this Vadjra, but inaccessible to me in this country.

Rainfall and Earthquake Periods.

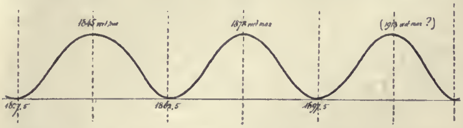
WITH reference to the remarkable letter of "A. B. M.," which appeared in your number of this week (May 19), p. 31, as to the recurrence of cold and wet periods at about thirty-five years' interval (measuring from the centre of one such period to that of the next), I beg leave to call attention to the fact that thirty-five years represents a marked period of recurrence of maximum frequency of earthquakes, as I showed in a paper which was submitted to the Royal Irish Academy in 1887, but not published. That a relation should exist between earthquakes, volcanic disturbances, and the atmospheric conditions which determine wet and dry periods, seems to me more reasonable to accept *à priori*, than to assume that these phenomena are quite independent of each other.

From Mallet's Catalogue of Earthquakes I have compiled a list between the dates 365 and 1842, showing the intimate relations between the shocks and immediate and violent atmospheric perturbations on those occasions (about 500 in all); this list could be very much extended for more recent times from Perry's and Falb's lists, and would be a valuable contribution on the subject.

But discussing simply the figures presented by your correspondent from this point of view, very interesting results can be shown. I begin by assuming (*a*) an intimate though undefined relation between most great earthquakes and intense volcanic action; (*b*) intense volcanic action in one or other of the great volcanic centres or lines of action during certain periods, giving rise to the emission of vast quantities of gases which rise into the upper atmosphere, and disturb or influence the upper currents; and (*c*) that the upper currents of the atmosphere are more and more looked on as dominating meteorological phenomena. Hence a dependency in the meteorological conditions which determine maxima of drought or wet, on maxima of volcanic action, but not concordance as to date or period. These lag upon the former. This may be roughly shown from the figures given by "A. B. M." He gives the following dates as maxima of wet periods.

The commencement of the curve corresponds to about the year 1827·5, which of itself will be found to represent a year of maximum intensity of earthquakes (it is interesting to note the record for June 3 of that year in Mallet's Catalogue "Martinique."

"At the same time the rain fell after sixty-six days' drought, no such instance of dry weather in the West Indies was remembered). The next minima (of wet) would correspond to 1862·5 (great earthquake in Greece, 26 Dec./61, and eruptions of



Vesuvius accompanied by earthquakes), and the last, to 1897·5, which fairly corresponds to the great earthquake of Assam, so fully noticed in your journal, as one of the most intense of modern times. Moreover, these figures may be presented otherwise. Taking the great earthquake of Lisbon as of date 1755, roughly we have the annexed succession of years showing at the two extremes the dates (approx.) of two of the greatest earthquakes of modern times, and to some extent showing that thirty-five years represents a period of maximum earthquake action, and agreeing roughly with the intervals of extreme drought and with periods of great volcanic activity.

1755
+ 35
1790

1895

As regards the year 1825, it is interesting to note that Mallet's Catalogue gives for July 26 and 27 of that year, "One of the most tremendous hurricanes on record occurred in the West Indies."

Of course a great deal has to be said as to the locality of the earthquakes, and as to the volcanoes to be considered. I certainly look on those of the Andes Cordillera as of prime importance by their influence on the upper currents.

Ebbing and Flowing Wells.

A case somewhat resembling those previously described (Nature, May 12, p. 45, and May 19, p. 52), occurs on the dormant volcano of Barren Island in the Andaman Sea. The only (comparatively) fresh water to be found on the island reaches the surface in the form of hot springs, which gush out close to the shore at the breach through the ancient cone. The springs are due to the percolation of the drainage water beneath the most recent lava streams, which have not yet fully cooled down. The level of the springs rises and falls with the tide, and the lower part of a well, which I caused to be dug in the ash about twenty yards from the shore, filled with hot water at the flow of the tide, and ran dry at the ebb. The bottom of the well was between tide levels. The water is brackish, but rather less so at high than at low tide, the reason of which appears to be as follows. The porous volcanic materials of the island below sea level are saturated by the water of the sea, the surface of this inland subterranean water rising and falling in connection with the rise and fall of the sea tide The drainage of the amphitheatre, then, soaks downwards until it reaches the inland salt water, over which, on account of the difference in specific gravity, it flows onward to the sea. At high tide, therefore, the drainage reaches the sea through materials which have been comparatively little wetted by salt water, while at low tide it percolates through, and washes, ejecta from which the salt water has just retired. The phenomenon is, of course, complicated by the difference in time between the inland tide and that at sea.

The springs are described in some detail in *Memoirs Geol. Surv. Ind.*, vol. xxi. p. 274 (also *Records G.S.I.*, vol. xxviii. pp. 31, 34). F. R. Mallet.
May 25.

NAVIGATION.

Navigation, in its widest sense, is generally defined as the art of conducting a ship from port to port, and may conveniently be divided into coasting and guiding the path of a vessel across the trackless ocean.

Coasting is principally pilotage, assisted by a few rules based on geometry and plane trigonometry, combined with a knowledge of that oldest and most valuable of seamen's friends, the mariner's compass. A knowledge of the compass in Europe is much older than is generally supposed. It was certainly used as far back as the beginning of the thirteenth century.

The compass plays a still more important part in deep sea navigation (with which this paper is more particularly concerned), which is so closely allied to nautical astronomy that in one sense of the word it includes it, whilst in another it distinguishes the terrestrial methods of finding the position of a ship at sea, from the more accurate methods of locating her whereabouts, that the researches and labours of the astronomer have placed at the disposal of the navigator.

The earliest efforts of the seaman, when he ventured out of sight of land, were directed by the compass, which of late years has been immeasurably improved, and by a log for measuring the rate of sailing, which has become almost as obsolete as the plane sailing and the plane chart by which he estimated his position. This method, proceeding on the assumption that the earth's surface is a plane, was fairly accurate for moderate distances near the equator, or even in higher latitudes if the vessel sailed on, or near a meridian, but was quite incapable of measuring differences of longitude, and if used, for instance, on a westerly course from Cape Clear, would produce an enormous error, if the departure or westing was taken as the difference of longitude. Owing to the uncertainty and variability of the wind, sailing vessels altered their course so often that, to save the labour of working out the difference of latitude and departure for each course and distance by trigonometry, the traverse table was introduced. It is simply the tabulated values of the sides of a number of right-angled triangles, where the hypothenuse is the distance, the perpendicular the departure, the base the difference of latitude, and the course the given angle. By means of this table it was easy to get the difference of latitude made good, by taking the difference between the sum of the northings and southings, and the departure made good, by subtracting the eastings from the westings, or *vice versâ*. This was called resolving a traverse. The inability of plane sailing to afford the difference of longitude led to the introduction of parallel sailing, middle latitude sailing, and Mercator's sailing, and the inestimable chart that bears the name of the latter. It is easily demonstrated by solid geometry, that the arc of a parallel of latitude between any two meridians is equal to the corresponding arc of the equator multiplied by the cosine of the latitude; so that if a ship sails on a parallel, it is a simple operation to convert her meridian distance or departure into difference of longitude. But a ship does not always keep to a parallel; in sailing, however, from point to point, she must leave one parallel and arrive at another. Now let the portion of the rhumb line between these two parallels be conceived to be divided into infinitely small parts, which will be sensibly straight lines on each of which is a triangle representing the corresponding difference of latitude and meridian distance. Then the departure will be the sum of all these meridian distances, and must be equal to the arc of a parallel somewhere between the two extreme ones. In middle latitude sailing it is assumed to be equal to the arc of the parallel that lies midway between the one left and that arrived at, and the difference of longitude is obtained as in parallel sailing, substituting the middle latitude for the parallel.

Though the above assumption is not strictly accurate (the real parallel always lying on the polar side of the middle latitude), the results deduced from it in favourable cases are such very close approximations as to be preferable to those obtained by Mercator's sailing, which is theoretically irreproachable.

About the middle of the sixteenth century, Gerard Mercator introduced the chart which has since borne his name, in which the meridians are all parallel and the degrees of latitude increased towards the poles, and on which the rhumb line (or loxodromic curve which on the sphere is a spiral approaching nearer to one of the poles at every convolution) cuts every meridian that it crosses at the same angle. Mercator does not seem to have understood the principles on which his charts should be constructed, for he left no description of them, nor were they even accurate, and it was left to an Englishman, Wright, to demonstrate that, as in making the meridians parallel the meridian distances were being increased in proportion to the secant of the latitude the lengths of the degrees of latitude must be increased in the same ratio. This is obvious from the fundamental formula of parallel sailing. On this principle Wright proceeded to construct a table of meridional parts, by means of which we get a meridional difference of latitude which bears the same proportion to the difference of longitude as the true difference of latitude bears to the departure. We have then two similar triangles with the course as a common angle, either of which can be resolved by the rules of plain trigonometry. Now, whilst this method is in all cases theoretically accurate, in finding the difference of longitude in a low latitude corresponding to the distance run and the difference of latitude, if the course be near east or west, its tangent being large will rapidly multiply any error in the meridional difference of latitude (due to neglecting decimals, for the parts are generally given to the nearest whole number), and thus produce a large error in the difference of longitude, whereas the departure multiplied by the secant of the middle latitude would not be open to the same objection; besides, the course would approximate to a parallel, and so small would be the error from treating the middle latitude as such, that the result would be practically if not scientifically accurate For reasons of a similar nature the course and distance run from day to day, if sailing near a parallel, are better found by middle latitude sailing, especially in low latitudes, unless the ship crosses the equator, when the portions on each side of it ought to be obtained separately if this method be used. In all cases where the foregoing conditions do not obtain, recourse should be had to Mercator's sailing. In a doubtful case the course and distance might be calculated by both methods, and the results compared. For the purposes of steering, the course is only required to the nearest degree and, as a general rule, for computing the distance to the nearest minute. If, however, the course be near east or west, its secant, being large and changing rapidly, is required to the nearest second to obtain the distance accurately. As the seconds are of no use, except to get the secant exactly, they may be done without by observing that the required secant will exceed its tangent, which is in the computation already by the same amount as the nearest tangent in the tables is exceeded by its secant.

Except the ship is being navigated along the equator or a meridian, none of the foregoing methods give the shortest distance between two points on the globe, nor the courses to steer to attain it. This can only be accomplished by great circle sailing. A knowledge of great circle sailing is much older than is generally supposed, though it is only of late years that it, or a modification of it, has been at all generally practised, and even now it is not as much used as it ought to be. The earliest record that I have been able to find of the application to navigational purposes of a principle that must have been long known to mathematicians and astronomers, is in a work on navigation by Captain Samuell Sturmey, published in the middle of the seventeenth century, in which the gnomic chart is described. The gnomic chart is to great circle sailing what Mercator's chart is to the sailing of that name, and this old navigator gives rules how to convert a log slate into a chart on this projection so that the great circle courses can be read off with a protractor. Whilst great circle sailing can never have been forgotten, even if little practised, the gnomic chart seems to have dropped out of men's memories, for two centuries later it was rediscovered simultaneously by Mr. Godfray, of Cambridge, and Captain Bergen. Within the next few years Knorr, Hillarett, Jensen and Herrle all brought out gnomic charts more or less like Godfray's, of which Herrle's seems the best and most convenient for finding the distance as well as the course. Before, however, the gnomic charts were reinvented, Towson introduced a diagram and set of tables for facilitating great circle sailing. By means of the diagram the vertex of the required great circle is found, and then taking the

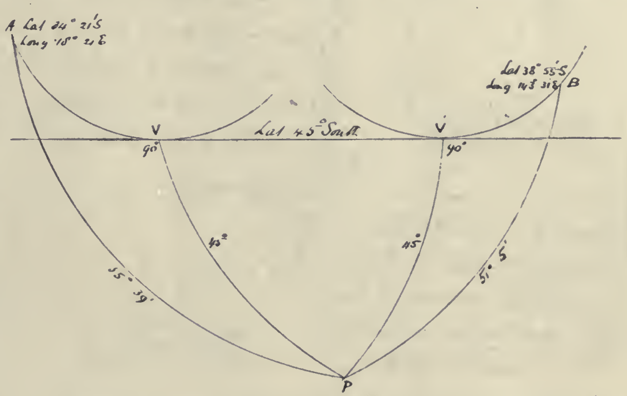

FIG. 1.—Showing the composite track from the Cape of Good Hope to Cape Otway, with 45° as maximum latitude. The composite track is from A to V, V to V′, and thence to B.
Cos AV = sin lat. A, cosec lat. V. | Cos APV = tan lat. A cot lat. V.
Cos BV′ = sin lat. B, cosec lat. V′. | Cos BPV′ = tan lat. B cot lat. V′
APB − (APV + BPV′) = VPV′ which × cos 45° = VV′.
Sin A = sec lat. A, cos lat. V and sin B = sec lat. B, cos lat. V′.

successive courses and distances out of the tables is a mere matter of inspection. A few years later Deichman endeavoured to improve on Towson's diagram, and Brevoort brought out a somewhat similar diagram to accomplish the same object. Lecky has pointed out that great circle courses, within certain limits, may be taken out by inspection from Burdwood's (and other) azimuth tables, and almost without limit from his own A, B, and C tables. Lecky, too, gives short rules for computing the first course and distance. With all these methods open to the navigator, great circle sailing ought to come to the front. One of the drawbacks to it is that in the parts of the world where it would save most distance, it leads through inclement regions and amongst ice, and not the least of Towson's merits was showing how to combine it with parallel sailing so that, without going to a higher latitude than was desired, the shortest track could be followed. He finds either by calculation or his tables the two great circles passing through the points of departure and destination whose vertices just touch the limiting parallel. The vessel is navigated along the first arc till the parallel is reached, along which she is kept till the vertex of the second circle is attained when she takes the great circle arc to her destination. This is demonstrably the shortest distance between the two places under the given conditions.

The labour of utilising great circle sailing by the rigorous method has been much magnified. It is not necessary to find the distance accurately (or even at all) every day, and the first and last courses are easily and quickly worked with the two co-latitudes and difference of longitudes (two sides and the contained angle to find the angles at the base); and for this purpose it is near enough in practice to take out the logs to three or four figures. This is the same formula as for time azimuths, which explains why great circle courses can be obtained from azimuth tables. Towson gets a right angle at the vertex, and so obtains brevity of solution. Now I will introduce a short method of my own, which I always use when the conditions are suitable. It is a very general practice to settle on the point to cross the equator according to the season of the year. Proceeding from Cape Leeuwin to Cape Guardafui, for instance, to be well to windward in the south-west monsoon, it is advisable to cross the line in about 60° E. long. Now, by working towards this point, the first course and distance may be obtained by quadrantal spherics quicker than by Mercator's sailing, because, though there are the same number of figures, the logs can be taken out in pairs, or triplets if the last course is required, to see if the ship is keeping on the same great circle. Unfortunately, it can only be used approaching the equator or in calculating a track thence to the next point of destination; but I have already shown how the courses alone can be quickly obtained in other cases, independent of the innumerable ways of getting them by inspection, and the graphic methods of Airy and Fisher, besides which there are various protractors and mechanical devices for those that favour such methods.

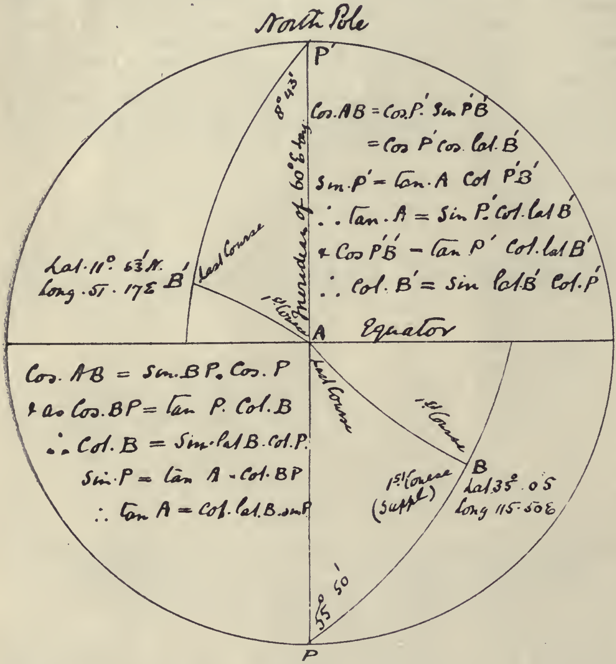

FIG. 2.

Example:

D. long. 55° 50′	Cot 9·83171	Cos 9·74943	Sin 9·91772
	Cot 9·59030	Cos 9·66279	Tan 10·07249

1st course N. 68° 44′ W. AB 62° 37′ Last course N. 49° 46′ W.
60

Great circle dist. B to equator 3757 miles.

Now, whilst the foregoing methods are all sufficient to enable the navigator to obtain the bearing and distance of his port or destination, they are far from being irreproachable as a means of finding the daily position of a ship at sea, though they are always used for this purpose in case no better position is obtainable, or if it is, to compare with it. The cause of the deficiency is the uncertainty of the elements used in the calculation. When a ship on any given day leaves a well-ascertained point of departure, her position next day is obtained by the course steered and distance run. But neither can be absolutely relied on. In the finest vessels afloat with the most perfect navigating appliances, the course steered, even in fine weather, will be uncertain to 1°, which is equivalent to a deflection of $1\frac{3}{4}$ miles in every 100. This may easily be trebled or quadrupled in bad weather if compass errors cannot be checked, which, with every possible care, are liable to sudden and unlooked-for changes. In bad steering vessels, or with badly-placed compasses, or where the errors are not frequently checked, or from a combination of these causes, the error in the course may amount to 10°, which is equivalent to a deflection of $17\frac{1}{2}$ miles in every 100. The distance run, under the most favourable circumstances, is liable to an error of 3 per cent., which head winds or other causes may easily double or, in exceptional circumstances, magnify still further. Then, again, the currents of the sea are the most uncertain element with which the navigator has to deal. Half a knot to a knot per hour is quite common, whilst five knots, or over, is not unknown. Except in a few localities, the direction is almost as uncertain as the strength. Even where currents run pretty regularly, these ocean rivers are not confined and held in position by fixed limits like those of the land, but are as flexible as snakes, which is perhaps the origin of the symbol denoting them on current charts, which at best only give a general idea what to expect: they are frequently deflected, or even reversed, by distant winds, or other causes quite beyond the ken of the navigator whose ship is being affected by them. With all these elements of uncertainty in the data used, it cannot be wondered at if the position by dead reckoning be of doubtful accuracy; and it would probably be more uncertain still, but that the numerous sources of error generally tend to compensate one another. It is, none the less, of the highest importance to the navigator to keep his log account with the greatest care, in case he has nothing better to depend on. Luckily, however, there are more accurate methods generally available, by which the navigator can find the position of his vessel—methods approximating to those of the astronomer in his observatory, whose more refined instruments and abstruse calculations supply the seaman with the data necessary to combine with his own observations, and fix the position of his ship with all needful accuracy. In a subsequent paper I will explain how this is done.[1]

J. F. RUTHVEN.

ANNIVERSARY MEETING OF THE LINNEAN SOCIETY.

THE anniversary meeting of the Linnean Society of London, held at Burlington House on May 24, was the occasion of presentation, by its Fellows, to Sir Joseph Dalton Hooker, G.C.S.I., C.B., F.R.S., of a commemoration gold medal, in addition to that of the Society's annual gold medal, which was awarded to Surgeon-Major G. C. Wallich, M.D., the veteran naturalist of the cruise of H.M.S. *Bulldog*. In presenting the medal to Sir Joseph Hooker, the President, Dr. A. Günther, F.R.S., made the following remarks.

The completion of a monumental work in botany, the "Flora of British India," has been chosen by our Council as a fit occasion for the Linnean Society to pay its tribute to the recognition of the eminent services which have been rendered to biological science by Joseph Dalton Hooker. A gold medal, specially struck for the occasion, of which copies could be distributed among his numerous friends and admirers, was considered to be the most appropriate and the most enduring form to serve as a memorial of this desire of the Society.

If I attempted, or were competent, to pass in review the work by which J. D. Hooker has advanced botanical science and enriched its literature, the few words I intend to address to you would swell into a biography; for of the sixty years which have elapsed since he entered the service of science, there are but few in which he has not left his mark upon its history.

The four years which he passed with the Antarctic expedition, and the three years during which he wandered among the ranges of the Himalayas, were the period in which he saw nature in her most diversified, grandest and purest aspects, and was brought face to face with the mysteries of the distribution of life over the globe. Then and for many years afterwards he made these phenomena and their causes the object of his special study. His writings on the subject have had the most powerful influence on, and were the guide in all subsequent inquiries. His travels were of the highest importance, and that not with regard to our biological knowledge alone; his intimate acquaintance with geology, meteorology, his proficiency as a surveyor have rendered his accounts of the countries visited by him equally valuable to the geographer.

When biology entered upon that eventful period of its history, in which the doctrine of continuous evolution by natural selection was striving to replace that of distinct creations, Hooker was one of the foremost champions of the former. Many systematic workers in zoology and botany were apprehensive at the time of dangers arising to their methods from the new doctrine. Hooker dispelled such fears by his own example; he continued his systematic work, but he showed at the same time that it was not the end, but only the means to the end, of biological research.

The part which he took, during the lifetime of his father, and during the twenty years of his directorship, in raising the Royal Gardens at Kew to their importance and eminence, is known to all of you. But I cannot pass this short allusion to his official work without referring to the position which Kew has taken as the centre of advice and help for the kindred institutions in India and the Colonies. This bond had been already established by the father; but it was strengthened by the son's personal acquaintance with their capabilities, and his sympathy with their needs.

His official duties, sufficiently arduous by themselves, did not prevent him from obeying other demands of science, when he was called upon to perform the functions of President of the British Association in 1868, and of the Royal Society from 1873–1878. And since his retirement from the public service in 1885, at an age when most men seek for rest from their labours, we have seen him still prosecuting his work with that single-minded devotion to science which has been characteristic of the whole of his life.

The prosperity of the Linnean Society, of which he has been a Fellow since 1842, has always been to him an object of special interest. Some of his most remarkable memoirs appeared in our *Transactions*; Bentham, who devoted years of care to the welfare of the Society, was connected with him by ties of closest friendship. And last, but not least, we remember that in honouring the son we are doing homage to the memories of the father and grandfather, both of whom were illustrious Fellows of the Society.

Sir Joseph Hooker, in acknowledging the presentation, said:

Mr. President, I cannot express my sense of the great, the exceptionally great honour which your Council has conferred upon me in the founding and awarding of this beautiful medal. In receiving it, let me assure you that I value it as much for the evidence it bears of the friendly regard of my associates as for their all too high estimate of my endeavours towards the promotion of science. Furthermore, let me say that from no scientific body could it be received by me with more cordial welcome than from the Linnean Society, which was the first to which I have the honour of belonging to enrol me amongst its Fellows, and which especially cultivates those branches of knowledge to which I have devoted the best years of my life. To these considerations must be added what you yourself have alluded to, namely, my hereditary interest in a Society of which my father and grandfather were very early Fellows, and both of them contributors to its *Transactions*. To this latter circumstance it may perhaps be due that I was elected at a very early age, being, I believe, the youngest member of our body with no further scientific claims on the support of my electors than that I was serving as a naturalist in the Antarctic expedition under Captain Ross, where I happened to be the youngest, as I am now the only surviving officer of those then under the command of that intrepid navigator. I may mention that Captain Ross was himself a Fellow, and had a copy of our *Transactions* in his cabin, which was a godsend to me. I was in the Falkland Isles when my election took place, and nearly a year and a half elapsed before my captain and I knew that we were fellow Linneans.

In 1842 the Lord Bishop of Norwich was President. He was the first of ten under whom I have been privileged to sit. Had the Society adopted the rule of biennial presidents I should have sat under thirty at least, which, in my estimation, would have detracted greatly from the dignity which I attach to the chair, and I venture to think from its utility also. In the year 1842 there were 610 members of the Society (including fellows, foreign members and associates) with fully one-fourth of whom I soon became personally acquainted. Twenty-eight years afterwards, that is about midway between the former date and the present time, the number of my personal friends in the Society had risen to one-half of the whole body. Our numbers are now 820, but the proportion of my personal friends among them has inevitably shrunk from my having outlived so many associates of my middle age. And this leads me to ask your indulgence for one more egotistical detail. It is that I am perhaps the only Fellow who personally knew four of the 169 naturalists who, 110 years ago, formed the nucleus of our Society. Of these four I knew two during my later teens: they were the Rev. W. Kirby, the author, with Spence, of the "Immortal Introduction to Entomology"; and Dr. Heysham, of Carlisle, an excellent entomologist and ornithologist. The others were Aylmer Bourke Lambert, a former President, and the last, as I have been informed, who wore in the chair the presidential three-cornered hat; and Archibald Menzies, who as naturalist accompanied Vancouver in his voyage in the Pacific, and who introduced the *Araucaria imbricata* into England. These all died very near the year of my election.

Referring now to the progress of the Society in status and efficiency during the years that have elapsed since 1842, the record cannot but be gratifying to its Fellows. Of this the best proofs are the increment in extent and value of its publications,

[1] Throughout this paper the earth has been treated as a sphere. Of course it is really a spheroid with a compression of 1/300 in the polar axis. This hardly affects general principles, though it introduces slight modifications and corrections in detail. For these, and the rules of computation *in extenso*, the reader is referred to such standard and practical works as Riddle, Raper, Merrifield, Lecky, and others.

and the interest taken in its meetings. From its foundation up to the date referred to (fifty-four years) eighteen volumes of the *Transactions* in quarto had been published. During the succeeding fifty-four years about double that amount have been produced in the same form, besides fifty-eight volumes of the *Journal* in octavo, which latter was not commenced till 1857.

Then as regards attendance at the meetings during the first years of my fellowship, it was miserably small. If my memory does not deceive me, I recall a night in Soho Square when only five Fellows supported the President and Secretary. There was a dearth of papers too, and the discussion of such as were brought forward was discountenanced by the chair. All this is now happily a thing of the past, and I should not have alluded to those bad times had not the Society given proof of that inherent vitality which supported it under a temporary depression, and subsequently raised it to its present position.

It remains, sir, to thank you cordially for coupling my father's name with my own in this award, but for which, indeed, I could not have accepted it without a protest. I inherited from him my love of knowledge for its own sake, but this would have availed me little were it not for the guiding hand of one who had himself attained scientific eminence; who by example, precept and encouragement kept me to the paths which I should follow; launched me in the fields of exploration and research, liberally aided me during his lifetime, and paved for me the way to the position he so long held at Kew with so great credit to himself, and benefit especially to our Indian and Colonial possessions.

The gold medal of the Linnean Society was received on behalf of Surgeon-Major Wallich by his son, and, in presenting it, Dr. Günther spoke as follows:—

The gold medal of the Society is awarded this year to a zoologist, to Dr. George Charles Wallich. Although Dr. Wallich's scientific work commenced some years before, it was the year 1860 in which he entered upon the line of inquiry with which his name will be ever associated. On the recommendation of Sir Roderick Murchison and Prof. Huxley he was attached in that year as naturalist to H.M.S. *Bulldog*, on her voyage across the Atlantic to survey the sea bottom for the laying of the proposed Atlantic cable. The materials obtained by the sounding operations were slender; but in working them out, Dr. Wallich showed that he had already grasped all the principal problems of deep-sea research. To the solution of these problems he applied his wide range of knowledge, the soundness and power of his reasoning, his originality and independence of thought. His work, "The North Atlantic Sea-Bed," incomplete as it is, stands as a lasting record of the progress made by him in our knowledge of deep-sea life, and of the impetus which he gave to subsequent deep-sea exploration.

For more than twenty years he continued to work in the same line of inquiry, and in investigating collateral subjects, notably the life-history, structure and relationships of those unicellular organisms which play so important a part in pelagic and bathybial life, the lithological identity of the ancient chalk formation, and of the calcareous deposits in the oceans of the present time.

The remarkable results which he obtained in his investigations were due not only to his accuracy and keenness as an observer, but also to the ingenuity of the methods applied by him. Thus at a time when our modern micro-chemical methods were unknown, he employed the electric discharge as a means of differentiating the nucleus, and he determined the excretory function of the contractile vacuole.

Your Council were of opinion that work of such originality, advancing so many branches of biology, was peculiarly fit to be honoured by the award of the Linnean medal.

NOTES.

WE notice with deep regret the announcement that Lord Playfair died on Sunday. The funeral will take place on Saturday at St. Andrews, Fifeshire.

WE are requested to state that the Chemical Society's banquet to the past presidents on June 9, and also Dr. Mond's garden party on June 10, are postponed in consequence of the death of Lord Playfair, the senior past president and the last surviving founder of the Society.

THE Ladies Soirée of the Royal Society will take place next Wednesday, June 8.

SIR WILLIAM H. FLOWER, K.C.B., has received, from the German Emperor, the Royal Prussian order "Pour le Mérite" for Science and Art.

THE death is announced of Prof. F. Müller, distinguished for his works on ethnology and philology.

PROF. G. H. DARWIN, F.R.S., has been elected a foreign honorary member of the American Academy of Arts and Sciences, in succession to the late Prof. J. J. Sylvester.

AN exhibition of specimens of practical work of candidates at the technological examinations of the City and Guilds of London Institute will be opened at the Imperial Institute next Thursday, June 9, by the Right Hon. Lord Herschell.

THE Albert Medal of the Society of Arts for the present year has been awarded, with the approval of the Prince of Wales, the President of the Society, to Prof. Robert Wilhelm Bunsen, Foreign Member of the Royal Society, "in recognition of his numerous and most valuable applications of chemistry and physics to the arts and to manufactures."

INFORMATION of the death of Mr. W. M. Maskell, Registrar of the University of New Zealand, has been received by the *Entomologist's Monthly Magazine*. Mr. Maskell was well known for his researches in *Coccidæ*; he also published papers on *Aleurodidæ* and *Psyllidæ* amongst insects, and on Desmids in microscopic botany. The majority of his papers have appeared in the *Transactions* of the New Zealand Institute, the first having been published in 1879. At first he restricted himself to the species found in New Zealand, but later on those of Australia (especially the curious gall-making *Brachyscelidæ*), Asia, &c., came under his notice, he having become a recognised authority on the subject of *Coccidæ*. He usually published at least one paper a year in New Zealand, the later ones being lengthy, and all copiously illustrated by his own drawings.

THE Berlin correspondent of the *Times* announces that the German steamship *Helgoland* has just started on an expedition to the North Pole. The ship is built entirely of steel. She carries on board provisions for thirteen months and four boats, two of which she picks up at Tromsö. Special care has been taken in the selection of her crew, some eleven in all. The leader of the expedition, Herr Theodor Lerner, is accompanied by Dr. Brühl, Dr. Römer, and Dr. Schaudien, who are all experienced travellers and men of science. Two other expeditions—both of American origin—are about to set out with the object of reaching the North Pole. Lieut. Peary will attempt the Pole from North Greenland, while Mr. Walter Wellman will make the effort from Franz Josef Land. Mr. Wellman is now in London, and will leave in a few days for Tromsö, Norway, where his ice steamer, the *Frithyof*, is ready for him, and whence she will sail in about three weeks for the Far North. In his party are Prof. James H. Gore, of Columbia University, who will make gravity determinations in Franz Josef Land; Lieut. Evelyn B. Baldwin, of the United States Weather Bureau, who was on the Greenland ice cap with Lieut. Peary, and who is an accomplished meteorologist and geologist; Dr. Edward Hofma, of the University of Michigan, naturalist and medical officer; and Mr. Quirof Harlan, physicist from the United States Coast and Geodetic Survey, a Norwegian experienced in Arctic work.

THE Home Secretary has appointed Dr. Oliver, of Newcastle-upon-Tyne, and Dr. T. E. Thorpe, F.R.S., Government Analyst, as experts to proceed to the Potteries for the purpose of inquiring into the various kinds of glazes in use there, and as to whether any substitutes can be found for those containing lead. Not only will the work undertaken by these gentlemen have a humane bearing and be of a scientific nature; it will be helpful also to the manufacturers. This is the first instance (says the *British Medical Journal*) in which the British Government has called to its aid expert help, not only to assist it in framing regulations for the health of the workers, but also of helping on industries. As the manufacturers are sure to co-operate heartily with those to whom has been entrusted this important special inquiry, it is to be hoped that results will be arrived at which will remove from one of our prosperous and oldest industries the stain that has so long lain upon it.

DR. AGAMENNONE, who has paid considerable attention to the velocity of earthquake-waves, has recently published a valuable paper on the mean surface-velocity of the pulsations from the great Calcutta earthquake of last June 12 (*Rend. della R. Accad. dei Lincei*, vol. viii., 1898, pp. 265–271). Relying on accounts which have already appeared in NATURE, he assumes the centre of disturbance to be in 25° N. lat. and 91° E. long. At Calcutta, which is 400 km. from this point, the time of occurrence was 11h. 4·6m. a.m. (Greenwich mean time) according to Mr. La Touche; and 11h. 7m. according to Mr. Oldham. The earthquake was registered by seismographs and magnetographs at nineteen observatories in Europe, the most distant being Edinburgh, 7970 km. from the epicentre. Excluding the record on the Parc St. Maur magnetograms, which differs considerably from the others, the mean surface-velocity of the earliest vibrations was either 9 or 11 km. per second, according to the time taken for Calcutta. These first rapid vibrations lasted for about 23 minutes, and were succeeded by large long-period oscillations, the mean surface-velocity of which was either 2·61 or 2·76 km. per second. At Rome, the period of these oscillations was about 10 seconds, and their maximum amplitude 12″. Thus, as it crossed Italy, the complete wave must have been 54 km. in length, and the height of its crest about half a metre.

SENOR ANTONIO BLAZQUEZ communicates to the *Boletino* of the Madrid Geographical Society a preliminary paper on a fresh investigation as to the precise length of the Roman mile. The question has been a constant source of difficulty in connection with the determination of the sites of ancient cities, and the tracing of former inhabitants of the peninsula, and a great deal of evidence is discussed which goes to show that the Roman and the Arab miles were of the same length: 1672 metres. The length formerly accepted was 1481 metres. The detailed investigation is promised in a future paper.

DR. C. DAMMANN adds another to the already numerous monographs on German rivers in a paper on the Wupper, published in the *Verhandlungen des naturhistorischen Vereins der preussischen Rheinlande*. A careful study is made of the geology and geomorphology of the river and its basin, and of the rainfall and drainage. The fact that the basin of the Wupper consists almost entirely of impermeable rocks, gives the sudden variations in the volume of the stream some special features, especially with regard to floods. Some idea of the rapidity of these changes is given by the record of the rate of discharge on three successive days: 52·7, 182·3, and 51·7 cubic metres per second.

IN Darwin's geological observations on the volcanic islands visited during the voyage of H.M.S. *Beagle*, reference is made to a "volcanic bomb" found in the interior of Australia. The specimen was composed of green obsidian, and was found on a great sandy plain between the rivers Darling and Murray, at a distance of several hundred miles from any known volcanic region. Many similar specimens of obsidian "buttons" have since been found in Australia, and the *Proceedings* of the Royal Society of Tasmania (1897) contains two short descriptive papers on their occurrence in Tasmania. How these singular objects found their way to some of the localities in Tasmania, where their occurrence in undisturbed quartz drift far away from any known volcanic source has been reported, is unexplained. That they are volcanic products is unquestionable; and their spheroidal or discoid form points to rotation while in a fluid state. It has been suggested that the objects came from lunar volcanoes, but it is highly improbable (even if they were ejected from the moon) that they would reach our globe, and if they did they could not penetrate the atmosphere. Mr. T. Stephens, the author of one of the papers referred to, thinks the aborigines of Australia are probably largely responsible for the distribution of the obsidian buttons over the mud-plains of Victoria and Riverina, but no such explanation can be given in reference to most of the places where they have been found in Tasmania. In a paper by Messrs. W. H. Twelvetrees and W. F. Petterd in the *Proceedings* mentioned above, the suggestion is made that the objects are products of terrestrial volcanoes of an acid or sub-acid type, formerly in eruption in the southern hemisphere. The nearest known source of tertiary obsidian is New Zealand, but whether the objects have been transported through the air from that island, or from the Antarctic continent or elsewhere, it is impossible at present to decide.

WE learn from the *Meteorologische Zeitschrift* for April that Signor Boffito, librarian of the Moncalieri Observatory, near Turin, intends to publish a repertorium of Italian meteorology, which, like the valuable repertorium of German meteorology published by Dr. Hellmann in 1883, will contain a practically complete bibliography of meteorological works written in the Italian language. As the meteorological literature of Italy was especially rich in the fifteenth and sixteenth centuries, the publication of the proposed work will be very welcome. Signor Boffito will be glad to receive notice of any works published in the Italian language in other countries.

IN the U.S. *Monthly Weather Review* for February an interesting account is given of the value of a searchlight for making weather signals known in large cities or seaports at an hour of the evening when it is too late to give warning by the usual method. In the month of February 1895, the searchlight for the unfortunate battleship *Maine*, then nearing completion, was lent for temporary use at the Chicago office of the Weather Bureau, and the experiments were conducted by the present chief of the latter institution. From observers and other persons it was ascertained that the signals were clearly seen at a distance of twenty miles. At present the great cost of maintaining the apparatus in operation would preclude its adoption, but in the event of the expense being eventually reduced, the author thinks it might be used by the Weather Bureau for the purpose of immediately disseminating forecasts made from the evening observations.

THE relative merits of the weather predictions issued daily by the U.S. Weather Bureau for one or two days in advance, and those published by "farmer's almanacs" a year or more in advance, were lately made the subject of newspaper paragraphs in America, and are commented upon by Prof. Cleveland Abbe in the *Monthly Weather Review*. Of course, no true comparison can be made between the results; for while the predictions made by the Weather Bureau are based upon actual observations of atmospheric conditions, the popular weather prophets depend chiefly upon inspiration and astrological combinations, though some do go so far as compile from the records of past years a table showing what sort of weather has prevailed most frequently on the respective days of the year, and use this table for predicting the weather of future years. The art of almanac preparation, however, is in the free use of a system of general terms which will apply just as well to a thunderstorm, a hurricane, or an earthquake. The warning "look out for something very unusual about this time," is a meteorological prediction of this character.

FOR the benefit of those who make a comparison between the prophesies of the almanac-maker and the forecasts of the U.S. Weather Bureau, Prof. Abbe delivers the following homily:—In connection with meteorology in general, and especially weather predictions, there is a popular tendency to make a mistaken use of the word "science." Knowledge is science as distinguished from the world of imagination, which is fiction. Whatever is logical and true may be called scientific, but whatever is illogical or untrue is certainly not scientific. A map or a survey that gives us an exact picture of the true location of every spot on the earth's surface responds to scientific geography. A catalogue of all the plants and animals on the earth or of the stars in the sky constitutes a biological or an astronomical survey, and is truly scientific. A series of maps of the weather at 8 a.m. daily is a scientific meteorological work, and any predictions of the weather that can be logically deduced from these maps is a scientific prediction. But a lot of predictions that are said to be deduced in defiance of sound logic and with a very imperfect knowledge of the laws of nature are fanciful fictions and not scientific, because they are contrary to all sound knowledge.

IT is well known that the Kea or Mountain Parrot of New Zealand has acquired the habit of attacking sheep, and making holes by means of its sharp and powerful beak in the backs of these animals for the purpose of abstracting the kidney fat, which appears to be esteemed as a luxurious diet. It is supposed that this peculiar habit or instinct was developed by the bird getting the fat from the skins of sheep that had been slaughtered; but this solution is not very satisfactory, as there appears nothing to connect the fat on the skins of sheep with the live animals. In a note published in the *Zoologist* (May 16), Mr. F. R. Godfrey, writing from Melbourne, offers the following solution of the mystery, which seems to him to be simple and satisfactory, and more rational than the sheep-skin theory. In the hilly districts of the Middle Island of New Zealand there is a great abundance of a white moss or lichen, which exactly resembles a lump of white wool, at the roots of which are found small white fatty substances, supposed by some to be the seeds of the plant, and by others to be a grub or maggot which infest it, which is the favourite food of the Kea. Probably the bird, misled by this resemblance, commenced an exploration in sheep, and this proving satisfactory, originated the new habit. In a note to this suggestion, the editor points out that Mr. Godfrey is in agreement with Mr. F. R. Chapman (New Zealand *Journal of Science*, 1891), who, describing a valley of the Upper Waimakariri, Canterbury, says: "A very interesting *Raoulia*, or vegetable sheep, was very plentiful on steep, rocky places; but I believe a finer species is found on Mount Torlesse. . . . It is said that the Keas tear them up with their powerful beaks, and that these birds learnt to eat mutton through mistaking dead sheep for masses of *Raoulia*."

As the British Patent Law at present stands, foreign inventors can obtain patents in this country without "working" their invention, and they take the fullest advantage of this state of affairs. To give an instance: in the five years from 1891 to 1895 no less than six hundred patents were granted to foreigners for coal-tar products, not a single one of which is being worked in this country. The object of Section 22 of the Patents, Designs, and Trade Marks Act (1883) was to ensure the working in the British Isles of inventions for which the privilege of British registration has been granted, either by the patentee or by others. In order to secure this object, the Section confers upon the Board of Trade authority to order the granting of licenses on equitable terms. Unfortunately, although the Act has been in force for fifteen years, this authority has never been used, because the prosecution of a petition for the exercise of such authority involves what is practically a very costly legal contest at the expense of the petitioner. Upon the invitation of the Board of Trade, a petition has at last been carried through with the approval of the Manchester Chamber of Commerce. The facts and issue of the prosecution of it are set forth in a pamphlet prepared by the Chamber, and they need only be read to understand that British trade and industry is seriously prejudiced by the present unsatisfactory state of the Patent Law. In France, if a patent is not worked within two years (and the patentee has to prove that it *is* worked), the patent is revoked, and is declared void. In Germany the law is similar, with this exception—that the patentee, instead of two, has three years' time within which to work his invention. What is wanted is a short amending Act which will bring our Patent Law in conformity with those of Germany and France; and it is with the object of calling attention to the need of such a provision that the Manchester Chamber of Commerce has placed the whole facts before the public.

A NUMBER of examples of *Abraxas grossulariata*, in which the markings of the fore-wings, which are usually of a bright yellow, were of a deep dull ochreous colour, were exhibited at a meeting of the South London Entomological and Natural History Society at the end of last year (*Proceedings* for 1897). The specimens were sent by the Rev. J. Greene, of Clifton, Bristol, who reared them from larvæ found on the shrubs of Euonymus, which appears to be their favourite food. During the past six years Mr. Greene has bred a large number of these insects under precisely the same conditions as regards food, temperature, light and darkness. The insects were kept indoors both as larvæ and pupæ, so wet and dry weather could apparently have no effect upon them; and they were all collected within a two-mile radius, where there was no difference of soil. And yet, under these uniform conditions, Mr. Greene produced at least two hundred and fifty varieties. A remarkable variation was noticed in the "contour" of the specimens—that is, in the length, breadth, and curvature of the upper wings; but it is difficult to determine the causes which can produce such a change in the form and shape of the wings. In Mr. Greene's opinion there is one, and one only method by which entomologists may reasonably hope to obtain varieties, namely, by "crossing" the imagines, dark with light, &c. He considers this to be the true cause of the varieties of *grossulariata* obtained by him.

THE drinking habits of some butterflies and moths are briefly described by Mr. J. W. Tutt in a paper published in the *Proceedings* of the South London Entomological and Natural History Society, 1897. A number of observat ons are cited showing that the drinking of large quantities of water by certain species is beyond question. Mr. Tutt concludes as follows:—"That they drink infinitely more than is required by their tissues under any possible conditions appears certain. Baron's note (NATURE, vol. xxviii. page 55, May 17, 1883) is sufficient proof of this; whilst we have known *Polyommatus damon* to sit for more than an hour motionless, except for the slight movements of sucking up and discharging the moisture almost continuously. What this internal bath may really mean we cannot even surmise. Another important factor as to this drinking habit is a strange one; the 'thirsty souls' are, so far as my own observation goes, and so far as De Nicéville's and Bates' remarks show, almost entirely males. Why is this drinking habit confined to one sex, and why is it indulged in whilst the females are away egg-laying, or presenting the strange phenomenon of a perfectly different habit from that indulged in by their lords and masters? It is of course quite reasonable to suppose that, if a number of exact observations be made, females in small numbers do visit puddles, and pools, and streams for drinking purposes. Certain it is that females come to sugar equally with males, but this we may take it is for food, and not for drink, and it is just in this that our difficulty lies. We know that moths and butterflies that visit sugar, over-ripe fruit, and similar dainties are of both sexes. They come, it seems, for food; but males alone seem to be attracted by pure water. Does their extra activity give them a greater need in this direction? and has a habit which was at first (and still is in a measure) a necessity become so pleasurable that excessive drinking has literally become a vice?"

MESSRS. SEELEY AND CO. will shortly publish a concise popular account of wireless telegraphy, by Mr. Richard Kerr, being the substance of lectures delivered by him in the principal cities of England, Scotland, and Holland. Mr. Preece will contribute a preface to the volume.

HERREN FEIEDLÄNDER, of Berlin, have just issued their Book-Catalogue No. 430, consisting of 103 pages, entirely devoted to the anatomy, physiology, and embryology of plants.

AN earnest appeal is made by the Rev. W. Porter, "Vonmueller," Arnold Street, South Yarra, Victoria, one of the trustees, for further contributions for the erection of a granite monument over the grave of the late Baron Ferdinand von Mueller, in the cemetery of St. Kilda.

DR. ERWIN F. SMITH reprints a lecture delivered before the Massachusetts Horticultural Society on the spread of plant diseases, in which he discusses the parts played respectively by insects and by the wind in the propagation of the diseases of plants.

THE May number of the *National Geographic Magazine* is devoted to an account of the geography, resources, and political conditions of Cuba, and contains as a frontispiece the portrait of Captain Charles D. Sigsbee, the commander of the ill-fated battleship *Maine*. For several years, prior to taking command of the *Maine*, Captain Sigsbee was Hydrographer of the Navy Department, and his contributions to our knowledge of the sea bottom, and its topography, place him in the front rank of scientific hydrographers.

MESSRS. TAYLOR, TAYLOR, AND HOBSON have issued a booklet of twenty-three pages setting forth the merits of their Cooke lens. Every photographer knows how difficult it is to obtain a lens which gives a sharply-defined image all over the field of view. By increasing the number of lenses, it is possible to overcome this difficulty and secure sharp definition even at the margins of a picture. The Cooke combination satisfies this photographic desideratum by the simplest means, only three lenses being used in its construction. The superiority of the lens over the symmetrical and other old types is strikingly shown in the book by a series of reproductions from the margins of plates.

THE eleventh part of Mr. Oswin A. J. Lee's illustrated work "Among British Birds in their Nesting Haunts" has been published by Mr. David Douglas, Edinburgh. Ten plates are included in this new part, representing nests of the robin, wren, rook, marsh tit, golden eagle, spotted flycatcher, teal, and pheasant. An insertion announces that the author is desirous of taking photographs of the nests of the following birds: kite, Montagu's harrier, honey buzzard, hobby, garganey, and ruff. If any reader is able to help Mr. Lee to procure these, intimation should be sent to him at 58 Manor Place, Edinburgh.

"WE have the satisfaction of being able again to look back upon a year of general activity and extended progress, which will bear comparison with any of its predecessors." The Report of the Marlborough College Natural History Society, from which these words have been taken, show that interest in scientific subjects is well fostered by the Society. The members are encouraged to observe and to contribute papers recording the results of their observation and reading, so that the Society, like other similar societies in our public schools, is of great assistance in developing very useful faculties. For instance, the following observation, by "E. A. M.," of climbing habit in frogs is interesting:—"Some frogs have taken up their abode for the last month in two deserted blackbirds' nests, built in round thick box bushes, about two feet from the ground. One frog is generally to be seen alone sometimes on or near the edge of the nest, sometimes comfortably ensconced in the middle, only his head peeping out. In the other nest there are now always two frogs." Mr. E. Meyrick describes and figures some cinerary urns discovered during excavations in the College grounds.

THE additions to the Zoological Society's Gardens during the past week include a Collared Peccary (*Dicotyles tajaçu*) from South America, presented by Mr. Eustace Grey; a Gazelle (*Gazella dorcas*, ♂) from North Africa, presented by Mr. J. D. Lambert; a Short-headed Phalanger (*Petaurus breviceps*) from Australia, presented by Mr. Julian T. Pym; a Small Hill Mynah (*Gracula religiosa*) from India, presented by Mrs. Strather; a —— Squirrel (*Sciurus*, sp. inc.), three Schlegel's Doves (*Calopelia puella*) from West Africa, presented by Mr. W. H. Boyle; two Malabar Squirrels (*Sciurus maximus*, var. *dealbatus*) from India, presented by Mr. R. C. Wroughton; an Algerian Tortoise (*Testudo ibera*) from North Africa, presented by Mr. Albert West; a Smooth Snake (*Coronella austriaca*), British, presented by Mr. Bryan Hook; a Black-shouldered Kite (*Elanus cœruleus*), a Tachiro Goshawk (*Astur tachiro*), a Spotted Eagle Owl (*Bubo maculosus*), two Infernal Snakes (*Boodon infernalis*), two Lineated Snakes (*Boodon lineatus*), a Smooth-bellied Snake (*Homalosoma lutrix*), four Rough-keeled Snakes (*Dasypeltis scabra*), eleven Rufescent Snakes (*Leptodira hotambœia*), four Rhomb-marked Snakes (*Trimerorhinus rhombeatus*), fifteen Crossed Snakes (*Psammophis crucifer*), a Cape Adder (*Bitis atropos*), three Puff Adders (*Bitis arietans*) from South Africa, presented by Mr. J. E. Matcham; a Gazelle (*Gazella*, sp. inc., ♂) from Senegal, two Black-striped Wallabies (*Macropus dorsalis*, ♂ ♀) from New South Wales, a Canadian Skunk (*Mephitis mephitica*), a Florida Tortoise (*Testudo polyphemus*) from North America, a Beccari's Cassowary (*Casuarius beccarii*) from New Guinea, a Sharp-nosed Crocodile (*Crocodilus acutus*) from Jamaica, deposited; two Mantchurian Cranes (*Grus japonensis*) from North China, purchased; an African Wild Ass (*Equus tæniopus*, ♂), two Barbary Wild Sheep (*Ovis tragelaphus*), two Black-necked Swans (*Cygnus nigricollis*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

SUN WORSHIP BY TUSAYAN INDIANS.—In the fifteenth annual report of the U.S. Bureau of Ethnology, and in recent numbers of the *American Anthropologist*, Dr. J. Walter Fewkes gives a detailed account of a group of the ceremonials which form the ritual practised by the Tusayan Indians. It has been known for some years that the aborigines of the semi-deserts in the south-western portion of the United States possess a remarkably elaborate system of belief and ceremonial, and Dr. Fewkes has devoted a considerable amount of attention to them in order to determine the significance of the various parts of the ritual followed. In the course of his investigations he has made a number of interesting observations on the astronomical means used for determining the time for ceremonials. He has found that among the Hopi Indians there are priests skilled in the lore of the sun, who determine, by observation of the points on the horizon where the sun rises or sets, the time of the year proper for their religious observances. An important ceremony is performed at the winter solstice, and in December 1897 Dr. Fewkes made a special journey to Arizona to study the ritual on the spot. This is not the place to refer to the ethnological aspects of the ceremonials witnessed by him, but the following extract from the Report of the U.S. Bureau of Ethnology will interest students of primitive astronomy.

"We are justified in accepting the theory that sun and moon worship is usual among primitive men. Whether that of the sun or of our satellite was the earlier, it is not in the province of this article to discuss, but it is doubtless true that sun worship is a very ancient cult among most primitive peoples. The Pueblos are not exceptions, and while we cannot say that their adoration is limited to the sun, it forms an essential element of their ritual, while their anhydrous environment has led them into a rain-cloud worship and other complexities. I think we can safely say, however, that the germ of their astronomy sprang from observations of the sun; and while yet in a most primitive condition they noticed the fact that this celestial body did not always rise or set at the same points on the horizon. The connection between these facts and the seasons of the year must have been noted early in their history and have led to orientation, which plays such an important part in all their rituals. Thus the approach of the sun to a more vertical position in the sky in summer and its recession in winter led to the association of time when the earth yielded them their crops with its approach, and the time when the earth was barren with its recession. These epochs were noticed, however, not by the position of the sun at midday, but at risings and settings, or the horizon points. The two great epochs, summer and winter, were, it is believed, connected with solstitial amplitudes, and the equinoctial, horizontal points, unconnected with important times to agriculturists, were not considered as of much worth. There is every evidence, however, that the time of day was early indicated by the altitude of the sun, although the connection of the altitude at midday with the time of year was subordinated to observations on the horizon."

STELLAR RADIATIONS.—Referring again to the problem of the measurement of stellar radiations, mentioned in our issue of May 12 (p. 39), the recent improvement in galvanometers ought to help the matter towards solution. At the meeting of the Physical Society on May 13, Prof. Ayrton said that the sensitiveness of these instruments had increased during the last few years in the ratio of 27 to 3,310,000. Of course it must be remembered that these figures apply to a particular class of instrument, and that they are based upon a somewhat empirical definition of the factor of sensitiveness. Nevertheless, they do indicate advance in the refinements of current-measurement.

It is to be hoped that similar attention may now be given to perfecting an electrometer for extremely small potential-differences; such an instrument is required for the development of photo-electricity generally. The sensitive plates of the cells used by Prof. Minchin for stellar measurement are only a few square millimetres in area; the advantage of this is that several of them can be placed together at the focus of a telescope. Their function is, not to give current, but potential differences when exposed to light. They respond chiefly to yellow radiations, and each plate, irrespective of its size, gives from one-third to one-half a volt, for daylight. If electrometers could be improved in the ratio 27 to 3,310,000, the experiments made by Pouillet, just fifty years ago, might be extended almost to the circumjovial planets.

THE LATE PROF. SOUILLART.—At the meeting of the Paris Academy of Sciences on May 23, M. Callandreau gave a short account of the late Prof. Souillart, whose death we have already announced. Prof. Souillart was elected a Correspondant of the Academy in succession to M. Gyldén, the Academy thus showing its esteem for the astronomer who during thirty years devoted his leisure to the study of the theory of the satellites of Jupiter, and succeeded in bringing out important complements of the chief work of Laplace. It was while studying under M. Puiseux, at the Normal School, that M. Souillart had his inclination turned to celestial mechanics. In 1865 his "Essai sur la théorie analytique des satellites de Jupiter" appeared in the *Annals* of the School, and formed the basis of two later memoirs—one, published by the Royal Astronomical Society, devoted to the analytical theory of the movements of the satellites; while the other, dealing with the reduction of the formulæ to numbers, appeared in the thirtieth volume of the "Mémoires des Savants étrangers." In addition to these publications, a series of notes appeared in the tenth, eleventh, and twelfth volumes of the *Bulletin astronomique*. The whole of these works formed the basis of the treatment of the satellites of Jupiter given by M. Tisserand in his "Traité de Mécanique céleste."

When M. Souillart left the Normal School he was appointed professor of mathematics in the Saint-Omer High School, and at the same time was attached to the Faculty of Sciences at Nancy. In 1873 he became professor of mécanique rationelle at Lille University, and, some years later, professor of astronomy, which post he occupied at the time of his death.

THE INDUSTRIAL APPLICATIONS OF ELECTRO-CHEMISTRY.

THAT electricity is able to bring about chemical change appears to have been observed for the first time about the middle of last century. With Volta's discovery of the principle of his pile, in 1792, it became possible to set larger quantities of electricity in motion, and in 1800, the year in which Volta described his first large battery, the study of the chemical effects of the electric current may be said to have commenced with the observations of Nicholson and Carlisle on the electrolysis of water. They were the first to notice the separate evolution of the products of the decomposition at opposite poles; so that our knowledge of electrolysis, upon which the majority of the applications of electro-chemistry depend, may be said to have been acquired in the nineteenth century.

In the early 'thirties it was repeatedly proposed to deposit metals by immersing the object to be coated in a solution of the metal, placing it in contact with a more oxidisable metal. An external source of current was applied to electrotyping in 1839 by Jakobi, Spencer and Jordan independently of each other; the first-named also describes the employment of electrolytic gas in producing lime-light. The use of a current generated by magneto-electric machines was patented in 1842, and, according to Mr. Swan, current generated in this way was employed by Messrs. Elkington at Birmingham in that year. It was not, however, until 1864-5 that the more perfect machines of Pacinotti and Wilde made it possible to produce the electric current at a sufficiently economical rate to permit of its employment in a chemical process on the manufacturing scale. The electrolytic refining of copper was patented by Mr. J. Elkington in 1865 and 1869, and in the latter year the first electrolytic copper refinery was erected at Pembrey, near Swansea. The progress of electro-chemical industry was at first slow, but the improvements in dynamos and steam-engines, stimulated by the rapid extension of the applications of electricity to lighting and other purposes, the development of water powers, and last, but not least, the impetus given to the study of electro-chemistry by the theories of Van 't Hoff and Arrhenius, have contributed to make this progress during the past decade extraordinarily rapid. A circumstance, the effect of which on the future development of the applications of electro-chemistry is not to be underrated, is the evolution of a new type of chemist—one, namely, who adds to his knowledge of chemistry a competent knowledge of physics and especially of electricity; there can be no doubt that the country in which the facilities for obtaining training of this kind are defective will be heavily handicapped in the future. With special electro-chemical laboratories being founded at almost every university and polytechnic in Germany, it is depressing to see so little being done in our own country (more especially since it is apparently becoming increasingly difficult for foreigners to obtain admission to the German laboratories).

The present position of technical electro-chemistry has not been attained without many failures; instructive and interesting as many of these are, it is impossible to refer to them within the limits of this article, which must, therefore be confined to a general description of processes actually employed.

The oldest and most important of these is the electrolytic copper-refining process. The copper containing 0·3 to 2 per cent., or sometimes more, impurity is cast into plates which are suspended, some 3 or 4 inches apart, in large, lead-lined wooden boxes. Between each pair of plates a thin sheet of pure copper is suspended, and the solution, containing 15 to 20 per cent. of crystallised copper sulphate and 5 to 6 per cent. of sulphuric acid, run in. The impure copper plates, of course, form the soluble anodes, the thin sheets receiving the deposit of pure copper. A current of from 100 to 200 amperes per square metre is usually employed, the E.M.F. being 0·2 to 0·4 volt. The electrical energy needed is, therefore, 0·1 to 0·2 electrical horse-power hour per pound of copper deposited. Considerable variations in the details of working are found in different works, owing to the varying local conditions. When a larger current density is employed the amount of electric energy required to deposit a pound of copper is greater, but, on the other hand, the copper is deposited more quickly, and therefore, for a given output, less copper is locked up in the baths, less labour is required, and a smaller plant is sufficient. In order to obtain a homogeneous deposit of copper the solution must be kept in circulation, otherwise a deficiency of copper near the kathode surface would arise, which would lead to the formation of a non-coherent impure deposit. Of the impurities in the anodes, gold, silver, and part of the arsenic and antimony remain undissolved, whilst iron, nickel, and the remainder of the arsenic and antimony pass into solution. The two latter metals are deposited along with the copper if they are allowed to accumulate too largely in the solution, especially if the amount of free acid present is small. The solutions must therefore be purified from time to time, and this forms the main difficulty of the process. By blowing air through the solution, after neutralising it with cupric oxide, ferric arsenate and basic antimony sulphate are deposited; but large quantities of copper sulphate are thus accumulated, which are difficult to dispose of. Where cheap power is available, the impure solutions may be electrolysed with insoluble anodes of lead and the copper, arsenic and antimony deposited; otherwise evaporation and recrystallisation must be resorted to.

The anode slimes which contain Au, Ag, Se, Te, Bi, Sb, and As, are worked up to recover the precious metals. In 1896, 137,000 tons of electrolytic copper were obtained, of which the United States produced more than all other countries together. The greater part of this pure copper is employed for electrical purposes, where its high conductivity is of paramount importance. The electrolytic copper is obtained in a coarsely crystalline condition, and is fused before use. Mr. Elmore aims at depositing the copper directly in the form in which it is to be employed; copper tubes, for example, are made by depositing the metal upon a rotating cylinder, the surface of the deposit being constantly polished by a prismatic piece of agate which moves backwards and forwards parallel to the axis of the cylinder. This produces a very dense and tough deposit, and at the same time permits of the employment of a current density as high as 600 amperes per square metre. The removal of the cylinder from the tube is very simple when it is made of some easily fusible alloy.

The electrolytic process for making aluminium has entirely superseded the chemical process, the superiority of the former (from a commercial point of view) being demonstrated by the diminution in the price of aluminium from over 20*s.* per lb. in 1888 to about 1*s.* 4*d.* to-day. The electrolyte employed is a solution of alumina in a fused mixture of the fluorides of aluminium and of the alkali or earth-alkali metals. Minet has used a mixture of common salt and aluminium fluoride, but it would appear that the solvent usually employed is cryolite from which iron and silicon have been removed by a preliminary electrolysis. The baths consist of large iron, carbon-lined boxes, the lining forming the kathode. The anode consists of massive blocks of carbon suspended above the bath, and dipping under the fused electrolyte almost to the bottom of the bath. The electrolyte is maintained in the fused state by the heat generated by the passage of the current, and the aluminium collecting on the bottom of the bath is run off from time to time. The alumina alone undergoes decomposition, the oxygen combining with the carbon anode and escaping as carbonic anhydride. Anhydrous alumina is shovelled on to the surface of the bath as required, and serves to protect the fused mass below from loss of heat by radiation. Although attempts have been made to refine aluminium containing iron and silicon, they do not appear to have met with success, and it is therefore necessary to exclude these impurities from the materials used. The pure alumina used in the process is prepared from bauxite. A current of 7000 amperes is passed through each bath (the current density being probably about 2·5 amperes per sq. cm. of kathode), an E.M.F. of about 5 volts being required. The current efficiency is considerably less than the theoretical amount, owing to some secondary action, so that from 14 to 18 electrical horse-power hours are required to produce a pound of metal. The annual production of aluminium is rapidly increasing, and is at present considerably over 2000 tons. Notwithstanding the very large consumption of electrical energy in this manufacture, it is interesting to note that the cost of the pure alumina is the largest individual item in the total cost of production.

The problem of utilising aluminium presents as great difficulties as that of its economical production. Mr. A. E. Hunt, of the Pittsburg Reduction Company, has recently given an interesting account of the applications of aluminium, from which it appears that these difficulties are being overcome.

The energetic reducing action of aluminium is utilised in many ways, the most important being the production of steel castings; two to five ounces of aluminium per ton suffices to remove oxygen from the steel, and so to obviate to a great extent the formation of blow-holes in the castings. A little aluminium added from time to time to the baths of molten zinc used in galvanising, removes the oxide and keeps the baths fluid. The addition of a little aluminium in making brass castings increases their soundness and strength in a similar way.

Aluminium is also used instead of brass for a multitude of small cast and stamped objects which do not require to be soldered; there would still appear to be no trustworthy method of permanently soldering aluminium. Aluminium may possibly be used as a conductor of electricity, though at present the advantage in price lies with copper; the specific conductivity of aluminium is 63 to 64 per cent. of that of copper, whilst copper is 3·3 times as heavy.

The history of the electro-metallurgy of zinc is mainly a record of failures. Zinc is readily deposited from neutral or slightly acid aqueous solutions or from the fused chloride, but, from the former, is very prone to separate in a spongy form. Mylius and Fromm show that this is probably due to the formation of traces of oxide, and is prevented by the presence of reducing agents. Vigorous circulation of the solution is also advantageous. The presence of metals more electro-negative than zinc, which deposit on it and promote its oxidation, also produces the spongy deposit. The difficulty of insuring the absence of such metals from solutions obtained from zinc ores, as well as the low price of the metal, which precludes any elaborate purification, probably account for the slow progress of this industry. Progress is, however, being made. Dieffenbach's process is in successful operation at Duisberg in Germany. In this a solution of zinc chloride, obtained by leaching a zinciferous iron pyrites after submitting it to chlorinating roasting, is electrolysed; but further details are wanting.

The Ashcroft process obtains coherent zinc by employing a somewhat basic solution of zinc sulphate or chloride in the kathode compartments of the electrolytic cells, whilst the Siemens and Halske process employs somewhat acid zinc sulphate solution. Both these processes are at work on the large scale, but their ultimate success does not seem to be yet quite assured; so that a more lengthy description may be dispensed with.

At Tarnowitz an alloy of zinc and silver with a little lead and copper, obtained by desilverising lead with zinc containing about 0·5 per cent. of aluminium, was refined electrolytically, using a slightly basic concentrated solution of zinc and magnesium chlorides as electrolyte, and rotating zinc plates as kathode. The insoluble anode mud thus obtained contained about 75 per cent. of silver, and the zinc deposited was almost chemically pure.

Electro-galvanising is also now somewhat largely employed, the electrolyte being a solution of zinc sulphate. Here again close attention to the current density and composition of the solutions is required to secure a smooth and adherent deposit.

Nickel.—Whilst it is perfectly easy to deposit a very thin film of nickel by electrolysis, the metal peels off if a thicker deposit is attempted. According to Foerster, however, tough, homogeneous plates of nickel of any thickness may be deposited from aqueous solutions of the sulphate or chloride if they are heated to from 50° to 90° C. The nickel obtained is, however, not so pure as is the case with copper, cobalt and iron being found in the refined metal in about the same quantities present in the unrefined. Electrolytic nickel is now a commercial article, part of it being obtained from alloys of copper and nickel containing a considerable amount of sulphur, which are used as anodes, the copper being first deposited, whilst the nickel goes into solution, from which it is subsequently deposited.

The electrolytic removal of tin from tin-plate is said to be carried on to a considerable extent. The tinned scrap is suspended in iron baskets which form the anode, and the tin deposited in the spongy form on sheet-iron kathodes, the electrolyte being a solution containing 12 to 15 per cent. of sodium chloride, to which a little caustic soda is added from time to time to prevent the precipitation of stannous oxide. The solution is warmed to 40° or 50° C., and since tin dissolves under these circumstances independently of the electric current, it is necessary occasionally to evaporate the solution and work up the residue for sodium stannate. Sodium is now made exclusively by the electrolysis of fused caustic soda. In Mr. Castner's process the heat generated by the passage of the current is utilised to keep the bath in the fused state. Magnesium is also a product of electrolysis. The small quantity produced is made at Hemelingen, near Bremen, by the electrolysis of perfectly dry, fused carnalite (magnesium potassium chloride). The iron crucible in which the salt is melted serves as kathode, the central carbon anode being surrounded by a perforated porcelain or stoneware cylinder which retains the chlorine.

The application of electrolysis to the precipitation of gold from cyanide liquors, marks an advance of some importance in the metallurgy of gold. Gold is not completely precipitated in a reasonable time by zinc from solutions containing less than 0·1 or 0·2 per cent. of free potassium cyanide, whereas with the electrolytic process the concentration of the solution is a matter of indifference. It thus becomes possible, by the employment of very dilute cyanide solutions, to extract economically the small quantities of gold contained in slimes and tailings which would otherwise have been thrown away. A further advantage of the electrolytic precipitation is that the gold obtained contains some 89 per cent. of gold, instead of the 70 per cent. contained in the zinc bullion. The solutions to be electrolysed contain from 0·01 to 0·05 per cent. of potassium cyanide, according to the nature of the ore treated, together with from 1 to 4 dwts. of gold per ton of solution, in the form of potassium aurocyanide. They have, therefore, a very high resistance. Owing to the very small quantity of gold to be deposited, however, a very small current is sufficient (0·6 ampere per square metre), and the baths can be worked with the moderate E.M.F. of 4 volts. The quantity of electric energy required is thus small, and its cost is almost negligible compared with that of the rest of the process. The solution flows into the electrolytic tank at one end, and passes alternately over and under the electrodes until it flows out of the tank deprived of 80 to 90 per cent. of its gold. The kathodes consist of thin sheets of lead, and the anodes of iron enclosed in canvas bags to retain the precipitate of prussian blue which forms on them. They are placed about 1½ inches apart. The gold remaining in the liquors flowing from the electrolytic tanks is not lost, these liquors being made up to strength with fresh cyanide and used again. After remaining in the tanks some months the lead kathodes are sufficiently rich in gold to be removed and submitted to cupellation. Owing to the important advantages already mentioned, the employment of this process is rapidly extending; in 1896, two years after the first installation of the process, over 46,000 ounces of gold were obtained in the Transvaal by means of it, and at present it is much more extensively used.

Turning, now, to the application of electrolysis to the production of substances other than metals, there is an important group of industries engaged in the electrolysis of potassium and sodium chlorides, producing, according to the conditions employed, caustic alkalis and chlorine, hypochlorites or chlorates.

In the first case it is necessary to keep the primary products of the decomposition separate, and this is accomplished in two ways: (1) by the use of a porous diaphragm; (2) by means of mercury. The manufacture of a diaphragm which shall be sufficiently durable with a solution of caustic soda on one side of it, and of chlorine on the other, is by no means easy. The fact that diaphragms are being successfully used proves, however, that the difficulties are not insuperable. A more serious drawback is the impossibility of separating the caustic alkali from the chloride. As soon as the solution at the kathode contains hydroxyl ions, these begin to migrate, under the influence of the current, toward the anode, in time passing into the anode compartment and giving rise to the formation of hypochlorites and chlorates and to the evolution of oxygen, and so diminishing the efficiency of the cell. It is therefore necessary to draw off the solution from the kathode compartment of the cell while it still contains much undecomposed chloride, and to separate this from the caustic alkali as far as possible during the process of concentration.

The process of Hargreaves and Bird avoids this to a great extent in a very ingenious way. The kathode in this process consists of a sheet of copper gauze, upon which the diaphragm is built up of asbestos mixed with some cementing material. The diaphragm, with the copper gauze outside, forms the outer wall of the cell which contains the solution of salt and the carbon anode. The caustic soda is thus formed outside the cell, and is washed down and converted into carbonate by a mixture of steam and carbon dioxide. The diaphragm is made so impervious that, when in good condition, no liquid will run out of the cell, and only three molecules of salt to 100 molecules of sodium carbonate are obtained. The diaphragms last about thirty days, but, according to Kershaw, yield less favourable results toward the end of the time. Hulin's process is somewhat similar to that of Hargreaves and Bird, the diaphragm-kathode consisting of a sheet of porous carbon through which the caustic soda solution is forced as quickly as it is formed by hydrostatic pressure inside the cell.

When mercury is employed as the kathode, the diaphragm becomes unnecessary, the mercury taking up sodium in contact with the salt solution and giving it up to pure water in another vessel. A great many devices have been contrived for causing the mercury to alternately perform these functions. The simplest and most effective is undoubtedly the rocking cell of Mr. Castner. This consists of a shallow oblong tank divided into three compartments by means of partitions which do not quite reach the bottom. A thin layer of mercury lying on the bottom of the cell lutes the spaces below the partitions, thus dividing the cell into three separate compartments. The two end ones contain strong brine and carbon anodes, the central one pure water and an iron kathode which is connected electrically with the mercury. The cell is tilted slightly from side to side, so that the mercury flows from one end compartment to the other, always covering the floor of the central compartment, however. In this way the sodium taken up at the ends is conveyed to the water in the centre. The central compartment forms really a galvanic element, consisting of sodium amalgam and iron in a solution of caustic soda; the connection of the iron to the mercury short circuits this cell, and therefore hastens the dissolution of the sodium. The caustic soda obtained in this way is practically pure, and the current efficiency over 90 per cent. of the theoretical value; whilst the electromotive force required is 4 volts for each cell.

If instead of keeping the products of the electrolysis of a salt solution separate they are mixed together in the cold, a solution of hypochlorite is formed. A limit to the concentration attainable is, however, quickly reached, partly owing to the electrolysis of the hypochlorite, partly to its reduction by the hydrogen evolved. Hermite employs rotating zinc kathodes, between each pair of which a platinum gauze anode is fixed, the electrolyte, consisting of a solution of salt and magnesium chloride, flows through the apparatus, yielding a weak bleaching liquor suitable for bleaching paper pulp or for deodorising sewage, in which latter case sea water may be used. Kellner attains the same result by using a long tank in which a large number of carbon plates are fixed in such a way that the solution flowing in at one end of the tank must circulate between each pair of plates before passing out of it. Only the two end plates are attached to the terminals of the dynamo, so that each intermediate plate acts on one side as anode, on the other as kathode.

The electrolytic preparation of potassium chlorate was patented by Charles Watt as early as 1851, but the idea was not put into practice until 1889, when Gall and Montlaur started the first electrolytic potassium chlorate plant at Villers-sur-Hermes in Switzerland. They employ thin platinum-iridium anodes and iron kathodes, and maintain the solution at a temperature of 50° to 60° C. by the heat evolved by the passage of the current. The electrolytic cell is divided by a diaphragm of porous earthenware into a smaller kathode, and a larger anode compartment, in order to prevent as far as possible the reduction of the chlorate by the hydrogen evolved at the kathode. A current of 10 amperes per sq. dcm., and an E.M.F. of 5 volts are used, and the caustic potash formed at the kathode transferred to the anode compartment sufficiently fast to absorb all the chlorine evolved. The potassium chlorate crystallises out in the anode compartment, its solubility being diminished by the employment of a saturated solution of potassium chloride as electrolyte. The diaphragm may be dispensed with, according to Oettel, if the solution is alkaline, because in that case potassium chlorate is not reduced, to any appreciable extent, by nascent hydrogen. High current density at the kathode, and low current density at the anode, promote the formation of chlorate, the best results being obtained when a quantity of oxygen is evolved, corresponding to some 30 or 40 per cent. of the current passed. The current efficiency is reported to be from 65 to 70 per cent., and there is no doubt that the electrolytic process will eventually displace the older chemical one, about one half of the world's consumption of chlorates being already supplied by it.

Of other electrolytic processes there is not very much to be said. In Mr. A. B. Brown's process for the manufacture of whitelead a 10 per cent. solution of sodium nitrate is electrolysed in order to obtain caustic soda and nitric acid, which are subsequently used for the preparation of lead nitrate and its precipitation as lead hydroxide, the latter being finally converted into lead carbonate by means of a solution of sodium bicarbonate.

Applications of electrolysis to tanning and to the purification of sugar have been frequently proposed, but nothing very definite is known as to their success.

Among organic compounds iodoform has long been prepared by the electrolysis of an alkaline solution of potassium iodide containing alcohol. According to Elbs and Hertz good results are obtained by electrolysing a solution containing 5 to 6 grams of sodium carbonate, 10 grams of potassium iodide and 20 cc. of alcohol in 100 cc. of water at a temperature of 60° C. with a current density not exceeding 1 ampere per square decimetre. Under these circumstances the current efficiency is over 97 per cent. and the iodoform produced perfectly pure.

It has been proposed to apply ozone to a great variety of purposes, but here again a lack of trustworthy information about the results is found. According to Mr. Swan, however, it is used in making vanilin and heliotropin. When used as a bleaching agent it is necessary to use it in conjunction with other substances, such as hypochlorites or hydrogen peroxide. Mr. Andreoli has devised an ozone producer in which the electrodes are furnished with numerous points and separated by a glass plate. In order to prevent the heating of the gas it is caused to pass rapidly throught the apparatus, and the electrodes are made hollow and cooled by internal circulation of water. The silent discharge is obtained by means of an alternating current dynamo and high tension transformer yielding a rapidly alternating current at a pressure of 10,000 volts or more. By this means 30, or under favourable conditions 40 grams of ozone are obtained for a horse-power hour.

Electro-thermal Processes.—The electric current possesses two considerable advantages as a heating agent; in the first place temperatures otherwise unattainable may be reached by its aid, and secondly the heat may be applied directly and economically to the substances which are to be caused to react. The three most important products of the electric furnace are carborundum, phosphorus, and calcium carbide.

Carborundum, a compound of carbon and silicon in equal atomic proportions, was prepared by Acheson in 1891, in the course of experiments on the artificial production of the diamond. It is remarkable for its extreme hardness, which is only inferior to that of the diamond. It is prepared by heating a mixture of powdered coke and sand, to which a little sawdust and salt are added in order to make the mass more porous, in a furnace 16 feet long, 5 feet wide and 5 feet deep, which is built up of loose fire-bricks. Through the end walls of the furnace bundles of 60 carbon rods, each 3 inches in diameter pass, which are connected inside the furnace by a cylindrical core of small pieces of coke. This core is surrounded on all sides by the mixture of sand and coke. The passage of the current through the core gives rise to a cascade of small arcs between the pieces of coke, which soon raises the whole core to a very high temperature which is communicated to the surrounding charge. A current of 6000 amperes at 125 volts pressure is passed for 36 hours, after which the furnace is allowed to cool and the hollow cylinder of crystalline carborundum surrounding the core removed. About 5·3 electrical horse-power hours are expended in producing a pound of the crystalline product, a considerable quantity of valueless, amorphous carbide of silicon being also formed at a greater distance from the core, where the temperature is lower. The carborundum is obtained in the form of steel grey to brownish green crystals, the coloration being due to iron; it is a valuable abrasive, cutting the hardest steel without destroying its temper; and is being largely used in place of emery. The production has increased from 15,000 pounds in 1893, when it was first made on a manufacturing scale, to about one and a half million pounds in 1897.

The manufacture of phosphorus in the electric furnace has been carried on for some years by means of the process of Readmann and Parker and Robinson. Wöhler found, as long ago as 1830, that phosphorus may be obtained from calcium phosphate by heating it to a high temperature with sand and carbon, calcium silicate and carbon monoxide being produced. The employment of the electric furnace has made it possible to use this process for the manufacture of phosphorus. Naturally occurring phosphates are used and siliceous material added, which will furnish a readily fusible slag. The finely-powdered mixture of these substances with carbon is fed in through a hopper at the top of a brick-lined trough, 18 inches square and 36 inches deep, through opposite sides of which the carbon electrodes are introduced. The fused slag collects at the bottom of the furnace, whence it is run off from time to time in the same way as in a blast furnace, whilst the mixture of phosphorus vapour and carbonic oxide pass to the condensing apparatus through an opening placed near the top of the furnace. More than 80 per cent. of the phosphorus contained in the materials used is obtained, the loss being largely due to the presence of iron which combines with phosphorus to form a phosphide which remains in the slag. The heat is concentrated mainly between the electrodes, so that the walls of the furnace do not suffer.

Calcium carbide was prepared by electrically heating together carbon and lime, in 1892 by Moissan in France, and by Willson in America; its manufacture is now carried out on a very considerable scale, both in America and in Europe. The production is said to be about 20,000 tons yearly. The furnaces employed vary considerably in details of construction and in magnitude. Those employed at Niagara consist of a square brickwork shaft in which a bundle of carbon rods, which forms one electrode, is suspended. The bottom of the shaft is closed by an iron rectangular box, running on rails, the bottom of which has a thick lining of carbon, which serves as the other electrode. The finely-powdered mixture of coke and lime is fed into the space round the upper electrode through channels in the brickwork sides of the shaft. The arc having been established between the electrodes, the mixture of coke and lime is shaken down into it, and converted into calcium carbide, which remains in a semi-fluid condition upon the lower carbon plate. The calcium carbide, being a fairly good conductor of electricity, now serves as the lower electrode, fresh material being constantly added to its upper surface until the iron box is full, when it is run out and a fresh one substituted for it. The current employed is 1700 to 2000 amperes, and the electromotive force 100 volts, a pound of the carbide being obtained for an expenditure of 2·25 electrical horse-power hours. When sufficient carbon is employed in the mixture, the electrodes are very little acted upon; the excess of carbon which is required depends very much on the kind of apparatus employed. A pound of well-made carbide yields 5 cubic feet of acetylene gas, the employment of which for lighting appears to be making some progress.

In concluding this brief sketch of the applications of electrochemistry, it is perhaps worth pointing out that, important and interesting as are the applications which have been made, those which yet remain are still more so. For example, it is possible, by compressing sulphur dioxide and air into separate carbon tubes dipping in dilute sulphuric acid, to cause the two gases to combine to form sulphuric acid, and at the same time furnish an electric current. The alluring prospect of obtaining electric energy as a bye-product in a chemical works, should be a sufficient incentive to efforts to overcome the numerous difficulties in the way.

THOS. EWAN.

THE STRANGLING OF AN ELEPHANT.

ONE of the elephants in Barnum and Bailey's Show, which has been visiting Liverpool during the past two weeks, having recently shown signs of insubordination, Mr. Bailey determined, in order to perfectly safeguard his visitors, to sacrifice the animal. He has had during his life occasion to destroy many elephants, which, as a rule, he has handed over to experienced veterinary and other surgeons, who have tried various methods, such as poisoning, shooting and bleeding. All have proved, however, unsatisfactory, because uncertain, tedious, and not seldom dangerous to those engaged in conducting the operations. On this occasion it was determined, after consultation with several experts and with the Secretary of the Royal Society for the Prevention of Cruelty to Animals, to kill the elephant by strangulation, which had once before been adopted with success by Mr. Bailey. Accordingly it was arranged that on a recent Sunday morning—the day most suitable to the Show people and that freest from intrusion by the public—Don, as the doomed elephant, who was supposed to be about twenty-two years of age and nearly 4½ tons in weight, was named, should be strangled.

At the appointed hour those specially invited—among whom were several veterinary surgeons, Dr. Forbes, Director of the Liverpool Museums (to whom the body was generously to be handed over as a gift from Mr. Bailey to the Museum), Dr. Roberts, and Mr. Burnham, of the Society for Prevention of Cruelty to Animals—found the elephant standing quietly in one of the large tents in line with some twenty to thirty others. A new Manilla rope was loosely wound three times around its neck, and its legs, fully stridden, were securely chained each to a post firmly driven into the ground alongside each limb. The animal was intentionally not isolated from its fellows, as it was feared that if separated by itself it would become restive and ill-tempered. The rope surrounding the beast's neck had one end secured to three strong pillars in the ground, some distance away and slightly in advance of the fore-feet; and the other, which terminated in a loop, was hooked to a double series of pulleys, to the tackle of which ninety men were attached. When all was ready, the slack was gently, quietly, and without any apparent annoyance to the elephant, which kept on eating hay, taken in till the coils round its neck were just taut. The word was then given, "Walk away with the rope." Amid perfect silence the well-disciplined company walked away with it without the least effort. So noiselessly and easily did everything work that, unless with foreknowledge of what was going to take place, one might have been present without realising what the march of these men meant. The elephant gave no sign of discomfort, either by trunk or tail; its fellows standing close by looked on in pachydermatous unconcern, and at the end of exactly thirty seconds it slowly collapsed, and lay down as if of its own accord. There was absolutely no struggle, and no motion, violent or otherwise, in any part of the body, nor the slightest indication of pain. In a few seconds more there was no response to the touch of its eyelashes or other parts of the eye, and this condition remained for a few minutes; but through, perhaps, the leakage into the chest of a small quantity of air, some slight sensitiveness returned to the eye, seen on touching its inner angle, though not the cornea. On slightly tightening up the rope, the chest gave one or two short throbs, and after six and a half minutes all movement ceased, and sensation was entirely lost; while at the end of thirteen minutes from the order "to walk away," the eye had become rigid and dim.

That no more humane, painless and rapid method of taking the life of a large mammal could be devised, was the opinion of all the experts who witnessed the execution of this elephant.

The skin and skeleton have been preserved for exhibition in the Municipal Museums, and all the important viscera have been placed in Formal, for future study by the Director and his staff. Prof. Paterson and Dr. Dunn, of University College, who very kindly aided in the dissection, have made a full study of certain parts of the nervous system, which they had not completed in the dissection made by them (on which they have recently contributed a valuable paper to the *Journal of Anatomy and Physiology*) of the "rogue" elephant poisoned last year in Liverpool. These points, and others which may turn out to be of interest on the fuller dissection of the present specimen, will be published in the *Bulletin* of the Liverpool Museums.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—On Tuesday evening, May 24, the Oxford University Junior Scientific Club held a very successful conversazione at the University Museum, which was tastefully decorated and lighted for the occasion. Over 1000 persons attended, and were received by the President, Mr. W. E. Moss (Trinity), and the other officers of the club. For the entertainment of the guests numerous exhibits and demonstrations of the most varied description were on view in the central court and the adjacent departments; and in the large lecture theatre two lectures were given: the first, by Prof. H. B. Dixon, F.R.S., of Owens College, Manchester, on "Climbing in the Rocky Mountains"; and the second, by Dr. Gustav Mann (New Coll.), on "Microphotography," both being well illustrated by lantern slides. A short lecture was also given in the geological lecture theatre by Mr. G. J. Burch, on "Artificial Colour-Blindness," in which evidence was brought forward to show that, instead of three, there are really four colour-sensations—red, green, *blue*, and violet. The reason so many experimenters have only detected three, is that a large number of people are colour-blind to either blue or violet. The lecturer's experiments consisted in fatiguing the optic nerve by exposure to special parts of the spectrum, and it was thus shown that the pure blue of the spectrum between violet and green could be eliminated. The Radcliffe Library was open during the evening, by kind permission of the librarian (Sir Henry W. Acland, Bart., K.C.B., F.R.S.), as was also the Pitt-Rivers' Collection, by permission of Mr. H. Balfour, the curator. The band of the Royal Artillery, with Sergt.-Major W. Sugg as conductor, gave an excellent selection of music.

IN view of the importance of ascertaining, with such accuracy as the conditions allow, the number of pupils receiving instruction in public and private secondary schools in England, the Lords of the Committee of Council on Education are repeating the inquiry first made in May 1897. Forms of inquiry have been sent to all those schools which are understood to be giving secondary education, and if one has not been received by the principal teacher an application to the Secretary of the Education Department will ensure the papers being sent.

VOTING by means of ballot papers through the post, Convocation of the University of London have placed Mr. J. Fletcher Moulton, who opposes the scheme for a teaching University, first on the list of those from whom Her Majesty will select a member of the Senate in succession to the late Sir Richard Quain. The two other candidates were Dr. J. B. Benson and Mr. P. Daphne. Mr. Moulton headed the poll by more than two hundred votes. It is not anticipated that the result of this election will influence the Government's intention to introduce the London University Bill at an early date.

THE London County Council has decided to lay out plots of ground in Battersea, Ravenscourt, and Victoria Parks in such manner as will afford assistance to scholars at elementary and secondary schools in the study of practical botany. Hardy typical plants belonging to twenty natural orders will be arranged in beds near the paths, one bed being devoted to each order. Each specimen will be labelled with its common name and its Latin or systematic name. Labels giving the names and natural orders will also be attached to the more important trees, shrubs and plants throughout the parks mentioned. Teachers holding printed orders issued by the Technical Education Board will be able to obtain from the superintendent in each park such specimens as may be required for botanical study. It is hoped that later on the arrangements may be extended to the cultivation of important types of the lower orders of plants, such as fungi, mosses, ferns, liverworts, &c., and facilities afforded for the study of aquatic plants.

A REPORT on the International Congress on Commercial Education, recently held at Antwerp, is given in the *London Technical Education Gazette*. The following items from the report are of interest:—The view of the majority of delegates present at the Congress was that *specialised* commercial education should not be commenced in primary and secondary schools, but that there was ample room for the development of higher commercial teaching. It is a significant fact that the city of Antwerp spends 2½ millions of francs on education out of a total revenue of 4 millions of francs. In connection with the discussion of the question as to what extent special commercial instruction should be given in secondary schools Dr. Stegemann, official German delegate, gave a long account of the German schools, more particularly of the "Realschulen" and of the "Fortbildungsschulen" (continuation schools). He said that the latter were principally supported by leading merchants and members of mercantile corporations, because they fully recognised the importance of giving to their clerks a theoretical education as the complement to their office training. Dr. Stegemann said that commercial instruction could be given in the secondary schools, without any specialisation whatever. "We in Germany do not care to know anything about a river unless it will float a ship, and new countries interest us only when they afford an outlet for our industry." Speaking afterwards upon the past and present of commercial education in Germany, Dr. Stegemann pointed out the solidarity which existed between the professors of their schools and the commercial men of the country, a union which led to the happiest results, inasmuch as the latter had given to the former the benefit of their practical business experience. In conclusion, he said that he ventured to counsel English educationists not to lose sight of the fact that, even in Great Britain, they must give to their young men a more extended and practical course of study if they wished to maintain the commercial prestige of their country. As to the aim of the continental higher commercial institutes, M. Heinzmann Savigno (Antwerp) said the object pursued at the Antwerp Institute, and at the other establishments modelled upon it, was not to furnish "clerks" in the ordinary acceptation of the word, but "merchants," who would be able to transact their business on a scientific basis, and give to their commercial transactions an impetus which would materially extend their country's home and foreign trade. They also aimed at the creation of men who would be properly prepared to be themselves professors of the higher commercial sciences, or to go forth into the world and effectively undertake the duties of the consular service. The speaker added that, in order to keep pace with the growing extension of colonial enterprise, he would strongly advocate the formation of a special class of men competent by their knowledge to take the lead in colonial development.

SCIENTIFIC SERIALS.

American Journal of Science, May.—On the properties of seasoned magnets of self-hardening steel, by B. O. Peirce. In searching for a material of which to make a set of standard measuring magnets which should be as permanent as possible and have small temperature and induction coefficients, the author tested a number of magnets made of some of the brands of "self-hardening" tool steel now in common use for lathe tools. He found that the temperature coefficient could be reduced almost indefinitely by cutting the rods long and thin.—Some lava flows of California, by F. L. Ransome. This paper deals with a strip of the middle, western slope of the Sierra Nevada. The volcanic eruptions began during the Miocene period and continued to the end of the Pliocene. The deposition of auriferous gravels both preceded and accompanied the deposition of volcanic material. The author distinguishes three separate flows of lava, which were eventually brought to an end by fresh andesitic eruptions. During Pleistocene time the present streams have dissected the Neocene lavas and tuffs, and have deeply cut into the Jurassic and older rocks.—Some new Jurassic vertebrates from Wyoming, by W. C. Knight. The University of Wyoming has in its collection of Jurassic vertebrates partial remains of four swimming saurians that in a general way resemble Plesiosaurs. The discovery of these remains is of considerable value to American Mesozoic geologists for correlating the American and European Jurassic. The largest of the four species surpasses in size the European Pliosaur, and it is described under a new genus, *Megalneusaurus*. The description given is founded upon a cervical, dorsal, and caudal vertebra; one fore-limb nearly complete; ribs, and the greater portion of the pectoral girdle. The genus represents the largest known animals of the order Sauropterygia.—On the estimation of manganese separated as the carbonate, by Martha Austin. The carbonate precipitated by means of alkaline carbonates is very uncertain. An improvement in the quantitative analysis may be effected by converting the carbonate first into oxide and then into sulphate by heating with a few drops of concentrated sulphuric acid.

Symons's Monthly Meteorological Magazine, May.—The climate of Algeria, by Dr. A. Thevenet, director of the Algerian Meteorological Service. The first subject dealt with is temperature. The absolute maximum in the shade is 122° at Orléansville (lat. 36° 40′ N., long. 1° 19′ E.), and the absolute minimum is given as 6°·8, at El-Aricha (lat. 34° 16′ N., long. 1° 23′ W., altitude 4364 feet). Sharp frost is not infrequent on the Sahara, but on the Mediterranean coast frost is rare. The air is not so dry as might have been expected; monthly means below 40 per cent. are very rare, except on the high plateaux and on the Sahara. The mean annual rainfall at Algiers, as recorded at four stations between 1838 and 1895, is 30·16 inches, but there is considerable divergence between the different records.—Results of meteorological observations at Camden Square (London) for April for forty years, 1858–97. The mean of all the highest maximum temperatures was 70°·7, and the mean of all the lowest minima was 29°·8. The average monthly rainfall was 1·66 inches, while in April of this year it was only 1·01 inches.—The gloomy summers of 1860 and 1879, and the nineteen years' cycle, by H. A. Boys. The author points out that there has been so obvious a parallel between most of the last few years and those years that preceded them by 19 and 38 years respectively, that ground has been given for watching whether the summer of 1898 will not prove gloomy and rainy like those of 1860 and 1879, at least in the midland counties.

Wiedemann's Annalen der Physik und Chemie, No. 4.—Some modifications in the quadrant electrometer, by J. Elster and H. Geitel. The drying apparatus is a wide side tube off the chamber containing the quadrants. It contains a wire attached to the movable end cover, and the point of the wire carries a piece of sodium, wiped or scraped to remove adhering petroleum or oxide. Below the sodium is a glass bulb, which catches the dripping moisture. The sodium is surrounded by a wire net to prevent its dropping bodily into the liquid.—Duration of electric oscillations of large periods, by J. Bergmann. Describes an improved apparatus for measuring oscillations with periods over one-millionth of a second.—Fluorescence and actino-electricity, by G. C. Schmidt. E. Wiedemann and the author have propounded the theory that the molecules, split up into ions by the action of light, give rise to fluorescence on recombination. This would lead to the conclusion that fluorescent bodies could not easily lose negative ions on exposure to light, *i.e.* would not be photo-electrically or "actino-electrically" sensitive. This conclusion is, however, not borne out by experiment, as no connection between the two phenomena can be established. It is found, on the other hand, that bodies which exhibit the strongest thermo-luminescence show also the strongest photo-electric action.—A new method of measuring dip and horizontal intensity, by G. Meyer. The dip may be measured without a magnet and without a galvanometer by means of a continually revolving inductor coil and a telephone. The axis of the coil is adjusted to the telephone minimum. The measurements are correct to within 3′ of arc. To measure the horizontal intensity, the earth's field is compensated by the field due to a current of known strength. Complete compensation is indicated by silence in the telephone.—An instrument for measuring astigmatism, by R. Straubel. This consists of two cylindrical lenses which rotate with respect to each other about a common axis. Artificial astigmatisn of any given amount may thus be produced.

FROM the articles in the *Journal of Botany* for March–May, we may select the following as of the most general interest:—The fifty years' limit in nomenclature, by the editor; in which he shows how impossible it would be to work such a rule in practice. Notes on Mycetozoa; and Mycetozoa of Antigua and Dominica, by Mr. A. Lister. Experiments in cross-fertilisation of *Salices*, by Mr. G. F. Linton. Some species of willow cross with great readiness, others with reluctance, and others obstinately resist all attempts at hybridisation. Wayfaring notes in Rhodesia, by Mr. R. F. Rand. The work of cross-fertilisation of the native flowers of Rhodesia appears to be effected largely by butterflies; but by far the most active agents are beetles.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 5—"On certain Structures formed in the drying of a Fluid with Particles in Suspension." By Catherine A. Raisin, B.Sc. Communicated by Prof. T. G. Bonney, D.Sc., LL.D., F.R.S.

Experiments have been made with various muddy fluids, which were allowed to dry under certain conditions, in order to study the forms assumed by the dried material. It seemed possible that these forms might throw some light on the origin of certain minor structures in rocks. Various pigments or powdered rocks (mostly very fine grained) were mixed with water and placed on microscope slides or larger pieces of glass, generally beneath a cover-glass.

In materials not of the very finest grain (*e.g.* prussian blue), the forms shown by the dried powder consist usually of two sets of elements, coarser and finer. The former tend to develop as branching stems, which are either bent and winding, forming a kind of maze, or somewhat rectilinear with terminal knobs. The finer material forms a feathery or fan-shaped pattern, generally at the margin of the deposit, and in the intervals between the coarser stems. It consists of successive curving lines, or of radial streaks and furrows. The different structures are combined in various patterns, of which one illustration is reproduced (Fig. 1). In addition, vesicular structures, cracks, and joints are developed in the dried mud, some of the cracks bearing even a certain resemblance to the appearance in frozen gelatin described by Prof. Sollas (*Trans. Roy. Ir. Acad.*, 1890). The mode of formation was studied by watching the films in the process of drying, and by comparing different examples. As the edge of the film gradually retreats, coarser stems begin to form, while fine material, remaining for a time in moist condition, afterwards dries as the fine pattern.

These various forms seem to illustrate, more or less closely, structures which occur in nature. Thus, dendritic deposits along joint-planes, or on other surfaces in rocks, although undoubtedly they often are the effects of crystallisation, may be sometimes formed by mechanical drying, or both conditions may co-operate. It is possible that some of the "pseudorganic" structures described in rocks, might really be the casts or replacements of dried streaks. Similar principles to those shown in these films may govern the formation of structures in

FIG. 1.—This shows near one edge a fine pattern with concentric lines and radial furrows; then coarser bent stems, which become smaller and reduced towards the further margin, while the fine material forms rather feathery tufts. Prussian blue. (Natural size.)

the mass of a rock, as, for example, the development of Landscape Marble (as explained by Mr. B. Thompson), or the growth of some agates and chalcedonic deposits. Even the solidification of certain igneous rocks, or the processes of secondary silicification, may be somewhat analogous. Further, the similarity shown in cracks and vesicles to those in some pyromerides seems to give support to the hypothesis that these nodules at an early stage were often in a semi-solidified condition with an external crust.

In conclusion, the forms resulting from the processes of crystallisation, which have been described in numerous papers by different authors, may be shortly compared; and some additional experiments have been made, especially as to the effects produced by the admixture of material in suspension (or of a colloid) with the solution of a crystallising salt. Spherulitic and dendritic forms, as described by Lehmann and other observers, may be developed, or even an imitation of micropegmatitic structure. Certain interesting forms of ice crystals (shortly described in NATURE, 1892, by Prof. Meldola, Prof. Bonney, and others) are shown, in a note by Prof. Bonney, to have been developed under somewhat similar conditions.

"The Relations between the Hybrid and Parent Forms of Echinoid Larvæ." By H. M. Vernon, M.A., M.B. Communicated by Prof. Ray Lankester, F.R.S.

The object of this research was to determine systematically, during a period of several months' duration, the exact relationships of structure and size existing between certain hybrid and parent Echinoid larval forms. The method of procedure was similar to that described in a former paper (*Phil. Trans.* B., 1895, p. 577).

Upon the cross *Sphærechinus* ♀-*Strongylocentrotus* ♂, twenty-two experiments were made. As a rule only 10 per cent. of the ova were fertilised, and only 1 per cent. of them reached the eight days pluteus stage. The hybrids were most easily obtained in the summer months, few or none of the ova being cross-fertilised in the winter. The hybrids obtained in May, June, and July were of an almost pure *Sphærechinus* type, only a third or less of them being of an intermediate or *Strongylocentrotus* type. In November, on the other hand, only about a sixth were of the maternal, and five-sixths of a semi-paternal type. Finally, in December and January all the hybrid larvæ were of this paternal type.

On the reciprocal cross of *Strongylocentrotus* ♀ and *Sphærechinus* ♂ eighteen experiments were made. During April, May, and June a fair number of the ova were cross-fertilised, but no plutei were obtained. In July and August some 47 per cent. of the ova were fertilised, and 29 per cent. of them survived to the eight days' pluteus stage. In November and December, on the other hand, not only were no plutei obtained, but as a rule not a single ovum was cross-fertilised. The hybrid larvæ themselves were of the pure *Strongylocentrotus* type.

These extraordinary variations in the capacity for cross-fertilisation seem to be due to the variations in maturity which the sexual products undergo with change of season. Thus in July and August most of the *Strongylocentrotus* individuals contain but very small quantities of ripe sexual products, or none at all; and the larvæ obtained may be as much as 30 per cent. smaller than those obtained in the winter and spring. At intermediate times of the year the larvæ are of intermediate size. It appears, therefore, that the *Strongylocentrotus* ♀-*Sphærechinus* ♂ hybrid is only formed at the time when the *Strongylocentrotus* ova have reached their minimum of maturity; whilst in the case of the reciprocal hybrid, it follows that as the maturity of the *Strongylocentrotus* sperm increases, it is able to transform first a portion and then the whole of the hybrid larvæ from the *Sphærechinus* to its own type. In other words, the characteristics of the hybrid offspring depend directly on the relative degrees of maturity of the sexual products.

As a result of the ten experiments made on the cross *Echinus* ♀-*Strongylocentrotus* ♂, it was found that the hybrid larvæ were on an average about 8 per cent. *larger* than the pure parental larval forms, and, moreover, that even more of the cross-fertilised ova developed to plutei than of the directly fertilised ones. In the reciprocal cross, only about 1 per cent. of the ova reached the pluteus stage, and these plutei were about 13 per cent. smaller than the pure maternal larvæ.

Various crosses, in several instances reciprocal ones, were also effected between *Strongylocentrotus*, *Sphærechinus*, *Echinus microtuberculatus*, *Echinus acutus*, *Arbacia*, *Echinocardium cordatum*, *Echinocardium mediterraneum* and *Dorocidaris*.

On performing cross-fertilisations with the colour varieties of *Sphærechinus*, there was found to be a distinct diminution of fertility. Series of experiments were made in June, July, November and December, the differential fertility seeming to gradually diminish with the progress of the season. Nevertheless, it was always most distinctly present. There was little or no infertility between the less definitely marked colour varieties of *Strongylocentrotus*.

April 28.—"A Compensated Interference Dilatometer." By A. E. Tutton, Assoc. R.C.S. Communicated by Captain Abney, C.B., F.R.S.

The author describes a form of Fizeau interference dilatometer which he considers combines the best features of the apparatus described by Benoit, and belonging to the Bureau International des Poids et Mesures, in Paris, and that described by Pulfrich, constructed according to the modifications introduced into the method by Abbe. Moreover, besides other improvements, a new principle, that of compensation for the expansion of the screws of the Fizeau tripod which supports the object, is introduced, which enhances the sensitiveness of the method so highly as to render it applicable to the determination of the expansion of crystals in general, including those of chemical preparations. Hitherto the application of the Fizeau method has been confined to such crystals as could be obtained large enough to furnish a homogeneous block at least a centimetre thick. A block only 5 mm. thick is ample for use with the author's compensated dilatometer. The principle of the compensation depends upon the fact that aluminium expands 2·6 times as much as platinum-iridium for the same increment of temperature. The author therefore employs, like Fizeau and Benoit, a tripod of platinum-iridium, and places upon its transverse table, through which pass the three screws, a disc of aluminium whose thickness is 1/2·6ths of the length of the screws. The space between the lower surface of the glass plate which is laid upon the upper ends of the screws to assist in producing the interference, and the upper surface of the aluminium, then remains constant for all temperatures under observation, and if a crystal is laid upon the aluminium compensator the whole amount of its expansion by rise of temperature is available for measurement by the interference method. Hence the method is no longer a merely relative one, affording the difference of expansion between the tripod and the substance investigated, but affords directly absolute measurements of the expansion.

The results of numerous determinations of the expansion of the platinum-iridium of the tripod are given, carried out with the surface of the tripod table and the cover-wedge separated at the long interval of 12 mm., by the aid of green mercury light. The mean value is very similar to that of Benoit, and is

$$\alpha = 10^{-9}(8600 + 4{\cdot}56t).$$

The result of several determinations in red hydrogen light of the expansion of the pure aluminium used for the series of compensators, carried out by the Fizeau relative method with a block 12 mm. thick, is

$$\alpha = 10^{-8}(2204 + 2{\cdot}12t).$$

Similar determinations for the black glass of the crystal-covering plates afford the value:

$$\alpha = 10^{-9}(7257 + 10{\cdot}4t).$$

In a subsequent memoir the author intends to present the results of determinations of the expansion of the sulphates and selenates of potassium, rubidium, and cæsium.

Physical Society, May 27.—Mr. Shelford Bidwell, President, in the chair.—A paper by Messrs. Edwin Edser and C. P. Butler, on a simple method of reducing prismatic spectra, was read by Mr. Edser. The production of interference-bands in a continuous spectrum is capable of furnishing a reference-spectrum, which can be employed to determine the wave-lengths corresponding to the bright lines in a spectrum of a metal or of a gas. The authors discuss various methods by which such bands can be formed. In their final experiments, an air-film between two plane parallel glass plates is inserted in front of the slit of the spectrometer, in the path of the incident light. Owing to the interference of the direct ray with that twice internally reflected, bright bands separated by dark intervals are observed in the spectrum; these bright bands correspond to a series of different waves, whose lengths are easily determined for the whole series, when two of them are known. The bands are much improved by partial silvering of the two internal surfaces of the glass. It has been found that ordinary plate-glass, if well chosen, is good enough for all these experiments. In order to adjust for parallelism, a spot of light, or the filament of a glow-lamp, is viewed through the silvered surfaces. A long train of images is generally visible; these must be brought into coincidence. If now a sodium flame is looked at through the film, interference bands are seen. These bands must be adjusted by pressure, to be as broad as possible. An arc-lamp is used for illuminating the collimator slit. The authors exhibited the apparatus, and showed photographs of spectra-scales with the appropriate wave-lengths, calibrated upon them by this method. The results there obtained were read from the spectrometer to 0·4 of a tenth-metre, with an ordinary pocket-lens. A simple graphic method enables wave-lengths, corresponding to a great number of spectral lines, easily to be determined by inspection. The phase-changes introduced by the silver do not affect the final result. Prof. Threlfall congratulated the authors on their discovery of a method that would greatly reduce the labour of calibrating spectra, and at the same time give such accurate results. Prof. Boys said the simplicity of the apparatus added greatly to the value of the method. It would seem to him better if the slit were somehow contrived within the film-space. All want of definition due to rays falling at different angles upon the collimator object-glass would thus be avoided, and only a small part of the glass plates, *i.e.* the slit, would require to be strictly parallel planes. The limit of accuracy in the authors' method depended upon the collimator, not upon the optical perfection of the silvering of the plates. Mr. Butler pointed out that previous methods had always required experienced spectroscopists for mapping-out results. In the new method that work could easily be done by an assistant. Mr. Edser said that by putting the two plates immediately in front of the slit only a very small part of the glass is concerned in the action, light coming through at an angle would not reach the lens in the collimator.—Prof. Boys, Vice-President, then took the chair, and Mr. Campbell Swinton read a paper on some further experiments on the circulation of the residual gaseous matter in Crookes' tubes. In the discussion that followed the former paper on this subject, at the Physical Society on March 25, 1898, Mr. Appleyard had suggested that, in tracing the cause of the rotation of the exploring mill, it would lead to simpler results if the vanes were made of some light conducting substance, for it was probable that mica introduced complications by retaining the charges. Prof. Boys then pointed out that the mica might be gilded. Such a tube has now been made by Mr. Wolff. With the gilded mica vanes so placed as to be outside the kathode stream, the mill behaves in a manner similar to the non-conducting insulated mill. It shows a greater tendency to assume a position of stability, due to electrostatic induction; this renders it somewhat troublesome in starting, but, when once under way, the mill rotates always when excited. Occasionally, when starting, a few reverse revolutions are observed; these are probably due to electrostatic influence and momentum, and also possibly to eddy currents in the residual gaseous matter. But it is found, in all cases, that rotation in the direction that indicates a stream of residual gaseous matter from anode to kathode, follows the reversal immediately after one or two oscillations. An electrometer connected to the mill through the pivot and needle-point, shows the vanes to be always electrified positively. The results are confirmed by a second tube with oblique vanes. The author concludes that at very high exhaustions there exists a molecular or atomic stream from anode to kathode, which carries a positive charge, and travels at high velocity outside the opposite kathode stream. Mr. J. Quick asked what was the minimum degree of exhaustion required to produce these results. Prof. Boys said that the experiment gave some amount of probability to the truth of Mr. Campbell Swinton's hypothesis, but it did not altogether prove the mechanical theory of rotation to be correct. He was glad that the chance suggestion at the last discussion had led to such interesting experiments being continued. Prof. Threlfall mentioned that Boettger had devised a method for gilding mica, by a chemical process, that was much to be preferred to ordinary gilding. Mr. Campbell Swinton said it was necessary to exhaust the tubes as completely as possible to a point where it was only just possible for any discharge at all to pass through them. If the rotation was due to electrification, there must still be some mechanical process whereby the charges get to the vanes—a stream of residual gas satisfied that condition.—The Vice-President proposed votes of thanks, and the meeting adjourned until June 10.

PARIS.

Academy of Sciences, May 23.—M. Wolf in the chair.—Notice on the late M. Souillart, Correspondant in the Section of Astronomy, by M. O. Callandreau.—Some remarks on the periods of double integrals, and on cycles of two dimensions in algebraic surfaces, by M. Émile Picard.—New researches on the reaction between pyrogallol and oxygen in presence of alkalies, by M. Berthelot. The reaction depends upon the nature of the alkali employed. The amounts of oxygen absorbed, and carbon monoxide evolved, were measured and the oxidation products studied.—Chronophotography applied to the study of muscular action in locomotion, by M. Marey. The paper is accompanied by four plates, illustrating the methods used. After a set of photographs of the living animal has been obtained, its skeleton is prepared, and these photographed upon the same scale. From these the curves of change of length of each muscle can be deduced.—The origin of the vertebrates, by M. Edmond Perrier.—On minimum surfaces, by M. C. Guichard.—On systems of differential equations which satisfy quadruply periodic functions of the second species, by M. Martin Krause.—On the determination of the terminal curves of spirals, by MM. C. E. Guillaume and J. Pettavel. A mechanical method for determining Phillips' curve for spiral balance springs.—On a new method of determining the mechanical equivalent of heat, by MM. J. B. Baille and C. Féry. A cylinder of copper is fixed in a rotating magnetic field, and the heating effect measured. The moment of the couple required to keep the sphere at rest and the velocity of the field can be exactly measured. The correction for cooling must be measured with great exactness. In the preliminary results quoted the values of J lie between 422 and 426.—On some experiments in submarine acoustic telegraphy with the aid of a microphone, by M. E. Hardy.—On the osmosis of liquids through a membrane of vulcanised rubber, by M. G. Flusin. Since the measurement of the limiting osmotic pressure could not be carried out with this membrane, the velocity of the osmotic current was determined from the liquid into ethyl alcohol. The amounts of liquid absorbed by the rubber were also determined, but these figures are not proportional to the velocities of osmosis.—Improvement of over-exposed negatives, by M. Mercier. The plate is immersed for two minutes in a solution of tartar emetic, dried and developed as usual with hydroquinone.—On an apparatus for aërating boiled or distilled water, by M. Maillet.—Recapitulation of the atomic weights calculated by the method of limited densities, by M. Daniel Berthelot. By the methods given in preceding notes the atomic weights of carbon, sulphur, nitrogen, and chlorine are calculated. The agreement between the numbers so obtained, and those obtained by chemical methods is so close that the original assumption may be regarded as proved, Avogadro's law being strictly true only at extremely small pressures.—On the determination of the molecular weights of gases; reply of M. Marqfoy to M. Daniel Berthelot.—On reaction zones, by M. Albert Colson.—On the phosphorescent mixtures formed by strontium sulphide, by M. J. R. Mourelo.—On the limits of inflammability of combustible vapours, by MM. H. Le Chatelier and O. Boudouard.—Spectrum analysis of some non-conducting minerals by fused salts, by M. A. de Gramont.—Synthesis of safranine, by M. Georges F. Jaubert.—Action of aluminium chloride and of chlorine in presence of aluminium chloride upon anhydrous chloral, by M. A. Mouneyrat. By the action of $AlCl_3$ upon chloral at 100°, besides the products already discovered by Combes, pentachlorethane, $CCl_3.CHCl_2$ is obtained, and the tetrachlorethylene which forms the main product of the reaction is formed from this by further heating with $AlCl_3$. With chlorine, under similar conditions, a good yield of hexachlorethane is obtained.—Estimation of phosphoric acid in superphosphates, by M. Léo Vignon.—New observations on *Peripatus*, by M. E. L. Bouvier.—On the carbon monoxide normally contained in the blood, by M. Maurice Nicloux. The amounts of gas given by the blood of animals from the country is sensibly the same as in that of animals in towns (Paris). The carbon monoxide would appear to be produced within the organism itself.—On fungi intermediate between *Tricophytons* and *Achorions*, by M. E. Bodin.—On the minerals of the basaltic fumerolles of Royat (Puy-de-Dôme), by MM. A. Lacroix and P. Gautier.—On the apatite from certain granulitic enclosures from Chuquet-Genestoux, by MM. A. Gonnard and Adelphe.—Urinary acidity and its determination, by M. Charles Lapierre.—Earthquake of May 6, 1898, communicated by M. Michel Lévy.

DIARY OF SOCIETIES.

THURSDAY, June 2.

Royal Institution, at 3.—Modern Methods and their Achievements in Bacteriology: Dr. E. E. Klein.
Linnean Society, at 8.—Notes on some Lories: Prof. St. George Mivart, F.R.S.—A Revision of the Genus Symblepharis: E. J. Salmon.—On the Food of the Uropoda: Surgeon-Captain H. A. Cummins.
Chemical Society, at 8.—The Action of Ether on Organic Acids and on Carbohydrates in Presence of Hydrogen Bromide: H. J. H. Fenton and Mildred Gostling.

FRIDAY, June 3.

Royal Institution, at 9.—The Development of the Tomb in Egypt: Prof. W. M. Flinders Petrie.
Geologists' Association, at 8.—Fossil Sharks and Skates, with special reference to those of the Eocene Period: A. Smith Woodward.

SATURDAY, June 4.

Royal Institution, at 3.—The Temples and Ritual of Asklepios at Epidaurus and Athens: Dr. R. Caton.

MONDAY, June 6.

Royal Geographical Society, at 8.30.—Circumnavigation of Lake Bangweulu: Poulett Weatherley.
Society of Chemical Industry, at 8.—The Conditions existing in Acetylene Generators: Prof. V. B. Lewes.
Institute of Actuaries, at 5.—Annual General Meeting.

TUESDAY, June 7.

Zoological Society, at 8.30.—On some Crustaceans from the South Pacific. Part II. *Macrura anomala*: L. A. Borradaile.—Report on the Gephyrea collected by Mr. J. Stanley Gardiner at Rotuma and Funafuti: Arthur E. Shipley.—Fourth Report on Additions to the Batrachian Collection in the Natural History Museum: G. A. Boulenger, F.R.S.

WEDNESDAY, June 8.

Geological Society, at 8.—On the Discovery of Natural Gas in East Sussex: C. Dawson.—Note on Natural Gas at Heathfield Station (Sussex): Dr. J. T. Hewitt.—On some High-Level Gravels in Berkshire and Oxfordshire: O. A. Shrubsole.—The *Globigerina*-Marls of Barbados: G. F. Franks and Prof. J. B. Harrison. With an Appendix on the Foraminifera, by F. Chapman.

THURSDAY, June 9.

Royal Society, at 4.30.—*Probable Papers*: Experiments on Aneroid Barometers at Kew Observatory and their Discussion: Dr. C. Chree, F.R.S.—The Nature of the Antagonism between Toxins and Anti-Toxins: Dr. C. J. Martin and Dr. T. Cherry.—Some Differences in the Behaviour of the Real Fluids from that of the Mathematical Perfect Fluid: A. Mallock.—On the Heat Dissipated by a Platinum Surface at High Temperatures: J. E. Petavel.
Royal Institution, at 3.—Modern Methods and their Achievements in Bacteriology: Dr. E. E. Klein.

THURSDAY, JUNE 9, 1898.

LORD RAYLEIGH'S "SOUND."

The Theory of Sound. By J. W. Strutt, Baron Rayleigh, Sc.D., F.R.S. Second edition, revised and enlarged. Two volumes. Pp. xiv + 480, and xvi + 504. (London: Macmillan and Co., 1894 and 1896.)

IT was neither to be expected nor to be desired that any alteration of the general plan of Lord Rayleigh's "Sound" should be introduced in a new edition. A few errors have been detected and corrected (they are very few indeed), and the book has been considerably enlarged; but the characteristic features of the new portions are those of the old, and our admiration is again aroused by the skilful interweaving of theory and experiment, each supporting and adorning the other.

We are grateful, too, that there is a continuance of the help which we have received from the author in "clearing our minds of cant," or rather of that unquestioning employment of conventional explanations which is its equivalent in physical science. For example, many would even now be contentedly repeating the ordinary text-book theory of the maintenance of vibrations in an electric bell had he not awakened them to the knowledge that it was wholly beside the mark; and the statement that "a simple vibration involves *infinite* continuance, and does not admit of variations of phase or amplitude" should be very useful to many more.

The first important addition is an investigation of the resultant of a large number of vibrations whose phases are accidentally distributed. An expression is found for the probability of a resultant intensity of any specified magnitude, and the mean intensity is shown to be the sum of the intensities of the components.

Under the head of intermittent vibrations, the difference between intermittence artificially imposed upon a simple vibration and the intermittence of beats is pointed out and employed to explain some experimental results obtained by Prof. A. M. Mayer.

A section is added dealing with unstable systems with one degree of freedom, and we are reminded that the possibility of periodic motion under the operation of impressed periodic force is no proof of stability.

The maintenance of vibrations is then discussed, and it is shown that if impulses are given to a vibrating system whenever it passes through its equilibrium position their effect is mainly upon the amplitude and the period is sensibly unaltered; while if they are given at the moments when the system is at rest the effect is mainly upon the period, the vibrations being neither encouraged nor discouraged. An investigation is also given of the theory of the maintenance of vibrations by a periodic force whose frequency is double that of the maintained system, as in one form of Melde's well-known experiment and in the crispations of a liquid observed by Faraday.

Next we come to a description of some of the principal methods for the accurate determination of absolute pitch, including, of course, the author's excellent comparison of a fork with a clock pendulum by the use of the phonic wheel. An account of this instrument has been given earlier in the book, and its use with a counting apparatus certainly brings a fairly good determination within the reach of experimentalists of very moderate skill. Another interesting method which is described is that of counting the two sets of beats of overtones which are heard when two notes whose interval is an equal temperament-whole tone are sounded on a harmonium. The method depends, of course, on the fact that in *maintained* vibrations the frequencies of overtones must be accurately multiples of that of the fundamental. The necessity of this correspondence is proved later, but a hint of it might have been given here with advantage to the student; for in acoustics, as in other matters, the progress of the human mind is from the vulgar credulity of accepting all overtones as accurately harmonic through the vulgar incredulity of doubting whether any can be so.

In the general treatment of vibrating systems an investigation of the effects of imposed constraints upon the periods is given, also the theorems of Routh relating to the roots of the equation defining the periods, with an extension to unstable systems; a section dealing with the reaction upon the driving-point of a system thrown into forced vibration is also added. Under the head of transverse vibrations of strings the propagation of progressive waves along a string whose mass is supposed to be concentrated at equidistant points is considered, and it is shown that there will be no such propagation if the frequency is above a certain critical value. The reflection of waves at the junction of two strings is treated, also reflection produced by gradual change of density, and it is shown how the analogue of dispersion in optics is introduced if the string is considered to possess finite stiffness, and that in this case the ordinary formula for the intensity of the reflection must be modified. Reflection at a junction is also discussed in the case of longitudinal vibrations of bars, and the weakness of the transmitted intensity when the change of velocity at the junction is considerable is pointed out.

A summary is given of the experiments of Elsas on forced vibrations of membranes, and the march of the nodal lines with varying frequency is described. In the chapter on vibrations of plates an account is given of the author's interesting observations on the notes of bells, and his ingenious method of obtaining the nodal lines corresponding to each note by utilising the beats produced by asymmetry.

The first volume ends with two new chapters, one on the vibrations of thin cylindrical and spherical shells, and one on electrical vibrations. In the latter the theory of oscillatory currents in circuits with capacity and induction is given, and applications to Hughes' induction balance and Wheatstone's bridge are discussed. The concentration of currents of high frequency on the outside of a conductor is also worked out, and the propagation of current waves along cables is treated, justice being done to Heaviside's work on the effect of inductance in diminishing distortion in telephony. The mode of action of the telephone is also discussed, and the author's results as to the minimum audible current are given.

In the chapter on aerial vibrations, which opens the second volume, some interesting phenomena depending upon the second order of small quantities are explained,

 G

the best known being the striations which are always seen in a Kundt's tube, and which are shown to be due to the tendency of solid particles to arrange themselves in chains perpendicular to the lines of alternating flow. An investigation of reflection at a corrugated surface follows, next comes a description of some experiments on diffraction of sound.

A general account of the mode of maintenance of the vibrations of a flute organ-pipe is then given, and attention is called to the fact that the note of the pipe when sounded is higher than the note to which it would resound, and that the difference increases with the wind pressure. The mutual influence of organ-pipes mounted side by side is considered; it has been shown how this influence militates against the successful application to pipes of Scheibler's method of determining absolute pitch. The maintenance of vibrations by increasing the pressure at a node at a time of maximum pressure and decreasing it at a time of minimum pressure by the introduction and removal of air or of heat is considered. (The student will find it a profitable mental exercise to satisfy himself that this mode of maintenance is consistent with the general principle that the force should be applied when the system passes through its equilibrium position; he may also note the analogy to the maintenance of the oscillations of a galvanometer needle by a small current suitably controlled by a reversing key). If, on the other hand, the moments of the most rapid addition and subtraction of heat are those of most rapid change of pressure, it is shown that the vibration is neither maintained nor damped, the effect being concentrated upon the period. It may be remarked that the passage from Newton's theory of sound to Laplace's, or *vice versâ*, in calculating the pitch of a pipe is a case exactly in point. Among the more important applications of maintenance by heat, singing flames and Rijke's sounding tubes are treated, also the sounds sometimes heard when a bulb has just been blown at the end of a glass tube. The maintained vibration of mercury contained in a U-tube, one end of which is connected with a heated bulb, is a visible example of the latter phenomenon, and the principle has been successfully applied to small hot-air motors. A short account of the conditions of maintenance in reed instruments is also given.

Under the head of fluid friction, Kirchoff's investigation of the effects of viscosity and heat-conduction upon the propagation of sound finds a place, and the behaviour of very narrow tubes towards sound is applied to the question of reflection at a porous wall. The theory of the vortices observed by Dvŏrák in Kundt's tubes is also investigated.

Four new chapters complete the book. The first deals with liquid waves under gravity and cohesion; in it are treated, among other matters, the determinations of surface tension by the measurement of ripples and by observations on the vibrations of a liquid cylinder, the importance of the latter method in permitting the examination of a newly-formed surface being pointed out. The instability of a liquid jet, the behaviour of drops in collision, and the vibrations of detached drops are also considered. The next chapter, on vortex motion, gives an investigation of the instability of stratified motion in a fluid, and its application to the theory of sensitive flames and smoke-jets. Bird-calls and aeolian tones are also shortly treated, some considerations as to pitch being deduced from the principle of dynamical similarity. A brief account of the propagation of vibrations in elastic solids follows, and the last chapter deals with facts and theories of audition. In it the author's experiments on the minimum amplitude of sound waves consistent with audibility are described, a discussion of Ohm's law and its exceptions is given, and, by the application of dynamical principles to the internal vibrators which on Helmholtz's theory form the analysing mechanism of the ear, the bearing of the degree of damping in these vibrators on the origin of dissonance, on the possibility of accurately judging pitch, and on the remarkable results of Kohlrausch as to the exceedingly small total number of vibrations requisite for the appreciation of a definite pitch, is explained. Finally, the conflicting views which have been held as to combinational tones, the perception by the ear of the phase relationship of two tones, and the characteristics of vowel sounds are discussed.

In NATURE of December 12, 1878, Prof. Helmholtz, after suggesting some of the above problems, wrote of the first edition of this book; "Lord Rayleigh certainly deserves the thanks of all physicists and students of physics; he has rendered them a great service by what he has done hitherto. But I believe I am speaking in the name of all of them if I express the hope, that the difficulties of that which yet remains will incite him to crown his work by completing it." This has now been done, but the only voice which could without impertinence utter praise is, alas, silent. L. R. W.

HAWKS AND HAWKING.

Hints on the Management of Hawks (Second Edition); *to which is added Practical Falconry Chapters, Historical and Descriptive.* By J. E. Harting. 8vo. Pp. viii + 268, illustrated. (London: H. Cox, 1898.)

MR. HARTING is such an authority on the art of hawking, and is, furthermore, such an excellent field naturalist, that it was only to be expected his volume on this branch of sport would reach a second edition. But, as the author states in his preface, the additions to the new edition, both as regards letter-press and illustrations, are so extensive as almost to give it a claim to rank as a new work.

From all points of view, management, rearing, training, and use in the field, as well as regards their natural history, Mr. Harting appears to have furnished all that there is to be told concerning hawks and hawking; and if the votaries of this sport are not satisfied with his efforts, they must indeed be hard to please. Some of the most interesting chapters in the volume are those relating to the now obsolete kite-hawking and heron-hawking; the one of which has ceased to exist from the practical extinction of the quarry, and the other from the altered physical conditions of the country. In all portions of his subject the author owes much to the artist, some of the illustrations being really exquisite, especially those from the pencil and brush of Mr. Lodge. What, for instance, can be more striking than the contrast between the figure of the heron sailing gracefully at ease on p. 153, and the same bird after being stricken by the peregrine two pages later? It is, of course, a drawback that so many of the illustrations depict birds and other animals in postures of pain, but this is inseparable from the subject. While commending the illustrations as a whole, a few, like the one of the hobby, appear to have been printed from somewhat worn blocks.

To those not conversant with the sport, it may come as a matter of surprise that so many species of the *Falconidæ* are trained in various countries for hawking; these ranging in size from the merlin and the hobby to the golden eagle, and their quarry from the snipe and the lark to the roe-deer, or even the wolf. As hawking with eagles is unknown in western Europe, the portion of Mr. Harting's work relating to that branch of the sport cannot fail to prove generally interesting. It would, of course, have been mere waste of space if the author had attempted to give full descriptions of all the various hawks and falcons employed in the sport; but as there is some considerable degree of confusion in regard to the species of eagles trained for hawking in Turkestan and other parts of the Russian empire, he has done well in giving a full discussion on the question. And here Mr. Harting, as usual, displays an intimate acquaintanceship with the zoology of the subject and the literature relating thereto. It appears from these observations that the bird commonly employed in Turkestan, where it is known as the berkut, is the golden eagle, but that other species, such as the Imperial eagle, are likewise trained; while it is stated that occasionally sea-eagles of two species are made use of.

Although it is by no means meant to displace the older and more bulky treatises, Mr. Harting's little volume ought to give the beginner all the information he requires for setting up a hawking establishment, either on a large or a small scale, and it will doubtless aid in maintaining interest in an ancient and exciting sport which ought by no means to be allowed to fall into neglect. R. L.

THE RUDIMENTS OF PHYSICS AND CHEMISTRY.

General Elementary Science. Edited by William Briggs, M.A., F.C.S., F.R.A.S. Pp. viii + 390. (London: W. B. Clive.)

Elementary General Science. By A. T. Simmons, B.Sc., and Lionel M. Jones, B.Sc. Pp. viii + 328. (London: Macmillan and Co., Ltd., 1898.)

THE new regulations for the matriculation examination of the University of London provide that on and after next January all candidates must present themselves for examination in the rudiments of physics and chemistry included in a syllabus under the head of "General Elementary Science." Following the "stream of tendency" of science teaching at the present time, the examiners announce in a note prefixed to their syllabus that the subjects "will be treated wherever possible from an experimental point of view. Candidates will be expected to have performed or witnessed simple experiments in illustration of the subjects mentioned in this syllabus." By making this announcement, the University of London has shown its intention to encourage the introduction and extension of practical methods of science teaching into our secondary schools; and there can be no doubt that if the examiners insist upon the possession of knowledge gained by demonstration and experience, instead of the transient information acquired by reading, their action will be the means of greatly improving the character of the scientific instruction given in the smaller secondary schools. Hitherto, many schools of this character have trained candidates for matriculation without showing them a single scientific experiment; the new curriculum will, however, make this state of things impossible, and will therefore be the means of increasing the efficiency of secondary schools.

The two volumes under notice have both been prepared to meet the new requirements of the London University, and they exemplify the old saying that "there is a right and a wrong way to do everything." In the volume edited by Mr. Briggs little attempt has been made to produce a book in the spirit of the new syllabus. Neither the first section of the book dealing with mechanics, nor the second section dealing with heat, light and electricity, can be regarded in any way as likely to lead to a practical acquaintance with scientific facts; they both contain a large amount of information concisely expressed, but the information is of precisely the same kind as appears in books prepared for students working under the old matriculation regulations. In other words, more attention is paid to arithmetical gymnastics in the regions of mechanics and physics than to experiment. The section on chemistry is better done, nearly one hundred experiments being described in it; but it is unequal in treatment, and contains too many equations and formulæ for a beginner in chemistry to understand. As a whole, the book is unsatisfactory; it contains information to be read and learnt by the student instead of descriptions of experiments to be performed, and though it may be useful as a training in providing exercises in physical arithmetic, it has no educational value.

The book by Messrs. Simmons and Jones is of quite a different character from that compiled under Mr. Briggs's direction. It contains an admirable course of practical work covering all the principles of mechanics, physics, and chemistry included in the new subject for London matriculation. No less than 310 experiments are described, and they are not only practicable, but can also be performed with simple apparatus. Many of the experiments, such as the pin-methods of proving the laws of reflection and refraction of light, the simple experiments on voltaic cells, and the method for heating a solid in a closed volume of gas (p. 258), are distinctly good, while most of them furnish evidence that the authors are describing matters of personal experience, and not hypothetical arrangements. The experiments alone provide a valuable set of practical exercises in elementary physics and chemistry, and if the descriptive text is read in connection with them, the student will be given a sound basis of scientific knowledge. The volume contains an instructive course of work which will be of real assistance to both teachers and pupils in schools where elementary science is taught.

OUR BOOK SHELF.

The Flora of Perthshire. By F. Buchanan White, M.D. Edited by James W. H. Trail, A.M. Pp. lxi + 407; with a portrait of the author, and a map of the county. (Edinburgh: W. Blackwood and Sons, 1898.)

IT had long been known that the late Dr. Buchanan White was preparing a "Flora of Perthshire," when his death in 1894 arrested the progress of the work. The manuscript was then put into the hands of Prof. J. W. H. Trail, who has edited it.

The book is well arranged; clear, perhaps at the expense of detail of secondary value. For such we must consider the long strings of exact localities, common in such works, in this one usually summed up into short general statements. There is no doubt that the book has been carefully planned, that its aims are broad, and that all matter not of real concern has been excluded. Here and there we find critical remarks, or statements of the variability of the species. These are interesting; but the great feature of the book is in the new data relating to the altitudes reached by plants. It will be noticed that the upper limits of species usually are in excess of those given more than half a century ago by H. C. Watson for the Eastern Grampians; also that they differ in different parts of the county. So many of the glens of Perthshire run east and west, and gather from this cause heat in a way which glens open to north winds do not. Perhaps this accounts for the difference. The subject is one yet wanting many observations.

The manuscript appears to have been less complete when it changed hands than was thought. As a result we see a slight want of uniformity. One, who, like Dr. Buchanan White, united into a single species *Viola tricolor* and *arvensis*, would not be likely to follow the division of the genus *Hieracium* to the extreme. It is, indeed, a cause for regret that the author left no outline of the introduction, which he could so well have written. The essay reprinted in its place only deals with one question; and for others, which would have found a place, we must seek in his published papers. A list of these papers is incorporated in the book with a memoir of the author.

I. H. B.

Manual Training: Woodwork. A Handbook for Teachers. By George Ricks, B.Sc. Lond. Pp. 187. (London: Macmillan and Co., 1898.)

WORKING in wood with carpenter's tools is now provided for in the curriculum of many public elementary schools, as well as in technical schools, with the object of training the manual and visual faculties to act in connection with the mental. Used with care, this manual work becomes a valuable educational agent, but unless it is carried out on an orderly system it degenerates into mere tinkering. Mr. Ricks has kept the true aims of manual training well in mind in the preparation of his work. "Our aims," he says, "must be wholly educational. We must arouse interest and quicken intelligence. We must develop and strengthen habits of attention, industry, and perseverance. We must train the eye to accurate observation, and the hand to dexterity in execution." The aspirations are commendable, and the author's experience has enabled him to develop a practicable scheme of work in which it is shown how they can be carried into effect. Beginning with a chapter on drawing as a factor in manual training in wood, this is shown to be the fundamental basis of the work. The necessity of exact measurement in all work, and the use of working drawings, is insisted upon; and rightly, for without drawings to scale, exact and intelligent handiwork is scarcely possible. An instructive chapter is given on the various woods used as timber, their structure, growth, preparation and properties. We notice that in explaining specific gravity with reference to timber, Mr. Ricks adopts as his standard the weight of a gallon of water (10 lbs.), the specific gravity of oak thus being 8, of beech 7, and so on. This is convenient for some reasons, but it is apt to create confusion; and if the child afterwards learns that the specific gravity of iron is 7, he will wonder whether the metal or the wood is the heavier.

After the preliminary chapters and exercises come systematic work on the use of carpenters' cutting tools, simple workshop operations, and bench work from working drawings. The book shows evidence of thought and experience, and should prove of service to teachers of manual training.

A Description of Minerals of Commercial Value. By D. M. Barringer, A.M., LL.B. Pp. 168. (New York: John Wiley and Sons. London: Chapman and Hall, Ltd., 1897.)

A SET of tables for the identification of minerals is very useful to mineralogists and others; and as this note-book contains such tables and little else, it is welcome. The information is conveniently arranged so that it can be quickly referred to, nevertheless there are so many omissions that the book cannot be used to the exclusion of other books on mineralogy, and consequently its chief claim to consideration, that of saving time, falls to the ground. For example, under the heading of lead ores, only galena and cerussite are mentioned, although six compounds of bismuth and five of antimony are described. It may be hoped that Mr. Barringer will see his way to making his book more complete in future editions.

Ludwig Otto Hesse's Gesammelte Werke, herausgegeben von der Mathematisch-Physikalischen Classe der Königlich Bayeirschen Akademie der Wissenschaften. (München, 1897.)

COLLECTED into one large quarto volume of over 700 pages, ranging in date from 1838 to 1874, we find here the mathematical articles in which Hesse laid the foundations of the modern analytical theory of Solid Geometry, with the details of which we are familiar in the treatise of Dr. Salmon.

The subjects discussed are all of geometrical interest, even where the title may indicate an algebraical flavour, as the analytical developments are such as arise from the investigations of geometrical properties. We may instance the researches on the Functional Determinant, called after the inventor the Hessian, which has played so important a part in the hands of Sylvester and Cayley. A biography, based on a memorial lecture by Prof. G. Bauer, completes the volume; in it a characteristic remark of Sylvester is embodied. It is interesting to learn that Jacobi utilised Hesse as a collaborator in developing the theory of the Attraction of Ellipsoids.

G.

Krōmskōp Colour Photography. By Frederic Ives. Pp. xvi + 80. (The Photochromoscope Syndicate, Ltd., 1898.)

MOST of our readers have either seen or heard of Mr. Ives' process of colour photography, known now under the name of the Krōmskōp System. In the small book we have before us, Mr. Ives gives the reader a concise account of the principles involved in this method of producing coloured pictures, describing and explaining at the same time the construction and action of the various krōmskōpes which are now being manufactured. This information will be found very serviceable to any one who wishes to attain the maximum of efficiency in this branch of photography. In addition to the above instructions, reference is made to the literature on the subject, and various extracts relating to the nature, theory, &c., of colour from writings of well-known men are inserted.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Liquid Hydrogen.

THE letter of W. Hampson, which appears in your issue of May 26, can only mean by implication to charge me with having utilised without acknowledgment an idea of his, conveyed through a third party, in my paper on the liquid hydrogen jet, published in 1895. Such a suggestion is absolutely without any foundation in fact. My results would have been attained had Dr. Hampson never existed, just as they have been developed. He certainly in no way contributed directly or indirectly to the success of those hydrogen experiments. Had Mr. Hampson attempted to consult me as to his plans, I should have declined to entertain them, just as I had treated, under similar circumstances, distinguished colleagues engaged in low temperature research; for no other reason than to avoid the possibility of controversy. Further, I never would have allowed my assistant either to consider or advise on the projected scheme of some other person about to engage in the same field of investigation, simply because such a position would be quite unprecedented, and certain to result in misunderstandings. W. Hampson is the only inventor or investigator who has not in a straightforward way approached me directly in such matters, and it is no excuse for his dubious course of action to say he had an "introduction." My assistant has explained his position in the matter in letters addressed to "*Engineering*" within the last few weeks. The paper of 1895, on gas jets containing liquid, has been a fruitful source of recrimination. No less than three patentees of low temperature apparatus—viz. Solvay, Linde and Hampson—have each recognised in its contents part of the essential subject-matter of their respective patents. It will be for these gentlemen to fight the matter out. Suffice it to say, that the statements made in my paper of 1895 remain a correct record of facts. Further remarks on the subject can be found in the Society of Arts *Journal* for March 1898; made during the course of a discussion on the Linde process.

The Hampson patent was not published before April 1896, and the first exhibition of the working apparatus took place towards the end of March of the same year; or some three months subsequent to my Chemical Society paper. Mr. Hampson declares in his letter that he "*was afterwards the first in this country to liquefy air and oxygen without employing other refrigerants.*" Now, in my paper of 1895 the following passages occur:—"With such a simple apparatus and an air supply at 200 atmospheres, *with no previous cooling*, liquid air begins to collect in about five minutes, but the liquid jet can be seen in between two and three minutes." "In the above experiments air is taken *at the ordinary temperature*, which is a little above twice its critical temperature, and is partially transformed in a period of time, which in my experiments has never exceeded ten minutes, simply and expeditiously into the liquid state at its boiling-point—194°, or a fall of more than 200° has been effected in this short period of time." J. DEWAR.

May 30.

Printed Matter and Photographic Plates.

IN connection with this subject it does not appear to be generally known that photographic negatives, after they have been developed and fixed, and especially if they have been intensified by means of the bi-chloride of mercury and ammonia process, are often strongly impressed by prolonged contact with printed matter. I first observed this many years ago, and have a large number of negatives in my possession which show the effect very strongly, I enclose a photographic negative taken by myself in 1882, which has remained since 1886 wrapped up in the accompanying advertisement sheet of the *Electrician*. As will be observed, the greater portion of the print in contact with the film is clearly legible. It is, however, worthy of note that it does not appear to be the printer's ink in this case that has produced the chemical action, but rather the paper itself, or some ingredient therein. Those portions of the film protected from contact with the paper by the ink have retained their original colour, while the other portions not so protected have become very considerably bleached. The printing on the side of the paper removed from the film does not seem to have had any effect.

It has probably been noticed by others that ordinary albumenised and sensitised photographic paper is also strongly affected in the course of time by contact with printed matter. In this case, also, the printing comes out as white lettering upon a darker ground. A. A. C. SWINTON.

The Transport of Live Fish.

YOUR readers may be interested to know of an experiment with the transport of live fish I am making, and so far successfully. I left Brisbane on April 16, taking with me four specimens of Ceratodus. This remarkable fish is doubtless sufficiently well known to your subscribers to render a description on my part unnecessary. D. O'CONNOR.

S.S. *Duke of Devonshire*, Colombo, May 16.

CEREMONIAL DANCES OF THE AMERICAN INDIANS.

READERS of NATURE do not need to be reminded of the important work being done by the Bureau of American Ethnology, which is conducted under Act of Congress "for continuing ethnologic researches among the American Indians under the direction of the Smithsonian Institution." The value of the researches that are being carried on, and the results of which are issued in the form of annual reports and bulletins, cannot be over-estimated; for the Indian customs and beliefs, which form the subject of the majority of the papers, are not destined to survive for many years. The Indian reserves are gradually being curtailed, the Indians themselves are slowly becoming civilised, and this process is naturally attended with change and decay of their primitive ceremonial and belief. It must be admitted that the Indian nature is slow to change, and retains its tribal instincts under a veneer of civilisation. In fact, the case of a young Arapaho Indian, who, though speaking good English and employed as a clerk in a store, thought it but natural that he should join his tribe in dancing the sun-dance for three days and nights without food, drink or sleep, is far from exceptional. But the change, though gradual, is constant, and at no distant period the American Indian will have ceased to furnish the anthropologist with opportunities for the study of primitive man. When that time arrives the value of these reports, compiled by trained observers in accordance with a scientifically organised plan, will be unique.

The present article is concerned with three of the papers published in the fourteenth, fifteenth and sixteenth annual reports of the Bureau. These papers may be classed and considered together, as they deal with certain ceremonial dances still practised by many of the Indian tribes. The longest of the papers is that entitled "The Ghost-dance Religion and the Sioux Outbreak of 1890," which is contributed by Mr. James Mooney, and is published in a volume by itself as Part ii. of the fourteenth annual report. The underlying principle of the ghost-dance is the doctrine that at some future time the whole Indian race, whether living or dead, will be reunited in a life upon earth untroubled by the fear of death, hunger, or disease. Most Indians hold that this change will be brought about by spiritual powers who will require no assistance from men, but at times of discontent medicine-men have sought to anticipate the Indian millennium by preaching a crusade against the further encroachments of the white population, and persuading their fellow tribesmen that in this resistance they will have the active support of their dead ancestors and relatives. Such a revival took place in 1890 among the Sioux, the largest and strongest Indian tribe in the United States. The cause of the outbreak may be traced to irritation at the encroachments made on their reserve and to the neglect of the Government to carry into effect their promises of furnishing supplies. As the area of their hunting-grounds was diminished, they had to depend for subsistence on their cattle and crops and on the rations allowed them by Government. In 1888 their cattle suffered from disease, in the two following years their crops were a failure, and their rations of beef were diminished by half. In 1890 they were on the brink of starvation, and ready to listen to the words of a messiah. In fact there is no doubt that hunger was the real cause of the rebellion, and not the ghost-dance itself, though this ceremonial was adopted as the means of propagating the crusade. That resistance to the whites had no part in the original doctrine of the dance is proved by the fact that in many other tribes which practise it no outbreak has occurred. The Sioux rebellion was put down after a short though costly war, and Mr. Mooney has given a detailed account of the campaign which was brought to a close by the battle at Wounded Knee. We are not here concerned with this somewhat melancholy chapter of Indian history, but will confine ourselves to the interesting account he has given of the ghost-dance with which the rebellion is generally connected.

No one is better qualified to give an account of this ceremony than Mr. Mooney, for he has had exceptional opportunities for studying it. From 1890, when the ghost-dance was beginning to attract attention, to the early part of 1894, he has studied it on several expeditions, his actual investigations among the Indians extending over a period of twenty-two months and entailing some 32,000 miles of travel. Not only has he frequently seen the dance performed, but he has taken part in it himself among the Arapaho and Cheyenne, and by means of his kodak and camera has obtained some valuable photographs. He also visited Wovoka, the messiah who inaugurated the recent revival, and by gaining the confidence of the Indians obtained from a Cheyenne Indian, Black Short Nose, a copy of the messiah's message, embodying the doctrine of the ghost-dance, which he had previously sent to the Cheyenne and Arapaho tribes. Mr. Mooney has given a very full and interesting account of the ceremony of the ghost-dance, but here we have not space for more than a sketch of its most striking features.

The place chosen for the dance is frequently consecrated by the sprinkling of sacred powder. Seven priests lead the dance, and seven women are sometimes added as leaders, the number seven being sacred with most Indian tribes. Those selected as leaders receive two feathers of the crow, the sacred bird of the ghost-dance, or one of the eagle, which is sacred with all Indians; and these feathers they thrust in their hair. Nearly all the dancers wear feathers, the painting and ornamenting of which is attended with great ceremony; while the faces of the dancers are painted with elaborate designs in red, yellow, green and blue. The dance generally begins in the middle of the afternoon, the leaders walking to the spot selected, where they form a small circle facing inwards and joining hands. Then without moving they sing the opening song in a soft undertone, and, having sung it once, repeat it, raising their voices to their full strength, and slowly circling round from right to left. This process is repeated with different songs. Gradually the people of the tribe gather round, and one after another joins the circle until any number, from fifty to five hundred, men, women and children, are in the dance. The object aimed at by all the dancers is to fall into a sleep or trance in which they will see their dead relatives and converse with them. Sometimes a dancer will work himself into the trance-state solely by the influence of the movements of the dance and the singing, but the dancers are generally helped by the medicine-men standing within the circle, who, in Mr. Mooney's opinion, unconsciously exercise hypnotic influence. The first symptom of the trance-state is a slight muscular tremor, and, as soon as a medicine-man perceives this he fixes his eyes on the dancer, uttering sharp exclamations and twirling a feather or small cloth rapidly in his face. Soon the dancer loses control of himself, staggers and breaks away from the ring, which closes up again. The medicine-man continues his passes, generally keeping the sun full in the face of the dancer, who becomes rigid and finally falls to the ground unconscious. The trance lasts sometimes ten minutes, sometimes for hours; for those who continue dancing are careful not to disturb any dancer in the trance. As Mr. Mooney has taken part in the dance himself, he has observed the various stages in the hypnotic trance, as will be seen from the following quotation:

"From the outside hardly anything can be seen of what goes on within the circle, but being a part of the circle myself I was able to see all that occurred inside, and by fixing attention on one subject at a time I was able to note all the stages of the phenomenon from the time the subject first attracted the notice of the medicine-man, through the staggering, the rigidity, the unconsciousness, and back again to wakefulness. On two occasions my partner in the dance, each time a woman, came under the influence, and I was thus enabled to note the very first tremor of her hand and mark it as it increased in violence until she broke away and staggered toward the medicine-man within the circle."

In addition to his observations of the actual ceremony of the ghost-dance, Mr. Mooney has made very careful studies of the songs employed by the dancers. As with church choirs in civilised countries, the leaders of the dance hold numerous rehearsals of the songs which are to be employed at the next dance; for though each tribe has certain songs which form a regular part of the ceremony, new ones are constantly being added by those who have experienced the trance. Mr. Mooney was often present at these rehearsals, and was thus enabled to take down many of the songs, and some of the airs he has put to music. In fact Mr. Mooney has treated his subject exhaustively, and has prefaced it with a discussion of the various Indian revivals due to prophets who preceded Wovoka. His paper, which runs into some 500 quarto pages, is full of material which will be of the greatest value to the anthropologist and student of religion.

Two somewhat shorter papers on certain ceremonial dances among the Indians are contributed by Mr. J. W. Fewkes to the fifteenth and sixteenth annual reports of the Bureau, which were issued during the course of last year. Like Mr. Mooney's memoir, Mr. Fewkes' papers also are of great value, as they are based on personal observations; he does not, however, enter at any great length into the doctrines which underlie the ceremonials he describes. His paper in the fifteenth annual report is entitled "Tusayan Katcinas," and in it he has given a careful record of the Katcina ceremonials as he saw them performed in the Hopi village of Walpi in Tusayan; his paper is the result of observations made by himself and by the late Mr. A. M. Stephen during the years 1890 to 1894. The word *Katcina* has a twofold meaning. It is used as a name for certain supernatural beings, subordinate to the greater gods, who are impersonated in Hopi ceremonials by men wearing masks; it is also employed as a name for the dances in which these men take part. The Katcina dances are carried on at fixed times during the period between the winter and the summer solstices, and their chief point of difference from the ceremonies performed by the Hopi during the rest of the year consists in the presence of the Tcukúwympkiyas, or masked figures; the men who wear the masks or helmets are supposed to be transformed for the time into the deities they represent. The times for the ceremonies are determined by the priests of the tribe by observing the points on the horizon where the sun rises and sets (see p. 111). Of the Katcina ceremonials the most elaborate is that termed Powámû. Extensive preparations are made before the dance, the old paint left from previous occasions being scraped off the masks, which are then carefully redecorated and ornamented with clusters of feathers. The dancers also decorate themselves, using iron oxide for painting their legs, knees and waists a pale red. On the occasion Mr. Fewkes describes, preliminary ceremonies took place at Walpi for a week before the first ceremonial day of the Powámû, in which masked men from the neighbouring villages of Tewa and Hano took part. We have not space here to enter into any detailed account of the elaborate ceremonials performed on this and the succeeding days, including songs, a kind of primitive drama, dances, ceremonial smoking, flagellations, sprinkling of liquids, casting of meal and pollen into liquids, the making of small dolls or images, &c. Mr. Fewkes has not attempted to explain the theoretical significance of the ceremonies, but has contented himself with accurately describing them as they were performed. We may note, however, that in his subsequent paper on the snake-dance he throws out the suggestion that these Katcina ceremonies are to be traced to a totemic origin.

Mr. Fewkes' paper contributed to the sixteenth annual report is entitled "Tusayan Snake Ceremonies," and is based on a comparative study of the snake-dance, which is now known to be performed at five Tusayan villages. At Walpi it is celebrated in its most elaborate form, and lasts for twenty days, though only on nine days do ceremonies actually take place. Sixteen days before the snake-dance occurs it is formally announced at sunrise, the chiefs of the village having been engaged in ceremonial smoking during the previous night. For the next seven days no ceremonies are performed, but on the eighth day the assembly takes place, and for nine days secret ceremonies continue, which close at sunset on the ninth day with a dance, in which snakes are carried in the mouths of the dancers; the four following days are days of purification. Mr. Fewkes admits that the meaning of the snake-dance is obscure, but inclines to the belief that the elaborate ritual is performed for two main objects—the making of rain and the growth of corn. He does not consider that the dance is in any way connected with actual snake-worship.

We have said enough to indicate the great interest of these papers, not only to the student of Indian ritual, but to anthropologists generally. If we may make one criticism, it is that in places they would, perhaps, have gained a little by compression.

ON A NEW CONSTITUENT OF ATMOSPHERIC AIR.[1]

THIS preliminary note is intended to give a very brief account of experiments which have been carried out during the past year to ascertain whether, in addition to nitrogen, oxygen, and argon, there are any gases in air which have escaped observation owing to their being present in very minute quantity. In collaboration with Miss Emily Aston we have found that the nitride of magnesium, resulting from the absorption of nitrogen from atmospheric air, on treatment with water yields only a trace of gas; that gas is hydrogen, and arises from a small quantity of metallic magnesium unconverted into nitride. That the ammonia produced on treatment with water is pure has already been proved by the fact that Lord Rayleigh found that the nitrogen produced from it had the normal density. The magnesia, resulting from the nitride, yields only a trace of soluble matter to water, and that consists wholly of hydroxide and carbonate. So far, then, the results have been negative.

[1] Paper to be read before the Royal Society on June 9 by Prof. William Ramsay, F.R.S., and Morris W. Travers. Received by the Society June 3.

Recently, however, owing to the kindness of Dr. Hampson, we have been furnished with about 750 cubic centimetres of liquid air, and, on allowing all but 10 cubic centimetres to evaporate away slowly, and collecting the gas from that small residue in a gas-holder, we obtained, after removal of oxygen with metallic copper and nitrogen with a mixture of pure lime and magnesium dust, followed by exposure to electric sparks in presence of oxygen and caustic soda, 26·2 cubic centimetres of a gas, showing the argon spectrum feebly, and, in addition, a spectrum which has, we believe, not been seen before.

We have not yet succeeded in disentangling the new spectrum completely from the argon spectrum, but it is characterised by two very brilliant lines, one almost identical in position with D_3, and almost rivalling it in brilliancy. Measurements made with a grating of 14,438 lines to the inch, kindly placed at our disposal by Mr. E. C. C. Baly, gave the following numbers, *all four lines being in the field at once*:—

D_1	5895·0
D_2	5889·0
D_3	5875·9
D_4	5866·65 + 1·7 to correct to vacuum.

There is also a green line, comparable with the green helium line in intensity, of wave-length 5566·3, and a somewhat weaker green, the wave-length of which is 5557·3.

In order to determine as far as possible which lines belong to the argon spectrum, and which to the new gas, both spectra were examined at the same time with the grating, the first order being employed. The lines which were absent, or very feeble, in argon, have been ascribed to the new gas. Owing to their feeble intensity, the measurements of the wave-lengths which follow must not be credited with the same degree of accuracy as the three already given, but the first three digits may be taken as substantially correct:—

Violet	4317	Blue	4834
,, ...	4387	,, ...	4909
,, ...	4461	Green	5557·3
,, ...	4671	,, ...	5566·3
Blue	4736	Yellow	5829
,, ...	4807	,, ...	5866·5
,, ...	4830	Orange... ...	6011

Mr. Baly has kindly undertaken to make a study of the spectrum, which will be published when complete. The figures already given, however, suffice to characterise the gas as a new one.

The approximate density of the gas was determined by weighing it in a bulb of 32·321 cubic centimetres capacity, under a pressure of 521·85 millimetres, and at a temperature of 15·95°. The weight of this quantity was 0·04213 gram. This implies a density of 22·47, that of oxygen being taken as 16. A second determination, after sparking for four hours with oxygen in presence of soda, was made in the same bulb; the pressure was 523·7 millimetres, and the temperature was 16·45°. The weight was 0·04228 gram, which implies the density 22·51.

The wave-length of sound was determined in the gas by the method described in the "Argon" paper. The data are:—

	i.	ii.	iii.
Wave length in air	34·17	34·30	34·57
,, ,, gas	29·87	30·13	

Calculating by the formula

$$\lambda^2_{air} \times \text{density}_{air} : \lambda^2_{gas} \times \text{density}_{gas} :: \gamma_{air} : \gamma_{gas}$$
$$(34{\cdot}33)^2 \times 14{\cdot}479 : (30)^2 \times 22{\cdot}47 :: 1{\cdot}408 : 1{\cdot}666,$$

it is seen that, like argon and helium, the new gas is monatomic and therefore an element.

From what has preceded, it may be concluded that the atmosphere contains a hitherto undiscovered gas with a characteristic spectrum, heavier than argon, and less volatile than nitrogen, oxygen, and argon; the ratio of its specific heats would lead to the inference that it is monatomic, and therefore an element. If this conclusion turns out to be well substantiated, we propose to call it "krypton," or "concealed." Its symbol would then be Kr.

It is, of course, impossible to state positively what position in the periodic table this new constituent of our atmosphere will occupy. The number 22·51 must be taken as a minimum density. If we may hazard a conjecture, it is that krypton will turn out to have the density 40, with a corresponding atomic weight 80, and will be found to belong to the helium series, as is, indeed rendered probable by its withstanding the action of red-hot magnesium and calcium on the one hand, and on the other of oxygen in presence of caustic soda, under the influence of electric sparks. We shall procure a larger supply of the gas, and endeavour to separate it more completely from argon by fractional distillation.

It may be remarked in passing that Messrs. Kayser and Friedlander, who supposed that they had observed D_3 in the argon of the atmosphere, have probably been misled by the close proximity of the brilliant yellow line of krypton to the helium line.

On the assumption of the truth of Dr. Johnstone Stoney's hypothesis that gases of a higher density than ammonia will be found in our atmosphere, it is by no means improbable that a gas lighter than nitrogen will also be found in air. We have already spent several months in preparation for a search for it, and will be able to state ere long whether the supposition is well founded.

LYON PLAYFAIR.

IT is now fifty-three years since I first met Playfair. He was President of the Chemical Section of the British Association in 1855 at Glasgow. Frankland and I were the Secretaries. Liebig attended the meeting, and stayed with his friend Walter Crum, and it was appropriate that Playfair, who was one of Liebig's most promising English pupils, should preside over a meeting of chemists at which his German master was present. Playfair then was in the height of his activity. His addresses in 1855, and again thirty years later, when he was President of the Association, although not containing much of striking originality, were clear, luminous expositions, as indeed were his speeches in the House of Commons, and latterly in the House of Lords.

In the year 1834, when he was fifteen years of age, he began to study chemistry under Graham, who was then professor at the Andersonian at Glasgow. After a short visit to his parents in India, where his father was Chief Inspector-General of Hospitals in Bengal, he followed Graham to London, and in 1838 went to Giessen to study under Liebig, then the rising star in the chemical firmament. There he became not only Liebig's pupil, but his friend; he worked at organic chemistry, publishing in 1841 his first paper on a new fatty acid contained in the butter of nutmegs, and in the following year he published an abstract of Liebig's report on organic chemistry as applied to chemistry and pathology. On his return to England, through Liebig's influence with James Thomson, a man who even in those early days saw the value of science as applied to industry, Playfair was appointed as chemist to the well-known calico printworks at Clitheroe. After a few years he exchanged this position for a more suitable one in the Royal Institution, Manchester, where he found more congenial society in the friendship of Dalton and Joule. It was whilst he was in Manchester that Playfair induced Bunsen, who had just perfected his process of gas analysis, to come over to Alfreton to collect the gases of the blast furnace. The results of this visit furnished the first evidence concerning the chemical changes occurring in the blast furnace, and were published in the British Association Reports for 1845.

It was in conjunction with Joule that Playfair's name is best known as an investigator, several memoirs on atomic volume and specific gravity appearing in their joint names in the Chemical Society's *Journal*, the most important result of which was the discovery of the well-known laws relating to the disappearance of the volume of the acid and of the base of crystals of hydrated salts. If Playfair had remained under the influence of Dalton and Joule, his record of original work would probably have been much longer than it is, but his activity was destined to be turned into other channels. Sir Robert Peel, who had heard of Playfair and formed a high opinion of his powers, appointed him on a Commission to inquire into the sanitary condition of large towns, and such matters he found more to his taste than purely scientific research. In recognition of the services which he performed on this Commission, he was appointed chemist to the Museum of Practical Geology. It was here that he carried out his best-known research, namely that on the nitro-prussides, a new class of salts characterised by giving a splendid purple colour with alkaline sulphides. A year or two later preparations were being made for the first great exhibition of 1851, and Lyon Playfair was chosen as a competent man to visit the manufacturing districts to secure the co-operation of persons interested in manufactures and commerce. This somewhat difficult task he accomplished with tact and success, and later on he took a leading part in the classification and arrangement of the exhibits, and the appointment of the juries was mainly left in his hands. A good story is told of his *savoir faire* at the opening of the exhibition, where it was of course desirable to have all nations represented. A very gaily-dressed Chinaman found himself in the procession side by side with the Archbishop of Canterbury, and was about to be removed to some less conspicuous position when the Prince Consort desired he might be left where he was. Playfair's efforts had been successful in obtaining the recognition of China, for, in the absence of any yellow-jacketed mandarin as ambassador, Playfair had got hold of a Chinese ticket-collector of a junk then being exhibited in the docks. Not only during the existence of the exhibition, but even up to the present time, Playfair left his mark on the results of that exhibition, for he was the guiding hand in the numerous and complicated transactions which have taken place since the purchase of the South Kensington Estate by the Royal Commissioners. The foundation of the Science Scholarships, which are now proving such a boon to the aspirants to scientific fame, was entirely Playfair's idea. Working in connection with the exhibition of 1851 brought him into personal contact with the late Prince Consort, in whose household he accepted a post, and it was to Playfair that the Prince was much indebted in his various schemes of land improvement and other scientific matters. A few years later, when the Science and Art Department was put upon a new footing, Playfair was appointed joint secretary with Sir Henry Cole; this partnership, as might be foreseen from the character of the two men, did not last long, and Playfair became Inspector-General of Government Museums and Schools of Science. A more permanent and satisfactory position was, however, now open to him. In 1856 he succeeded Gregory as Professor of Chemistry in the University of Edinburgh, and in this position he remained for thirteen years, and the wags said that he was the only Scotchman who, having tasted the flesh-pots of Egypt, was ever known to return to the land of cakes not plum—but oats.

As Davy's greatest discovery was Faraday, so it may be said that Playfair's was Dewar, who acted for some time as his assistant. The five months' duties of the Edinburgh chair did not by any means exhaust his energies. On the occasion of the second great exhibition of 1862, his services were again called for, and in 1868 he was returned to Parliament in the Liberal interest as representing the Universities of Edinburgh and St. Andrews, a seat which he held for seventeen years. His Parliamentary labours were arduous and important, and his name will go down as representing the reorganisation of the Civil Service. He also presided over many important Committees and Royal Commissions; indeed, it may be said that for many years no official inquiry was considered satisfactory without the advice of Playfair, whose clear head and common sense were always readily placed at the service of the nation. He was Postmaster-General in Gladstone's ministry of 1873, and on the return of the Liberals to power in 1880 he was elected Chairman of Ways and Means, a post which in those stormy days was no sinecure. At the election of 1885, finding his Liberal views did not coincide with those of the University constituencies, he offered himself as a candidate for South Leeds, and was returned also in 1886 and 1892. He was Vice-President of the Council during Mr. Gladstone's short administration of 1886, but was not offered office in 1892, but received the honour of a peerage, which was given him more for his political than his scientific eminence. Playfair was the last remaining original member of the Chemical Society. The banquet which was to have been given in his honour and in that of the other past presidents of fifty years' standing has had to be postponed owing to his somewhat sudden death.

It is to him that we owe the first movement with regard to technical instruction, and his name will go down to posterity as one "who loved his fellow men."

He was laid to rest at St. Andrews, the city from which his family sprang. His merit was recognised by representatives of the Queen and of the Prince of Wales, and numerous friends and admirers, both scientific and political, as well as by the citizens of St. Andrews.

H. E. R.

OSBERT SALVIN, F.R.S.

ORNITHOLOGY and entomology have sustained a great loss by the death of Mr. Osbert Salvin, which occurred on the 1st inst. at his beautiful residence Hawksfold, near Haslemere. The second and only surviving son of the late Mr. Anthony Salvin, the well-known architect, he was born in 1835, and received his education at Westminster and Trinity Hall, Cambridge, where he graduated as a Senior Optime in the Natural Science Tripos of 1857. Immediately after taking his degree he, together with Mr. W. H. Hudleston (then Simpson), joined Mr. (now Canon) Tristram in his natural history exploration of Tunis and Eastern Algeria, where they passed five months. In the autumn of the same year Mr. Salvin proceeded to Guatemala, where, chiefly in company with the late Mr. G. U. Skinner, the celebrated collector of orchids, he stayed till the middle of 1858, returning to Central America (henceforth always to be associated with his name) about twelve months later. He again went out in 1861, accompanied by Mr. Frederick Godman, and continued the explorations he had already begun, but was home again in 1863. In 1865 he married Caroline, the daughter of W. W. Maitland, Esq., of Loughton in Essex, and with her subsequently undertook another voyage to Central America. In 1874, on the foundation of the Strickland Curatorship in the University of Cambridge, he accepted that office, which he filled until 1883, when, on his father's death, he succeeded to the property at Hawksfold, and removed thither, though there was scarcely a week in which he did not pass some days in London; for with Mr. Godman he had conceived the idea of bringing out a "Biologia Centrali Americana," being a complete natural history of the countries lying between Mexico and the Isthmus of Panama. This gigantic task, by far the greatest work of the kind ever attempted, taxed all their united efforts, and those of the many contributors they enlisted, and is still in progress. Before beginning this, Mr. Salvin had edited the third series of the *Ibis*, of which he was one of the founders, and had brought out a "Catalogue of the Strickland Collection" in the Cambridge Museum. He contributed also the *Trochilidæ* (Humming-birds) and *Procellariidæ* (Petrels)—on which he was the acknowledged authority—to the British Museum "Catalogue of Birds," and almost his latest labour was that of completing and arranging the late Lord Lilford's "Coloured Figures of British Birds"; while the Royal Society's "Catalogue of Scientific Papers" enumerates forty-seven published by Mr. Salvin alone, twenty-three by him and Mr. Godman jointly, and fifty-four by him and Mr. Sclater—all before 1884.

Mr. Salvin was a Fellow of the Royal, Linnean, Zoological and Entomological Societies, on the Councils of each of which he frequently served; and it may be truly said that there were few naturalists whose opinion was more often sought, for his advice was generally sound. His figure was well known at the Athenæum Club, and last year he was elected an Honorary Fellow of his old College. He will be greatly missed by a large circle of friends, to whom his quiet and unassuming manners greatly endeared him.

N.

NOTES.

THE freedom of the city of Edinburgh is to be conferred on Lord Lister on June 15.

THE annual ladies' conversazione of the Royal Society was held yesterday, as we went to press.

THE Prince of Wales will open the new buildings of the University Extension College, Reading, on Saturday next, June 11.

A FLORAL fête and children's floral parade will be held in the gardens of the Royal Botanic Society, Regent's Park, from 2 to 7 o'clock to-morrow (Friday).

THE city of Como, the birthplace of Alexander Volta, is preparing to worthily celebrate in 1899 the hundredth anniversary of the invention of the Voltaic or Electric Pile. To commemorate this important event, which has led to some of the greatest discoveries of the present century, there will be held at Como, from May 15 to October 15, an International Electrical Exhibition, to which will be annexed a national exhibition of the manufacture of silk—a branch of trade much developed in Como—and an international exhibition of the machinery, preparation, and process of working the same. Italian and foreign electricians are invited to a Congress, which will be held for the purpose of discussing the progress and applications of electricity. Como is a flourishing city on the main line of St. Gothard, and forty kilometres from Milan. It is pleasantly situated at the foot of the Rhaetian Alps, and on the shores of the most beautiful lake of Lombardy, to which it gives its name. An electrical exhibition ought to succeed in Italy, where the abundant hydraulic power greatly facilitates electric works. The application of electricity to the manufacture of silk must be of interest in Como, where the silk-works are of ancient date, and rapid progress is being made, though the industry is indebted to foreign countries for the machinery and implements. We are informed that foreign inventions will be greatly valued at the exhibition, and will be well placed. For the encouragement of exhibitors, the city of Como has decided to give a sum of 10,000 francs in prizes for new inventions in the field of electricity.

The title of the evening lecture which Prof. W. J. Sollas, F.R.S., will deliver at Bristol on September 9, at the meeting of the British Association, will be "Funafuti, the Study of a Coral Island." Mr. Herbert Jackson has chosen "Phosphorescence" as the subject of his evening discourse on September 12. Mr. W. Whitaker, F.R.S., will be the chairman of the conference of delegates of corresponding societies. Subscriptions to the local fund being raised for the expenses of the meeting now amount to 3665*l.*, and it is hoped that this will be increased to at least 4000*l.*

Our Paris contemporary, the *Revue Générale des Sciences*, has arranged with the Orient Steam Navigation Company, Limited, for the *Lusitania* to make a special cruise to Norway and the North Cape from July 15 to August 10. The boat will leave Dunkerque on the former date and proceed to Bergen, from which place it will go up the coast to the North Cape, calling at Trondhjem, Tromsoe, Hammerfest, and other places of interest. After viewing the midnight sun, the party will leave the North Cape on July 25, and will be taken down to Christiania, visiting many places on the way. Prof. J. Thoulet, professor of mineralogy and oceanography at the University of Nancy, and Baron Jules de Guerne, general secretary of the Société Nationale d'Acclimatation de France, will accompany the tourists, and will give short lectures, with lantern illustrations, on the various features of interest in the places visited. The programme is an attractive one, and provides a pleasant and instructive means of spending a holiday.

A valuable circular (No. 18), dealing with the physics of timber, has just been issued by Prof. B. E. Fernow, Chief of the Division of Forestry of the U.S. Department of Agriculture. The paper is given exceptional importance by the development of a formula worked out by Mr. S. T. Neely, showing how the strength of beams can be determined from the compression strength. In testing timber to obtain its various coefficients of strength, the test which is at once the simplest, most expedient, satisfactory and trustworthy is the "compression endwise test," which is made by crushing a specimen parallel to the fibres. All other tests are either mechanically less easily performed, or else, as in the case of cross-bending, the stresses are complex, and the unit coefficient can be expressed only by depending upon a doubtful theoretical formula. It is, therefore, of great practical value to have a relation between the cross-bending strength—the most important coefficient for the engineer—and the compression strength, and this is what Mr. Neely has found. His discovery is expressed in the following conclusion:—"The strength of beams at elastic limit is equal to the strength of the material in compression, and the strength of beams at rupture can be directly calculated from the compression strength; the relation of compression strength to the breaking load of a beam is capable of mathematical expression." This enunciation is of far-reaching importance, and a comparison of calculated with observed results given in the circular is convincing as to the efficiency of the formula. It is to be hoped that other and similarly successful scientific investigations into the physics of timber will be made in the U.S. Division of Forestry.

The mysterious phenomenon known as "Barisal Guns" or "Mist-poeffers" forms the subject of a useful paper by Dr. A. Cancani in the last *Bollettino* (vol. iii. No. 9) of the Italian Seismological Society. The observations on which his discussion is founded are collected from places in or near the inland province of Umbria, where the noises are known as "marina," it being the popular belief that they come from the sea. The sound is quite distinct and easily recognised; it is longer than that of a cannon-shot, and, though more prolonged and dull, it is not unlike distant thunder. It invariably seems to come from a distance and from the neighbourhood of the horizon, sometimes apparently from the ground, but generally through the air. The weather when the "marina" is heard is calm as a rule, but that it often precedes bad weather is shown by the common saying, "Quando tuona la marina o acqua o vento o strina." The interval between successive detonations is very variable, sometimes being only a few minutes, or even seconds. They appear to be heard at all times of the day and year, the experience of observers differing widely as to the epochs when they are heard most frequently. With regard to the origin of the "marina," Dr. Cancani concludes that they cannot be due to a stormy sea, because "mist-poeffers" are frequently observed when the sea is calm; nor to gusts of wind in mountain gorges, for they are heard on mountain summits and in open plains. If their origin were atmospheric, they would not be confined to certain special regions. Nor can they be connected with artificial noises, for they are heard by night as well as by day, and in countries where the use of explosives is unknown. There remains thus the hypothesis which Dr. Cancani considers the most probable, that of an endogenous origin. To the obvious objections that there should always be a centre of maximum intensity (which is never to be found), and that they are so rarely accompanied by any perceptible tremor, he replies that, in a seismic series, noises are frequently heard without any shock being felt, and of which we are unable to determine the centre.

The American Academy of Arts and Sciences have decided to award the Rumford Medal to Prof. James E. Keeler, director of the Lick Observatory, "for his application of the spectroscope to astronomical problems, and especially for his investigations of the proper motions of the nebulæ, and the physical constitution of the rings of the planet Saturn, by the use of that instrument."

The honour of Knight of the Order of the Polar Star has been conferred upon Dr. J. Scott Keltie by the King of Sweden and Norway.

Dr. R. Koch has been consulted by the East African Protectorate as to preventive measures against rinderpest, which is again rampant in the interior. Dr. Macdonald, the principal medical officer, and Veterinary-Captain Haslam, M.D., have visited Zanzibar to represent the Protectorate on this and other infectious diseases. Dr. Haslam will proceed to the seat of the disease, and direct preventive measures.

We learn from the *British Medical Journal* that the monument to Pasteur, which is to be erected in Paris in the space in front of the Pantheon, is now almost completed. M. Falguière, the sculptor, has introduced certain modifications into his original design, in which Pasteur was simply represented as overcoming Death, which was in the act of flight. Now a group of a mother with her child, thanking Pasteur, has been added on the right, while behind the central figure Fame is shown crowning him with laurels. The international subscription to the memorial now amounts to nearly 13,000*l.*

The Local Government Board, acting under the recommendations of recent Commissions as to the cultivation in glycerine of vaccine lymph before such is applied to the human body, has (says the *Times*) leased a large laboratory and several office rooms at the British Institute of Preventive Medicine, on the Thames Embankment, for the purpose of cultivating the lymph. The bacteriological expert who has been appointed to take chief control of the new laboratory is Dr. F. Blaxall, lecturer on bacteriology at Westminster Hospital. He will have an assistant, who has already been nominated, and an efficient staff. The calves from which the vaccine lymph is taken will be kept for the present at the Government calf establishment near the Foundling Hospital, and the lymph will be taken thence to the Thames Embankment in its pure state to be prepared and stored in glycerine.

WE regret to announce that Mr. Henry Perigal, the treasurer of the Royal Meteorological Society, died on Monday at the advanced age of ninety-seven years. Mr. Perigal was the author of various works on astronomy, bicycloidal and other curves, kinematics and the laws of motion, probable mode of constructing the Pyramids, &c. He was a constant attendant at the meetings of various London scientific societies until within two years of his death. He was a Fellow of the Royal Astronomical, Royal Microscopical, and Royal Meteorological Societies, as well as a member of several other scientific associations.

THE *Times* announces the death of the Rev. Percival Frost, F.R.S., on Sunday last, in his eighty-first year. Born at Hull, he was educated at Beverley, Oakham and Cambridge, where he was second wrangler and first Smith's prizeman in 1839, Fellow of St. John's College from that year until 1841, mathematical lecturer at Jesus College from 1847 to 1859, mathematical lecturer at King's College, Cambridge, from 1859 to 1889. He had been a Fellow of King's College since 1882, and was elected a Fellow of the Royal Society in 1883. Dr. Frost was the author of treatises on "Curve Tracing," "Solid Geometry," "The First Three Sections of 'Newton's Principles,'" as also of numerous papers published in various mathematical journals.

SIR ROBERT RAWLINSON, K.C.B., eminent by his works in civil and sanitary engineering, died on Tuesday, May 31, at the age of eighty-eight. He was a vice-president of the Society of Arts, and from 1849 to 1888 was chief engineering inspector of the Local Government Board. He took a foremost part in the development of sanitary science, and as a member of the Army Sanitary Commission in the Crimea was able to vindicate the soundness of his sanitary teaching. The beneficial results obtained by the Commission led to increased attention being paid to sanitary requirements, and thus brought about a very great reduction in the annual mortality of the British Army. Sir Robert Rawlinson acted as chairman of the Royal Commission on the Pollution of Rivers in 1866, and also served on the Commission which inquired into the sanitary condition of Dublin in 1879. He became a member of the Institution of Civil Engineers in 1866, and president in 1894. At one period he took a considerable part in the proceedings of that body, discussing mostly questions connected with drainage and water supply, of which his official position gave him a wide experience.

IT has already been announced that the autumn meeting of the Iron and Steel Institute will take place at Stockholm on Friday and Saturday, August 26 and 27 next. Particulars of the special transport arrangements, which have been made for the convenience of members attending the meeting, have now been issued. A special steamer, of over 3000 tons, chartered by Dr. H. S. Lunn and Mr. Woolrich Perowne, will leave Newcastle-on-Tyne on Wednesday, August 17, and will proceed by way of the Baltic Canal, Kiel and Wisby to Stockholm, where she will lie, and serve as a floating hotel, from Thursday, August 25, to Sunday, August 28. The return journey will be by way of Copenhagen, Gothenburg and Christiania. Dr. Lunn and Mr. Perowne have also arranged for the S.S. *St. Sunniva*, a one-thousand ton boat, to leave Leith on Saturday, August 20, proceeding by way of Christiania to Stockholm, where she will lie on Friday, Saturday and Sunday, August 26, 27 and 28, proceeding from Stockholm to St. Petersburg, and returning by way of Copenhagen and the Baltic Canal. The Orient Steam Navigation Company, Limited, have re-arranged the itinerary of their pleasure cruise No. 3 to the Baltic, so as to bring their S.S. *Lusitania* (3912 tons) to Stockholm on Thursday, August 25, and to keep her there until Sunday, August 28. The itinerary includes visits to Copenhagen, Wisby, Stockholm, Kronstadt, St. Petersburg, Kiel, and the Baltic Canal. The Great Eastern Railway Company has promised to afford special facilities to members travelling by the Continental route. The arrangements which are being made by the Local Reception Committee for the instruction and pleasure of the members, and the ladies accompanying them, are making satisfactory progress, and the detailed programme will be issued in due course.

IN view of the forthcoming conference of representatives of Sea Fishery Committees convened by the Board of Trade, a preliminary meeting of the representatives was held on Tuesday at the Guildhall, Westminster, to obtain a consensus of opinion on the subjects which are to be considered. It was resolved that a deputation should urge on the Government the need of legislation to protect immature sea fish and the enlargement of the powers of Sea Fishery Committees. A resolution was also carried in favour of the formation of an association of Fishery Committees.

THE Belgian Government having decided to offer a premium of 50,000 francs to the inventor of a paste for matches which will be free from white phosphorus and which will ignite on cloth or any other surface, a Ministerial decree has been issued determining the conditions. The competition will be international in character, and will remain open until January 1, 1899. Communications on the subject are to be addressed to M. Woeste, the president of the Commission appointed to adjudicate, at 2 Rue Laterale, Brussels.

HERR N. A. MÖLLER, in Eberswalde, has sent us a communication in which he states that he has undertaken a labour of love which will not be easy unless he is helped by many who are in the position to assist him. Fritz Müller, the naturalist, an old friend of his, died in Brazil, and Herr Möller wishes to raise a monument to his name by publishing a work which will contain an account of his life, character, method of work, his most important letters, and if possible his most valuable scientific writings. With this intention Herr Möller requests all those of our readers who possess any manuscripts, letters, &c., which may be found useful in such a biography, to forward them to him in Eberswalde, where they will be taken the greatest care of and returned when finished with.

A SYLLABUS prepared by Mr. R. De C. Ward, containing an outline of requirements in meteorology, intended for use in preparing students for admission to Harvard College and the Lawrence Scientific School, affords evidence that careful and systematic work in meteorology is given more encouragement in the United States than it receives here. The scheme of work indicated in the syllabus will train the student to scientific methods of investigation, and will make him to some extent a thinker and investigator on his own account.

IN our issue of April 8, 1897 (vol. lv. p. 542), we drew attention to an important investigation by Dr. O. Pettersson, with the object of showing that certain relations existed between the behaviour of the Gulf Stream and the subsequent general character of the weather over Europe, the results of which were based upon observations made during about twenty years at three stations on the Norwegian coast. In the *Meteorologische Zeitschrift* for March last, Dr. W. Meinhardus, of Berlin, continues the investigation in an article entitled, "On some

Meteorological Relations between the North Atlantic Ocean and Europe during the Winter Half-year," based upon a much longer series of observations. The results confirm those of Dr. Pettersson in a very satisfactory way, and show that a good idea of the temperature over a large area may be predicted with a considerable probability of success, and that, generally speaking, a high (or low) temperature of the Gulf Stream on the Norwegian coast in the first part of the winter (November to January) is usually followed by a high (or low) air-temperature in Central Europe in the latter part of the winter (February to March) and the early spring (March and April). It will be seen that the investigation refers entirely to the winter months.

MR. H. PARKER gives, in the *Ceylon Observer* of May 12, a detailed account of the abnormal rainfall of 31·72 inches in twenty-four hours, experienced at Nedunkeni, in the Northern Province of Ceylon, last December, and already briefly described by a correspondent in these columns (p. 78). Nedunkeni, eleven miles down the southern road to Mullaittivu, and 122 feet above sea-level, is a small village a little to the east of the dividing ridge of North-Central Ceylon, and though itself in the catchment area of the eastern Per Aru, which flows through Tannir Murippu Tank, it is only a little to the south-west of the point where three separate drainages meet. Forest, containing a thick growth of high trees, extends over the neighbourhood, and more especially for many miles from the south to the east. For about three years a rain-gauge has been established in the grounds of the dispensary in the village, and its records are regularly transmitted to the Public Works Office, and are published among the rainfall returns. Although the mean annual rainfall at Nedunkeni is probably little more than 50 inches, the fall for last December was 67·07 inches, and of this amount 31·72 inches were measured at 9.30 a.m. on December 16 as the rainfall of the preceding twenty-four hours. From an examination of the position of the rain-gauge, and the testimonies of the observers, Mr. Parker concludes that most probably the actual rainfall was in excess of the recorded amount.

WEATHER influences on farm and garden crops are discussed in an interesting address by Mr. Edward Mawley, published in the *Quarterly Journal* of the Royal Meteorological Society (April). After giving a short sketch of the climate of the British Isles as a whole, Mr. Mawley considers separately some of the effects produced on vegetation in this country by varying temperatures, by scanty and heavy rains, by sunshine and by wind; and afterwards treats of the leading farm and garden crops, and their special requirements with regard to atmospheric conditions. The paper should be of service in showing how intimate the connection is between meteorology, agriculture and horticulture.

MR. T. MELLARD READE informs us that a very large boulder of gypsum has been uncovered by the excavations in the brickworks of Mr. Ed. Peters, Cooks Lane, Great Crosby, near Liverpool. It is embedded in and completely surrounded by a thick bed of brown boulder clay, the bottom of the boulder being about 17 feet below the surface of the ground. The boulder measures 11 feet by 6 feet by 6 feet extreme dimensions, and weighs about 13 tons. "Small pieces of gypsum and plates of selenite are," adds Mr. Reade, "not uncommon in our boulder clays; but this individual boulder not only far surpasses in size any drift fragments of gypsum hitherto found, but is actually the largest boulder of any sort that I have seen taken out of the boulder clay, or recorded from it in the neighbourhood of Liverpool."

IT is known that a function of two variables x and y may have a maximum or minimum value along every straight line passing through a certain point O without the function necessarily being itself a maximum or minimum at that point. A simple proof that the same cannot be the case if the function is a maximum at O, not only for all *straight* lines, but also for all continuous lines through O, is given by Signor G. Vivanti in the *Atti de Lincei*, vii. 8.

THE Royal Academy of Sciences of Naples has hitherto been supposed to have originated about the year 1732, but from a communication published in its *Rendiconto*, by Prof. Federico Amodeo, we learn that the foundation of the Academy has been traced back thirty-four years earlier. In 1698, under the Viceroy, Luigi della Cerda, Duke of Medinacoeli, there was founded, in Naples, a literary and scientific society called the Palatine Academy; this society appears to have been overlooked by historians, owing to the fact that no published writings of its members had come before their notice. Prof. Amodeo has now succeeded in discovering a number of printed papers, notably two scientific works of the mathematician Antonio Monforte, affording abundant proof of the existence and activity of this, the parent of the present Academy, which thus dates from the year 1698.

PROF. P. DE HEEN continues his researches on so-called "infra-electric" radiations in the current number of the *Bulletin de l'Académie royale de Belgique*. The author is led to the conclusions that every source of disturbance in the ether gives rise not only to known radiations, but also to other rays vibrating in a different manner. These rays have the same properties as Röntgen rays in the matter of their action on dielectrics, charged conductors and electric fields, and differ from them in the matter of wave-length. They are absorbed so much more readily than ordinary light waves, that any such rays which emanate from the sun are completely sifted out by our atmosphere. In accordance with M. Perrin's views, the discharge of a conductor by these rays is chiefly due to their action on the lines of force. Lastly, an electric field is found to behave towards infra-electric rays as an opaque medium.

AN extremely simple commutator for converting an alternating current into a direct one is investigated by Signor A. Dina (of Zürich) in the *Rendiconti del R. Istituto Lombardo*, xxxi. 9. From the experiments of Prof. Grätz (of Munich) and Herr Pollak (of Frankfort), it appears that an aluminium element capable of evolving oxygen at the anode produces a remarkable weakening of the current, and if the electromotive force is less than 22 volts, practically no current flows; but if the pole in question is made the kathode, no perceptible change in the current takes place, the electromotive force of the element being less than 1 volt. Hence it is easy, by arranging such elements in series, to obtain a combination which will only allow currents to pass in one direction, and which will resist any required electromotive force in the opposite direction. From experiments now described, the present writer concludes that the action of the elements is similar to that of a condenser, the aluminium becoming coated with a film of oxide which plays the part of dielectric. Signor Dina has not succeeded so far in putting the method to any practical use, though Herr Pollak claims to have done so.

A SERIES of experiments on the action of opaque tubes on Röntgen rays passing down them is described by Prof. Villari (*Atti dei Lincei*, vii. 8, and *Rendiconto dell' Accademia di Napoli*, iv. 3, 4). In a series of previous experiments, Prof. Villari found that in traversing a long tube opaque to them, these rays lose a large part of their power of discharging an electrified conductor at the end of the tube. This effect the author now attributes to the action of the tube in cutting off lateral rays, which, by their action on the surrounding air, would accelerate the discharge. In the matter of photographic action, Prof. Villari finds no difference between rays which have passed through a tube and those which have not, and he concludes that Röntgen rays are neither reflected nor diffused by the walls of the tube, and that the transmitted rays are probably in no way modified by its presence.

MR. ERNEST HOSE communicates to the *Sarawak Gazette* for May some observations on an encounter between a python and wild pigs in the jungle at Tambak. A young pig had been seized by a large python, and the cries of distress summoned about twenty of the herd to an attack. They gored the python savagely with their tusks, and so harassed and lacerated it as to force it to relinquish its prey. The python was ultimately killed by Mr. Hose.

AN interesting note on Chinese antiquities is given in the consular report on Shashih (C. 8648–108 of 1898), just issued. Shashih contains a pagoda dating, it is said, from the ninth century, and there are other remains. There are distinct traces of the town having been at one time fortified, the earth nucleus of a wall and six brick gateways being still visible. The place is one of considerable interest to the archæologist and student of ethnography. All round Chingchou, which is about two miles from the north-west extremity of Shashih, are mounds, earthworks, look-out terraces, &c., the remains of ancient cities and fortresses, which mark the sites of successive capitals and strongholds of the ancient kings of Ch'u and their local successors from the very dawn of authentic history. These remains are not described in the report, but it is stated that the traditions attached to them cluster round the capture of the capital of Ch'u by the Prince of Ch'in in 278 B.C., its destruction as an independent kingdom half a century later, the part it played in the wars of the second and third centuries A.D., and the momentary revival of independence in the tenth century as the principality of Nan P'ing.

ANOTHER report on China, very important for commercial purposes, "Trade of Central and Southern China" (C. 8649–29 of 1898), contains some geographical and other notes of interest, together with maps. K'uei Fu is interesting as one of the oldest sites of Chinese occupation in these parts, dating from the beginning of our era. Geographically it marks the point of junction of the limestone mountains, athwart which the Yang-tze has forced a way in 100 miles of rapids and gorges, and the red sandstone formation of Ssŭ-ch'uan. A mile beyond Tzŭ-t'ung-chen there is a once-renowned Buddhist temple, and still noteworthy for its gigantic figure of Buddha, about 80 feet high, 5 feet across the toes of one foot, cut in high relief out of the solid rock and overlooking a bad rapid in the river, over which it is thought to have a sort of divine superintendence. Though cut in A.D. 1126, it is still in excellent preservation, and evidently much respected. The temple on the bluff behind the image was once on a grand scale, but it has been allowed to fall into utter ruin. In the region beyond this is the plain of Sui-ning, composed of solid alluvium 30 feet deep. There are frequent little temples to the god of the soil, usually of solid stone, the image being enclosed by open fretwork, so that the god cannot see out. The city of Ch'êng-tu is defended by huge walls and gates. The first wall was built in the third century B.C., shortly after the Chinese reduced the old aboriginal state of Shu, and began to colonise this country; the present wall was built in 1784, and is really a magnificent structure, and in almost perfect preservation. Opposite the city of Chia-ting has been cut in high relief a huge figure of Maitreya Buddha, no less than 380 feet high. Between Hêng-chiang and Lao-wa-t'an is the territory of the independent people Lolo, a race akin to the Thibetans, and perhaps the Burmese, who peopled these parts before the Chinese, and whom the latter have never subdued, although they have been attempting the enterprise for nearly 2000 years. The eastern part of the Red Basin was early peopled by the Chinese race, and in the third century A.D. Ch'êng-tu was the capital of the western of the three kingdoms into which China was then divided. At the end of the Ming dynasty (1640) the inhabitants were destroyed in one of those social cataclysms that have occurred with much regularity every few hundred years in Chinese history. When order was restored by the present dynasty, the province was colonised chiefly from Hupei and Hunan on the east. Altogether this is a most interesting report; and though intended for trade, the ethnographer and geographer will obtain many useful notes therefrom.

UNDER the title of "The Adulteration of Dairy Produce," Mr. R. Hedger Wallace has brought together a mass of statistics relative to the quality of the articles which come under the above head. The author's original paper was read before the Royal Scottish Society of Arts in Edinburgh, and it constitutes a formidable indictment against the conduct of dairying both at home and abroad. The butter we import is apparently frequently shamefully adulterated. The reputed pure Normandy and Brittany butters, we are told, for example, have been found to contain as much as from 30 to 40 per cent. of margarine; and not only is this latter material employed to swell the volume of first-class butter exported to this country from these districts, but butter of inferior quality is imported from Central France, Italy, and even Australia, to be *blended* and forwarded to us as the best Normandy and Brittany butter. Another plan consists in importing Belgian butter, which enjoys a by no means high reputation, and then shipping it from Calais to England as Normandy butter, whilst Australian butter is also *worked up* to sell in London under the Isigny mark, a noted brand of Normandy butter. In the space of a little over two years it appears that of the samples of butter taken at port of entry into this country and analysed, 10½ per cent. of the Dutch samples were adulterated, 2 per cent. of the Danish, 19 per cent. of the German, 5½ per cent. of the Norwegian, and 7 per cent. of the Russian. Unfortunately such adulteration is not confined to our friends across the Channel, and the practice of working up butters, as it is called, is carried on at home as well. It is clear that such extensive adulteration, as Mr. Wallace assures us goes on in the butter trade, ought to be energetically dealt with by our public authorities. Another important matter discussed by the author is the use of antiseptics or preservatives to milk, technically known as "drugging" the milk. We know that the addition of chemicals to milk as preservatives is prohibited in France on the grounds of unwholesomeness; cannot we induce responsible officials in this country to bring this matter to the notice of the Government, and have such treatment of milk included under the head of adulterants? The New York law on dairy products, passed in 1893, enacts, among other things, "that milk is adulterated to which has been added, or into which has been introduced any foreign substance whatever." Surely it is time steps were initiated, if not by authorities responsible for the purity of our food supplies, then by the public themselves, to put a stop to so reprehensible a practice.

As contributions to our knowledge of the Flora of India, we have received reprints of the tenth portion of the materials for a Flora of the Malayan Peninsula by Dr. George King, and of a paper on some new Malayan orchids by Dr. G. King and Mr. R. Pantling.

IN the *Kew Bulletin* No. 132, Mr. George Massee has a note on the obscure disease which is often very destructive to young fruit trees, known as "slime-flux." Mr. Massee attributes the injury to the combined attacks of a Schizomycete, *Micrococcus dendroporthes*, and of the aquatic condition of a fungus *Torula monilioides*. The *Micrococcus* is the active agent in producing fermentation, but can enter the tissues of the plant only through injuries in the bark.

THE additions to the Zoological Society's Gardens during the past week include a Servaline Cat (*Felis servalina*), a Serval (*Felis serval*) from Uganda, presented by Mr. Francis G. Hall; a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, presented by Mr. P. G. Dupuch; two Golden Eagles (*Aquila chrysætus*), European, presented by Edgar Baxter; a Yellow-billed Sheathbill (*Chionis alba*), captured at sea, presented by Captain H. W. Schlemann; a Bean Goose (*Anser secetum*), European, presented by Mr. W. H. St. Quintin; two Egyptian Kites (*Milvus ægyptius*) from Congoland, presented by the Rev. R. H. C. Graham; a Common Viper (*Vipera berus*) from Cornwall, presented by the Rev. John Harris; a Burchell's Zebra (*Equus burchelli*, ♂) from South Africa, deposited; two Black Hornbills (*Lophoceros nasutus*) from West Africa, a Yarrell's Curassow (*Crax carunculata*) from South-east Brazil, a Guan Ortalida from South America, a Double-ringed Turtle Dove (*Turtur bitorquatus*) from Java, purchased; an English Bull (*Bos taurus*) born in the Gardens.

Erratum.—In the classification of Bacteria given in the review of Prof. Migula's work on "Systematic Bacteriology," which appeared in last week's NATURE, the term "genus" should be substituted for "species."

OUR ASTRONOMICAL COLUMN.

THE COMPANION TO PROCYON.—As is well known Prof. Schaeberle discovered in November 1896 a companion to Procyon, which he suggested would prove the theoretical companion predicted by Bessel. This difficult object—difficult on account of its nearness to Procyon, not by reason of its faintness—has been satisfactorily observed at the Yerkes Observatory, thus confirming Prof. Schaeberle's measures, the motion of the object, and its suggested identity with Bessel's companion. We have now the following measures:

1896, November ...	P = 318°·8 ...	D = 4″·59
1897, October ...	P = 324·1 ...	D = 4·70
1898, March ...	P = 326·0 ...	D = 4·83

Prof. Barnard, who reports the observation, says that when the seeing is good, the companion star is a very conspicuous object and easy to measure with the bright star in the field unobscured. It was estimated to be one magnitude fainter than the old companion, which is of about the twelfth magnitude. This description, however, scarcely agrees with that of Prof. Schaeberle, who states that he made a measure of the star in November 1897, ten minutes before sunrise, and when looking along the outside of the telescope Procyon was no longer visible in the sky. This would imply that the comes was brighter than the thirteenth magnitude, and therefore more observations may be anticipated.

THE LIVERPOOL OBSERVATORY.—We have received the annual report of the director of the Liverpool Observatory, and are glad to see that he is making some attempt to break away from the mere meteorological observations, which have so long held sway at this observatory. The present attempt is a very small one, consisting merely in the observation of the Right Ascension of some of the circumpolar stars that Prof. Auwers has suggested should be continuously observed, with the view of affording more frequent opportunities, and more accurate determinations of the azimuthal error of transit instruments. Cometary observations have always formed a part of the routine work of this observatory, since the appointment of the present director. These are still being actively prosecuted, when the brightness of the comet permits. We notice also that the observatory is taking some part in the inquiries that are now going on in seismometry and the physics of the earth's crust.

SUNSPOT PERIODS AND NATURAL PHENOMENA.—In an article entitled "Le Soleil et la Nature" in the *Bulletin de la Société Astronomique de France* for June, M. Camille Flammarion brings together some very interesting data concerning the connection between the sunspot period and the yearly return of swallows, cuckoos and nightingales, and the flowering of chestnuts and lilacs. The observations have been extended over several years. In the case of the chestnuts and lilacs, M. Flammarion himself commenced the series in the year 1871, and not only observed the same trees every year when they began to bud, but employed the same scale of observation from the first; the observations are thus homogeneous throughout. In the remarkable series of figures accompanying the article, M. Flammarion has grouped together the observations of three years, and plotted curves which undoubtedly suggest a connection between one another, and with that representing the number of spots on the sun. Further, when spots are most numerous migratory birds return to any one place earlier in the year than usual, and when spots are at a minimum they do not come back until a much later date. In the case of swallows this is very remarkable, as observations of their time of return have been made since 1853, a period of forty-five years. The curve has a period of about eleven years, and the times of the maxima and minima correspond well with those of the sunspot curve.

Another curious fact M. Flammarion points out is that the curves showing the temperature of the months of March and April and the mean temperature of the year are nearly identical for the period covered by the years 1876–97.

DOUBLE AND MULTIPLE SOUTHERN STARS.—On April 28 of this year we noted in this column that Dr. T. J. J. See had published in the *Astronomical Journal*, Nos. 431–432, some details of his plan of double and multiple southern stars, and the first part of a catalogue of new double stars. In the current numbers of the *Astro. Nachr.* (Nos. 3495–6) he publishes a further catalogue containing the measures of those systems made at the Lowell Observatory during the past year and four months. In many instances these measures are the first that have ever been made, and on that account a great part of the accompanying results possess a degree of interest equal to that of the first measures of new double stars. Messrs. W. A. Cogshall and S. L. Boothroyd have ably assisted Dr. See in this work.

THE ROYAL OBSERVATORY, GREENWICH.

ON Saturday last (June 4) the Astronomer Royal presented his annual report to the Board of Visitors of the Royal Observatory, Greenwich. As usual the numerous guests numbered among them many astronomers and other men of science; and the weather, though at times threatening, proved sufficiently fine to allow the buildings and instruments to be comfortably inspected. The following brief *résumé* is taken from the report:—

Buildings.

The buildings on the south side of the grounds, which form part of the new physical observatory, are now approaching completion, having been delayed somewhat by a failure in the supply of terra-cotta. Up to the present time the construction of the magnetic pavilion has not been commenced, although provision has been made for it and a good site selected. It is hoped that this will no longer be delayed, for the amount of iron recently used in the construction of the new physical observatory has a very decided effect on all the magnetic instruments in the old buildings. For some months past we have noticed a scaffolding outside the dome of the 28-inch. This we read was put up in February last in preparation for erecting a balcony round the building, but the plans were subsequently reconsidered and modified, and the work in consequence delayed. The electric light and telephone communication has been extended to the new buildings, and a new accumulator house is being constructed in the basement on the north-east side of the physical observatory to replace the shed in which they are now located.

Transit Circle.

A diagram on the wall of the transit room showed a curve which had been plotted, the points in the curve representing the number of R.A. observations and circle readings for each year from 1877. A glance at this curve showed that the number of transit observations during the more recent years has increased by leaps and bounds, and where in place of the usual 4000 observations per year in 1877–80, the number now has reached the figure 11,000. This year the transits, counting separate limbs as one observation, amount to 11,441, excluding determinations of collimation error 297 and level error 651. The circle readings were 10,626. The correction for the R.D. discordance for 1897 has been found to be very small, amounting to $+0''.068 + 0''.104$ sin L.D. The colatitude of the transit circle obtained from 800 stars in 1897 was 38° 31′ 21″·69, differing by $-0''.21$ from the adopted value.

The mean error of the moon's tabular place (computed from Hansen's lunar tables with Newcomb's corrections) is $-0^s.142$ in R.A. and $+0''.27$ in N.P.D. deduced from 95 observations. These are equivalent to an error of $-1''.97$ in longitude and $+0''.16$ in ecliptic north polar distance.

The New Altazimuth.

The axis of this instrument has been considerably stiffened, and modifications in the friction rollers have been made to relieve the weight of the instrument on its bearings. Changes have also been made in the illumination of the field and microscopes. In December last the instrument was brought into working order; but regular observations have only recently been commenced, as the determination of division errors, and other observations necessary to test the stability of the instrument, occupied several months' work.

The observations on the whole show satisfactory stability in the instrument, the collimation, level, and azimuth being steady. Long series of observations of the nadir point have been made to test the stability of the microscopes and of the instrument generally for zenith-distance observations. Discordances were found in the results given by the two circles, which, after a considerable time had been spent, were traced to the wheel carrying one of the sets of microscopes, which was found to have worked loose. This was remedied recently, and the accordance in the results from the two circles appears now to be satisfactory. But large changes in the readings of the individual microscopes are found on turning the instrument into different azimuths, which, however, would not affect the observations, as the microscopes come back to sensibly the same readings for the same azimuth. As, however, this implies a displacement of the microscopes relatively to the circles when the instrument is turned, Mr. Simms is considering whether the supports of the microscopes and pivots can be stiffened.

Thompson Equatorial.

Photographic tests with the 26-inch object-glass, varying the distance between the two lenses, show that the images were never good when away from the centre of the field. The glasses were, therefore, sent back to Sir Howard Grubb for alteration, and have only just been returned. A few trial photographs show that the "coma" is now corrected, but that a slight refiguring is still required. This, we are told, is being now done by Sir Howard Grubb at the observatory.

The 30-inch Cassegrain, mounted on the other end of the declination axis, has been employed for obtaining photographs of the moon, star clusters, and star fields. These have all been obtained at the secondary focus, the focal length of the mirror being somewhat longer than that for which the tube was designed, making it impracticable to take photographs with it at the primary focus. Dr. Common proposes to supply another mirror of the correct focal length, 11 feet 3 inches.

The photographic spectroscope has been completed, and is mounted at the back of the cell of the 30-inch mirror, but the diagonal prism to reflect the rays from the Cassegrain telescope into the collimator has not yet been mounted and adjusted.

The 28-inch Refractor.

This instrument was in use for micrometric measurements from 1897 May 11 to 1898 May 10, with the exception of about seven weeks, from August 5 to September 23, when it was used for photography, the crown lens being reversed. During the year 273 double stars have been measured, each star being measured on the average on two nights; the distance between the components of these stars is less than 1″·0 in 156 cases, and in 63 less than 0″·5.

From August 5 to September 25, 1897, the instrument was used with the crown lens in the photographic position. During this period 110 measurable images of 17 double stars were obtained on dry collodion plates. The closest of these pairs were:—

	Magnitudes.	Distance.
		″
Σ 2881	7·7 and 8·2	1·6

Σ 2799	6·6 ,, 6·6	1·3

Astrographic Equatorial.

The following statement shows the progress made with the photo-mapping of the heavens:—

	For the Chart. (Exposure 40m.)	For the Catalogue (Exposures 6m., 3m., and 20s.)
Number of photographs taken	363	147
,, successful plates	285	118
,, field photographed successfully	283	110
Total number of successful fields reported 1897 May 10	551	814
Number of photographs, previously considered successful, rejected during the year ...	6	15
Total number of successful fields obtained to 1898 May 10 ...	828	909
Number still to be taken	321	240

An important but unsatisfactory discovery has been made by an examination of all the plates on the shelves. This has shown that 166 catalogue plates out of 909—that is, nearly one-fifth of the total number—and 90 chart plates out of 828 have deteriorated owing, probably, to the effect of damp in the building in which they have to be stored pending the completion of the new physical observatory. There is difficulty in warming this building adequately, and the books, as well as the photographs stored there, have suffered from damp. The film has, in some cases, left the glass, and in the others shows signs of doing so. Of the 166 damaged catalogue plates, 57 have been completely measured, 23 partially measured, and 86 are not measured.

The importance of making duplicates as soon as possible of all negatives in such a work as this cannot be underrated. Positives on glass of all the 90 damaged chart plates were taken, and these are uninjured.

Of the fields still required, 197 are within 10° of the Pole, and no photographs of this part of the sky have yet been taken, the work being purposely deferred till near the epoch 1900. It is proposed to begin taking these now, and the settings of the scales for the guiding stars are partly computed.

Spectroscopic and Heliographic Observations.

No spectroscopic observations have been made during the last twelve months.

With the Dallmeyer photo-heliograph photographs of the sun have been secured on 191 days, 355 of these being selected for preservation, besides nine photographs with double images of the sun for the determination of zero of position. With the Thompson 9-inch photo-heliograph twenty-two photographs were taken on twelve days. Photographs to supplement the Greenwich series have been received from India and Mauritius up to 1898 February 22.

For the year 1897 Greenwich photographs have been selected for measurement on 183 days, and photographs from India and Mauritius (filling up the gaps in the series) on 181 days, making a total of 364 days out of 365 on which photographs are available. The importance of utilising the clear sky of India and Mauritius for obtaining the photographs can hardly be better demonstrated than by the figures given above, which show that on only one day out of the whole year a photograph record of the sun's disc was not secured.

There has been but little change in the mean daily spotted area of the sun for the period covered by the report as compared with the preceding one. The progress towards minimum has shown itself rather in the increase of days when the sun was wholly free from spots, than in the poverty of the displays of spots on the days when the sun's surface was disturbed.

It will be remembered that about the time of the recent eclipse in January there were several, comparatively speaking, large spots on the solar disc, considering that the minimum period was so near at hand.

The remark made regarding the deterioration of the astrographic plates applies also to many of the solar photographs, an examination having shown that some of those stored in the new library and in the museum of the physical observatory, both gelatine and wet collodion, have suffered from damp, spots of mildew being found on the film, though much more frequently the mildew is confined to the uncoated side of the glass.

Magnetic Observations.

Fortunately for the magnetic records secured at the observatory, the proposed electric tram-line in the neighbourhood of the Deptford Cattle Market has been successfully opposed. That this would have seriously damaged the records there can be absolutely no doubt, since it would have been only 1¼ miles from the observatory: even now small agitations, due to the running of trains on the South London Electric Railway, 4½ miles from the observatory, can be clearly traced from the year 1890 on the horizontal and vertical force sheets, synchronising with the disturbances in the earth current registers.

The principal results for the magnetic elements for 1897 are as follows:—

Mean declination	16° 50′·4 West.
Mean horizontal force by the Gibson instrument in the library ...	3·9877 (in British units). 1·8387 (in metric units).
Mean dip	67° 5′·5 (by 9-inch needles). 67° 6′·8 (by 6-inch needles). 67° 7′·1 (by 3-inch needles).

These results are to a certain extent affected by the iron in the new physical observatory and in the new altazimuth pavilion. To eliminate this effect as far as circumstances would allow, observations have been made during the past year on the site selected for the new magnetic pavilion in Greenwich Park, which is presumably free from any disturbing effect of iron. The horizontal force has been observed monthly on this site with the two deflection instruments (Gibson and Elliott), the declination occasionally with the Elliott instrument, and a dip with a Kew dip circle (Dover 74).

It appears from these observations that the declination at the observatory has been increased by 3′ to 4′ through the introduction of iron.

The mean horizontal force obtained with the Gibson instrument in the park is 1·8366 in metric units. In the same units we have also the following differences:—

Gibson in library—Gibson in park ...	+ 0·0021
Elliott in library—Elliott in park	+ 0·0084
Elliott in its usual position in library—Elliott on Gibson pier	+ 0·0060
Gibson in park—Elliott in park	+ 0·0010

All the magnetic disturbances during 1897 were of a comparatively trifling nature.

Meteorological Observations.

The mean temperature of the year 1897 was 50°·3, being 0°·9 above the average for the fifty years 1841–1890.

During the twelve months ending 1898 April 30, the highest daily temperature in the shade recorded on the open stand was 90°·2 on June 24. The highest reading recorded in the Stevenson screen was 87°·4 on the same day. The monthly mean temperatures were in excess of their corresponding averages in every month with the exception of May, September, and March. In January the excess amounted to 5°, the mean temperature for that month being 43°·6. In the preceding fifty-seven years there is one instance only of a higher mean temperature occurring in January, viz. in 1884, when it was 43°·9. A mean value equal to the present January value (43°·6) was also recorded in two other years (1875 and 1890). The winter of 1897–1898 was remarkably mild throughout, and the temperature of the air fell to freezing point (or below) on twenty-nine days only—ten of these occurring in March and seven in December. The lowest temperature recorded during the winter was 23°·3 on December 24. [The lowest temperature recorded in January was 30°·0.] The mean temperature for the five months 1897 October to 1898 February, was 44°·6, being 2°·4 in excess of the average value. During the whole period of fifty-seven years (1841 to 1897) this value has only been exceeded three times, viz. in the winter of 1876–1877, when the mean for the five months was 45°·8, in the winter of 1845–1846, when it was 44°·8, and in the winter of 1865–1866, when it was 44°·7. A mean value of 44°·6 (the same as that for the present year) was also recorded in the winter of 1848–1849, and in that of 1868–1869.

The number of hours of bright sunshine recorded during the twelve months ending 1898 April 30, by the Campbell-Stokes instrument, was 1529 out of the 4454 hours during which the sun was above the horizon, so that the mean proportion of sunshine for the year was 0·343, constant sunshine being represented by 1.

An interesting comparison is made between the results as given by the new and the old ball of the sunshine recorder for 1897. With the former 1542·6 hours were registered throughout the year, while with the latter only 1268·4 hours, the excess with the new ball amounting to 274·2 hours during the twelve months.

The rainfall for the year ending 1898 April 30 was 17·33 inches, being 7·21 inches less than the fifty years' average. The number of rainy days was only 149. This is a very small annual rainfall; the three smallest falls during the preceding fifty years being 16·38 inches in 1864, 17·61 inches in 1867, and 17·70 inches in 1858.

Personnel.

No change of any importance has been made with regard to the staff during the past twelve months, Mr. Dyson continuing to take special charge of the astronomical department, and Mr. Cowell the astro-physical department, in which is included the magnetic and meteorological branch.

GUTTA PERCHA.

In a recent course of three lectures[1] delivered before the Society of Arts, and subsequently revised and reprinted from the *Journal* of the Society, with additional illustrations and appendices in the form of a bulky pamphlet, Dr. Obach dealt very fully with the history, origin, treatment and properties of gutta percha.

In the first lecture the early history, botanical derivation and geographical distribution of this substance were related, and the analyses of various commercial "brands," as well as exhaustive statistics of the annual imports and exports of the material were given.

In the second lecture the mechanical cleaning processes and chemical washing and hardening processes were described and illustrated, and also the different methods of extraction of gutta percha from removable parts of the trees, such as twigs and leaves, explained. This lecture concluded with an enumeration of the various *natural* substitutes for gutta percha which have been proposed at various times, including the interesting material known as *balata*.

The third lecture dealt with the mechanical and electrical properties of gutta percha and its application for various technical purposes, also its behaviour towards water, oxygen and ozone. In conclusion the *artificial* substitutes for gutta percha were briefly discussed.

The following is a short report on those parts of the third lecture which we think may be more especially interesting to the readers of Nature.

In order to simplify matters, Dr. Obach selected from the numerous sorts of gutta percha which make their appearance on the Singapore market twelve different "brands," which may be considered as typical; they are distinguished by the name of the locality whence they are derived. For direct comparison and easy reference these twelve materials were divided into four groups, each group comprising materials more particularly related to each other. The groups were designated as "Genuine," "Soondie," "White," and "Mixed."

It was explained that cleaned gutta percha consists essentially of two constituents, viz. a hydrocarbon termed pure gutta (G) having the composition $C_{10}H_{16}$, and being therefore isomeric with oil of turpentine, and a resin (R) containing more or less oxygen, and consisting principally of two substances named Albane $C_{10}H_{16}O$, and Fluavile $C_{20}H_{32}O$. Besides these proximate components there is also a variable amount of extraneous matter present in every commercial gutta percha, even after the most scrupulous cleaning, which consists of finely-ground bark, wood fibres, vegetable colouring matter, grit, &c., summarily termed dirt (D), and of water (W).

Dr. Obach has found that the physical and mechanical properties of the various sorts of gutta percha depend almost exclusively on the relative proportion of gutta and resin, *i.e.* the ratio $\frac{G}{R}$, whereas the electrical properties depend chiefly on the nature of the gutta and, to a lesser extent, upon that of the

1 "Cantor Lectures on Gutta Percha," by Dr. Eugene F. A. Obach, F.I.C., F.C.S., M.I.E.E.

resins, but also very largely upon the amount and the character of the impurities contained in the material.

The specific gravity of cleaned gutta percha of average composition is very nearly the same as that of water, but that of individual brands deviates considerably from it, some being about 3 per cent. lighter, and others about 2 per cent. heavier, as will be seen from Table I., which gives the specific gravities for eleven definite brands and an average material obtained by mixing a number of different cleaned materials in the masticator. The table also gives for comparison the specific gravities of balata, of gutta percha extracted from leaves with petroleum spirit by Dr. Obach's patent process, and also of pure Para-caoutchouc.

The exceptionally low specific gravity of the gutta percha from leaves is to be attributed to the fact that it consists almost entirely of pure gutta.

TABLE I.—*Specific Gravity of Cleaned Gutta Percha.* (2·2 mm. sheet.)

Group	Name of brand	Spec. grav. at 15° C.	Ratio G/R
I. Genuine	Pahang	0·9858	3·9
	Banjer red	0·9868	4·0
	Bulongan red ...	0·9911	3·4
II. Soondie	Bagan	0·9709	1·44

	G.P. from leaves ...	0·9625	51·90*
	Para-caoutchouc ...	0·9275	—

* Not 5·19, as erroneously stated in the *Journal* and Reprint.

The absorption of water by gutta percha was ascertained by immersing strips of the cleaned material in water and weighing them at regular intervals for about eighteen weeks. The results of these tests made on representative materials of the four groups which have been mentioned, and on gutta obtained from leaves, on balata and caoutchouc, are graphically shown in Fig. 1.

The curves shown on the left of the diagram (Fig. 1) represent the average results obtained for the different brands composing the various groups or "classes," as well as the results for gutta percha extracted from leaves, for balata, and also for pure Para-caoutchouc; but the curves on the right of the diagram were indirectly obtained by calculation and represent the absorption, which would have taken place if each specimen tested had entirely consisted of the kind of gutta which is characteristic of it. The reason for this reduction of the results to "pure gutta" is that the water is exclusively absorbed by this component and not by the resin, which has been found impervious to it.

It will be seen from the diagram, that it is the group of "genuine" materials which absorbed the most water, both before and after the reduction to "pure gutta"; whereas of the materials as such, it is the "white" sorts which are the least permeable to water, and of the "pure guttas" that of the material extracted from leaves.

Pure Para-caoutchouc, as is generally known, has a considerably greater absorptive power for water than even the most permeable kind of gutta percha.

The temperature at which gutta percha becomes plastic, a physical property of practical importance, depends almost entirely upon the relative proportion of gutta and resin. The great difference existing in that respect between the different sorts was demonstrated in the lecture by an experiment illustrated in diagram (Fig. 2).

The apparatus consists of a frame, *f*, holding three strips of gutta percha, 1, 2, 3, under the tension of springs S_1 S_2 S_3, the frame is lowered into a beaker of water, V, and the latter slowly heated, the arrangement being such that an electric current is established, and an alarum, A, sounded as soon as a strip becomes sufficiently soft to allow the spring to pull it apart. The three materials employed contained 2½, 38 and 60 per cent. of resin, and the temperatures at which they softened were found to be 55°, 48° and 42° C. respectively.

Another physical property, viz. the time required by gutta percha to harden or set again on cooling, after having previously been softened by heat, also depends mainly on the relative percentage of gutta and resin, as was pointed out by the lecturer.

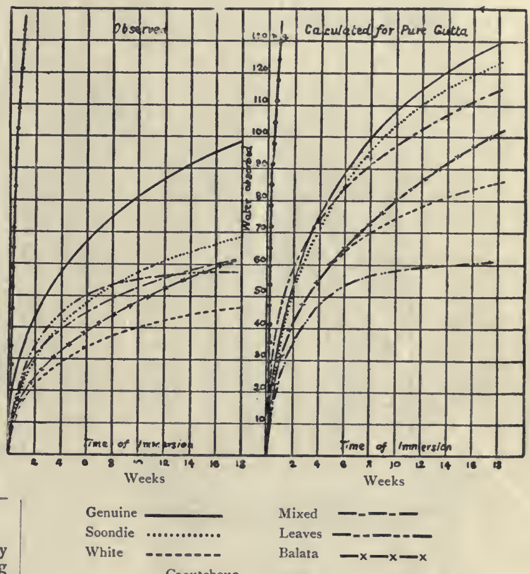

FIG. 1.—Absorption of water by different "classes" of gutta percha. (Thickness of sheet 2·2 mm.; area, 1 sq. dm.; weight, 10 g.)

The mechanical properties of gutta percha, of which the tensile strength is the principal one, are in their turn also greatly affected by the percentage of resin.

The important electrical properties of gutta percha chiefly depend on the nature of the gutta, and, to a lesser extent, on that of the resin, but only slightly on the relative proportion of these two components.

The insulating property of gutta percha was stated to have been first observed by Dr. Werner von Siemens in 1846. Faraday also noticed it shortly afterwards, and called attention to it in March 1848.

Dr. Obach showed the two principal electrical properties by means of an electroscope arranged as shown in Fig. 3. The instrument was provided with a flat brass disc, P, at the top, and below it two pith rods, *p*, *p*, were suspended on either side of a fixed strip of brass, *m*. When a piece of gutta percha tissue was spread over the brass disc and the electroscope charged by means of the brass knob, *k*, at the side, the pith rods diverged and remained stationary. If the fingers were now placed on the covered disc, the rods slightly converged and then again remained stationary. On withdrawing the hand, the rods took up their former diverged position.

This simple experiment demonstrated at once the excellent insulating property of gutta percha and its inductive capacity. Its insulating power was shown by the fact, that the tissue formed an efficient screen between the hand and the brass disc of the electroscope, to prevent the latter from being discharged. Its inductive capacity was shown by the temporary fall of the pith rods, indicating the "binding" of the charge on them when the tissue was touched by the hand.

Per se the insulation of gutta percha should be as high as possible, and the inductive capacity as low as possible; but whereas the latter property is mostly associated with other good qualities of the material, such is not always the case with a high insulation.

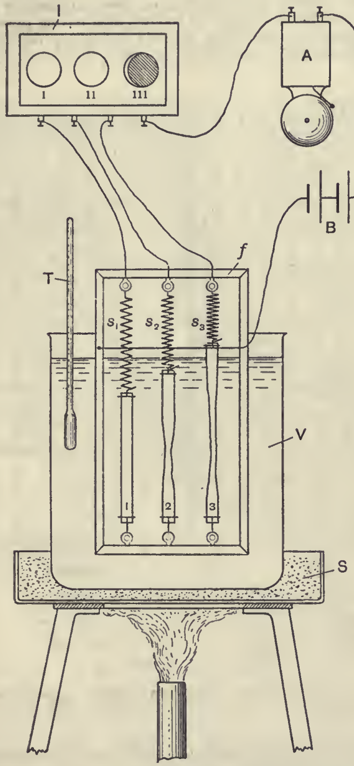

Fig. 2.—Softening temperature of gutta percha.

Faraday apparently had some difficulty in 1848 in obtaining gutta percha having a sufficiently good insulation. He found that this was due to an excessive amount of water contained in the commercial material. This is an important matter, and experiments were shown by Dr. Obach to demonstrate the effect of different percentages of water on the insulating power of gutta percha. The electroscope was charged until the rods fully diverged. Strips of gutta percha, containing approximately 15, 10, 5 and 2½ per cent. of water, were then successively brought into contact with the brass knob, the finger being held against the other side of the strip. When the strip containing 15 per cent. of water was brought into contact with the knob, the pith rods slowly converged, and did not regain their former position on removing the strip, which showed that the charge had been dissipated. On repeating the experiment with the next strip, containing 10 per cent., the charge disappeared much more slowly; the strip containing 5 per cent. of water was next tried, and this was found to be an almost perfect insulator and practically equal to the best strip with 2½ per cent. of water. It must be mentioned however, that different sorts of gutta percha behave differently in this respect. The specific insulation and inductive capacity of various specimens of gutta percha are given in a table in comparison with other materials, such as paraffin wax, colophony, ebonite, &c., but space does not permit us to reproduce this interesting table here. The figures show how greatly the electrical data vary for different kinds of gutta percha. For instance, the insulation resistance per cube knot was only 382 megohms for an otherwise excellent specimen of gutta percha, and 139,300 megohms for a specimen of considerably inferior description. Gutta percha extracted from leaves has usually a comparatively high insulation, exceeding that of paraffin wax, colophony and ebonite, but the insulation resistance of pure vulcanised caoutchouc is higher still, approaching the maximum obtained with ordinary gutta percha. The specific inductive capacity also varies greatly, the lowest values per cube knot

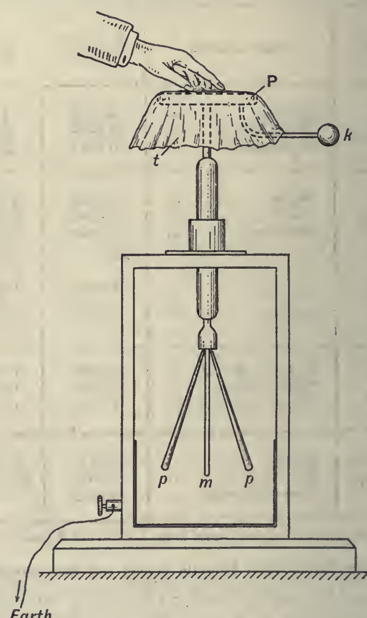

Fig. 3.—Insulation and electrostatic capacity of gutta percha.

being ·0466 and the highest ·0801 microfarad. In this respect the gutta obtained from leaves by Dr. Obach's process compares favourably with any ordinary gutta percha. Pure Para-caoutchouc also has a very low inductive capacity, viz. ·0446 mfd., which is lower than that of the best gutta percha, but paraffin wax is lower still, viz. only ·0411 mfd. Water, on the other hand, has the highest known inductive capacity of any substance, *i.e.* 1·348 microfarad per cube knot. The significance of this will be seen on comparing the values in Table II., which gives the insulation and inductive capacity of several "brands" of gutta percha, each with a high and low percentage of water.

The dielectric strength of insulating materials is another property, which is daily becoming more important. From tests made on gutta percha-covered cores of submarine cables, it has been found that a thickness of $\frac{1}{8}$ inch of this dielectric is pierced by about 40,000 volts, and one of $\frac{1}{16}$ inch by about 28,000 volts.

The next table (III.), which is abstracted from a large table in the *Journal*, contains the chemical composition and the physical, mechanical and electrical properties of the first grades of the twelve principal brands of gutta percha.

The figures show how largely the physical and mechanical properties depend on the relative proportion of gutta and resin, *i.e.* the ratio $\frac{G}{R}$. The temperatures given as those at which the material softens and at which it becomes pliable, have only a relative value, as they apply to the particular method of testing here employed, but for comparative purposes they are most valuable.

The softening temperature is determined as follows:—A thin sheet of the gutta percha to be tested is very slowly heated in a water bath, and a small stud from time to time brought to bear upon it with a definite pressure. As soon as the stud leaves a permanent impression on the surface of the sheet, the temperature of the water is noted and recorded as the "softening temperature."

The temperature at which the material becomes pliable is thus determined:—A strip of the material of definite dimensions is held vertically in a bath of water; the upper end of the strip is attached to a cord, passing over a pulley and carrying a known weight, the strip being thus subjected to a constant tension. The temperature of the water at the moment when the weight is able to pull the strip asunder, is taken as that of "pliability."

The "time of hardening" is that taken by the material, heated to the temperature of pliability, to become sufficiently rigid to resist the pressure of the stud in the apparatus used for determining the softening temperature, the water surrounding the strip being maintained at 75° F.

With a view to investigating the action of oxygen on cleaned gutta percha more thoroughly than had hitherto been done, Dr. Obach conducted an exhaustive series of experiments having for their special object a direct comparison of the avidity with which the different "brands" of gutta percha absorbed oxygen under similar conditions. For this purpose small spheres, of 2 cub. cm. contents and 8 sq. cm. superficial area, were enclosed in glass tubes filled with oxygen and inverted over mercury troughs. The tubes had a capacity of about 30 cub. cm., and each contained two spheres. They were refilled as soon as the composition of the residual gas approached that of the air, the oxygen used containing about 7 per cent. of nitrogen. The mercury troughs were placed outside a window on the south front of the laboratory exposed to full sunshine. The experiment extended over twenty-four weeks, and during that period the total amount of bright sunshine amounted to 680 hours.

The smoothed curves, given in Fig. 4, show the average amount of oxygen in cub. cm. absorbed by each of the four different groups of materials and for comparison, also that absorbed by gutta percha obtained from leaves and by balata. As in the case of the experiments on the absorption of water, two sets of curves

Note.—Each series of figures in this table represents the average result obtained with a number of individual lots of the particular brand.

are given—one representing the absorption of oxygen by the materials as tested, and the other the absorption calculated for "pure gutta," since here also it is mainly this constituent by which the absorption takes place.

The appendix to the lectures, given in the reprint, contains the results of a complete chemical analysis of the identical specimens of gutta percha used for the determination of the specific gravity and the experiments on the absorption of water and oxygen.

Experiments were also shown to demonstrate the remarkable difference in the behaviour of gutta percha and caoutchouc towards ozone, thin tissue of the former resisting the action of strongly ozonised oxygen for a considerable time, whereas a caoutchouc membrane was pierced by a jet of this gas impinging on it in a few moments. The lecturer also spoke of the applications of gutta percha hardened by extraction of the resin according to his process, proposing it for the use of boats for the arctic regions, on account of its considerably greater strength than that of ordinary gutta percha at very low temperatures, which was demonstrated by experiments.

He also showed that the elasticity of golf balls, as shown by the height of rebound when allowed to drop on a stone slab, depended almost entirely on the percentage of resin in the gutta

percha of which they are made; and consequently the treatment by the hardening process is now invariably resorted to, except in the case of gutta percha obtained from leaves by chemical precipitation processes, which consists almost entirely of pure gutta, as has been already mentioned.

HORN-FEEDING LARVÆ.

SOME few months ago I received a consignment of skulls of antelopes from West Africa, the specimens having been shot by the late Lieut. R. H. McCorquodale, 3rd Dragoon Guards, and on opening the cases I was much struck by the appearance of the horns; all, without exception, were infested by singular thin finger-like protuberances which seemed to grow from the horn, leading me at a first impression to the immediate conclusion that they were some species of fungi; on a nearer inspection I found them to be cocoons, and not having seen anything like them before I looked into what literature I could find on the subject.

As it is, generally speaking, only travellers, or those in touch with travellers, who have the opportunity of seeing the actual cocoons on the horns, a sketch and a few salient points will doubtless be of interest. The skull, that of a Hartebeest, was exhibited at the Linnean Society on January 20 last, and is the original of the sketch; the cocoons are cylindrical and closed at the outer end like the fingers of a glove, extremely tough and composed of a dark grey felt substance, evidently the comminuted fibres of horn, the largest being about three inches in length; these cocoons are formed by the horn-feeding larvæ of the moth known as the *Tinea vastella*, and the following is a description of the insect:—Very pale gilded ochraceous shining. Head ochraceous and tufted above, palpi porrect, pubescent, extending a little beyond the front, much shorter than the breadth of the head, third joint lanceolate, much shorter than the second. Abdomen extending much beyond the hind wings. Legs rather long, hind tibiæ thinly fringed. Wings long, narrow, fringe rather long, fore wings slightly acute, exterior border very oblique, under side and hind wings purplish cinereous, excepting the fringe. Length of the body seven lines, of the wings sixteen lines.

A very interesting point with regard to the habits of this insect, which has not yet been cleared up, but upon which I hope to be able to throw some light, through the observations of

Cocoons ½ natural size. Skull and horns ⅓ natural size.

officers now serving in Africa, is, that it has been asserted to feed on the horns of living animals; and in support of this I will quote the following:—"Dr. Fitzgibbon many years ago while in Gambia stated he was surprised at finding grubs enclosed in cases, which projected from the horns of animals freshly killed, the blood not being yet dry, the carcases of the animals being exhibited in the market place." This statement is recorded in vol. i. of the *Proceedings* of the Dublin Zool. Soc. "In contradiction, Lieut.-Colonel Wenman Coke said he had shot large numbers of various species of horned animals in South Africa, but that he had never seen the horn of a living animal perforated by one of these larvæ, although he had seen many dead horns infested with them. Colonel Coke is most confident that the larvæ never attacks a living animal; he says that had this been the case it could not have escaped his observation; Mr. Truman concurs in expressing great doubt as to the correctness of the theory that the larvæ feed on the horns of living animals." We have the strong evidence of Dr. Fitzgibbon, and might argue that, as the fibrous substance of the horn undergoes little or no change at the death of the animal, there seems no reason why the moth should not deposit its eggs when the living animal is at rest, nor why the larvæ should not penetrate the horn. I venture to assert as my own opinion, and that of many sportsmen from whom I have made inquiries, that the larvæ does not feed on the horns of living animals; had this been the case, it would not have escaped the observation of some of our "mighty African hunters." Thus Dr. Fitzgibbon's statement stands alone; the question must, however, remain *sub judice*.

The habitat of the moth was generally supposed to be Africa, but Sir George Hampson showed me some specimens which he had collected in various districts in India.

I am indebted to Lord Walsingham, who kindly gave me some very useful notes, he having himself written a few years ago on the subject; also to Mr. P. H. Miller for a very faithful sketch.

W. H. McCORQUODALE.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—In connection with the Congress of Physiology and the Congress of Zoology to be held in Cambridge towards the end of August, the University proposes to confer the honorary degree of Doctor of Science on the following distinguished foreign representatives. For Physiology: Prof. Bowditch, Harvard; Prof. Golgi, Pavia; Prof. Kronecker, Berne; Prof. Kühne, Heildeberg; and Prof. Marey, Paris. For Zoology: Dr. Anton Dohrn, Naples; Prof. Milne-Edwards, Paris; Prof. Haeckel, Jena; Prof. Hubrecht, Utrecht; and Prof. Kowalevsky, St. Petersburg.

The annual report of the Museums Syndicate testifies to the great activity of the science departments and the ever-growing importance and value of the collections acquired by the University. Numerous expeditions have left Cambridge to prosecute researches in far distant lands, and have returned with important and extensive trophies of their work. South America, through Mr. Graham Kerr and Mr. Budgett, has yielded some fine zoological series. The South Pacific fauna has been illustrated by the spoils of Mr. Stanley Gardiner of the Funafuti expedition. Dr. Willey has brought unique contributions from New Britain; and both he and Prof. Flinders Petrie have greatly enriched the magnificent collection of crania under the charge of Prof. Macalister. Other additions are due to Dr. Haddon (Torres Straits), Sir W. L. Buller (Macquarrie Island), Prof. Wiltshire and Mr. H. H. W. Pearson (Ceylon), and many other workers and benefactors.

Mr. Frank Morley, of King's College, the author of numerous works and memoirs in pure mathematics, has been approved for the degree of Sc.D.

The complete list of matriculations for the year has now been published. It appears that 931 students have joined the University in 1898, as compared with 887 in the preceding year.

Dr. Alex. Hill has been re-elected Vice-Chancellor for the ensuing academical year.

Mr. R. Pendlebury, and Mr. A. E. H. Love, F.R.S., Fellows and Lecturers of St. John's College, have been appointed University Lecturers in Mathematics.

A University Lectureship in Chemical Physiology is to be established in connection with Prof. Foster's department, but the University is unable to assign any stipend to the post at present. The lecturer will be remunerated from the students' fees.

Hitherto the same persons have acted as examiners in Anatomy and in Physiology respectively for the Natural Sciences Tripos, Parts i. and ii., and for the Medical examinations. The number of candidates has increased so largely (it is now 310 in physiology, and 252 in anatomy) that the work involved is too much for one pair of examiners. It is accordingly proposed to divide the duty by appointing separate examiners for the Tripos and for the M.B. examinations.

PROF. E. B. FROST, of Dartmouth College, has been elected professor of astrophysics at Yerkes Observatory; and Prof. E. F. Nichols has been appointed professor of physics in Dartmouth College.

MR. WILLIAM BUTLER DUNCAN, of New York City, has presented to Yale University the Hotel Majestic at New Haven, to be used as a dormitory, and to be called the Duncan Dormitory.

IN replying to questions referring to the Government measures which it is intended to bring forward shortly, Mr. Balfour informed the House of Commons on Monday that the Lord President of the Council would introduce, "in another place," a Bill dealing with the organisation of secondary education, and he hoped the London University Bill would be passed.

ABOUT a year ago the Lords of the Committee of Council on Education decided to make inquiries as to the number of pupils in public and private secondary and other schools (not being public elementary or technical schools) in England, and the teaching staff in such schools. These schools are very various in character, in constitution, and in size; but, broadly speaking, they furnish to the country what is known as secondary or intermediate education in its different grades, and fill the gap between the public elementary schools and the universities or university colleges. They include schools in which educational efficiency is at a minimum, and schools (unfortunately but a small proportion) where rational methods of instruction are followed. The results of the inquiries made through the Education Department have just been published in a Blue Book. The Return represents the first attempt which has been made in this country to give a statistical survey of the schools in the great province of national education which is intermediate between the public elementary schools and institutions of academic rank or for technical training. It shows the various forms of control and ownership under which these schools are carried on, but, as they do not come under any comprehensive system of inspection, no pronouncement can be made as to their educational efficiency or inefficiency. The number of pupils in the 6209 schools comprised in the Return are 291,544; of these 158,502 are boys, and 133,042 are girls. Only 9 per cent. of the boys are more than sixteen years of age, and 11 per cent. of the girls. As to the staff, 32 per cent. of the boys' schools are without graduates on the attached staff, 73·8 per cent. of the girls' schools, and 81·3 per cent. of the mixed schools. From this it will be seen that 61·6 per cent. of all the schools on the Return have only non-graduates on the exclusively attached staff. Of course, this division into schools with graduates and without graduates on the staff only affords a rough criterion as to the character of the instruction, for graduates are not necessarily good teachers, nor are good teachers necessarily graduates. It is, however, time that steps were taken to insist upon all private schools giving public guarantees of their educational efficiency.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, May 5.—Dr. A. Günther, F.R.S., President, in the chair.—Dr. Bernard Renault and Prof. Max Carl Wilhelm von Weber were elected Foreign Members of the Society.—A paper was read by Sir John Lubbock, Bart, M.P., F.R.S., on some Spitsbergen Collembola. Owing to the well-known tolerance of cold by insects belonging to this order, it was, he thought, not surprising that several species should occur in Spitsbergen. Eleven species of *Collembola* had been found in Greenland, as recorded by Meinert (Vidensk. Meddel., 1896, pp. 167–173), and five species were already known from Spitsbergen. He was now able to add two more, one of which was new. This he proposed to call *Isotoma spitsbergenensis*. The second species, *Isotoma quadrioculata*, had been previously met with in Greenland. Both of these were obtained by Mr. Trevor Battye during Sir Martin Conway's expedition to Spitsbergen in 1896.—Miss Ethel Barton, by permission of the President and Council, read a paper on the structure and development of *Soranthera*, a genus of brown Algæ (*Phæophyceæ*) containing a single species, *S. alvoidea*.—Mr. J. T. Cunningham read a paper dealing with the evolution of animal structure, and entitled "The Species, the Sex, and the Individual." The general conclusion arrived at by the author was that adaptation was not produced indirectly by selection from indefinite variations, but directly by the influence of stimulation in modifying the growth of the parts or organs of the body.

Geological Society, May 18.—W. Whitaker, F.R.S., President, in the chair.—The garnet-actinolite schists on the southern side of the St. Gothard Pass, by Prof. T. G. Bonney, F.R.S. The author described the field relations and the microscopic structures of a group of schists or gneisses characterised by the frequent presence of conspicuous garnets and actinolites which are exposed on the southern slopes of the St. Gothard Pass and for some distance west and east, on the northern side of the Val Bedretto. These rocks in the field might be regarded as highly-altered sedimentary strata (as the author once thought) or as a group of igneous rocks (originating possibly in magmatic differentiation) affected by fluxion-movements anterior to consolidation. To the latter view he now inclined, but considered the schistosity and the peculiar minor structures to be the results of crushing (generally without marked shearing) followed by very considerable mineral reconstruction.—On the metamorphism of a series of grits and shales in Northern Anglesey, by Dr. C. Callaway. While mechanical force has been concerned in producing the more intense metamorphism of the lower part of the series, the author was not disposed to advance this as the sole cause of the changes produced.—On a volcanic series in the Malvern Hills, near the Herefordshire Beacon, by H. D. Acland. It is suggested that the rocks may be the volcanic equivalents of the plutonic rocks of the Malvern axis, faulted down and protected by the bend in the axis which occurs in the neighbourhood of the Herefordshire Beacon.

Chemical Society, May 19.—Prof. Dewar, President, in the chair.—The following papers were read:—The liquefaction of hydrogen and helium, by J. Dewar. Hydrogen was liquefied by allowing the gas cooled to $-205°$, and under 180 atmos. pressure, to expand; about 1 per cent. of the gas liquefied. Helium was liquefied by cooling in liquid hydrogen.—The action of formaldehyde on amines of the naphthalene series, Part 1, by G. T. Morgan. Formaldehyde acts on β-naphthylamine in alcoholic solution containing hydrochloric acid yielding naphthacridine, and bases of the composition $C_{21}H_{13}N$, $C_{22}H_{16}N_2$, and $C_{23}H_{18}N_2$.—On the constitution of oleic acid and its derivatives, Part 1, by F. G. Edmed. Pelargonic and azelaic acids, as well as two hydroxystearic acids, are formed on oxidising oleic and elaidic acids; the author therefore assigns the constitution $CH_3(CH_2)_7CH : CH(CH_2)_7 CO_2H$ to the two latter acids.—Stereoisomeric derivatives of camphor, by T. M. Lowry. On recrystallising dibromochlorocamphor,

its rotatory power changes, indicating the existence of stereoisomerism.

Cambridge.

Philosophical Society, May 16.—Mr. F. Darwin, President, in the chair.—On the figures produced on photographic plates by electric discharges, by Mr. J. A. McClelland. When an electric discharge has passed to the surface of a photographic plate a distinct figure is produced when the plate is developed, and the form of the figure is dependent on the sign of the discharge. The object of the paper is to determine whether these figures are produced by some direct electrical action on the film, or by the light which accompanies the discharge. Figures were taken with the plates in air at various pressures, and as the pressure was diminished the branching lines in the figures became broader and less distinct, as they would if produced by the light of the discharge in the air close to the film. The transparency of various substances was tested, and while no effect was produced through thin slips of ebonite, the effect through glass and mica was quite distinct. The experiments seemed to show that the light of the discharge was chiefly instrumental in producing the figures. The difference in the positive and negative figures is due to the difference in the discharge in air in the two cases.—On a method of facilitating the measurement of temperature by platinum thermometry, by Mr. E. B. H. Wade. Attention is drawn to the inconvenience arising from the fact that equal increments of the resistance of platinum wire do not represent equal increments of the temperature. A form of Wheatstone's Bridge is then described in which the inconvenience disappears. The resistance of the platinum is balanced by that of two resistance boxes in parallel, plugs being transferred from one box to the corresponding places in the other till the balance is obtained. It is shown that when this is done, equal increments of the resistance in one box may be made to represent equal increments in the temperature of the platinum wire. Accuracy is not sacrificed in obtaining the simplification resulting from this method.—The development of *Peripatus novæ-britanniæ*, by Dr. A. Willey. The ova are without yolk, and the nutrition of the embryo is effected by the development of a large trophic vesicle, which occupies the entire dorsum of the embryo, and projects far in front of the embryo as a head-fold and behind as a tail-fold. The trophic vesicle is thus a hollow closed cylinder lined internally by endoderm and externally by ectoderm, the cells of the latter being adapted for absorption of nutriment. The trophic folds were compared with the amniotic folds of insects. The trophic cavity becomes the gastral cavity of the adult, and in the transformation from one to the other the endoderm undergoes certain changes. It secretes a basal membrane and a cuticular membrane simultaneously with a great increase in thickness; and between the two membranes the endoderm contains numerous small and large yolk-like globules, which are probably to be regarded as reserve nutrient matter to tide the embryo over the first few days of its independent life. This late deposition of reserve nutrient matter derived ultimately from the maternal organism, as opposed to foreign ingested matter, is probably of some significance with regard to the question of the lecithality of the ovum. The embryo lies outside on the ventral surface of the trophic vesicle just as an insect embryo lies upon the yolk.—On Röntgen rays and ordinary light, by Mr. C. Godfrey. Prof. J. J. Thomson has shown that the sudden stoppage of an electron gives rise to a thin electric pulse which is propagated through the medium; these pulses he identifies with Röntgen rays. The application of Fourier analysis shows that the assemblage of these pulses is equivalent to a mixture of simple harmonic waves of all wave-lengths; a peculiar feature is that these waves are absent whose lengths are sub-multiples of the thickness of the pulse. Most of the energy is resident in the short waves; but about 1/1000 of the whole energy will be visible light. The pulses suggested by Sir George Stokes as affording an explanation of Röntgen rays differ from Prof. Thomson's in one respect; the integrated displacement through the thickness of the pulse is zero. On this property Sir G. Stokes bases his proof that there will be no diffraction; and it may be seen that these pulses (taken to be of the same thickness as Prof. Thomson's) will have only 10^{-9} of this energy in the visible spectrum.—On the possibility of deducing magneto-optic phenomena from a direct modification of an electro-dynamic energy function, by Mr. J. G. Leathem. The method initiated by Maxwell for the explanation of the Faraday effect depended on the direct insertion of a magneto-optic term in the energy. This method was extended by Fitzgerald and others to the explanation of Kerr's effect, namely the modification introduced in the circumstances of optical reflexion by magnetisation of the reflector. A difficulty occurred, however, in satisfying all the interfacial conditions, which virtually showed that such a scheme was not formally self-consistent. The origin of the discrepancy has been traced by Mr. Larmor ("Report on the Action of Magnetism on Light," Brit. Assoc., 1893) to omission to secure what may for shortness be called the electromotive incompressibility of the medium: in the ordinary problem of optical reflexion there is no tendency for this to be disturbed, but when Maxwell's magneto-optic energy terms are included, the reaction against compression introduces what may be termed an electric pressure, which must appear in the equations. It was necessary to compare the modified scheme thus obtained with experimental knowledge: and the calculations given in this paper show that in fact it does not represent the phenomena. The paper is only a summary of the actual calculations, because since they were completed the author has shown ("On the Magneto-optic Phenomena of Iron, Nickel and Cobalt," *Phil. Trans.* 1897), that the other rigorous theory formulated as an alternative by Mr. Larmor (*loc. cit.*), which leads to an analytical scheme practically the same as those advanced on various hypotheses by Fitzgerald, Goldhammer, Basset, Drude, and others, is in much more satisfactory agreement with experiment. This brief history of the subject shows the desirability of the examination of the consequences involved in the former method of explanation; the result is, however, what was to be expected by those who adhere to the more recent formulation (Larmor: "A Dynamical Theory of the Electric and Luminiferous Medium," Part 3, *Phil. Trans.*, 1898) of optical theory, which treats a material medium as free æther pervaded by discrete molecules involving in their constitution electrons considered as nuclei of intrinsic æthereal strain. On such a view a continuous energy function is not the starting-point, and the influence of these discrete nuclei could hardly be conceived to modify the propagation in the intervening æther in so fundamental a manner as an electromotive pressure would demand.—On the solutions of the equation $(\nabla^2+\kappa^2)\psi=0$ in elliptic coordinates and their physical applications, by Mr. R. C.

Maclaurin.—On the interpretation of divergent solutions of the hypergeometric equation, by Mr. W. McF. Orr. The author obtains divergent series satisfying a general hypergeometric equation, and estimates the error involved in choosing a finite number of terms of such a series as a solution of the equation.

EDINBURGH.

Royal Society, May 16.—Lord Maclaren in the chair.—Prof. Crum Brown read a paper on the origin of certain of the Phœnician alphabet characters. The idea was to ascertain whether any of them can plausibly be regarded as modifications of others. It was suggested, for example, that *Aleph* was deduced from *Argin* by the addition of a central vertical stroke, *Heth* from *He* and *Tsade* from *Zain* by the addition of a vertical stroke at the left side, *Caph* from *Gimel* and *Samesh* from *Zain* by the addition of a horizontal stroke, *Pe* from *Beth* by opening the loop (or *vice versâ*), *Daleth* from *Tau* by the addition of a diagonal stroke, &c. Attention was called to the risks of being misled by accidental resemblances and to the bearing of such guesses on de Rougé's hypothesis.—Mr. T. C. Baillie read a paper on the thermal conductivity of nickel. The value he obtained by use of Forbes' method was ·117. What was believed to be a better value, namely ·103, was obtained by a new method, which had the great merit of giving an experimental value of the thermal conductivity directly without requiring the specific heat to be known. A short bar had its one end kept at a steady high temperature as in the Forbes' experiment. To the other end a small cap was attached, through which a steady stream of water was passed. The temperature of the water was taken just as it entered the cap, and just as it left it. The quantity of water passed in a given time being known, the amount of heat lost from the end of the bar to the water was calculated in terms of the specific heat of water. By means of thermometers set at intervals along the bar, the gradient of temperature was indicated, and a good approximation to the value of the gradient at the position occupied by the cap could be calculated. These measured quantities, the gradient and the heat lost, give at once the conductivity. The paper also contained an account of a simple method for determining the thermometer corrections.—Prof. D'Arcy Thompson, in a paper on the crab in mythology, drew attention to the fact that in old coins the crab is always found associated with those deities which are astrologically connected with the zodiac sign *Cancer*, and with animals that give names to constellations which are astronomically related to the constellation Cancer.

PARIS.

Academy of Sciences, May 31.—M. Wolf in the chair.—Photographic studies on some parts of the surface of the moon, by MM. Lœwy and Puiseux.—Remarks on the third part of the photographic atlas of the moon, published by the Paris Observatory.—On the preparation and properties of the di-alkylamido-anthraquinones, by MM. A. Haller and A. Guyot. Dimethyl-amido-benzoylbenzoic acid heated at 180° with strong sulphuric acid gives about one-third of the theoretical yield of dimethyl-amido-anthraquinone. The yield is more than doubled by starting with the reduction product, dimethylamido-benzoyl-benzoic acid, condensing this with sulphuric acid, and oxidising the product with ferric chloride. The corresponding ethyl derivatives were prepared in a similar manner.—On the creation of new articulations between bones normally independent, in the case where the old articulations cannot be reconstituted owing to their having been completely destroyed, by M. Ollier.—Formation in blood serum, under the action of chemical substances, of a material capable of coagulating the bacilli of true tuberculosis, by M. S. Arloing. It has been shown in a previous paper that the blood serum of tuberculised goats contains a substance which is capable of coagulating the tubercle bacilli from a homogeneous culture. It is now shown under that prolonged treatment, by injection of such substances as eucalyptol, guiacol, creosote, and solution of corrosive sublimate, the blood serum acquires the same property, the last-named substance giving the most active serum. The author points out that all these chemical substances have been proposed for the treatment of tuberculosis in man.—On a flying apparatus, by M. Ader. The apparatus described does not belong to the class of aeroplanes, but attempts to reproduce the curves of the wings of birds in flying.—On surfaces of total constant curvature, by M. C. Guichard.—On the form which by the suppression of certain terms becomes a development in complete series, by M. Riquier.—On a method of determining the order of a fringe of high order, by MM. Ch. Fabry and A. Perot. The fringes produced by the interference of the reflections from two parallel silvered plates some three or four centimetres apart are of a very high order. By throwing simultaneously rays of two different known wave-lengths (say red and green), and noting the positions of exact coincidence of a red and green ring, the order can be determined.—On the kathode rays, by M. P. Villard. If the antikathodic wall of a Crookes' tube is covered with cupric oxide glass, cuprous oxide is formed by the action of the rays. This reduction is attributed to hydrogen, furnished by the traces of water given up by the glass. In a tube with mercury electrodes, in which the vacuum was formed by boiling out with mercury, no kathode rays could be formed.—Action of some carbonates upon chromous acetate, by M. G. Baugé.—On the states of equilibrium of a ternary system, lead-tin-bismuth, by M. Georges Charpy. The results are expressed in the form of a curve, Thurston's triangular diagram.—On dimethylpiperazine and some phenolic combinations of this base, by MM. P. Cazeneuve and Moreau.—Heats of neutralisation of phenyl-phosphoric acid, by M. G. Belugou.—On some halogen derivatives of ethyl-phenyl-ketone, by M. A. Collet. The ketones described were prepared from propionyl and bromo-propionyl chlorides, and the halogen benzene derivative by Friedel and Craft's reaction, and include ethyl-*p*-chlorphenyl-ketone, ethyl-*p*-bromophenyl-ketone, bromoethyl-*p*-chlorophenyl-ketone and bromoethyl-*p*-bromophenyl-ketone, together with their oximes, and phenylhydrazones.—On the solipedisation of the Equidæ during recent times, by M. G. Joly. A comparison of the osteology of the horse of the quaternary period with that of the present day shows that the alterations of structure corresponding to increased speed can be readily traced, and are probably still going on.—On *Acinetospora pusilla* and the sexuality of the Tilopteridæ, by M. C. Sauvageau.—On the growth of a green plant, in absolute darkness, by M. R. Bouilhac. The algæ nostoch can be grown in complete absence of light, and has a green colour, although less intense than when grown in sunlight. It is essential that glucose be present in the culture fluid.—On polymorphism, by M. Fred. Wallerant.—Examination of a combustible material by means of the X-rays, by M. H. Couriot. The method affords a ready means of determining the amount ot mineral impurity present in a coal.—The artesian basin of the "Oued Rir," and the best means of utilising its irrigation waters, by M. Georges Rolland.—On the distribution of gluten and its immediate principles in the farinaceous nucleus of the wheat grain, by M. E. Fleurent.—Influence of asphyxia upon the amount of carbonic oxide in the blood.—Production of carbon monoxide in the organism, by M. Maurice Nicloux. The carbonic oxide found in the blood would appear not to be derived from the air, but to be a substance formed normally by the organism.—Researches on the ostioles of the cerebro-spinal system, by M. J. J. Andeer.

AMSTERDAM.

Royal Academy of Sciences, April 23.—Prof. van de Sande Bakhuyzen in the chair.—Mr. Hamburger on the result of experiments showing that venous propulsive pressure promotes in a high degree the destruction of bacilli anthraces and their spores, which have been introduced under the skin.—Prof. Pekelharing presented a paper by Dr. G. C. J. Vosmaer and himself, entitled "Observations on Sponges," which will be published in the *Transactions* of the Academy.—Prof. Franchimont presented on behalf of Dr. P. van Romburgh a paper for publication in the report of the meeting, entitled "On the occurrence of cinnamic methyl ether in *Alpinia Malaccensis*, Rosc." On distillation with water the rootstocks of this plant yielded about 0·2 per cent. of ethereal oil, specific gravity 1·039 at 27°, exerting a right-handed rotation of 1°·5 in a tube 200 mm. in length. On the temperature being lowered, cinnamic methyl ether crystallised out—the liquid residue seemed to contain terpenes—which substance was not only detected by vapour density and analysis, its melting-point, 36°, and its boiling-point, 159°, but it also saponified, after which the two components, into which it was split up, were detected, cinnamic acid by its melting-point, 133°, and its other properties; methyl alcohol *e.g.* by the formation of the addition product with nitro-trimethylphenylenediamine, which crystallised in orange-coloured needles. Cinnamic methyl ether in chloroform, on being treated with bromine, yielded a dibromic addition product, melting at

116°, consequently phenyl $\alpha\beta$-dibromic propionic methyl ether. The leaves of this plant, too, are rich in methyl cinnamite. This is the first instance of cinnamic methyl ether being found in the vegetable kingdom.—Prof. van Bemmelen made on behalf of Dr. E. A. Klobbie a communication entitled "Qualitative-analytic determination of osmic tetroxide," which will be inserted in the report of the meeting.—Prof. H. A. Lorentz on optical phenomena, depending on the mass and the charge of the ions (II.). The author discussed the question whether the density of the absorbing gas itself and of other gases, with which it is mixed, has any influence on the position of the absorption lines in the spectrum. The formulæ show no appreciable influence, if the absorption is small in a layer of the thickness of one wave-length.

DIARY OF SOCIETIES.

THURSDAY, June 9.

Royal Society, at 4.30.—On a New Constituent of Atmospheric Air: Prof. W. Ramsay, F.R.S., and Morris H. Travers.—Experiments on Aneroid Barometers at Kew Observatory and their Discussion: Dr. C. Chree, F.R.S.—The Nature of the Antagonism between Toxins and Anti-Toxins: Dr. C. J. Martin and Dr. T. Cherry.—Some Differences in the Behaviour of Real Fluids from that of the Mathematical Perfect Fluid: A. Mallock.—On the Heat Dissipated by a Platinum Surface at High Temperatures: J. E. Petavel.

Royal Institution, at 3.—Modern Methods and their Achievements in Bacteriology: Dr. E. E. Klein.

Mathematical Society, at 8.—On the General Theory of Anharmonics: Prof. E. O. Lovett.—Point-Groups in a Plane, and their Effect in determining Algebraic Curves: F. S. Macaulay.—On a Regular Rectangular Configuration of Ten Lines: Prof. F. Morley.—On the Calculus of Equivalent Statements (eighth paper): H. MacColl.—On the Conformal Representation of a Pentagon on a Half Plane: Miss M. E. Barwell.—On a Continuous Group defined by any Given Group of Finite Order (second paper): Prof. Burnside, F.R.S.

FRIDAY, June 10.

Royal Institution, at 9.—Some Experiments with the Telephone: Lord Rayleigh.

Royal Astronomical Society, at 8.—Observations of Phenomena of Jupiter's Satellites in the Year 1897: John Tebbutt.—Occultations of Ceres and Venus: Cambridge Observatory.—Reply to Dr. Rambaut's Note on the Effect of Chromatic Dispersion: David Gill.—Right Ascensions and Declinations of Eight Stars in Aquarius, and their Probable Proper Motions: C. J. Merfield.—Further Researches on the Orbit of γ Lupi: T. J. J. See.—On the Actinic Qualities of Light as affected by different Conditions of Atmosphere]: Rev. J. M. Bacon.

Physical Society, at 5.—Exhibition of a Model illustrating Dr. Max. Meyer's New Theory of Audition: Prof. S. P. Thompson, F.R.S.—Attenuation of Electric Waves along a Line of Negligible Leakage: Dr. E. H. Barton.—Diffusion Convection: A. Griffiths.

Malacological Society, at 8.—On the Land Shells of Curaçoa and the Neighbouring Islands: Edgar A. Smith.—On the Anatomy and Synonymy of the Genus of *Mariaella* (Gray): W. M. ON LABORATORY ARTS.

On Laboratory Arts. By Richard Threlfall, M.A., Professor of Physics in the University of Sydney. Pp. xii + 338. (London: Macmillan and Co., Ltd. New York: The Macmillan Company, 1898.)

THERE are certain passages in the preface of Prof. Threlfall's valuable contribution which it may be useful to quote before dealing with the book itself.

"It often happens that young physicists are to be found whose mathematical attainments are adequate, whose observational powers are perfectly trained, and whose general capacity is unquestioned, but who are quite unable to design or construct the simplest apparatus with due regard to the facility with which it ought to be constructed. That ultimate knowledge of materials and of processes which by long experience becomes intuitive in the mind of a great inventor of course cannot be acquired from books or from any set course of instruction. There are, however, many steps between absolute ignorance and consummate knowledge of the mechanical arts, and it is the object of the following pages to assist the young physicist in making his first steps towards acquiring a working knowledge of 'laboratory art.' . . . Before all things the means indicated must be definite and reliable. It is for this reason that the writer has practically confined himself to matters lying within his own immediate experience, and has never recommended any process (with one or two minor exceptions, which he has noted) which he himself has not actually and personally carried through to a successful issue. . . . With regard to the question as to what matters might be included and what omitted, the general rule has been to include information which the author has obtained with difficulty, and to leave on one side that which he has more easily attained. . . . Though no doubt a great deal can be done with inferior appliances where great economy of money and none of time is an object, the writer has long felt very strongly that English physical laboratory practice has gone too far in the direction of starving the workshop, and he does not wish, even indirectly, to give any countenance to such a mistaken policy."

The writer of this notice feels so strongly the importance of the subject of the first and last of these extracts that it is only with an effort that he can forego the opportunity which they offer of airing views, and confine himself to the more prosaic duty of review.

The second extract is one which shows that the first essential in a work of this kind is complied with. A mere collection of recipes for making and doing all sorts of things which have been collected from anywhere and everywhere, while not absolutely useless, is necessarily untrustworthy. Without the personal certificate of a man who is both a physicist and a mechanician, no description of a process for making or doing anything will necessarily be the most appropriate or even serviceable at all. With such a certificate, however, any one with but little experience of any particular laboratory art may set to work upon it with reasonable confidence.

The first chapter, of ninety pages, is upon the manipulation of glass and on glass-blowing for laboratory purposes. Of all laboratory arts probably glass-blowing and working, not including the work of the optician, looks more easy when practised by an adept, and seems more utterly and hopelessly impossible when tried for the first time, than any other. It is one which every experimentalist must acquire in some degree, and which as a fact, with a little practice and suitable help, is one of the easiest in which to make progress. Shenstone's well-known little book has been found invaluable by many, the little work of Bolas has recently been reviewed in these columns, and now we have new advice on the same subject, differing in some points, as is to be expected, but the result of personal experience. The subject is one in which any opportunity of watching a glass-blower of skill is worth more than any written instruction, but it is one in which occasional and hurried opportunities of watching a process can be supplemented most usefully by description. Practice, however, is essential, whatever guide to procedure may be attainable.

The writer's experience of the average student is that it is not sufficient to tell him even several times that he must not begin glass-blowing operations upon dusty tubes. The very elaborate description of a really proper way of cleaning a glass tube so as to fit it for the best class of work may, perhaps, induce this individual to take the trouble at least to wash out his tubes.

Prof. Threlfall does not approve of the type of blowpipe usually furnished by the instrument maker, nor apparently does any writer on the subject. He describes a simple form of oxygen blowpipe that is suitable for working lead-glass or unusually infusible glass. For larger work with lead-glass he prefers a system of four blowpipes, the flames of which meet upon the work. The superiority of lead-glass where the nature of the experiment will admit of it is duly insisted on. It is a pity that owing to the miserable blowpipes to be found in laboratories, the beginner never gets a chance of realising how excellent lead-glass really is.

The instructions given for cracking or cutting the larger sizes of glass tubes do not quite accord with the writer's experience. The well-known point of melted glass and the flame-pencil with a very small flame are described as being suitable for leading a crack round a tube. The writer has found with tubes that are not too large, a thick copper wire mounted in a handle and bent at the end into such a form as to make a good long contact with the glass, enables one with a little practice to lead a smooth crack round the tube along any predetermined line with an accuracy and quickness not approached by any other process. It is often possible with a single heating of the wire to "cut" a tube an inch or more in diameter either square across or at an angle as great as 30°, and so nearly in a plane that five minutes' grinding on emery cloth will remove the whole of the old surface.

On p. 49 there is a figure showing an ordinary glazier's diamond mounted on a frame, so as to bear upon the exterior of a rotating tube. No doubt as this is described a tube may be cut that way, and in that case, perhaps, no exception should be taken. But since glass tubes cool from the exterior, the inner surface is ultimately in a state of stretch, while the exterior surface is in a state of compression. As a consequence, glass tubes and vessels in general are far more sensitive to even microscopic scratches inside than out. For this reason, it is preferable to mount the diamond at the side of the end of a stick or metal rod provided with a sliding stock like a marking gauge. With such an instrument, tubes may be cut with facility and accuracy. In the same way it is not easy to cut a circular hole in an ordinary glass shade; but if a glazier's diamond is used on a compass within the shade, the piece will drop out at once.

There are useful instructions on boring holes in glass. Of course, the nature of the tool and of the process depends upon the size of hole and thickness of glass. It will be news to most people, however, to read, after the process of drilling with a file is described:

"It is not, however, necessary to use a file at all, for the twist drills made by the Morse Drill Company are quite hard enough in their natural state to bore glass. The circumferential speed of the drill should not much exceed ten feet per minute. In this way the author has bored holes through glass an inch thick without any trouble, except that of keeping the lubricant sufficiently supplied."

The writer has always believed that a pyramidal end to a drill—that is, a drill of the old-fashioned flat pattern, but with the two faces meeting at the point, not joined by a cross-edge—was the best form for drilling glass, *i.e.* when a diamond drill is not available. Such a drill, made dead hard and well lubricated, certainly drills holes in thick glass with remarkable facility. The success of the Morse twist drill, where such cross-edge is always present, would seem to indicate that there is nothing essential in the pyramid theory. The application of the methods of the mechanical engineer to the work of glass is carried a step further on p. 74, where the reader is told to give up grinding glass to form in many cases where this is the usual practice, but instead to chuck it in the lathe and turn it with a steel tool ground to an edge of 80° and well lubricated. After this, any one who has not worked glass in this way would almost expect to read—the best way to start the Morse drill in glass boring is to use a dead hard and sharp centre punch, and give it a smart blow with a light hammer.

An appendix to the first chapter should be found useful, since the interest in experimenting with Röntgen tubes shows no sign of decaying. Complete and detailed instructions are given for making all the parts of these tubes, for putting them together, for making a suitable pump, and for completing by exhaustion and sealing.

The second chapter is upon glass grinding and optician's work. This is one which the great majority of experimentalists will look upon as outside their practical requirements. There is no doubt that the art of optical grinding, as distinct from mere lapidary performances, is one of the most fascinating for the very few who have laid themselves out to practise it. It, however, is one which cannot be embarked upon in five minutes. A good deal of material and apparatus has to be collected before a start can be made, and at the best the processes seem slow and tedious; they are, moreover, of a kind that cannot be hurried. On the other hand, where the practical physicist finds himself in some outlandish place, it may very well be worth his while to acquire the art of grinding and polishing plane and curved surfaces, and of attaining the skill, if he has the patience, of figuring these with the precision that optical work demands. For those within reach of the real or working optician—quite a distinct type from the shoptician—it is barely worth spending the time for the sake of the work to be done, though it may be for the sake of the pleasure that succeeding in a difficult art will bring to the worker. But this is luxury.

On the other hand, occasions arise in experimental work where it is important to be able to do on the spot and at once some operation of a kind which, taken by itself, the experimentalist would prefer to put in the hand of the instrument maker, but which it may be imperative to perform on the spot, even though the technical success may be inferior to that of a second-rate professional.

The whole series of operations required in making an achromatic object-glass of small size are described, not because any one wanting such a glass would be well advised to make one, but because such a description includes all the ordinary routine of optical work, and a beginner would find it a good training. After this the construction of small lenses and of galvanometer mirrors is described. The author tried making these mirrors of fused quartz and of crystalline quartz, as well as of glass, and has concluded that for the most perfect thin mirrors slices of the crystal are better than anything. In this conclusion the writer of this notice agrees.

The construction of large mirrors and object-glasses for telescopes is dealt with; but in the writer's opinion this, while good enough, is somewhat out of place, for it is not possible to devote enough space to the very wonderful art of testing the surface at the centre of curvature. The formula for the longitudinal aberration of the parabola at this point is not given, nor is the reader warned that the formula of Draper, which is so constantly quoted for this, only gives half the correction.

Sections 68 and 69 should be valuable to many. They are both quotations from Brashear, whose optical masterpieces are known of, if they have not been actually seen by every experimentalist in the world. The first is on the cleaning of dirty object-glasses, and the second on the working of plane surfaces on rock salt.

Some attention is given to the peculiar difficulties of producing optically plane surfaces of any size. Lord Rayleigh's beautiful method of testing the figure by interference with a free surface of water just above it is referred to rather than described. While interference methods of testing are shortly described—and they have the undoubted value that they indicate the magnitude and position of any errors—it is, perhaps, unfortunate that the very handy method of testing the goodness of a plane surface by the use of a telescope and artificial star is not properly described.

The chapter on optical work is really full of valuable information. The fact that some criticism has been offered is perhaps owing to the fact that the subject is one upon which no two people would have quite the same views. The writer must, however, here express his disappointment at not finding any indication of the value of carborundum for these processes. He has never lost an opportunity of trying to collect real experience on this material, practically without success. His own very limited experience is all in favour of the virtues which the makers so forcibly set out. It seems impossible in this country to learn anything about it directly.

The third chapter is on all sorts of things that the manipulator in materials ought to know. The first of these is on Margot's method of coating glass with aluminium and of soldering aluminium, or even glass, by means of its aluminium coat! Prof. Threlfall vouches for the practical ease and success of these processes. He gives full details of the very simple process.

The second is on Boettger's process of depositing bright gold upon glass, just as silver is deposited. This also the author has proved to be satisfactory. The question arises whether it might not be worth while, where colour is not important, to use gold in the place of silver in reflecting telescopes for the sake of the permanence that should in this way be attainable.

The third is on slitting with a disc and diamond dust and making rock sections generally. This, however, does not require particular notice except, perhaps, the curious statement that the author was surprised how difficult it was to learn anything about this art. Vol. iii. of Holtzapffel surely cannot have been in his mind when he wrote this.

A large amount of space is given to the fullest details of the different methods of making and mounting quartz fibres and of their properties. No one with this before him need have any doubt about embarking upon this laboratory art. The writer of this notice had produced the first of some articles on the subject in the *Electrician*, but on seeing Prof. Threlfall's book, felt that the ground was so well and accurately covered that it would be a mistake to go over it again. The curious property of the quartz fibre discovered by Prof. Threlfall, of becoming at ordinary temperatures very slightly *more* rigid as the temperature rises, is referred to; and the suggestion which the writer of this notice also put forward tentatively years ago is made, that chronometer balance-springs made of fused quartz might have some advantage. This curious rise in rigidity with temperature is also noticed by Mr. S. J. Barnett in a valuable paper in the *Physical Review* for February last. Another point referred to by both these writers is the extraordinarily small coefficient of expansion of melted quartz. Benoit gives the extreme coefficients for crystalline quartz as $\cdot 0^5 72$ and $\cdot 0^4 133$. Barnett found for three quartz fibres $\cdot 0^6 3$, and for a rod of fused quartz $\cdot 0^6 2$. There is one part of the description of the manipulation with quartz fibres where the writer would add to Prof. Threlfall's description. On p. 220 the method of handling the fibre, cutting it off, and mounting it so as to be of the right length is described. Instead of a board to work on, however black it may be, a piece of looking-glass lying flat on the table is infinitely superior. This was suggested years ago by some kind friend, but who it was the writer is ungrateful enough not to remember.

The writer prefers when blowing quartz fibres of extreme tenuity for suspension purposes, not to blow a maze on to some screen, but, using a finer flame, to blow out a single fibre which may often be found joining the two rods, and either thick enough to show colour or generally far too fine to do so, corresponding in fact to the black of the soap-bubble.

Soldering, brazing, silver soldering, all essential everyday arts, are next described well and fully; but whether these descriptions will make these actually easy arts ever seem so to beginners is a question. Perhaps enough is not made of the sweating process carried out without any bit, or any preliminary cleaning or preparation of any kind. On the other hand, under brazing and silver soldering, the great use of a bit made of clean iron wire in showing the melted metal where to go when it does not flash at once, might be added in a future edition.

Insulators and conductors used in the construction of apparatus are next considered. Prof. Threlfall is probably the only person who has turned to useful account the writer's discovery of the superlative insulating properties of rods of melted quartz, even in an atmosphere saturated with water. Their application to a number of electrical appliances is described and figured.

Glass, ebonite, mica, micanite, celluloid, paper, paraffin, wood, slate, and marble are all discussed from the point of view of a constructional material with insulating properties. The electrical and mechanical properties of a large number of alloys, such as platinoid, manganin, &c., close this long and most valuable chapter.

The last chapter is upon electro-plating, chiefly gold, silver, copper and nickel, and upon allied arts. The writer has often heard that the best nickel plating is really cobalt. He hoped to, but did not, find any enlightenment upon this point.

An appendix upon platinising glass concludes the book.

This notice, already too prolonged, and yet insufficient, is enough to show that the experimentalist has now a most useful guide in a large number of processes. It is not possible to describe every process. The personal certificate is what gives value to those that are chosen. It is to be hoped that with Prof. Threlfall's valuable guide, instead of despising them, some of our growing physicists may be encouraged to make themselves familiar with some, at any rate, of those arts which Newton and Faraday cultivated with such astonishing skill and success.

C. V. BOYS.

A NEW TEXT-BOOK OF ZOOLOGY.

A Student's Text-Book of Zoology. By Adam Sedgwick, M.A., F.R.S. Vol. i. Pp. 600. (London: Swan Sonnenschein and Co., Ltd., 1898.)

MR. SEDGWICK has produced the first part of what must prove to be a very useful treatise for University students, if the remaining portions of the work are as well carried out as is the present.

In this volume Mr. Sedgwick gives an account of the Protozoa, Porifera, Cœlentera, Platyhelminthes, Nemertea, Nemathelminthes, Rotifera, Mollusca, Annelida, Sipunculoidea, Priapuloidea, Phoronidea, Polyzoa, Brachiopoda, and Chætognatha. The method adopted is strictly systematic: the larger groups are described and characterised in turn, the enumeration extending as far as families, which are also briefly characterised, important illustrative genera being cited. The work is, in fact, written on the lines of the translation of the "Zoology" of Prof. Claus, which Mr. Sedgwick gave us some years ago; but instead of merely producing a new edition of that work, he has written a new book introducing his own views and his own conception as to what are important facts and useful schemes of classification.

A distinctive feature of the work is the number of excellent woodcuts which Mr. Sedgwick has culled from a very large variety of sources. The text-books of Korschelt and Heider, Perrier, Lang, Claus, Wasielewski and Bronn's Thierreich have been laid under contribution for *clichés*, and the author is to be congratulated on the admirable collection he has brought together. The book is intended to be and is as brief as is consistent with an intelligible exposition. Yet it seems hardly possible that Mr. Sedgwick will be able to complete it in another volume of the same size. He has still to treat of the Echinoderma, the entire series of Arthropoda and the Vertebrata (which he would probably call the Chordata).

There are in the book one or two noticeable and original statements and classificatory innovations which it will be interesting to mention here. Mr. Sedgwick holds, as is well known, special views on the subject of cell-structure. He accordingly defines the Protozoa as "Animals in which there is one nucleus, or, if more than one nucleus, in which the nuclei are disposed apparently irregularly and without relation to the functional tissues of the animal. Conjugating cells of the form of ova and spermatozoa are never formed." In contrast with these the Metazoa are defined as "Animals in which the ordinary (so-called adult) form of the species has more than one nucleus, and in which the nuclei are for the most part arranged regularly and with a definite relation to the functional tissues of the animal (so-called cellular arrangement). Special conjugating individuals of the form of ova and spermatozoa are always formed."

With reference to this it may be remarked that the nuclei of, say, muscular tissue in Metazoa cannot be shown to have any more definite relation to the functional contractile substance than has the nucleus of a gregarine to its functional contractile substance, and the same kind of remark is true in reference to many other active structures in the two groups compared.

It surely is not possible to maintain that conjugating cells of the form of ova and spermatozoa are never formed in the Protozoa when we include (as Mr. Sedgwick does) the Volvocinean Flagellata in that group.

The account of the Protozoa is more complete than is usual in text-books of this size and scope, and the figures of Hæmosporidia and Myxosporidia, borrowed from Wasielewski, are particularly good, though the account on p. 63 of Hæmamœba Laverani is not quite satisfactory.

Mr. Sedgwick, as might be expected from his own important share in elucidating the subject, is very clear and precise in defining the "cœlom," and in explaining its real nature. He does not, however, as one could have wished, give the actual history of the word "cœlom," and the steps by which the erroneous views of Haeckel, the Hertwigs and other German authorities have been set aside. He says, "formerly the word cœlom was used as synonymous with body-cavity or peri-visceral cavity, and no distinction was recognised between the body-cavity of the Arthropoda and the same structure in such forms as Vertebrata." I think it is worth noting that, as a matter of fact, the word cœlom was introduced by Haeckel in the year 1872, in the first volume of his "Kalkschwämme," p. 468, in the following words :

"Die wahre Liebeshöhle" (contrasted by Haeckel with the digestive cœlenteron of Cœlentera, to which the term "body-cavity" or "Leibeshöhle" was undesirably applied) "welche bei Vertebraten gewöhnlich Pleuroperitonealhöhle genannt wird, und fur welche wir, statt dieses neunsylbigen Wortes die bequemere zweisylbige Bezeichnung Cœlom (κοῖλωμα, τὸ, die Höhlung) vorschlagen, findet sich nur bei den höheren Thierstämmen bei den Würmern, Mollusken, Echinodermen, Arthropoden und Vertebraten."

For Haeckel the typical cœlom was the pleuroperitoneal cavity of the Vertebrate. At the time when he wrote, that cavity was supposed to have arisen phylogenetically by a splitting of the mesoblast; hence the failure of Haeckel to distinguish other cavities, such as the hæmocœl of Arthropoda and of Mollusca from the true cœlom. I gather from Hertwig's text-book of Embryology that I was the first to point out that the "schizocœl" (as Huxley called it) of higher Vertebrates could be and should be interpreted (in consequence of Balfour's discoveries in Selachian development) as an enterocœl—a pouch, in this case without lumen—which arises as a solid outgrowth from the enteron, the opening out of its cavity being delayed. Thus the cœlom is now characterised by Sedgwick as "a part of the enteric cavity which has lost its connection with that portion which constitutes the alimentary canal in the adult." The enteric pouches of the Actinozoa are "an incipient cœlom." Further, it is recognised by Sedgwick that "the cœlom, in addition to its mechanical relations, has two most important functions : the one of these is to bud out the reproductive cells, and the other to secrete the nitrogenous waste." The essential cells of the gonads and of the nephridia are parts of the cœlom. Mr. Sedgwick's own researches on the development of Peripatus served more than anything else to establish that the cavity of Arthropods, which I had termed "hæmocœl," is distinct from cœlom, and that there is—quite apart from hæmocœl—a true cœlom in Arthropoda reduced in the adult to nephridial and perigonadial rudiments. My own observations on the pericardium of Mollusca, and on the vascular system of both Molluscs and Arthropods, as well as the work of my pupil Gulland on the coxal glands of Limulus, had tended, before this, to show the existence of "cœlom" distinct from "hæmocœl" in both those groups. Thus the erroneous notions promulgated in the "Cœlomtheorie" of the Hertwigs were superseded. I am distinctly of the opinion that this step forward—viz. the recognition, definition and characterisation of the true "cœlom" as distinct from "hæmocœl"—has been due to English observations and English doctrine, and I think that a full account of the history would be valuable to students.

Mr. Sedgwick necessarily has something to say in this connection concerning the supposed communication of vascular system and cœlom in the Leeches. In his excellent account of those animals (in which he not only discusses Acanthobdella, but introduces Kowalewsky's recent figure of its anterior segments) Mr. Sedgwick lays great stress on Oka's recent observations upon Clepsine, and concludes that "we are bound to hold, provisionally at any rate, that in Leeches, as in other animals, the blood system and cœlom are separate from one another." I quite agree that there are probabilities in favour of Mr. Sedgwick's conclusion. Twenty years ago, and at intervals since then, I have endeavoured to put the matter out of the region of probabilities, but in spite of the careful researches made in my laboratory by A. G. Bourne and others, I have not yet succeeded in so doing. After all, it should be possible, by modern improved methods, to test this question of continuity in *Hirudo* by means of actual injection. There are "other animals," it must be remembered, in which there is free communication between the cœlom and the vascular system, to wit, the not unimportant animals known as Vertebrata.

In his classification of the Mollusca, Mr. Sedgwick has taken his own line, and refused to follow Pelseneer in the separation of the Chitons from the Gastropoda, though he places Neomenia and Chætoderma in a separate class, the Solenogastres, for very good reasons which he sets forth.

The creation of a separate phylum for each of the small groups of Sipunculoidea, Priapuloidea, and Phoronidea is perhaps legitimate in the present state of knowledge, though the questions involved are of a very difficult nature, and the facts known insufficient to give one great confidence in any of the proposed classifications affecting those animals.

Mr. Sedgwick excludes the Platyhelminthes, the Nermertea, the Nemathelminthes, and the Rotifera from the Cœlomata; but he does not argue at any length the question as to whether there are or are not cœlomic rudiments in each of these groups. The perigonadial sacs of Platyhelminthes and Nemertea and their nephridia may be interpreted as modified developments from cœlom, though it would no doubt be difficult to show that they are so. It must, however, be remembered that in such matters the assertion that A *is not* B is as positive and definite a statement, requiring just as full a proof, as the statement that A *is* B.

The chief omission which has to be noted in Mr. Sedgwick's book is that which I have recently pointed out in other works—namely, an insufficient historical account of the discoveries, hypotheses, conceptions and terms (with immediate reference to chapter and verse), the bringing together and explanation of which is the purpose of the writer's labour. Mr. Sedgwick is not so determined to omit history and the names of contemporary workers as are some other writers of text-books. He does not make a profession or virtue of this practice, and in many cases gives an immediate reference to a special memoir, or even cites a naturalist's name, after mentioning an important fact or theory. At the same time, he cannot be said to have done what could easily have been done in this respect without materially increasing the size of his book. Of course, all such references and discussions must be in proportion to the size and scope of the text-book in which they should appear, and Mr. Sedgwick not unfrequently does give a historical reference. But why should he not tell us, for instance, who invented the name Protozoa, what he meant by that term, and how it came to have its present limitations? Why should he not tell us (p. 533) who proposed the separation of Sipunculoidea and Echiuroidea which he adopts? Why should he not give credit to Dr. Hudson for his most interesting discovery of the six-legged Rotifer *Pedalion*, instead of printing Hudson's drawing of his discovery with the label "from Perrier after Gosse?" Mr. Sedgwick very properly states in a footnote that the classification of the Polychæta adopted by him is that of Dr. W. B. Benham, to whose work he refers. It would, I think, have helped many of his readers if he had given some account of the source of classification and terms used by him, in all other instances. Putting aside such suggestions for improvement, I think we must recognise that Mr. Sedgwick's book is a very good one, ably put together, and likely to be extremely useful; it is, in fact, not only the last, but the best zoological text-book—so far as the first volume goes—in the language. E. RAY LANKESTER.

THE ANALYSIS OF ORES.

Methods for the Analysis of Ores, Iron and Steel, in Use at the Laboratories of Iron and Steel Works in the Region about Pittsburg, Pa. Pp. iv + 133. (Easton, Pa.: Chemical Publishing Co., 1898.)

A COLLECTION of the methods in use in the modern laboratories of steel works must be useful if only for comparison, but the present book cannot take rank with standard works such as those by Blair and Arnold. One notes a sameness in the modes of procedure, varied, however, in some instances by questionable modifications, more especially as regards phosphorus determinations.

Sufficient attention has not, on the whole, been given to the exact relative proportions of nitric acid, molybdate, &c. Most of the operators are apparently content to assume that it is sufficient to add, in all instances, measured quantities of the reagents required. This is contrary to the writer's experience: each analysis should be conducted in accordance with the conditions observed at the time; it is not enough to merely add fixed quantities of reagents, but the operator must judge for himself, more especially as regards the use of nitric acid.

In practice the best and most accurate results are obtained by the direct weighing of the molybdate precipitate, using the magnesia method only as a check.

Volumetric methods are useful where rapid determinations are required for check purposes, but are not so trustworthy as the weight method, *i.e.* when proper precautions are taken and the necessary experience gained.

Sulphur.—The evolution method cannot be dispensed with in an ordinary steel works, but is only useful for rough determination; it is little better than a qualitative method, as has been repeatedly demonstrated.

Apparently we have no better method than with aqua regia and subsequent precipitation with barium chloride. It is well known, however, that discordant results are often obtained. At present a rapid and strictly accurate mode of determining sulphur has yet to be devised; this for various reasons well-known to analytical chemists.

As regards the estimation of manganese, nickel, copper, &c., little need be said; there is not much that is novel in the methods, which are fairly good and are such as are usually practised. The same is applicable to carbon determinations, with the exception of barium hydroxide as an absorbent (A. G. McKenna), which the author recommends; as also the complete analysis of chrome iron, which appears a mode of procedure sufficiently accurate for all practical purposes.

Analysis of Ores, &c.—Mr. James M. Camp's method for rapid analysis of blast furnace cinders apparently gives results useful to the blast furnace manager, but the determination of manganese, from Mr. Camp's own showing, cannot be neglected.

The writer has used the colorimetric method both for iron and manganese, especially iron; it is most important to make frequent iron determinations, for obviously iron in the slag is equivalent to loss of metal in the pig-bed. The colour method is rapid, good for iron in slag, and more accurate than the weight process.

Determination of Silica in Ores.—One notes that potassium sulphate or hydrofluoric acid are sparingly used, American chemists relying chiefly on the sodium carbonate method. In this country preference is given to the use of the former; chemical results are considered more accurate, with economy of time.

Determination of Iron.—The bichromate method leaves nothing to be desired as regards slags, ores or minerals in general, but is not very suitable for the accurate determination in iron or steel. Most chemists are content in iron or steel analysis to give the iron by difference, but if a method could be devised whereby the absolutely pure iron could without question be determined within ·001 per cent., such a factor would in the present state of our knowledge be invaluable. Those who have studied the recent developments of the chemistry of iron will understand this.

On the whole, American practice seems inferior to the English; some of the methods quoted are practically obsolete in this country. This applies more especially to manganese determinations—only two chemists when using the gravimetric method for manganese take note of the previous necessary removal of barium when ores are being analysed, to say nothing of other possible impurities.

Very many of the processes given seem devised merely for speedy work, regardless of accuracy; on the other hand, some needless complications have been introduced with consequent loss of valuable time.

JOHN PARRY.

OUR BOOK SHELF.

Electro-physiology. By W. Biedermann. Translated by Frances A. Welby. Vol. ii. Pp. vii + 500. (London: Macmillan and Co, Ltd., 1898.)

MISS WELBY has now completed her translation of this work. The second volume is equal to the first in scientific interest and importance, and the technical difficulties of rendering it into English have been overcome with even greater success.

Prof. Biedermann deals with the main subject of the volume, that of the "electro-physiology" of nerve, much more from a physiological than from an electrical point of view. In every branch of it he is able to give us the results of his own work, or of those of the distinguished colleague with whom he was for so many fruitful years associated at Prague; so that the student who desires to appreciate the experimental basis of Hering's doctrine cannot have a better guide than is here provided for him. It must not, however, be supposed that the work is mainly theoretical; on the contrary, on the subjects of which it treats, it is the best "reference-book" that the physiological worker has at present at his disposal.

In addition to the chapters on nerve, the volume contains a very carefully written chapter on the electrical endowments of the plant-cell, another on electric fishes, and a third on the electrical response of the retina to the stimulus of light. In discussing the first two of these special subjects, Biedermann derives his data chiefly from English sources. In the elaborate and copiously illustrated chapter on electric fishes, the reader will find a complete account of Prof. Ewart's investigations of the development and structure of the electrical organ in the rays; and of Prof. Gotch's researches on Torpedo. In like manner the chapter on the electromotive properties of excitable tissues of plants is mainly based on English researches on *Dionæa*, of which it contains a very full *résumé*. It is a satisfaction to the writer of this notice that the main results of his own investigations have been accepted by his German colleague, and particularly to observe how fully he has appreciated the evidence they afford of the essential identity of the elementary processes of plant and animal life. J. B. S.

Open-air Studies in Botany: Sketches of British Wild-flowers in their Homes. By R. Lloyd Praeger, B.A., B.E., M.R.I.A. Illustrated. (London: Charles Griffin and Co., Ltd., 1897.)

THESE open-air studies should appeal to people who live in the country, and who care about the wild plants around them. A glance through the pages recalls many a country ramble, and a good point about the treatment in the book is that an attempt is made to connect the flora of a locality with the physical conditions which prevail there. It is a pity, however, that the author should have not adopted the names in common use for his plants—*e.g. Scilla festalis* the wild hyacinth or *Volvulus* for *Convolvulus* both look and sound pedantic. Moreover the glossary, which forms a necessary appendix, is sometimes disfigured by misleading statements; thus a carpel is stated to be that part of a flower which contains an ovary. But in spite of occasional slips and blemishes, the positive merits of the book should secure for it a fair measure of success.

The Journal of the Iron and Steel Institute. Name Index. Vols. I–L (1869–96). Edited by Bennett H. Brough. (London: E. and F. N. Spon, Ltd., 1898.)

THE Iron and Steel Institute was founded in 1869, and since its establishment it has done most useful work by arranging periodical meetings for the discussion of practical and scientific subjects bearing upon the manufacture and use of iron and steel. The papers published in the Institute's *Proceedings* are here indexed, and they make a solid contribution to knowledge. The volume contains a short history of the Institute, a list of papers contained in the first fifty volumes arranged chronologically, a list of these papers arranged according to subjects, an index of the authors, and a complete index to the authors of all papers, communications, and abstracts published in the fifty volumes. The complete index will thus be of service in showing the development of the science of iron and steel.

A Simplified Euclid. Book I. By W. W. Cheriton. Preface by Elliott Kitchener. Pp. iv + 111. (London: Rivingtons, 1898.)

SO many simplified Euclids have been published during the last few years, that an addition to their number should seem superfluous. In the one before us the compiler claims that after teaching the subject for some years he thinks that the form he proposes in this book should supply a long-felt want. The method he adopts is to print the proposition exactly as it should be written out by a schoolboy, using sufficient abbreviations to save time in writing without confusing the mind of the pupil. Each proposition is printed on the left-hand side of the page, notes and exercises being printed on the right. The book has many points in its favour.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Origin of the Aurora Spectrum.

PROF. RAMSAY gives the wave-length of the principal line in his new gas as 5566. It will no doubt also occur to others that this is very near the wave-length of the aurora line, which Vogel has measured as 5569. It should be mentioned in connection with this line that Profs. Liveing and Dewar have observed one very near it at 557 in sparks taken in liquid oxygen. The second green line given by Prof. Ramsay as 5557, seems also to have been seen by these observers (*Phil. Mag.*, xxxviii. p. 237, 1894). ARTHUR SCHUSTER.

Manchester, June 10.

The Action of Electric Discharges on Photographic Plates.

REFERRING to the paper on this subject, read on May 16, by Mr. J. A. McClelland, at the Cambridge Philosophical Society, and reported in your issue of June 9 (p. 142), perhaps I may be allowed to mention that very similar experiments, with the deduction that the effect is chiefly due to light, and not to electrolytic or other action, were described by myself in a paper to Section A of the British Association, at its Edinburgh meeting in 1892, and will be found fully reported in the *Electrical Review* for August 26 of that year.

I do not know whether others have observed the fact that when strong sparks from an induction coil or influence machine are allowed to traverse the sensitive surface of an ordinary photographic dry plate, that a dark line, delineating the path of the spark, is immediately produced, and can clearly be seen without any necessity for photographic development. Further, that such lines, though faint to commence with, darken appreciably after a few minutes lapse of time, and still more so in the course of a few hours. This appears to indicate that whatever the precise action of the spark on the film, this action continues after it has once been started. Further, it is a curious fact that these lines, if examined with a magnifying glass, are always found to consist of two dark lines with a light space between them. This is specially noticeable immediately after the spark has passed, the space apparently filling up with lapse of time. A. A. C. SWINTON.

66 Victoria Street, London, S.W., June 10.

A High Rainbow.

ON Sunday afternoon, May 29, while sitting in my yard, my twelve-year-old son called my attention to a rainbow which he had discovered while lying on his back looking up at the sky. The local time here was 5.40 p.m., and the sun, therefore, about an hour and a half high. The bow was in the west, and about 70 degrees from the horizon, with its convex side to the sun. The colours were fairly well brought out, the red being on the convex side of the arc, and the violet on the concave side. The figure on p. 132 of Tait's "Light" shows a short arc near the zenith, which is a fair representation of what was seen here. I have not read an account of what was seen by Helvetius further than is contained in Prof. Tait's book, and do not know whether the arc seen by him near the zenith showed the rainbow colours. In this case I do not see any of the other halos seen by Helvetius. There were but few very thin clouds, and no rain at all. SIDNEY T. MORELAND.

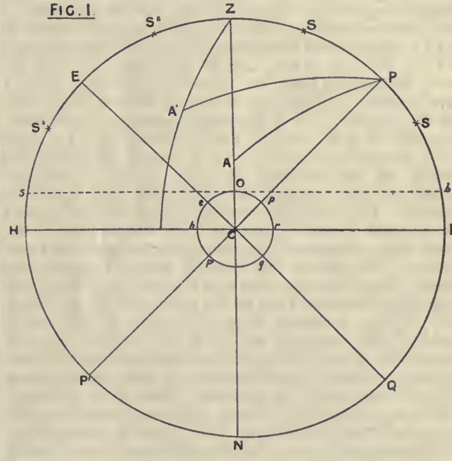
Lexington, Virginia, U.S.A., June 2.

NAUTICAL ASTRONOMY.

IF the compass is the navigator's sheet-anchor, the sextant is certainly his best bower; and just as the former was known, if not generally used in Europe, about a century before Flavio Gioia got the credit of discovering it, so the latter was invented by the transcendent genius of Sir Isaac Newton, more than half a century before it was re-invented by Hadley in 1731. Newton does not seem to have suggested its adaptability for navigational purposes, or if so, it was not sufficiently known or taken up, and I am not aware of any reason to suspect that Hadley knew of Newton's discovery.

The principal use the navigator puts the sextant to is that of measuring the altitudes of heavenly bodies—that is, the angle at his eye subtended between the object and the visible horizon. Now the *rational* horizon may be defined as the plane perpendicular to the plumb-line through the earth's centre, or the circle traced by the meeting of this plane with the celestial concave. The *sensible* horizon is generally defined as a plane parallel to the former through the eye of the observer; but this can only coincide with the *visible* horizon if the eye of the observer is at the surface of the earth—as if he were immersed in the sea, till a horizontal line from his eye would be a tangent to the sphere at that point. But the eye of the observer is always above the surface of the sea; and the more it is raised, the more the visible horizon is depressed, and a correction called "dip" has to be applied to an altitude measured to it, to reduce it to what it would have been had the eye been at the sea-level. Again, before this *apparent* altitude can be used for position-finding, it has to be still further corrected for

FIG. 1.



refraction, due to the bending of the rays of light, in passing through the earth's atmosphere, and in the case of sun, moon, or planet for parallax, to reduce it to the angle at *the centre of the earth and to the rational horizon.* Both these corrections are zero when the body is in the zenith, and a maximum at the horizon. Parallax is the angle at the observed body, subtended by the semi-diameter of the earth under the feet of the observer, which will be reduced to a point when the body is in the zenith. If the body has an appreciable semi-diameter, it has to be applied to the altitude of the limb to get that of the centre.

In the diagram (Fig. 1), let H E Z P R Q N P′ represent a meridian of the celestial concave, and the inner circle the corresponding meridian of the earth; let Z be the zenith, N the nadir, P and P′ the poles of the heavens, being the points in the celestial concave, which would be perforated by the earth's axis if indefinitely produced: then H R will represent the rational horizon, the plane of which, passing through C, is normal to the plumb-line Z O N, *s* O *b* will represent the sensible horizon (O being the position of the observer), E Q, the plane of which is normal to P P′, will be the equinoctial, whose plane coincides with that of the terrestrial equator. On a meridian from E Q towards either pole, the declination of a heavenly body (corresponding to latitude on the earth) is measured, and from the first point of Aries (the celestial meridian passing through which is the prime meridian of the heavens) right ascension is measured round eastward, instead of east and west, as longitude on the earth.

Now let the reader imagine his eye to be at C, that the earth is a transparent sphere, and that it and its atmosphere are absolutely free from refrangibility, then every point in the celestial meridian would be seen through its prototype on the surface of the earth, and any and every angle at C, measures the same arc of the celestial meridian, and of the one on the surface of the earth. Now, what is true here holds good for every other meridian—every other great circle of the celestial concave, and the one that has the same plane on the earth's surface.

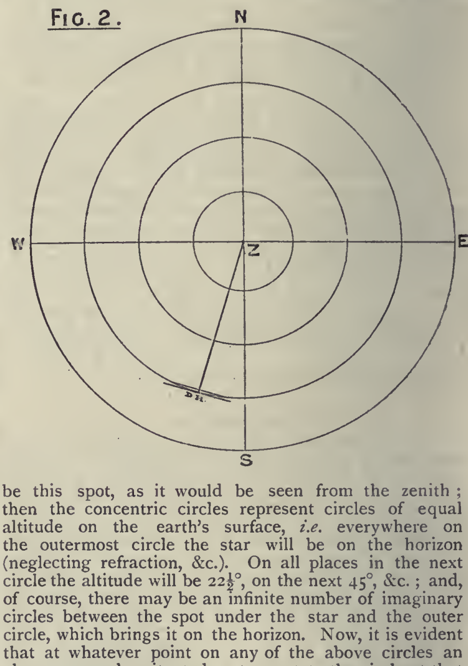
The latitude of a place is the arc of a meridian, intercepted between the place and the equator, consequently *e* O is the latitude of O; but *e* O and E Z are both measured by the angle *e* C O, and E Z = P R, each being the complement of P Z, which accounts for one of the best-known rules in nautical astronomy, viz. that the altitude of the pole = the latitude of the place; so that if there was a star at P, its altitude would give the latitude without any further computation. Let S, S′, &c., be the positions of stars on the meridian. But very little consideration will make it clear that if the observer can measure one of the arcs S R, S^1R, S^2H, or S^3H, and at the same time get the star's declination from the *Nautical Almanac*, it is a mere question of addition and subtraction of arcs to obtain the latitude. P S is the complement of the declination, and $PS + SR = ES^1 - ZS^1 = ES^2 + ZS^2 = ZS^3 - ES^3 = EZ$, the latitude of O. This is known as finding the latitude by the meridian altitude. It gives one line parallel to the equator, on which the ship must be situated. To fix her position on it, we must get another line to cross it, which passes through the position of the vessel, when, manifestly, she must be at the point of intersection. The nearer the cross is to right angles the better. To do this we must find the time, and thence by comparison with the time at the prime meridian (Greenwich is now accepted by most nations as the prime meridian), the meridian on which the ship is situated. Neglecting minor differences and irregularities, the sun appears to revolve round the earth in twenty-four hours, or at the rate of 15° in an hour. Now if we find that it is 9 a.m. at the ship, when it is noon at Greenwich, the ship must be in longitude 45° W. If, on the other hand, the chronometer showed 5 a.m. the vessel would be in longitude 60° E. The Greenwich time may be calculated from a lunar observation, which the perfection of the modern chronometer and the shortening of voyages have driven out of the field. To get the time at ship, we have recourse to spherical trigonometry, or rules and tables based on it, to calculate the hour angle. The sun's westerly hour angle is the apparent time at place (A.T.P.), which is converted into mean time (M.T.P.) by applying the equation of time, which, like declination, &c., is supplied by the *Nautical Almanac*. If the body observed is a star, we get the M.T.P. by adding to the hour angle the star's right ascension, and subtracting that of the mean sun, which is a transposition of the well-known and useful equation, ✳'s hour-angle = M.T.P. + mean ☉'s R.A. − ✳'s R.A. which we use for time azimuths, and for finding when a body will cross the meridian, for when hour angle = 0

M.T.P. = ✳'s R.A. − mean ☉'s R.A.

Now, just as the simplest way of getting the latitude is by a body on the meridian, so the best way of calculating the time for longitude is by using the altitude of the sun or a star on the prime vertical (*i.e.* the vertical circle passing through the E. and W. points of the horizon). If, by means of this altitude, or any other way, we could tell the exact instant that the body was on the prime vertical, there being a right angle in the triangle A P Z (Fig. 1), we could calculate the time by right-angled spherics from any two of the three sides, colatitude, polar distance and zenith distance, or their complements latitude, declination and altitude. But in practice, whilst it is easy to get the meridian altitude, it is impossible to be sure of getting the altitude exactly on the prime vertical. It is, however, comparatively easy to observe a body near enough to the prime vertical to be very favourably situated for finding the time by oblique spherics (or formula deduced from it), and thence the longitude; and this, combined with the meridian altitude, is perhaps the simplest and most favourable method of fixing the position at sea. However desirable, it is by no means necessary that the body be near the prime vertical, though, generally speaking, the further it is removed from it, the less favourable the conditions, till at last the triangle becomes an impossible one.

Every particular star is, at every instant of time, in the zenith of some spot on the surface of the earth. At any given instant of time, let Z, in the accompanying figure,

FIG. 2.



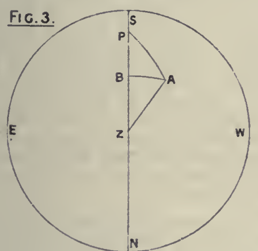
be this spot, as it would be seen from the zenith; then the concentric circles represent circles of equal altitude on the earth's surface, *i.e.* everywhere on the outermost circle the star will be on the horizon (neglecting refraction, &c.). On all places in the next circle the altitude will be 22½°, on the next 45°, &c.; and, of course, there may be an infinite number of imaginary circles between the spot under the star and the outer circle, which brings it on the horizon. Now, it is evident that at whatever point on any of the above circles an observer may be situated, a tangent to the circle at that point will be at right angles to the bearing of the body; but a small portion of the circle may be represented by a similar portion of the tangent, and it is evident that the larger the circle (which is equivalent to the smaller the altitude), the longer the portion of its circumference that may with impunity be treated as a straight line. This straight line is known as "a line of position." The line of position obtained from a meridian altitude differs from all others in this, that the ship is not only on the circle of equal altitude, but on its vertex,[1] and the tangent may be assumed as of infinite length.

[1] Compare figure in paper on "Navigation," (p. 104) illustrating composite sailing, where, however, the circles that touch the parallel are great circles.

The line of position by an altitude for time was first discovered by Captain Sumner, who, being doubtful of what latitude he was in, worked an observation with three different latitudes. On projecting these positions on the chart, he found that all three were in a straight line, which produced, led to the Smalls light, whose bearing he thus had, without knowing how far it was away. He steered along the line till he found it. He did not observe, however, that this line was at right angles to the sun's bearing, nor would it have shortened his problem if he had, because it then took as many figures to calculate one longitude and the azimuth as two longitudes with different latitudes. In these days, when azimuths can be taken out of tables by inspection, nearly half the figures are saved by using the azimuth to obtain the line of position.

Thus, no matter what the bearing of a heavenly body, if we can observe its altitude and the corresponding time at Greenwich, it will afford us some information as to the position of the ship. If it is on the meridian, with a minimum of labour we get the latitude in the simplest and most accurate way available to the navigator. If it is not too far in azimuth from the meridian, there are plenty of methods by which the observation can be reduced to the corresponding meridian altitude, and the latitude obtained. If it is on the prime vertical, the line of position will be a portion of a meridian. If it is on any intermediate bearing, the line of position will be at

FIG. 3.



right angles to the bearing of the body, through the latitude by account, and the longitude deduced from it and the observation. Any two lines of position, provided they do not cross at such an oblique angle that the intersection is ill-defined, will fix the position of the vessel. When the star is so far from the meridian, and the time too uncertain to be favourable for working as an ex-meridian, and yet too far from the prime vertical to give an accurate hour angle, the new navigation, originated by the French, and introduced into England by Captain Brent and Messrs. Williams and Walter, R.N.,[1] gives a better line of position than the older methods. By it you calculate the *altitude* for the position of the ship by dead reckoning. If this agrees with the observed altitude (corrected), the line of position is at right angles to the bearing of the star, through the position by D.R. If, however, the observed altitude is, say, 10′ greater than that calculated, the ship must be that much nearer the spot on the earth where it was in the zenith at the moment of observation; so you lay off 10 miles (1 sea mile being practically 1′ of a great circle) from the D.R. position, in the direction of the star, and through this point rule the line of position at right angles to the bearing; or the corrections for the D.R. latitude and longitude may be calculated by trigonometry (see Fig. 2).

The triangle A P Z (see Figs. 1, 3, 4 and 5) is the most important in nautical astronomy. Up to this, I have only referred to it as a means of finding hour angles (angles at P); but not only is it also used for finding azimuths (angles at Z), for if the time be accurately known, we can utilise it for finding the latitude by a star with a large hour angle. To make it clearer, and avoid complicating Fig. 1, I give figures here on the plane of the horizon. In these, let A represent three different stars, and from A let fall a perpendicular on the meridian. Then right-angled spherics can be utilised, and the latitude obtained with fewer figures than by the new navigation. Either before or after the ✱ or ✱s shown in the figure, are obtained for latitude, observe one on or near the prime vertical, for longitude and time, which will give accurately the hour angles of the latitude ✱s, allowing, of course, for any easting or westing made between the observations. Then

$$\text{Sin AB} = \sin h \sin p,\ \tan \text{PB} = \cos h \tan p \text{ and } \cos \text{ZB} = \sin a \sec. \text{AB}$$

h being the hour angle, p the polar distance, and a the true altitude. The sum or difference of PB and ZB = the colatitude. This method is even shorter than it appears at first sight (because the logs. can be taken out in pairs), and is concise and accurate when the data is trustworthy, and, even if the hour angle is doubtful, will give a good line of position.

Unfortunately, the navigator has often to work with data that are more or less doubtful. In the triangle, A P Z, he uses the three sides to find the hour angle (P). Of

FIG. 4.

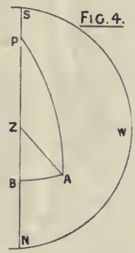


FIG. 5.

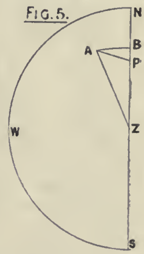

these the polar distance is accurate; the latitude is often doubtful enough to affect the hour angle, though not generally the line of position, and the altitude may be vitiated in various ways. It therefore behoves him to take his observations in a way that errors, that he can neither detect nor avoid, will neutralise each other. Few human eyes are optically perfect; the best sextants, though beautiful instruments, are not absolutely faultless, and their errors are liable to alter by a knock or jar; the sea horizon is fickle, and refraction uncertain; but the whole of these errors may be minimised, if not absolutely, eliminated, in the resulting latitude—for example, by observing (Fig. 1) the ✱'s S^1 and S^2. With about the same altitude, their refraction will probably be similarly affected; the horizon is *generally* subjected to the same influences all round; the personal and instrumental errors may be taken as constant, for the same observer and sextant, at any particular time and place when the altitudes are somewhat similar. Suppose the sum of these errors to be $-2'$, and unallowed for, the effect would be, in each case, to make S^1 and S^2 appear nearer Z than the truth; and while each resulting latitude would be 2′ wrong, the mean would be correct.

Again, in the single altitude problem (Figs. 3, 4 and 5), if the time had been calculated by two stars, one east and the other west, the time and thence the hour angles of the latitude ✱s would be less liable to the foregoing errors; and if the three stars were taken and worked for latitude, each would be a check on the others, and opposite bearings would tend to neutralise errors of

[1] "Exmeridian Altitude Tables and other Problems," by these authors, is an excellent work.

altitude. At the same time, single observations very generally give sufficient accuracy for all the purposes of navigation, though they are not to be so absolutely relied on as a systematic set.

I must not conclude without another word on the lunar method of finding the Greenwich time, which I dismissed rather summarily, further back, in favour of chronometers. For long voyages across the ocean, when a vessel is from fifty to one hundred days without sighting land, lunars may still be used, as before the days of steam, not so much for finding individual longitudes as for *rating the chronometers*, and for this purpose it is essential that a series of distances be measured on each side of the moon, and the mean of all the easterly ones, meaned with the average result of those taken to the westward, to eliminate as far as possible personal and instrumental errors. An expert lunarian, who practises regularly, may find out by experience about how much on each side, single distances, measured east or west, would place his ship; otherwise, the result of a single lunar could not be relied on to give the longitude to nearer than $\frac{1}{2}°$ or 30′, even if taken under favourable circumstances. In a steamer vibration almost precludes the observation, and the chronometers ought seldom to be 5s., and never 30s. wrong. In ports where there are not time-balls, the chronometer errors can be found accurately with the artificial horizon, observing, if possible, ✱s east and west, or the ☉ and ☽, or even by the ☉ alone. It is generally possible to verify the errors at sea by sighting land, or even to get a fair rate, by observing ✱s E. and W. of meridian to the sea horizon. An error in the chronometer does not alter the *direction* of a line of position, but moves it bodily E. or W.

As an example of the use of a single line of position, suppose a steamer to be approaching Cape Finisterre from the Channel, and only able to obtain one observation, the sun right ahead. The line of position, being at right angles to her path, will be a good check on her speed, but none whatever on the course she has made good. On the other hand, if the sun (or star) had been observed on her beam, the line of position would be no check on the speed, but would indicate the course made good, and whether, if it was continued, it would clear the land. In soundings, a line of position may be combined with the depth of water to fix the position.

The tendency of modern navigation is to become too stereotyped—to do everything by tables, which obscure the mental vision, and to relegate to the bookshelf that knowledge of theory which, combined with practical experience, is the surest guide to the navigator in deciding on the best way of utilising his observations, and which method, in any particular case, will give him the best line of position. If theory is not the only thing that will teach him, that while when the sun culminates near the zenith, he can get good observations for time within a few minutes of its passing the meridian, a Sumner line derived from such observation would be almost useless, owing to the smallness of the circle of equal altitude; it will certainly make him acquainted with the fact in a tenth of the time that unaided experience will. Some of the so-called short methods are only short because of preliminary calculations that are not counted by the authors in the work, and which may all go for nothing if some particular altitude is not obtained, that a passing cloud may render it impossible to measure; or else they involve several vexatious interpolations, which are quite as much trouble, and, if performed mentally, much more liable to error, than taking out and adding up a few lines of logarithms.[1]

[1] Every aspiring young navigator should make himself acquainted with spherical trigonometry, especially with "Napier's Analogies," which combine the brevity of short methods and special tables with the accuracy of pure mathematics. He should also accustom himself to drawing the figures for his problems till he can see the triangle in his mind's eye without a diagram.

Finally, it is better to get several observations of different bodies at (or about) the same time, than two of the same, with the requisite interval for change of bearing, because one of these observations has to be reduced to what it would have been if taken at the same place as the other, and the reduction may be vitiated by errors of the run, as explained in the paper on "Navigation," which it is one of the great objects of nautical astronomy to detect and be independent of. J. F. RUTHVEN.

THE LONDON UNIVERSITY BILL.

ALL friends of scientific and educational progress will be glad that the second reading of the London University Statutory Commission Bill was carried in the House of Commons on Tuesday without a division, and has been referred to the Standing Committee on Law. We are thus brought within sight of a long-delayed and much-needed reform, and all who have assisted in educating public opinion upon the measure, with the object of removing the unreasonable obstruction placed in its way, may congratulate themselves upon the success which their efforts have at last achieved. It is not to the credit of Ministers that a scheme of such deep importance to the best interests of the country should have been permitted to languish for so long a period, seeing that the necessity for establishing a teaching university in the metropolis is admitted by practically all public bodies connected with science and higher education in London. Had they possessed the courage of their convictions the measure would have passed into law without difficulty in 1896 or 1897, and its withdrawal upon each occasion must be counted as a lost opportunity. The opposition which then threatened the scheme would doubtless have collapsed so completely as it did on Tuesday, when it received so little support that the measure was agreed to even without a division. We reprint from the *Times* some parts of the speech made by Sir John Gorst in moving the second reading, and of the speeches which followed.

Sir John Gorst commenced by giving a general history of the scheme for a teaching University, and pointed out that the present Bill is based on the report of the Cowper Commission, which unanimously recommended that there should be no second University in London, and that the necessary modification of the constitution of the London University should be effected by means of a statutory Commission. He continued: "I should like to inform the House of the various bodies by which this scheme has been considered and accepted. It has, first of all, been accepted by the Senate of the University of London by a majority of 22 to 2—practically a unanimous acceptance by the Senate of the University of London. It has been accepted by the Royal College of Physicians, by the Royal College of Surgeons, by the Society of Apothecaries, by University College, by King's College, by the Bedford College for Women, by the twelve medical schools which exist in London, by six theological colleges, by the Society for the Extension of University Teaching, by the Technical Education Committee of the London County Council, by the Corporation of the City of London, by the City and Guilds Institute, by the Polytechnic Council, by the Royal Society, and all the other learned societies in London; and, finally, it has been accepted by the Convocation of the University. I say it has been accepted by the Convocation of the University of London because, by the charter of the University, a particular mode is specified in which the Convocation of the University of London shall express its opinion on the subject. The Convocation expresses its opinion by a meeting at which discussion takes place, and at which a vote is given by the persons there present. Such a meeting of Convocation has been held, and this present scheme has been approved in that legal and formal manner in which the charter of the University requires the opinion of Convocation to be expressed—by a majority of 460 to 239."

Referring to the views of graduates as shown by voting papers, Sir John Gorst said, "Even assuming that the existing graduates of the University of London were unanimous in their objection to the present scheme, I do not know why the personal feelings of London graduates should stand in the way of a great national reform—of a national development of higher education—when in the scheme, as I shall presently show, their rights and interests, such as they are, are most carefully and most securely preserved. There is a further objection brought forward which we shall no doubt hear of from the right hon. baronet, the member for the University of London, and that is a claim that the Convocation of London should have a veto upon any scheme which Parliament may enact for the purpose of developing the University of London. That claim is based upon Article 21 of the charter, which says that if a new or supplemental charter is given by the Crown to the University of London, the power of accepting it shall be exercised by the Convocation of the University. The answer to that is, first of all, that this is a restriction which applies to the charter and not to the action of this House. The Crown may very properly restrain its own power of granting any further charter, but it cannot restrain the power of the Houses of Parliament."

Sir John Gorst proceeded to point out how carefully the objections and fears of those who are opposed to this Bill have been met in the scheme which has been laid before Parliament. He said :—

"I am informed that there is a genera agreement among learned and scientific men, not only in this country, but in the whole of the civilised world, that in the highest parts of progressive science the attainments of students cannot be tested unless the teachers have some voice in setting the subjects of examination. That being the danger to be guarded against, the Bill appoints seven Commissioners by whom the statutes of the new University are to be framed. The Commissioners are Lord Davey; the Bishop of London; Sir William Roberts, a medical doctor and a Fellow of the University of London; Sir Owen Roberts, who is well known as having taken an active part in the spread of modern education; my hon. colleague the senior member for Cambridge University (Prof. Jebb); Michael Foster; and Edward Henry Busk, chairman of Convocation of the University of London. These Commissioners are constituted to frame the statutes for the purpose of carrying out the general scheme of the commission—that is, to so modify the existing University of London that it may fulfil the functions of a teaching University. I think the House may very well trust men like those I have named to frame statutes that will be in accordance with the best interests of education."

"The Government recommend this Bill to the House. It is not their scheme; it is a scheme which is the result of very long controversy and of a great deal of compromise, of give-and-take on the part of the various bodies, and they think it is a satisfactory conclusion of a very long discussed question. It will give a teaching University to London in the only way in which it can be given—namely, by the modification of the constitution of the existing University, and, in doing this, so far from injuring the existing University, it will increase its utility and its reputation."

Mr. Harwood moved an amendment for the rejection of the Bill, and Mr. Yoxall seconded it, but their views received little sympathy.

In speaking against the bill, Sir John Lubbock said those who had opposed the Bill had done so on four main grounds: first, that the result might be to imperil the position of science; secondly, that it might put the country colleges and private students at a disadvantage as compared with the candidates from London colleges; thirdly, that it might tend to lower the standard of the degrees; and, fourthly, that it took away the right at present possessed by his constituents to veto any change which in their judgment would interfere with the great work being carried on in the University. His objections were fully answered by Mr. Bryce, who, in the course of his remarks not only reminded his right hon. friend that Convocation had approved of the scheme, but also said that he should deny that Convocation had any more moral right than legal right to say what should be done with the University of London. He appealed to hon. members present who knew something both of the University of Oxford and of Cambridge, and he did not hesitate to say that the reforms which were passed some forty years ago with the greatest possible benefit and advantage both to the country and those Universities would never have been passed at all if the decision had rested with Convocation. His right hon. friend had set up, on behalf of the London University, a claim which was never listened to for a moment in that House in the case of the ancient Universities of Oxford and Cambridge. He submitted that they were not injuring the existing graduates. They were going to make the University a far more powerful and dignified body, and, incidentally, to enhance the value of her degrees. On a view of the whole matter it could not be shown that any injury at all would be done to the existing University. The work of teaching was incomparably more important than the work of examining. Much superstition attached to the degree; it was not so important as many people were inclined to believe; its value was as a test of teaching and stimulus to study, and the more it was made subordinate to teaching the better for education. For a long time the Bill had been wanted, for many schemes had been tried and had failed, and this scheme had received almost unanimous support from the teaching bodies and the approval of leading scientific men anxious to have a teaching University in London. He could not conceive that there was any foundation for the fear that science teaching or science examination would suffer; that was the last danger into which the new Senate would be likely to fall. All who had the well-being of University teaching at heart, who desired the extension of technical education with better facilities for the humbler classes of the community should unite in support of the scheme, which was approved by both political parties, and he earnestly hoped the House would accept it.

After other speeches the amendment was by leave withdrawn, and the Bill was read a second time, and referred to the Standing Committee on Law.

THE ART AND SCIENCE BUILDINGS AT SOUTH KENSINGTON.

THE agitation against the new departure of the Government in relation to the proposed extensions of the Science and Art Buildings at South Kensington grows apace.

Following upon the Report of the Select Committee of the House of Commons, and the Memorial addressed to Lord Salisbury by the President and Council and many Fellows of the Royal Society, comes still another Memorial, this time from the Royal Academy, and already signed by the President and Council and many members of the Royal Academy, with other representatives of Art, strongly urging that the policy stated in 1890 should be adhered to.

The Royal Academy memorial runs as follows :—

Memorial to the Most Honourable the Marquis of Salisbury, K.G., F.R.S., Premier and Secretary of State for Foreign Affairs.

Whereas in 1890 Parliament voted 100,000*l*. for the purchase of a site at South Kensington upon which to erect suitable buildings for the Science Museum of the Department of Science and Art, and for the extension of its science schools, in accordance with the recommendations of the Royal Commission, over which the Duke of Devonshire presided in 1874, as well as of various committees and other high scientific authorities, and of a Treasury committee appointed in 1889.

And whereas when in 1891 the Government had proposed to erect an art gallery on the site, a memorial, signed by the president and officers of the Royal Society and representatives of the Universities of Oxford, Cambridge, and of many other learned bodies both in London and in the provinces, was addressed to your lordship, showing cause why the site should not thus be allocated.

And whereas the scheme was withdrawn, and it was stated by the late Right Hon. W. H. Smith, M.P., in the House of Commons on April 16, 1891, that the "Government has at disposal more than three acres of vacant land facing the Imperial Institute, and considerable areas beyond to the south of the present Southern Galleries. A portion of these vacant lands can be utilised for the extension of the College of Science and for the future growth of the science collections. Additions to the College of Science must, in any case, take the form of a separate building divided from the present building by Exhibition Road"; while the Chancellor of the Exchequer, the Right Hon. G. J. Goschen, informed the deputation which waited on the Lord President of the Council in May 1891, that "we hope to bring science into one centre fronting the Imperial Institute."

And whereas this arrangement which left the ground on the east of Exhibition Road for the extension of the Art Museum has been generally accepted since 1876, when the Royal Commission for the Exhibition of 1851 offered land and a building with a view of carrying out the recommendations of the Duke of Devonshire's Commission in 1874 to provide the needed accommodation for science at South Kensington.

And whereas we are informed that this arrangement is in danger of being altered by the erection of science buildings on the east side of Exhibition Road.

We, the undersigned members of the Royal Academy and others practising various branches of the arts as a profession, desire most respectfully to express to your lordship our strong opinion that it is desirable to adhere to the former policy, which has been acted upon and publicly acknowledged by the Government since 1890, considering the urgent need of much additional space even for the present art collections of the South Kensington Museum, and the necessity for making some provision for their proper development, we are convinced that any attempt to provide on the east side of Exhibition Road for the necessary expansion of the science buildings will render it impossible to meet the future requirements of the industrial arts, for the promotion of which the South Kensington Museum was founded. We also feel that in praying your Lordship to reserve for art that portion of the land which still remains vacant on the east of Exhibition Road, we are not making an exorbitant demand. The whole plot of ground belonging to the Government on that side is much smaller than that devoted to the Natural History Museum, which only represents one branch of science without either teaching or applications, while the space on the east of Exhibition Road has to provide not only for the Art Museum, but also for the administrative offices of the Department of Science and Art, the Royal College of Art, and part of the Royal College of Science.

We hope to be able to give the full list of signatures next week.

NOTES.

AT the annual meeting of the Royal Society for the election of Fellows, held on Thursday last, the following were elected into the Society:—Mr. H. F. Baker, Prof. E. W. Brown, Dr. Alexander Buchan, Mr. S. F. Harmer, Mr. Arthur Lister, Lieut.-General C. A. McMahon, Prof. W. Osler, Hon. C. A. Parsons, Prof. Thomas Preston, Prof. E. Waymouth Reid, Mr. Alexander Scott, Mr. A. C. Seward, Mr. W. A. Shenstone, Mr. H. M. Taylor, and Mr. James Wimshurst. The certificates of these new Fellows, setting forth the scientific work accomplished by each, were reprinted in NATURE of May 12.

THE ladies' conversazione of the Royal Society was held on Wednesday in last week, and was attended by a large and brilliant assembly. Most of the objects and experiments which were shown at the conversazione were exhibited at the soirée held at the beginning of May; and as these have already been described in NATURE (p. 61), it is unnecessary to refer to them again. The exhibit which attracted the greatest amount of attention was the spectrum of krypton, the new constituent of atmospheric air, discovered by Prof. Ramsay and Mr. Travers.

PROF. H. A. LORENTZ, of Leyden, and M. Émile Picard, of Paris, have been elected, by the London Mathematical Society, honorary foreign members, in succession to the late Profs. Brioschi and Hertz.

WHEN Hutton published the two volumes of his famous "Theory of the Earth," in 1795, he left a third in manuscript, which was declared by his friend and biographer, Playfair, to be necessary for the completion of the subject. Yet this important contribution to science has not only never been published, but seems to have almost passed out of mind. Sir Archibald Geikie last year set inquiries on foot with the view of trying to trace the lost manuscript. A portion of the volume, comprising Chapters iv. to ix., came into the possession of Leonard Horner, who eventually presented it to the library of the Geological Society of London, where it has remained since 1856. But every effort to discover the rest of the work has hitherto failed. At Sir Archibald's request, the Society has agreed to publish the six chapters in its possession, each of which is complete in itself; and he is now engaged in preparing the work for the press. The chapters contain some interesting narratives of Hutton's journeys in Scotland in search of illustrations of his theory. In particular, they include his account of the celebrated visit to Glen Tilt, where he found the granite veins which filled him with such exuberant delight that his guides were convinced he must have discovered a vein of silver or gold. They contain also an account of an expedition into Galloway, and a remarkably full description of the geology of the island of Arran. The volume will be interesting to geologists as a continuation of one of the great classics of their science.

AS the two last nominations of foreign knights of the Prussian Order *pour le mérite* have fallen to British subjects, it may be of interest to give a list of the existing members. The Order received its French title from its founder, Frederick the Great, who, as is well known, had a partiality for that language. It was at first given for military services only, but its statutes were remodelled in 1842 by King Frederick William IV., and the class "für Wissenschaften und Künste" was instituted. The German knights of this class, with whom the election into the Order practically rests, are limited to thirty in number, and at present are: A. Menzel, Chancellor; T. Mommsen, Vice-Chancellor; the other members in the order of election being, in the Section of Science: R. W. Bunsen, Max Müller, E. Zeller, T. Noeldeke, J. V. du Vernois, A. Auwers, E. Pflüger, H. Vogel, A. v. Baeyer, O. Fürst v. Bismarck, F. Kohlrausch, H. Grimm, H. Brunner, A. v. Kölliker, H. Usener, W. Hittorf, A. Weber, C. Neumann and Schwendener. In the Section of Art: L. Knaus, A. Achenbach, J. Schilling, R. Begas, F. Schaper, E. v. Gebhardt, H. Ende and A. Hildebrand. The foreign knights, limited to the same number, are, in the Section of Science: O. v. Boethlingk, C. Hermite, Sir G. G. Stokes, N. A. E. v. Nordenskjöld, M. Berthelot, O. v. Struve, Lord Kelvin, Lord Lister, V. Jagic, P. Villari, H. Kern, J. G. Agardh, M. J. de Goeje, G. V. Schiaparelli, F. Imhoof-Blumer, J. H. van 't Hoff, A. O. Kowalevsky, W. Stubbs (Bishop of Oxford), O. Montelius, Sir John Murray and Sir W. H. Flower. In the Section of Art: L. Alma Tadema, G. Verdi, G. Monteverde, E. Wauters, L. Passini and F. Pradilla.

A SPECIAL meeting of the Royal Geographical Society will be held on Monday, June 27, at 4.30 p.m., when Prof. Elisée Reclus will describe his plans for the construction and erection of a great terrestrial globe on the scale of 1 : 500,000 (8 miles to an inch). The president, Sir Clements R. Markham, K.C.B., F.R.S., will occupy the chair. The subject is one which will interest both geographers and engineers.

THE Royal Commission for the Paris Exhibition of 1900 are now prepared to circulate information respecting the exhibition. The classification and rules for exhibitors, together with forms of application for space, can be obtained by applying to the Secretary of the Royal Commission, Paris Exhibition 1900, St. Stephen's House, Westminster, S.W.

IN connection with the seventieth meeting of the Society of German Naturalists and Physicians, to be held at Düsseldorf in September, a series of exhibitions of scientific apparatus and objects has been arranged. An exhibition of objects illustrating the history of medicine and science will be open from July to the end of September. An exhibition of apparatus and photographs illustrating scientific applications of photography will commence in August and continue open until the end of September. New instruments and apparatus will be exhibited from September 17 to September 28, and prizes will be awarded for the best of them. Any machine, apparatus, preparation, or object invented since 1888 may be entered for this exhibition. Objects illustrating methods of instruction in physics and chemistry will be exhibited from September 17 to September 25. Communications referring to the exhibitions should be addressed, Herrn Director Frauberger, Düsseldorf, Friedrichsplatz 3/5.

THE sixty-sixth annual meeting of the British Medical Association will be held at Edinburgh on July 26-29, under the presidency of Sir T. Grainger Stewart. A detailed statement of the arrangements which have been made for the meeting appears in the *British Medical Journal.* An address in medicine will be delivered by Prof. T. R. Fraser, F.R.S.; an address in surgery will be delivered by Prof. Thomas Annandale; and an address in psychological medicine will be delivered by Sir John Batty Tuke. The programme of business arranged by the officers of the sixteen sections is long and varied. In addition to the sections in which the business of the annual meeting is ordinarily carried on, there are for the first time this year sections devoted to medicine in relation to life assurance and to tropical diseases, two departments which have grown into positions of great practical importance during the present generation. A considerable number of distinguished members of the medical profession resident in America and the Continent of Europe have accepted invitations to take part in the proceedings.

THERE are at Prague two distinct botanical gardens, one belonging to the German, the other to the Bohemian University. The former is now under the direction of Prof. R. v. Wettstein, the latter under that of Prof. L. Celakovsky.

THE Rev. Arthur C. Waghorne, Bay of Islands, Newfoundland, for nearly twenty-five years a missionary in Newfoundland, offers for sale collections of Labrador and Newfoundland plants, both flowering and flowerless, named by competent authorities.

WE learn from the *Oesterreichische Botanische Zeitschrift* that M. Philippe Plantamour-Prévost has bequeathed his villa "Mon repos," on the shore of the lake, to the city of Geneva, for the reception of Delessert's herbarium, and for the botanic garden founded by A. P. de Candolle.

IN a note in the *Kew Bulletin*, No. 135, for March 1898, reference is made to the probable success of a process for the artificial manufacture of indigo on a large scale. The Badische Anilin und Soda Fabrik, Ludwigshafen, is now manufacturing "indigo-blue" at a price which very seriously threatens the prosperity of the culture of indigo in India.

ACCORDING to the *Botanical Gazette*, the coming meeting of the American Association for the Advancement of Science at Boston promises to be one of the most notable in the history of the Association. It is the fiftieth anniversary, and special efforts are being made to arrange a worthy celebration. The local committees have been appointed, and the week selected is August 22-27. The local secretary is Prof. H. W. Tyler, of the Massachusetts Institute of Technology.

PROF. JOHN W. HARSHBERGER, of the University of Philadelphia, pleads, in the *Botanical Gazette*, for the establishment of a tropical botanical station in Mexico. The locality especially advocated is a station called Las Canoas, on the Mexican Central Railroad, 144 miles from Tampico. Las Canoas is situated in a beautiful basin-shaped valley 3500 feet above the sea-level. There is an abundant supply of pure water, and the air is clear and bracing. The vegetation is described as of great luxuriance, and the flora is remarkably varied and beautiful. A temporary station could be established here with very little expense, and the virgin forest would supply enough botanical material for years to come.

AN important investigation in connection with mortality is being carried out jointly by the Institute of Actuaries and the Faculty of Actuaries, under the superintendence of Mr. T. G. Ackland, who now has a staff of thirty clerks constantly at work upon a large body of cards containing statistics supplied by assurance companies. The whole of the data relating to the experience in respect of annuitants have been dealt with, and the tables are now in the press. In response to applications made by the Presidents of the Institute and the Faculty, life assurance offices have undertaken to contribute liberally towards the cost of the investigation, which will necessarily be very heavy. The contributions of the companies at present promised or received amount to 10,953*l.*, which sum, it is hoped, will cover the larger portion of the expense, and thus relieve the Institute and the Faculty from any anxiety as to their ability to carry to a satisfactory conclusion this valuable investigation.

FROM a report before us we see that last year was an eventful one in the history of the New York Zoological Society, and it ended in the establishment of the Society as a permanent institution for the promotion of zoological knowledge. All the original objects have been furthered, and noteworthy results have been obtained. The proposal by the Society that 261 acres of land in South Bronx Park should be set apart as the site of the New York Zoological Park, has been unanimously adopted by the Commissioners of the Sinking Fund. The general plan of the Park has been completed and approved by the Park Commissioners. The collections and animal buildings, to cost not less than 250,000 dollars, are to be presented to the City by the Society; and the City is to prepare the ground for occupancy, and to maintain the Zoological Park when established. The sum of 100,000 dollars has been subscribed towards the gift from the Society to the City. This was the amount which had to be raised before the plans could be proceeded with, and work could not be commenced until it was subscribed. Since March 15, 1897, the membership of the Society has increased from 118 to 600; but in order to carry out the plans on a scale worthy of New York, the Society should enroll at least 3000 annual members. The Society has decided to systematically foster both the painting and sculpture of animals; and, with the idea of establishing a school of animal painting and sculpture, provisions for studios have been made in the plans of several of the buildings.

WE are glad to learn from the sixth annual report of the Sonnblick Society for the year 1898 that several improvements have recently been made in the arrangements of this important mountain station, and that the various observations and experiments are carried on with vigour. The meteorological observatory at the summit has now been quite separated from the visitors' refuge which existed in the same building, and a well-equipped station has also been established at the foot of the mountain, at which comparative observations will be regularly made, and will render those at the summit of higher value. These elevated stations are of much scientific interest in connection with the frequent ascents by manned and unmanned balloons for the purpose of investigating the higher regions of the air.

WE have received from Mr. N. A. F. Moos, the Director of the Bombay Observatory, his report to the Secretary to the Indian Government for the year ending March 31, 1898. This observatory is devoted chiefly to terrestrial magnetism and meteorology, astronomical observations being restricted solely to time observations. All the magnetographs have been in constant action throughout the past twelve months. On June 12 the traces clearly showed the small vibration due to the earthquake on that day; and on September 21, at 10h. 40m., small disturbance noticed in the horizontal force curve was traced to the earthquake in Borneo. The statement showing the extent to which the various observations have been reduced, and the reductions checked, indicates that these keep good pace with the observations themselves, nearly everything being checked to either February or March of this year.

THE following remarks from a lecture on the aims and methods of pharmacology, recently delivered at Oxford by Dr. W. J. Smith Jerome, and published in the *Lancet*, will interest many scientific investigators:—"Another method by which pharmacological knowledge is to be obtained is that which is generally understood as research. This, I think, is an ideal form of work, and the leisure and acquirements needed for it are, in my opinion, well worth striving after. A laboratory, it is true, may not be an attractive object. It is not usually gratifying to the æsthetic sense; there are apt to be too many and too obvious manifestations of matter apparently in the wrong place, but it possesses, or at least should possess, one of the fundamental attributes of beauty—viz. a fitness for the purpose it is intended to subserve; and if in itself not beautiful, it enshrines what is *par excellence* 'a thing of beauty and a joy for ever.' It enshrines, it is pervaded by, the spirit of truth—truth which serves both as a lamp to illumine and as a beacon to direct, and yet which shines with a pure and steady ray on those alone who seek to follow it in singleness of purpose. The work performed accords most aptly with Matthew Arnold's description of the work of nature. 'Toil unsevered from tranquillity. . . . Labour that in lasting fruit outgrows far noisier schemes, accomplished in repose, too great for haste, too high for rivalry.' And though it must be granted that the methods of the laboratory, like those of nature, are occasionally harsh, it must also be conceded that its results are useful and its aims beneficent. But even into this paradise of toil there enters or may enter one insidious sin—the lust of what is called 'priority.' This must be fought against and overcome, or else, like a gathering cloud, it will, if left unchecked, roll onwards and most surely darken all. And why should it not be fought against and overcome? Each fact discovered in the pursuit of knowledge, discovered it matters not by whom or when, and even when unimportant in itself, may prove a stepping-stone by which that knowledge mounts to other and far higher things. This is the worker's real recompense; it is this pregnant possibility which makes work, honest work, like virtue, its own great reward."

THE current number of the *Annales de l'Institut Pasteur* contains an account, by Dr. Sanarelli, of the preliminary results he has obtained in the use of antitoxic serum in cases of yellow fever. It will be remembered that Dr. Sanarelli was the first to isolate the specific bacillus of yellow fever, and he has since been endeavouring to procure through its agency an efficient antitoxin. Great difficulties have been experienced in rendering animals satisfactorily immune to infection, and it takes from twelve to fourteen months' treatment before a horse can be regarded as vaccinated. Dogs, which have undergone a series of inoculations during a year or more, and are ultimately able to withstand a large dose of the toxin, are still very adversely affected by each fresh inoculation of the virus. So far this anti-yellow-fever serum appears to exert a protective action against yellow-fever microbes, but not against their toxins, and in the present state of the investigations good results can apparently only be hoped for when the serum is employed at a very early period after infection, or as a precautionary measure to ward off the disease; in this latter respect, Sanarelli has obtained some highly encouraging results. The Government of the province of Saint Paul in Brazil have now decided to establish an institute for promoting the further study of the serotherapy of yellow fever, and it is hoped that before long the elaboration of a specific treatment, both curative and preventive, will succeed in banishing a disease which is with justice looked upon as the scourge of the American continent.

THE *Klinisches Jahrbuch*, published by Gustav Fischer of Jena, contains in its last number the report drawn up by Messrs. Kirchner and Kübler on leprosy in Russia. These gentlemen were deputed by the German Government to conduct this inquiry, and made a careful tour of inspection through the Russian eastern provinces right up to St. Petersburg. It is very difficult to obtain an accurate estimate of the number of cases of leprosy in Russia, as compulsory notification of the disease has only been recently introduced, but it is stated to be about 5000. Of late years great energy has been displayed in endeavouring to prevent the spread of infection. Numerous leprosy isolation hospitals have been established, and many of these were visited by the inspectors. They call attention to the fact that the majority of these leprosy establishments have been founded not by the Russian Government, but by the great landed proprietors in the district, and that private munificence helps largely in dealing with cases. The authors express decidedly their firm conviction of the contagious character of the disease, and state that the only hope of stamping it out is to establish institutes for the isolation and treatment of its victims.

MUCH attention has been paid in Italy during the last few years to the pulsations of distant earthquakes, and to the best means of recording them. In a valuable paper contributed to the *Bollettino* of the Italian Seismological Society (vol. iii. No. 9), Prof. Grablovitz compares the different types of instruments now in use for their registration. He deprecates the recommendation of an instrument for universal employment as premature, and as discouraging the improvement of other apparatus. Nevertheless he attempts to clear the ground so far as regards the mode of registration, preferring the mechanical methods used in Italy to the photographic methods used in Germany and England, on account of their comparative cheapness and the greater velocity that can be given to the moving paper. On this last point he lays special stress, as it gives a clearer diagram and enables the time of the different phases to be determined with greater accuracy.

IN the same journal, Dr. Cancani illustrates the value of these remarks by describing the horizontal pendulums recently erected by him at the Observatory of Rocca di Papa, near Rome. These are similar in principle to the instrument employed by von Rebeur-Paschwitz, but are much larger, the distance of the tip of the recording pen from the vertical through the upper fulcrum being 2·70 metres. Each pendulum carries a mass of 25 kg. and has a period of oscillation of 12 seconds. The record is made on a strip of paper which passes under the pens at the rate of 60 cm. an hour. A tilt of one second at right angles to the plane of the pendulum deflects the pens 2 mm. The interesting records of the Calcutta earthquake given by these pendulums is reproduced (on half the natural scale) in NATURE, vol. lvi. p. 346.

THOUGH fishing is carried on at most of the villages and towns around the coast of Jamaica, the amount of fish obtained is far from sufficient to supply the needs of the population of the island. It has long been surmised, however, that the industry is capable of considerable extension, that the waters are teeming with suitable fish, and that with improved modern methods, such as steam-trawling, sufficient fish might be obtained to render the fresh supply more adequate to the needs of the inhabitants, and that native cured fish should in a large measure take the place of the imported article. With this in mind, the Carribbean Sea Fisheries Development Syndicate was formed last year in England, and a steam trawler was chartered to test the possibility of increasing the fishing industry. The operations and results are described by Mr. J. E. Duerden, Curator of the Jamaica Museum, in the *Daily Gleaner* of April 16, and from them it appears that the endeavour to establish a fishery industry in Jamaican waters on the large scale attempted will not meet with success; firstly, on account of the coral nature of the greater part of the sea-floor rendering the use of a trawler impossible; secondly, and more important, because of a general scarcity of fish. It is a curious fact that fish from deep water, on being brought to the surface, are nearly always so distorted by the expansion of the gases within them as to be rendered useless for market purposes. With regard to the scientific results of the experiments, an abundance of material other than fish was obtained, some of which has been presented to the Museum of the Institute of Jamaica, and is briefly described by Mr. Duerden. Perhaps the most remarkable feature of the hauls from a depth of about ten fathoms is the variety, abundance, and size of the sponges. A large, black, massive, almost spherical form occurred in great quantity; specimens 5½ feet round and 20 inches high were often dredged. The small pores were thickly inhabited by a small species of the Crustacean *Alphæus*. Special interest attaches to the re-discovery of the peculiar West Indian genus *Bergia*, concerning the exact scientific position of which there is much doubt. The corals met with in greatest abundance by the trawl were the various species of *Madrepora*. Sometimes large pieces would be brought up, but usually only the small more fragile branches remained entangled in the net. A few other species of corals not obtainable from shallow water were also secured.

THE South-eastern Union of Scientific Societies recently held its third annual congress in Croydon, the Mayor and Corporation having placed the Town Hall at the service of the union for the purpose. The aim of the union is "to win for science such benefits as are found to accrue in manufactures from division of labour; and in trade, commerce, and finance from co-operation." No attempt, however, is made to secure uniformity among the thirty-one societies affiliated to the union. Last year's president of the union was the Rev. T. R. R. Stebbing, F.R.S., and the president-elect, who opened the congress, was Prof. G. S. Boulger. In his presidential address Prof. Boulger directed attention to the position of natural history in this country sixty years ago, with special reference to the character of field work and its organisation; contrasted that position and that character with those of our present-day geology and biology; traced briefly the cause of the difference, and suggested some lines along which future energies should be directed. The address was very appropriate to the occasion, and an instructive statement of the great change which the Darwinian theory had produced in scientific thought. The programme of the congress included papers by Mr. E. Lovett, on "The Folk-lore of Amulets and Charms"; Dr. H. Franklin Parsons, on "The nature of the soil in connection with the distribution of Plants and Animals"; "Entomology as a Scientific Pursuit," by Mr. J. W. Tutt; "Ancient and Modern Dene Holes and their Makers," and "Natural Gas in Sussex," by Mr. C. Dawson; "Place of Geology in Education," by Prof. Lobley; and "Photography in relation to Science," by Mr. J. H. Baldock. There was also a discussion of "Ideals for Natural History Societies, and how to attain them." The meeting was well attended, and should result in increased interest being taken in the study of nature.

THE fifth volume of the elaborate "System of Medicine," edited by Prof. Clifford Allbutt, F.R.S., has just been published by Messrs. Macmillan and Co., Ltd. The contents refer to diseases of the respiratory organs, of the pleura, and of the circulatory system.

AN interesting address upon "Light and Fire Making," delivered by Mr. Henry C. Mercer, has been issued by the Bucks County Historical Society, Doylestown, Pennsylvania. The address contains forty-five illustrations explaining the methods of producing fire by friction of wood, and by striking flint and steel; they also show some of the forms of lamps, candles, torches, and lanterns used in America and elsewhere.

AMONG handy reference volumes must be placed the "Yearbook of Scientific and Learned Societies," published by Messrs. Charles Griffin and Co., Ltd. The new volume contains particulars with regard to the constitution and membership of scientific societies in Great Britain and Ireland, lists of papers read during 1897 before societies engaged in fourteen departments of research, and a good index.

THE fourth edition of Prof. Wiedersheim's "Grundriss der vergleichenden Anatomie der Wirbelthiere" has just been published by the firm of Gustav Fischer, Jena. Since the appearance of the third edition five years have passed, and so much new work in morphology has been done in this period that the book has had to undergo complete revision. Not only has the new material been assimilated, but various changes have been made in the typography, and all references to authors have been placed in the excellent bibliography appended to the volume. Dr. Wiedersheim mentions that the second English edition of his work, adapted from the German by Prof. W. N. Parker, was prepared under his guidance, and the new material in the present German edition was taken into consideration.—The third revised edition of the attractive and exact "Lehrbuch der Botanik für Hochschulen," by Drs. Strasburger, Noll, Schenck, and Schimper has been published by Gustav Fischer. The first edition was published only four years ago, and the fact that three editions have now appeared is a testimony to its value and popularity. Botanists who have a difficulty in reading the German text will be glad to see the English translation which Messrs. Macmillan have lately published.—A large number of questions referring to heredity are discussed in the work entitled "La Famille Névropathique," by M. Ch. Féré, the second edition of which has been published by M. Félix Alcan, Paris. The volume brings together much information on the laws of inheritance in relation to disease, and the numerous references it contains will be found very valuable by students of heredity.—A second edition of a "Syllabus der Pflanzenfamilien," by Dr. Adolf Engler, has been published by the firm of Borntraeger, Berlin. The volume contains brief notes on medicinal and useful plants, and is intended more particularly for use by students of special and pharmaceutical botany.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Miss Nellie Biggs; a Dorsal Squirrel (*Sciurus hypopyrrhus*) from Central America, presented by Miss Trelawny; a Ring-necked Pheasant (*Phasianus torquatus*) from China, presented by Dr. C. Danford Thomas; a Pin-tailed Whydah Bird (*Vidua principalis*) from Africa, presented by Madame Caté; an Eyed Lizard (*Lacerta ocellata*), European, presented by Mr. H. F. Witherby; an Indranee Owl (*Syrnium indranee*) from Ceylon, a Florida Tortoise (*Testudo polyphemus*) from North America, deposited; four Wonga-Wonga Pigeons (*Leucosarcia picata*) from New South Wales, a Naked-throated Bell-bird (*Chasmorhynchus nudicollis*) from Brazil, a Burrowing Owl (*Speotyto cunicularia*) from South America, two Purplish Guans (*Penelope purpurascens*) from Central America, a Sarus Crane (*Grus antigone*) from Northern India, a Four-lined Snake (*Coluber quatuorlineatus*), European; an Angulated Snake (*Leptodira annulata*) from Tropical South America, four Azara's Opossums (*Didelphys azaræ*) from La Plata, purchased.

OUR ASTRONOMICAL COLUMN.

ENCKE'S COMET.—Of the three comets which are due to return this year—namely Encke's, Winnecke's and Wolf's, having periods of 3⅓, 5½, and nearly 7 years respectively—the first seems to have just been found, according to a Kiel telegram dated June 14. Prof. Hussey, telegraphing to Kiel, states that Mr. Coddington, on June 11, 9h. 13·1m. Lick mean time, found a comet, which he terms bright, in position R.A. 16h. 24m. 45·9s. and Declination (south) 25° 14′ 20″, the daily motions in these coordinates being 51′ and 36′ respectively. The comet thus lies in the constellation of Scorpio, a little to the north of the bright star *α*. A further telegram from Mr. John Tebbutt, dated June 14, states that this observer found the comet on June 12 in position R.A. 16h. 21m. and Declination (south) 25° 52′ at 9h. 22·9m. Lick mean time.

Much interest is attached to this comet, since its period is one of the shortest known. It was first seen in 1818 by that diligent observer Pons, on November 26, perihelion being passed in the following January. It was Encke, however, who undertook to investigate its motions, proving that its period extended over 3⅓ years, and he predicted its return in 1822. At every succeeding return the comet has been observed, and it was even discovered that prior to 1818 it had been three times observed by Méchain, Caroline Herschel, and Thulis in the years 1786, 1795 and 1805. At its last return, in 1895, it was just visible to the naked eye at the time of its maximum brightness.

NEW DETERMINATION OF THE EARTH'S DENSITY.—Herr F. K. Ginzel, in the current number of *Himmel und Erde* (June, Heft 9), describes a new determination of the mean density of the earth by Dr. C. Braun, a former director of the observatory at Kalosca in Hungary. The apparatus used for this purpose was a torsion balance constructed by Dr. Braun himself, and from the description we learn that, excepting the suspension wires, glass globe, chronometer, chronograph, microscopes, and a few small parts, everything was made by himself. The method employed differed mainly from previous determinations in that the torsion balance was enclosed in a glass globe from which all air had been extracted. So complete was the vacuum that after four years no change could be detected. We leave our readers to gather from the above-mentioned source more details regarding the apparatus itself. The observations were begun in the year 1892, and two years later the computations were commenced. After all allowance had been made for corrections the final result gave for the value of the mean density of the earth 5·52765, which nearly corresponds with the best determination made by Prof. Boys. Herr Ginzel, in concluding his article, tells us that, disregarding the very high scientific importance that will be attached to this new determination, if we consider that Dr. Braun is considerably advanced in years, somewhat hard of hearing, and has not been blessed with good health during the last few years, and that he has been thinking over this problem for eleven years in addition to his usual official duties, all will agree in saying that this work is a rare proof of the scientific energy and ideal power of sacrifice for one man.

THE LARGE REFRACTORS OF THE WORLD.—The question of the efficiency of refractors of large apertures has recently been discussed in many articles, and the latest we owe to Prof. G. E. Hale, who deals in *Science* (May 13) with the frequently asked question, "Do large telescopes pay?" Prof. Hale points out the special kind of work to which refractors of large aperture should be employed, and shows that when used by a skilled observer very important work can be accomplished which would be impossible with a small aperture. An instrument, say, of forty inches aperture is more advantageous than one of ten inches, in that, first, it has the power of giving much brighter images, thus rendering faint stars visible. It can, secondly, give an image of a celestial body of measurable dimensions four times as large as that given by a lens of one-fourth its aperture and focal length; and, thirdly, its capacity of rendering visible, as separate objects, the components of very close double stars or minute markings upon the surface of a planet or satellite. Prof. Hale concludes that all the money and time and labour are well spent on refractors of large aperture, and he suggests that further sums might well be expended, particularly in the southern hemisphere, in the establishment of still more powerful instruments.

A propos of large refractors, a fairly complete list of existing large refracting telescopes appears in the current number of the *Observatory* (June), in which are given details concerning the aperture, focal length, location, maker, and date of erection of the various instruments. America comes first as regards the number of instruments and largest size of aperture, followed by France, England and Germany in the order respectively of the number of refractors exceeding 13·4 inches.

THE LEEDS ASTRONOMICAL SOCIETY.—It is always with pleasure that we refer to scientific societies for the promotion and extension of astronomical knowledge, when we know that they are doing useful work in this respect. The *Journal* (No. 5) of the Leeds Astronomical Society for the year 1897 is a good example of the interest displayed by its members in fostering astronomy, and during the past year many interesting papers were read at their meetings. Among these may be mentioned that on the nebular origin of our solar system, by Mr. Barbour, who refers to and extends the significant relationships between the distances and masses of the four superior planets suggested by Mr. Sutcliffe of Bombay, and previously referred to in this column (vol. lvi. p. 424). Other papers read had for their subjects the heat of the sun, the planet Venus, orientation of Egyptian temples, density of the earth, &c. This number contains also an excellent likeness of the retiring president, Mr. Washington Teasdale.

RECENT EXPERIMENTS ON CERTAIN OF THE CHEMICAL ELEMENTS IN RELATION TO HEAT.[1]

THE discovery that different substances have different capacities for heat is usually attributed to Irvine, but there can be no doubt that Black, Crawford, and others contributed to the establishment of the idea. The fact that equal weights of different substances in cooling down through the same number of degrees give out different amounts of heat, may be illustrated by the well-known experiment in which a cake of wax is penetrated with different degrees of rapidity by balls of different metals heated to the same temperature. But for the quantitative estimation of the different amounts of heat thus taken up and given out again, the physicist must resort to other forms of experiment, each of which presents difficulties of its own. Broadly speaking, three principal methods have been used in the past for the estimation of "specific heats." The first is based upon the observation of the exact change of temperature produced in a known mass of water by mixing with it a known weight of the substance previously at a definite temperature above or below that of the water. The second consists in determining the quantity of ice melted when the heated body is brought into contact with it in such a way that no heat from any other source can reach the ice. And the third method consists in observing the rate at which the heated body falls through a definite range of temperature when suspended in a vacuous space.

The process of intermixture with water was used by the earlier experimenters in the last century, and some of the best results extant have been obtained by this process, which, however, is not so easy as it appears when the highest degree of accuracy is desired.

Lavoisier and Laplace in 1780 devised the ice calorimeter which bears their name, and in a most interesting memoir, which is reprinted among Lavoisier's works, they show that they were familiar with the idea which in modern times is known as the principle of the conservation of energy. In this memoir they give the results of experiments in which the specific heats of iron, mercury, and a few other substances are estimated with a very tolerable approach to accuracy. Although many of the metals were known to them, it would not have been possible, had they persisted in this work, to make the discovery which was reserved for Dulong and Petit thirty-five years later, for the atomic theory had not been conceived and no atomic weights had been determined.

Dulong and Petit (*Ann. Chim.*, 1817, vii. p. 144) seem to have used at first the method of mixtures, and to have found by direct experiment that the specific heat of solids (metals and glass) increases with the temperature. They also studied (after Leslie) the laws of cooling of bodies; and two years after the publication of their first paper on the subject, they (Petit and Dulong, *sic*) arrived at the remarkable general expression which is associated with their names (*Ann. Chim.*, 1819, x. 395).

[1] A discourse delivered at the Royal Institution, Friday evening, May 13, by Prof. W. A. Tilden, D.Sc., F.R.S.

After pointing out that all the results of previous experiments, except those of Lavoisier and Laplace, are extremely incorrect, they describe their results obtained by the method of cooling, conducted with many precautions to avoid error.

The statement of the law is best given in the words of the authors (p. 405):

"Les atomes de tous les corps simples ont exactement la même capacité pour la chaleur."

Here the question rested till resumed, many years later (1840), by Regnault, who in his first memoir (*Ann. Chim.*, 73, 5) points out the difficulties which attended the acceptance of the statement of Petit and Dulong in the form in which they gave it. He then discusses the three principal experimental methods, viz. (1) fusion of ice, (2) mixture, (3) cooling, and decides in favour of the second, which he used throughout his researches. The general form of the apparatus used by the great physicist has been a model for the guidance of successive experimentalists since his time.

Another quarter of a century elapsed before the question of the specific heat of the elements was resumed by Hermann Kopp. His results were communicated to the Royal Society, and are embodied in a paper printed in the *Philosophical Transactions* for 1865. After reviewing the work of his predecessors, he describes a process by which he has made a large number of estimations of specific heat, not only of elements but of compounds of all kinds in the solid state. Concerning his own process, however, he remarks that "the method as I have used it has by no means the accuracy of that of Regnault" (p. 84).

In 1870 Bunsen introduced his well-known ice-calorimeter. This is an instrument in which the amount of ice melted by the heated body is not measured by collecting and weighing the water formed, but by observing the contraction which ensues when the ice melts, contained in a vessel of special form. The results obtained by Bunsen himself are uniformly slightly lower than those of Regnault for the same elements.

Since that time experiments have been made by Weber, Dewar, Humpidge, and others in connection especially with the influence of temperature in particular cases.

Setting aside the elements carbon, boron, silicon and beryllium, as providing an entirely separate problem, the question is whether the law of Dulong and Petit is strictly valid when applied to the metals. Kopp, in his discussion of the subject, came to the conclusion that it is not; but the grounds for this conclusion are unsatisfactory, since neither the atomic weights nor the specific heats were at that time known with sufficient accuracy.

It has been customary to assume that the divergencies from the constant value of the product, At. Wt. × Sp. Ht., are due partly to the fact that at the temperature at which specific heats are usually determined, the different elements stand in very different relations to their point of fusion; thus lead at the temperature of boiling water is much nearer to its melting-point than iron. It has also been attributed to temporary or allotropic conditions of the elements. As to the relation to melting-point, the specific heats of atomic weight seem to be practically the same in separate metals and alloys of the same which melt at far lower temperatures. For example, the atomic heat of cadmium is 6·35, of bismuth 6·47, of tin 6·63, and of lead 6·50; while the mean atomic heat in alloys of bismuth with tin, and lead with tin, ranges from 6·40 to 6·66 (Regnault), which is practically the same.

Again, while the melting-point of platinum is at a white heat, and it becomes plastic at a low red heat, the specific heat at this lower temperature is very little less. Many other metals change considerably in properties at temperatures far removed from their melting-points, without substantial change in their capacity for heat.

As to allotropy it is a phenomenon which is comparatively rare among metals, and in the marked cases in which it occurs we have no information as to the value of the specific heats in the several varieties (such as the two varieties of antimony and the silver zinc alloy of Heycock and Neville), and they may be left out of account. Bunsen compared the so-called allotropic tin obtained by exposing the metal to cold for a long time, and found it ·0545 against ·0559 for the ordinary kind (*Pogg. Ann.*, 141, 27). In dimorphous substances, such as arragonite and calcite, there is often no difference. Regnault found for these two minerals ·2086 and ·2085 respectively.

The differences between metals hammered and annealed, hard and soft, were also found by Regnault to be very small (*Ann. Chim.* [3] ix.):—

Hard steel	·1175	Same, softened ...	·1165
Hard bronze	·0858	Same, softened ...	·0862

Kopp came to the conclusion, *first*, that each element in the solid state and at a sufficient distance from its melting-point has *one* specific or atomic heat which varies only slightly with physical conditions; and, *secondly*, that each element has essentially the same specific or atomic heat in compounds as it has in the free state. This last is practically identical with the statement which is known as Neumann's law. With Kopp's conclusions I agree, but from some of Regnault's results, coupled with my own, the effect of *small* quantities of carbon and, perhaps, of sulphur upon the specific heats of metals is greater than has been supposed.

If we take the results of Regnault and of Kopp, and combine them with the most accurately known atomic weights, the products are still not constant.

ATOMIC WEIGHTS MOST ACCURATELY KNOWN (1897), COMBINED WITH SPECIFIC HEATS.

	A.W. (H=1)	S. H. Regnault	S. H. Kopp	At. Ht. Regnault	At. Ht. Kopp
Copper	63·12	·09515	·0930	6·01	5·87
Gold	195·74	·03244	—	6·35	—
Iron	55·60	·11379	·1120	6·33	6·23
Lead	205·36	·03140	·0315	6·45	6·47
Mercury liq.	198·49	·03332	—	6·61	—
− 78° to + 10° sol.	198·49	·03192	—	6·34	—
Silver	107·11	·05701	·0560	6·11	6·00
Iodine	125·89	·05412	—	6·81	—

The law of Dulong and Petit is therefore only an approximation, but this may perhaps be due to impurity in the materials used. That is the problem which I have endeavoured to solve.

The introduction of a new method of calorimetry by Prof. J. Joly, and the excellent results obtained by the author in the use of the differential form of his instrument (*Proc. R. S.*, 47, 241), led me to think that with due attention to various precautions, such as exact observation of the temperatures and practice in determining the moment at which the increase of weight due to condensation is completed, results of considerable accuracy might be obtained.

The problem is to find two elements very closely similar in density and melting-point which can be obtained in a state of purity, and then to determine with the utmost possible accuracy the specific heat of each under the same conditions. The two metals cobalt and nickel were selected for the purpose. They were examined by Regnault, but the metals he used were very impure.

The cobalt employed in my experiments was prepared by myself. For the nickel I am indebted to Dr. L. Mond. Both were undoubtedly much more nearly pure than any metal available in Regnault's time. The results obtained are as follows:—

SPECIFIC HEATS OF COBALT AND NICKEL. PURE FUSED.

Cobalt S.G. $\frac{21^\circ}{4^\circ}$ 8·718	Nickel S.G. $\frac{21}{4^\circ}$ 8·790
·10310	
·10378	
·10310	·10953
·10355	·10910
·10373	·10930
·10362	
Arith. mean ·10348	·10931
Atomic heat	?

Further experiments will be made, because a single well-established case of this kind is sufficient to decide the question. Already, however, I feel certain that Kopp's conclusion is right, and that the law of Dulong and Petit, even for the metals, is an approximation only, and cannot be expressed in the words of the discoverers. For although the exact values of the atomic weights of these two elements are not known, it is certain that they are not so far apart as would be implied by these values for the specific heats, even assuming that the value for nickel is, as I believe, slightly too high.

Two other examples of somewhat similar kind are shown by gold and platinum, copper and iron.

SPECIFIC HEATS OF GOLD AND PLATINUM. PURE FUSED.

Gold S.G. $\frac{18^\circ}{18^\circ}$ 19·227	Platinum S.G. $\frac{18^\circ}{18^\circ}$21·323
·03052	·03147

Arith. mean ·09232	Arith. mean ·11030
Atomic heat 5·83	6·13

For the gold I naturally applied to my colleague Prof. Roberts-Austen. The platinum I prepared from ordinary foil by re-solution, and reprecipitation as ammonic chloride, &c. Both metals were fused into buttons before use. The atomic heats come closer together than those of cobalt and nickel.

Copper and iron differ considerably in melting-point, but both at the temperature of 100° are far removed from even incipient fusion. The copper was prepared from pure sulphate by electrolysis, the iron by reduction of pure oxide in pure hydrogen. Notwithstanding all our care, it was disappointing to find it contained ·01 per cent. of carbon, the source of which I am at a loss to explain. This iron is purer than any examined by Regnault or Kopp.

The differences observed between Co and Ni, and between Au and Pt, are manifestly not due to allotropy or to differences of melting-point, which in these cases can have no effect on the result.

So large a difference must be due to peculiarities inherent in the atoms themselves, and differences of atomic heat are to a certain extent comparable with the differences observed in other physical properties which, like specific volume, specific refraction, &c., are approximately additive.

If we try to think what is going on in the interior of a mass of solid when it is heated, the work done is expended not only in setting the atoms into that kind of vibration which corresponds to rise of temperature—that is, it makes them hotter—but partly in separating the molecules or physical units from one another (= expansion), and partly in doing *internal* work of some kind, the nature of which is not known. A difference between metals and non-metals has been brought out by the researches of Heycock and Neville, who find that metals dissolved in metals are generally monatomic; whereas it is generally admitted that iodine, sulphur and phosphorus in solution are polyatomic. It is, moreover, remarkable that although in respect to specific heat each element in a solid seems to be independent of the rest with which it is associated, when the separate elements are dispersed in vapour some rise in separate atoms like mercury, some in groups of atoms I_2, S_6, As_4, P_4, and these groups, as the temperature is raised, are simplified with very varying degrees of readiness.

Sulphur vapour, for example, diminishes in density from 7·9 at 468°, to 4·7 at 606° (Biltz), that is, from about S_7 to S_4, and iodine from density 8·8 at 253°, to 5·6 at 1570° (V. Meyer), that is, from about I_2 to $\frac{2}{3}$ I_2, but the dissociation of As_4 and P_4 begins only at much higher temperatures, while with mercury there is no corresponding change.

But, although these groups are taken as the chemical molecules, the physical unit in the solid is certainly the atom, whether united by combination or mere mixture.

The two metals, cobalt and nickel, with which I began my inquiry, have nearly the same atomic weight, but they differ from each other remarkably in chemical properties. For example, nickel forms a compound with carbonic oxide; on the other hand, cobalt produces many remarkable ammoniacal compounds, to which there is nothing corresponding among the compounds of nickel.

Having put aside the common excuses for the observed divergencies from the law of Dulong and Petit, we are compelled to look round for some other hypothesis.

The constitution of carbon compounds is now explained by a hypothesis concerning the configuration of the carbon atom introduced by Van t' Hoff and Le Bel twenty-five years ago, and which is now accepted by the whole chemical world. It seems not unreasonable to apply a similar hypothesis to the explanation of those cases of isomerism which have been observed in certain compounds of the metals, notably chromium, cobalt, and platinum. This has already been done by Prof. Werner of Zürich. Of course, as there is no asymmetry, there are no optical differences in the pairs of compounds thus represented. If the constitution of compounds can be safely explained by such hypothesis, this implies peculiarities in the configuration of the individual constituent metals around which the various radicles are grouped in such compounds, and hence peculiarities in the behaviour of such metals in the elemental form may possibly be accounted for. For the atom of cobalt, Prof. Werner employs the figure of the regular octahedron. For nickel, therefore, which differs from cobalt, especially in yielding the remarkable carbonyl compound discovered by Mond, and by not yielding ammines like those of cobalt, and in other ways, a different figure must be chosen. This, however, is for the present a matter of pure speculation.

SCIENCE IN THE THEATRE.

THE assimilation of nature on the stage! To what extent is assimilation possible, and what are the necessary methods and appliances for obtaining a satisfactory assimilation? This practically was the subject of a very valuable paper prepared for the Society of Arts by Mr. Edwin O. Sachs, the architect, which led to an animated discussion at the crowded meeting before which it was read. The title of Mr. Sachs' paper, it is true, was briefly "Stage Mechanism," but he went far beyond the mere description of the various appliances that can be used for obtaining certain scenic effects, and, more especially in his introduction, treated the subject on broad lines.

Though the presentation of drama and opera with some attempt at realistic surroundings is now accepted as a matter of course in all civilised countries, it can but rarely be said that the attempts are successful. In fact, only of recent years has the London manager been able to give us the presentation of indoor scenes with some claim to merit, and this only by building up his various scenes piecemeal in a most cumbersome way, which is all that is possible where the changes of scene are few and the "run" long. As to the presentation of scenes out of doors, the London manager has most lamentably failed, no matter how well painted individual canvases may have been, or how tricky the arrangements of individual scenic effects. A sky that looks like so much blue calico hanging on a wash-line, a horizon with angles, a tree that looks like a piece of cardboard, or a moon which suddenly rushes into the sky and then remains stationary, are all anomalies, and form only a few of the innumerable details which tend to make a scene incongruous.

Now according to Mr. Sachs, who fully recognises the attempts that have been made from time to time by Sir Henry Irving, Mr. Beerbohm Tree, Sir Augustus Harris, and others

FIG. 1.—Electric Turntable Stage. (From "Stage Construction.")

(assisted by such eminent painters as Mr. Burne-Jones, or Mr. Alma Tadema), the reason for the anomalous scenes we see to-day is to be primarily found on the one side in the inherited prejudice of the stage against the adoption of anything that is new; and on the other, in that curious want of recognition which the stage fails to obtain, not only from the Government and public authorities generally, but from men of science who do not hesitate to use their knowledge for far more prosaic matters, such as, for instance, the tinning of food, the condensing of milk, &c. Mr. Sachs' assertions as regards the prejudice with which innovations are met with on the stage were amusingly confirmed in the discussion by Mr. Mulholland, who explained the difficulties he had in trying to do away with the tin-tea-tray thunder so often heard on our stages, and of course many curious anecdotes could be told of how the ignorant stage-carpenter, or the stage-manager who is afraid of making experiments, or the prejudiced scenic artist who is afraid that improved effects might take away from his influence, all vie with one another in leaving the stage as it has been for a hundred years or more. Mr. Bernard Shaw also most wittily and scathingly showed how badly things are generally managed.

Now we cannot but recognise, as Mr. Sachs indicated, that much has been done in the way of painting good scenery. But what, as he said, is the use of the most beautifully painted piece of canvas if it is badly hung, wrongly lighted, and waves with every draught that there may be on the stage? What use is there, Mr. Sachs asked, in having a beautiful panorama scene, costing a thousand pounds, if the extra five pounds be grudged for a suitable appliance to make that panorama run smoothly? Mr. Moul, of the Alhambra, argued that there seldom were any spare five pounds. But there should be. Why not let the panorama scene cost ten pounds less and have the appliances?

Of course the average playgoer is not very critical; he is satisfied, as a rule, with the highly coloured picture and the blaze of light, and having been equally blind to the beauties of nature, sees nothing of the incongruities of the scene. He "sees" an actor with a streak of limelight following him round the stage, but does not grumble; he "sees" the actress, with her features distorted owing to a brilliant light from the footlights on her chin and a dark shadow on her forehead, but he does not know that there is anything wrong about this. Only that small percentage of playgoers who have visited some of the large model continental stages, or the Wagner productions at Bayreuth, perhaps appreciate the anomalies of the old English stage, and scoff at what the caterers of our public entertainments choose to put before them. They know full well the harmonious effect often obtained on a well-managed continental stage, where the faults, if any, do not lie in the want of recognition of the true art requirements, but are to be found in the poor quality of the scenery, for the improvement of which there may not be funds available. How regrettable it is, as Mr. Sachs pointed out, that we cannot have in the metropolis a happy combination of the artistic mounting of the Continent with the beautiful scenery for which our managers are ready to pay lavishly.

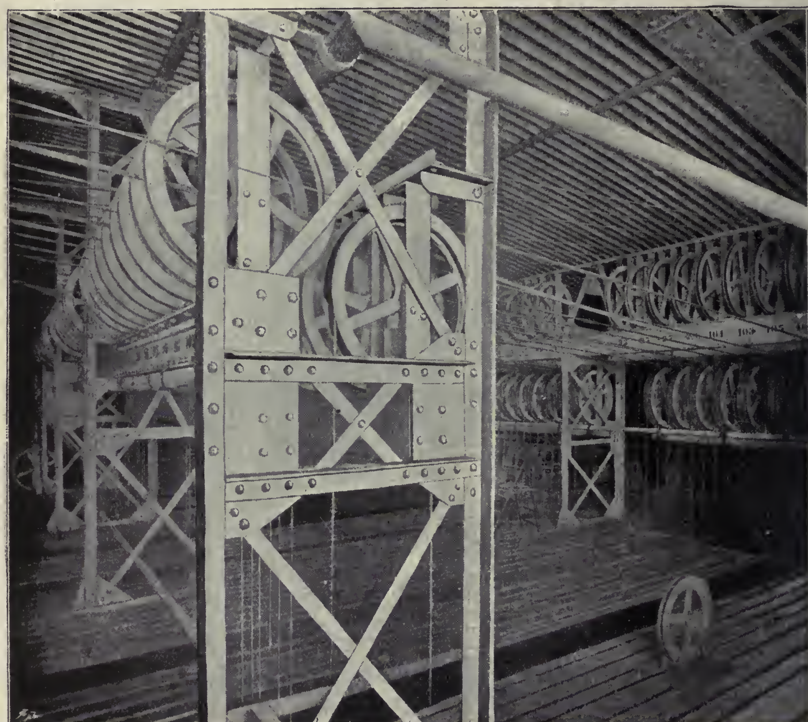

FIG. 2.—Court Theatre, Vienna. View of "Gridiron." (From "Modern Opera Houses and Theatres.")

When, however, we go into the detail of Mr. Sachs' instructive paper, we find that the vast subject which he has covered does not lend itself to a short article of this description, nor perhaps would his arguments be appreciated without the many illustrations which he was able to put before his audience at the Society of Arts. Yet we would point out that, in the first place, he divided the stages he had under consideration into (1) wood stages, (2) wood-and-iron stages, and (3) iron stages; and that he then again subdivided them according to the power used for moving the scenery, or obtaining certain effects, be it manual labour, hydraulics, or electricity.

In speaking of the wood stage of the metropolis, Mr. Sachs naturally does not omit to refer also to the wood stage of the Continent, which is but little better than our own; nor when he spoke of the wood and iron stage of Paris did he omit to speak of our "Palace" Theatre of Varieties, which is the solitary example of a theatre in this country in which a combination of wood and iron is to be found. When Mr. Sachs, however, came to speak of the iron stage, and more especially the iron stage worked by hydraulics or electricity, he had to confess that there was not a single iron stage to be found throughout the United Kingdom, that there was no stage worked by electric machinery, and that the only appliances in which hydraulics are being employed in this country were some so-called "bridges" at Drury Lane. But on the continent, the iron stage, with all its improvements for lighting, for showing a curved horizon, and —to summarise—for giving some semblance of nature, is already to be found in considerable numbers and of considerable variety.

By Mr. Sachs's courtesy we are able to show two illustrations—one of the great electrical turntable stage for Munich, so useful for Shakespearean drama, where a quick change of scene is desirable, and the other of a hydraulic stage at Vienna worked on the suspended system. In the first case a general view is shown which well describes itself. In the latter case a view of the "gridiron" is shown, which plainly indicates the modern forms of wiring adopted.

But we cannot go further into the technical detail of the question, and we only trust that Mr. Sachs's words will have had some effect on the many managers and stage engineers who had come to hear him, not forgetting Herr Kranich, from Bayreuth, one of the leading exponents of scenic mounting on true art lines.

But whatever may have been the influence of Mr. Sachs's advocacy, we would end by quoting him where he said "that the real secret of perfect scenic art lies in illusion, *i.e.* in visual deception, or in not allowing the eye of the spectator to discern the means whereby the semblance of reality is obtained; mere actuality will not accomplish this—crude realism alone would then result."

What the scenic artist and the stage-manager must attempt, according to Mr. Sachs, is to obtain a successful illusion; and this, he argues, is obtainable, not by any great *radical* reform, as desired by irresponsible faddists, but a *practical* reform of the methods and appliances which are to-day used on the stage of the metropolis, and which are, unfortunately, quite a hundred years too old.

Why should not our stage have the full benefits of science and art as practised now on the approach of 1900 A.D., instead of the makeshifts with which the world was satisfied at the beginning of the last century?

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Want of accommodation in more than one department of the University museum renders it impossible to carry on satisfactory work. The extracts printed below, from the report of the delegates of the museum, tell of a condition of "hope deferred, which maketh the heart sick." Prof. J. Burdon-Sanderson reports:—"The Regius Professor of Medicine takes this opportunity of expressing his bitter disappointment that another year has been allowed to pass without any step having been taken towards providing adequate accommodation for the teaching of medical science in the University. It is in his judgment to be feared that if the reasonable requirements of the medical school continue to be disregarded, its further development will be checked, and that the progress of those departments of teaching which have common interests with it will be seriously interfered with." Prof. R. B. Clifton, Professor of Experimental Philosophy, says: "Some electrical apparatus has been placed in the room formerly allotted to the professor as a private laboratory, and with that in the room devoted to the electrical work of the preliminary classes, it is now possible to offer some, though very restricted, facilities to Honour students who wish to gain experience in the methods of measuring electrical quantities. The professor and demonstrators have now, however, no place in which they can carry on research; and all attempts to undertake work of this character must in future be abandoned. After twelve years of fruitless effort to obtain extended accommodation for Honour students, and the means of providing for the increasing number of those working for the preliminary examination—a class of students not contemplated when the laboratory was designed—it is probably quite useless to trouble the delegates with any further application for assistance in this direction." It will be difficult for men of science on the Continent and in the United States to believe that so little encouragement is given to scientific work in the University of Oxford.

The 191st meeting of the Junior Scientific Club was held in the physiological lecture-room of the museum on Friday, June 10. After private business, Mr. V. H. Veley, F.R.S., read a paper on *Coleothrix methystes*, the active micro-organism which Mrs. Veley and himself recently discovered in "faulty" rum, and, it is hoped, will shortly form the subject of a monograph. After the paper a discussion took place, in which Dr. Ritchie and others joined.

CAMBRIDGE.—Mr. A. E. H. Love, F.R.S., of St. John's College, has been appointed University Lecturer in Mathematics in the room of Mr. Glazebrook, resigned.

The Senior Wrangler this year is Mr. R. W. H. T. Hudson, of St. John's College, son of Prof. W. H. H. Hudson, of King's College, London. Miss Cave-Browne-Cave, of Girton, is bracketed fifth wrangler.

The Vice-Chancellor announces that donations amounting to over 6000*l.* have been received for the University Benefaction Fund, started last year. A large number of the donations are ear-marked for the Medical School. A bequest of 10,000*l.* has also fallen to the University, but it is assigned to the foundation of a prize or scholarship in memory of the late Dr. Allen, Bishop of Ely.

Mr. C. F. Hadfield, of Trinity, and Mr. R. C. Punnett, of Caius, have been nominated to the University tables at the Naples Zoological Station; and Prof. E. W. MacBride, of St. John's, to the table at Plymouth.

The General Board propose that Mr. W. N. Shaw, F.R.S., should be appointed assistant-director of the Cavendish Laboratory for the ensuing year, in the place of Mr. Glazebrook.

DR. R. A. HARPER has been appointed professor of botany at the University of Wisconsin.

AT a meeting of the Court of Edinburgh University on Monday a letter was read from a benefactor of the University, intimating that he is prepared to give to the University such a sum as may be necessary, but not exceeding 10,000*l.*, to build and equip a laboratory and class-room to be used exclusively for the teaching of public health, the site of the proposed building to be provided by the University.

THE foundation-stone of a separate department for instruction in the technology of the leather industries, was laid at the Yorshire College, Leeds, on Monday. The ceremony was performed by Mr. A. B. Kent, Warden of the Skinners' Company of London, who have provided 5000*l.* in order to establish this department, and will contribute towards the working expenses.

THE new laboratories of physiology and pathology at the University College, Liverpool, will be formally opened on October 8. The laboratories have been erected and equipped in the most adequate way for study and research by the Rev. Thompson Yates, at a cost of 25,000*l.* Lord Lister, President of the Royal Society, has consented to perform the opening ceremony; and the Victoria University will take advantage of his visit to Liverpool to confer upon him the honorary degree of doctor of science.

AT the Science and Art Department on Friday last a conference was held of organising secretaries and other representatives of local organisations which have been recognised by the Department as responsible for science and art instruction within their several districts. The Vice-President of the Committee of Council on Education (Sir John Gorst) presided, and the conference was attended by representatives from a number of ounties. Various matters connected with the administrative arrangements between the local authorities and the Department were considered and decided.

AT the instance of the Headmasters' Conference, the Headmasters' Association, the Headmistresses' Association, and the Conference of Catholic Schools, a Bill dealing with the subject of secondary education will be introduced into Parliament this Session. The Bill proposes to transfer the powers relating to secondary education now vested in the Charity Commission, the Science and Art Department, and the Education Department to one central authority under the Committee of the Privy Council on Education, and to establish local secondary education authorities to administer areas not less than those of a county or a county borough. It is contemplated that the reconstituted Education Department will consist of two sections, for secondary and primary education respectively, these two sections being under one permanent secretary, who will be advised by chief assistant secretaries in regard to each of these two chief divisions of departmental work. The Bill further provides for the registration of secondary schools according to their different types and of teachers qualified to teach. The residue under the Local Taxation (Custom and Excise) Act, 1890, is to be allocated to education, and in the case both of residue and of Imperial grants now paid through the Science and Art Department such portions as the Treasury shall determine are to be allocated to secondary education and to technical instruction respectively.

THE new buildings of Reading College, under which name the University Extension College at Reading will in future be known, were opened by the Prince of Wales on Saturday. The College was established in 1892 as a direct outcome of Oxford University Extension work. Mr. H. J. Mackinder was appointed Student of Christ Church, Oxford, his appointment being made "with a view to giving system and completeness" to the educational work of one of the University Extension centres. His services were offered to Reading, and were accepted; and, largely owing to his efforts during the past six years, the College has advanced to the position it now occupies. The first home of the College was restricted to an ancient building, formerly part of the Hospital of St. John, attached to the Abbey of Reading. The accommodation was soon found to be insufficient for the increasing number of students. Mr. Herbert Sutton, chairman of the Council, purchased the vicarage of St. Lawrence, adjoining the Hospitium, and the acquisition of this property enabled certain necessary enlargements to be made, including the building of a dairy institute. The cost of the College properties and buildings exceeds upwards of 20,000*l.*; and it was this amalgamation of old and new buildings in one central educational organisation, to be known as Reading College, that the Prince of Wales formally opened on Saturday. In responding to the toast of "The Royal Family," at the luncheon after the opening ceremony, the Prince of Wales remarked:—"In the work we have done to-day, we have inaugurated an institution which has for its object the advancement of higher education, especially in those branches more particularly connected with science, art, and agriculture. To me this is particularly interesting on account of the early associations which render it a matter of interest to know that the new College owes its inception and encouragement to the University of Oxford, and to Christ Church, my old College. The presence of the Vice-Chancellor of Oxford and of the Dean of Christ Church, as well as the attendance of many other eminent men from Oxford, is a proof of the interest they take in this movement. Let me mention that the heads of colleges and the Hebdomadal Council have satisfied themselves of the high standard of efficiency of the education in Reading College, and have agreed with great liberality to affiliate Reading College to the parent University to the extent of conferring on it the privilege of allowing students, after spending three years at Oxford and passing certain scientific examinations there, to proceed to Reading, where one year's further study in the science and practice of agriculture should count as part of their University career, and entitle them to the B.A. degree on the completion of their full course. This proposal, although supported by a large and influential University, was, on a division, rejected by two votes, the numbers being 47 to 45. The interest which I take in University Extension teaching, which now includes agriculture, leads me to hope that another year may see the adoption of the important policy advocated by the important bodies to which I have alluded, and that its provisions may be carried through the subsequent stages to render it law."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 12.—"The Electrical Response of Nerve to a Single Stimulus investigated with the Capillary Electrometer." Preliminary communication. By F. Gotch, M.A., F.R.S., Professor of Physiology, University of Oxford, and G. J. Burch, M.A. (Oxon).

By means of a very sensitive capillary electrometer the authors have obtained photographic records of the electrical response in the sciatic nerve of the frog when excited by a single stimulus. The records differ in character according to the condition of the nerve. In uninjured nerve a rapid displacement of the meniscus in one direction is followed by a corresponding displacement in the other direction. In nerve which is the seat of a persistent electromotive change, whether through local injury or the passage of an appropriate polarising current, the record shows that the initial rapid displacement is succeeded by a prolonged after-effect of similar sign. The records are sufficiently pronounced to allow of the calculation of the E.M.F. of the potential difference between the electrometer contacts causing the initial displacement; this may reach as much as 0·032 volt, and attains its maximum very rapidly. In fresh nerve at 6° C. the first indications of such electrical change occur 0·002 second after the single stimulus has been applied at a distance of 30 mm. from the capillary contacts. The after-effect develops more slowly, taking from 0·006 to 0·01 second to culminate, its maximum E.M.F. is only one-tenth that of the initial change, and it subsides slowly; it is present in every nerve when one of the capillary contacts lies upon the cross section of the nerve.

"On the Magnetic Susceptibility of Liquid Oxygen." By Profs. J. A. Fleming, F.R.S., and James Dewar, F.R.S.

May 26.—"Note on the complete Scheme of Electrodynamic Equations of a Moving Material Medium, and on Electrostriction." By Joseph Larmor, F.R.S., Fellow of St. John's College, Cambridge.

This paper (in continuation of previous memoirs) undertakes in general form the exact expression of the electrodynamic relations of moving media which are polarisable, or are in motion through the æther. No foundation is available from which to investigate the modification that the ordinary equations of MacCullagh and Maxwell must then undergo, without going back to molecular theory. When that is done the crucial point in the investigation is the transition from a theory concerned with the individual molecules to a mechanical theory concerned only with the element of volume: this requires a separation between the influence of neighbouring molecules which affects only the structure of the material at that place, and the influence of the matter in general which induces polarisation and mechanical strain in the structure. It is shown that to express the influence of magnetic polarisation of the material, and also the influence of convection of electrically polarised material, these agencies must be replaced analytically by equivalent distributions of electric current. The resulting scheme of equations is wide enough to include the whole field of electrical and optical phenomena in continuous bodies, whether fixed or in motion, of which various cases are again incidentally considered.

Physical Society, June 10.—Mr. Shelford Bidwell, President, in the chair.—Dr. S. P. Thompson described and exhibited a model illustrating Max Meyer's theory of audition. Max Meyer abandons the audition theory of Helmholtz, and contends that analysis takes place in the ear otherwise than by resonance of the Corti organ. Imagine a jointed system, like a hand, to be oscillated from one end, *i.e.* from the finger-tips, A small motion affects only the top joints, but a large motion affects the whole structure. Such a structure is the membrane of the inner-ear. It widens towards one end, and is effectively damped by the contained liquid. Wave-motions of different amplitudes run along it to different distances before they are extinguished; these distances are recorded by nerves, and are thereby communicated to the Corti organ. In the model, the compound-wave to be analysed is cut out on the edge of a disc of zinc, so that, as the disc revolves, the motions are communicated to a frame-work. If the frame is thus moved through more than a certain distance, a displacement occurs which sets a second frame in motion, and so on to a third and fourth. The depth to which the motion penetrates is indicated by a series of glow-lamps connected electrically to the frames. Prof. Ayrton said it had for some time past occurred to him, when considering the way in which an expert telegraph clerk reads siphon-recorder signals on a long cable, that it might be possible to analyse waves without the supposition of a resonating apparatus. The clerk interprets not so much the motions to one side or other of the zero-line, as the rate of change of velocity, *i.e.* the acceleration of the siphon. This had been recognised in the design of those relays for long cables, where the lever makes contact when the received current exceeds a certain value, and breaks contact when the current falls below a certain minimum. Messrs. Siemens had adopted a relay in which the lever was carried on the suspended coil of a D'Arsonval galvanometer by a pivot with a small amount of friction. If contact was made, the coil could, nevertheless, continue its motion in a given direction. If that direction altered, contact was immediately broken, and the lever passed over to the opposite stop, thereby reversing the local circuit. It was possible that, in the process of hearing, something akin to this took place, the ear behaving as a mechanism responsive, not by resonance to the complete waves, but by its sensitiveness to changes of direction of the received impulses. Dr. S. P. Thompson thought that a mechanism similar to the relay described by Prof. Ayrton was contained in the telautograph of Elisha Gray; it was a "Prony" mechanism. In the acoustical problem the ear was probably sensitive to abrupt changes of shape in the waves as well as to reversals. In the case of mistuned octaves, something is heard that suggests "revolving" in the ear, indicating a cyclic change. In this regard it was necessary to take into account the phase-relations as well as the relative intensities of the component tones.—Mr. E. H. Barton then read a paper on the attenuation of electric waves along a line of negligible leakage. It forms a sequel to a paper communicated to the Physical Society and printed in their *Proceedings* of December 1897 and January 1898. Shortly after the publication of the earlier results, Mr. Oliver Heaviside drew attention to Lord Rayleigh's high-frequency formula for the "effective resistance" of wires to alternating currents, and suggested that the formula might be approximately applicable to the case; but he thought the experimental value of the attenuation would be considerably higher than the one derived from calculations. Mr. Barton here repeats the work, with special precautions as to the mode of insulating the parallel copper wires through which the wave-train proceeds. The value of the attenuation constant deduced from these experiments is 0·000013. By applying Lord Rayleigh's formula for the effective-resistance of the circuit, and using this value in Mr. Heaviside's expression for the attenuation, the calculated constant is 0·0000062. To account for the discrepancy, the author points out that the effective-resistance formula was originally developed for a wire placed at a considerable distance from other parts of the circuit, and for currents following the harmonic law. Whereas, in the experiments the conditions are (1) wires 1·5 mm. diameter, only 8 centim. apart, and (2) the waves are propagated in the form of a damped train, with the large end leading; they are extinguished after ten or a dozen vibrations. Mr. Oliver Heaviside (communicated) pointed out that, as there was human interest in error, it might be worth mentioning that at first it was supposed the previous experiments of Dr. Barton made the index of the attenuation factor to be six times that of the long-wave theory for simple periodic waves. And it was hard to account for so large a discrepancy. The discovery of an error in the figures, reduced the result from six to two. The small depth of the surface-layer of effective conduction, and the distance apart of the wires, seemed now to make it improbable that Dr. Barton's first reason (1) was adequate to account for the doubling of resistances. The second (2) was of course a substantial reason for increased resistance. A third one, Mr. Heaviside suggested, was the external resistance at the boundary of the waves. A combination of the second and third reasons, with a little of the first, might account for most of the extra attenuation observed, and, if more was wanted, one could "try the K.R. law." Mr. Appleyard said it was rather to be regretted that, in all the experiments, the distance between the wires had been the same, *i.e.* 8 cms. By taking a few different values (1) might have been checked. Lord Rayleigh's formula for the effective-resistance, involved the square-root of the magnetic permeability of the wires. The author had, throughout, used copper, a paramagnetic metal, and had assumed $\mu = 1$. It would be of advantage to try other metals. Mr. Barton, in reply, said he would make further experiments with the two conductors at different distances apart, and he would also try iron wires. With iron, the thickness of the surface-layer of the effective conductor was about one-thirteenth that of copper. Iron should therefore give a greater value of the attenuation than copper.—Mr. A. Griffiths then read a paper on diffusive convection, a phenomenon analogous to caloric convection. The differences of density that produce convection-currents are not due to changes of temperature, but to variations in the quantity of dissolved substance per unit volume. The author has devised an apparatus consisting of a vessel divided horizontally by a diaphragm, through which pass two vertical tubes of unequal lengths. A solution of copper-sulphate, maintained at constant strength, is placed in the lower compartment. The upper compartment is filled with water. Diffusion takes place up the tubes. One tube is 4 cm. long; the other is 4·05 cm. The tops of the tubes are exactly at the same level. Up the longer tube, and down the shorter, diffusive convection occurs at the rate of 5 cm. per year. This flow *increases* the quantity of copper-sulphate transmitted by the long tube by about 2 per cent., and *diminishes* that transmitted by the shorter tube by about the same amount. Consequently, the resultant increase due to the motion is only a fraction of 1 per cent. To detect the flow, the author employs a second piece of apparatus, in which the upper ends of the tubes are separated by a capillary, containing coloured liquid. By this means the motion is considerably magnified. Dr. S. P. Thompson asked whether, in a case where a large tube was used in determining the velocity, the viscosity of the liquid would not play a very much less part than with narrow tubes. Mr. Griffiths explained that viscosity was not important until very small tubes were considered, *e.g.* those of the order 0·001 mm. diameter.—The President proposed votes of thanks to the authors, and to Dr. Max Meyer for lending the Society his model.—The meeting then adjourned until June 24.

EDINBURGH.

Mathematical Society, May 13.—Mr. J. B. Clark, President in the chair.—The following papers were read:—On the second solutions of Lamé's equation, by Mr. Lawrence Crawford (communicated by Mr. J. W. Butters); on the insolation of a sun of sensible magnitude, by Mr. A. Ritchie Scott; the singular solutions of a certain differential equation of the second order, by Mr. Hugh Mitchell.

PARIS.

Academy of Sciences, June 6.—M. Wolf in the chair.—New photographic studies of the surface of the moon, by MM. Lœwy and Puiseux. A discussion of the data contained in the third part of the photographic atlas of the moon.—On a new absolute electrodynamometer, by M. Marcel Deprez. In the system described, the forces due to the action of the current are simple algebraic functions, rigorously and without approximation, of the dimensions of the fixed and movable circuits.—On a new constituent of the atmosphere, by MM. William Ramsay and Morris W. Travers (see NATURE, p. 127). M. Berthelot observed that the green ray of krypton coincided almost exactly with the bright green line of the aurora borealis. He suggested the name *eosium* for the new element.—On the propagation and deformation of the tidal wave which ascends rivers, by M. Partiot. The curve of the experimental results obtained on the Gironde and Garonne are compared with five formulæ; of these, that suggested by M. Boussinesq agrees best with the experiments.—On surfaces of total constant curvature, by M. C. Guichard.—On the systems of differential equations which satisfy the quadruply periodic functions of the second species, by M. Martin Krause.—On discontinuous functions which are allied to continuous functions, by M. R. Baire.—On the determination of the order of interference fringes, by MM. A. Perot and Ch. Fabry.—On the rotatory power of quartz in the infra-red, by M. R. Dongier. A comparison of the experimental results with those calculated from a formula given by M. Carvallo.—On the discharge of a Leyden jar, by M. R. Swygedauw.—Comparison of the Hertzian field in air and in oil, by M. Albert Turpain. In a resonator kept in a plane-perpendicular to the direction of the wires the wave-lengths vary with the nature of the dielectric; if the resonator is in the same planes as the wires, the wave-lengths are independent of the nature of the dielectric.—On resonators, by M. Oudin. The resonator now used consists of a solenoid of bare copper wire wound round a cylinder of paraffined wood, the high frequency current being produced by the arrangements of Hertz, of Tesla, or of d'Arsonval. This resonator creates a very intense alternating field, a Geissler tube being lit up at two metres distance. The discharge resembles in appearance that of a statically charged body, and causes lesions of the skin similar to those produced by the X-rays.—Visibility of the blind spot in the retina, by M. Aug. Charpentier. The experiments cited show that the spot where the optic nerve enters the retina, although insensible to light and blind in the proper sense of the word, is really represented in space by positive visual sensations occupying the same place, as if it were replaced in the eye by a real piece of retina in continuity with the rest of the membrane.—Quality of the fifteen vowels of the French language, by M. Monoyer.—Action of ammonium persulphate upon the silver in photographic negatives and the utilisation of this action, by MM. Lumière and M. Seyewetz. By means of a 5 per cent. solution of ammonium persulphate it is possible to reduce an over-exposed photograph in a manner not possible with the reagents previously suggested for this purpose, the persulphate acting first upon the most opaque portions of the negative, and leaving the half-shadows untouched.—On the causes of the imperfections in radiographs brought about by the use of reinforcing screens, by M. A. Londe. Comparative photographs were made with five screens, the platinocyanide of barium and of potassium, sulphide of zinc, Becquerel's violet sulphide, and Kahlbaum's screen. Whilst some of these increased the rapidity of action of the X-rays, it was always at the expense of clearness of definition, the image being accompanied by a kind of halo. Hence these screens cannot be employed in delicate work.—On the constitution of the ternary alloys, by M. Georges Charpy. A microscopical study of the bismuth-lead-tin and copper-tin-antimony alloys.—On the yttrium earths contained in the monazite sands, by M. O. Boudouard.—On the carbonic acid of the atmosphere, by MM. Albert-Levy and H. Henriet. The differences occasionally observed between the amounts of atmospheric carbon dioxide as determined by potash and baryta respectively, may possibly be due not to a different absorptive power for the gas with the two reagents, but to a slow oxidation of the organic matter present in the air which proceeds with different velocities in the two cases.—On a crystallised hepta-acetate of ouabaine, by M. Arnaud. Obtained by the action of acetic anhydride in presence of zinc chloride upon ouabaine.—On some acetals of pyrocatechol, by M. Ch. Moureu.—Nitration of cellulose and its hydroxy- and oxy-derivatives, by M. Léo Vignon.—A new mucin extracted from an ovarian cyst, by M. Charles Lepierre.—On the Holothuria collected by the *Travailleur* and *Talisman*, by M. Rémy Perrier.—On the embryogeny of *Serpula infundibulum* and *Hydroïdes pectinata*, by M. Albert Soulier.—Polymorphism in an Annelid (*Dodecaceria concharum*), by MM. Félix Mesnil and Maurice Caullery.—On the sexuality and relations of the Sphacelariaceæ, by M. C. Sauvageau.—On the palæozoic layers on the southern declivity of the Montagne-Noire, by M. J. Bergeron.—Characteristics of the bitumenous schist of the Bois-d'Asson (Basse-Alpes), by M. C. Eg. Bertrand.—On the transport of the sick, by M. Bonnafy. A discussion of the relative merits of State hospital-transports or ships chartered from the mercantile marine for this purpose.

DIARY OF SOCIETIES.

THURSDAY, June 16.

Royal Society, at 4.30.—Observations on Stomata: Francis Darwin, F.R.S.—Note on the Attenuation and Exaltation of the Virulence of the Organism of Texas Fever: A. Edington.—Mathematical Contributions to the Theory of Evolution. V. On the Reconstruction of the Stature of Prehistoric Races: Prof. K. Pearson, F.R.S.—On some Expressions for the Radial and Axial Components of the Magnetic Force in the Interior of Solenoids of Circular Cross Section: C. Coleridge Farr.—On the Source of the Röntgen Rays in Focus Tubes: A. A. C. Swinton.—On the Constituents of Argon: Prof. W. Ramsay, F.R.S., and M. W. Travers.—And other Papers.

Linnean Society, at 8.—Observations on the Seasonal Variations of Elevation in a Branch of Horse-Chestnut Tree: Miller Christy.—On Pantopoda collected by Mr. W. S. Bruce in Franz-Josef Land: G. H. Carpenter.—Morphological Relationships of the Actiniaria and Madreporaria: J. E. Duerden.—On some Fossil Leporines: Dr. C. I. Forsyth Major.

Chemical Society, at 8.—Ballot for the Election of Fellows.—Preparation of a Standard Acid Solution by Direct Absorption of Hydrogen Chloride: Dr. G. T. Moody.—Researches on the Terpenes. III. Halogen Derivatives of Fenchene and their Reactions. IV. On the Oxidation of Fenchene: J. A. Gardner and G. B. Cockburn.

SATURDAY, June 18.

Geologists' Association (London Bridge, L.B.S.C.), at 12.25.—Excursion to Crowborough. Directors: G. Abbott and R. S. Herries.

MONDAY, June 20.

Royal Geographical Society, at 8.30.—Tirah: the Geographical Results of the Recent Afridi Campaign: Colonel Sir T. Hungerford Holdich.

Society of Chemical Industry, at 8.—Aluminium as a Heating and Reducing Agent (in the Production of Chromium and other Metals): Dr. Hans Goldschmidt and Mr. Claude Vautin.

Victoria Institute, at 4.30.

TUESDAY, June 21.

Zoological Society, at 8.30.—Remarks upon Series of Specimens of Lepidosiren and other Fishes obtained in Paraguay: J. Graham Kerr.—Report on the Collection of Fishes made by Mr. J. E. S. Moore in Lake Tanganyika during his Expedition 1895–96; with an Appendix by Mr. J. E. S. Moore.—On the Scorpions, Spiders, and *Solpugæ* collected by Mr. C. Steuart Betton in East Africa between Mombasa and Uganda: R. I. Pocock.

Royal Statistical Society, at 5.—Annual General Meeting.

Royal Photographic Society, at 8.—Photographic Images: Captain W. de W. Abney.

WEDNESDAY, June 22.

Geological Society, at 8.—Post-Glacial Beds exposed in the Cutting of the New Bruges Canal; T. Mellard Reade.—High-level Marine Drift at Colwyn Bay: T. Mellard Reade.—Observations on the Geology of Franz Josef Land: Dr. Reginald Koettlitz.—Notes on Rocks and Fossils from Franz Josef Land brought home by Dr. Koettlitz, of the Jackson-Harmsworth Expedition, in 1897: E. THURSDAY, JUNE 23, 1898.

THEORETICAL MECHANICS.

Theoretical Mechanics: an introductory treatise on the Principles of Dynamics, with applications and numerous examples. By A. E. H. Love, M.A., F.R.S., Fellow and lecturer of St. John's College, Cambridge. Pp. xiv + 379. (Cambridge: at the University Press, 1897.)

THIS book is vibrating with dynamical modernity, and proves in effect that Theoretical Dynamics has not yet been reduced to the level of one of the Exact Sciences; and so it shows little tendency to bridging over the gap still existing between the two modes of treatment of the one science of Mechanics. The two different methods are described by Newton in the preface of the "Principia"—

"Auctoris præfatio ad lectorem. Cum Veteres Mechanicam (uti Auctor est Pappus) in rerum Naturalium investigatione maximi fecurunt; et Recentiores, missis formis substantialibus et qualitatibus occultis, Phænomena Naturæ ad leges Mathematicas revocare aggressi sint: Visum est in hoc Tractatu Mathesin excolere, quatenus ea ad Philosophiam spectat.

"Mechanicam vero duplicem Veteres constituerunt: Rationalem quæ per Demonstrationes accurate procedit, et Practicam. Ad Practicam spectant Artes omnes Manuales, a quibus utique Mechanica nomen mutuata est. Cum autem Artifices parum accurate operari solent, sit ut Mechanica omnis a Geometria ita distinguatur, ut quicquid accuratum sit ad Geometriam referatur, quicquid minus accuratum ad Mechanicam. Attamen errores non sunt Artis sed Artificum. . . .

"Pars hæc Mechanicæ à Veteribus in Potentiis quinque ad artes manuales spectantibus exculta fuit, qui Gravitatem (cum potentia manualis non sit) vix aliter quam in ponderibus per potentias illas movendis considerarunt. . . ."

Rankine had this preface in his mind in preparing his inaugural address (1856), a "Preliminary Dissertation on the Harmony of Theory and Practice in Mechanics," prefixed to his treatise on Applied Mechanics.

"In physics and mechanics the notions of the Greeks were very generally pervaded by a great fallacy, which obtained its complete and most mischievous development amongst the mediæval schoolmen, and the remains of whose influence can be traced even at the present day—the fallacy of a *double system of natural laws;* one theoretical, geometrical, rational, discoverable by contemplation, applicable to celestial, ætherial, indestructible bodies, and being an object of the noble and liberal arts; the other practical, mechanical, empirical, discoverable by experience, applicable to terrestrial, gross, destructible bodies, and being an object of what were once called the vulgar and sordid arts."

We want in our theoretical treatises more of the spirit expressed on the title-page of Hayes's Fluxions, 1704, "A work very useful to those who would know how to apply Mathematics to Nature."

To do this we must come to close quarters, and "missis formis substantialibus et qualitatibus occultis" fire off the elegant artillery of analysis; in fact, reduce the formulas to their numerical applications; it is in this way only that the various differences so notable in the mode of treatment in different schools can ultimately become reconciled.

Suppose we set up our author as the champion of the first of these two schools of thought described above by Rankine, and pit him against Prof. Perry, as the champion mathematician of the engineers.

The first point of dispute will be the measurement of force; the engineer will insist on retaining in Dynamics the statical gravitational measure of force, considering that he works in a field of gravity, practically uniform over the surface of the Earth, on which the human race is imprisoned; and also because the gravitational measure of a force is the only one capable of direct experimental determination to the highest degree of accuracy; this is not the case with the absolute measure of force, the one solely adopted in the demonstrations of the present treatise.

There are certain advantages in recording the results of cosmical, electrical, magnetical, and astronomical results in absolute measure; for if the author should succeed in having his treatise adopted on another planet, his C.G.S. units would be immediately applicable, on the assumption of perfect astronomical observation and measurement; but for experimental verification each planet would have recourse to its own gravitation system.

A problem proposed recently in an American technical journal, "to find the work required to lift the Earth one foot," might perhaps serve a useful purpose in focussing discussion between the merits of absolute and gravitation measure.

A curious note on the last page of this treatise dismisses the units in which all our engineering calculations are carried out, in a few lines, such as—

"Thus the equation which we write $P = mf$, where P is the force producing acceleration f in a body of mass m, could be written in these units $P = (m/g)f$, where g is the same constant."

"It does not tend to simplicity that the writers who use these (*i.e.* the gravitation) units also use the word 'weight' for the quantity we call 'mass,' and the letter W where we use m, and thus they write the above equation $P = (W/g)f$."

"Much confusion has thereby been produced."

But Prof. Perry will retort by saying that the confusion is produced by those writers who never have to employ the theory they teach; and that the words "frequently not" should be changed to "never" in the statement in § 299—

"The C.G.S. system of units, although generally used in scientific work, is frequently not employed in practical applications of science."

Such a thing as an arithmetical mistake is unknown among those who work with gravitation units; the same cannot be said of the adherents of absolute measure who are very apt to slip a g in their calculations (there is a g missing in the result of ex. 60, p. 75.)

How does our author reconcile his definitions in Chapter v. with the precise legal terminology of the Act of Parliament on Weights and Measures?—

"The *weight* in vacuo of the platinum *weight* (mentioned in the First Schedule to this Act), and by this Act declared to be the imperial standard for determining the imperial standard pound, shall be the legal standard measure of *weight*, and of measures having reference to *weight*, and shall be called the imperial standard pound, and shall be the only unit or standard of *weight* from which all other *weights* and all measures having reference to *weight* shall be ascertained."

How does Mr. Love propose to edit this clause? The word *weight* makes its appearance seven times where Mr. Love says the right word to employ is *mass;* he cuts the Act of Parliament to pieces on p. 98; and we have mass occur in almost every line. And if the word *weight* is to go, what is to be done with *pound*, *poids* (de kilogramme), and *avoirdupois*, all derived from the Latin *pondus?* According to § 91, *pondus* is given in dynes, and the word *pondus* above must be replaced by *massa.*

If this process of Restoration (to use the banal architectural word—

> "to erect
> New buildings of correctest conformation
> And throw down old, which he called *restoration*."
> DON JUAN.)

is to be carried out systematically, what is to be done with the words "in ponderibus movendis" of Newton's preface? and how are Ovid's lines to be restored describing the statue of Ladas, the work of the sculptor Myro?—

> "Quæ nunc nomen habent operosi signa Myronis
> Pondus iners quondam duraque massa fuit."

Or again the lines—

> ". . . et gravitate carentem Æthera. . . .
> Cum quæ pressa diu massa latuere sub illa . . ."

Love's *Dynamics* versus Ovid's *Ars amatoria!* not to mention the ecclesiastical usage of Christmas, Childermass, Candlemass, Ladymass, Lammas, Loafmass, Martinmass, Soulmass, Michaelmass, . . . now exciting controversy in another place.

"The common use of the word "weight" covers two notions which are essentially distinct, the notion of pressure which a heavy body exerts on a support, and the notion of quantity of matter. In scientific writing and speaking, different words must be used to express distinct notions" (p. 99).

A very useful aphorism, worth adding to Newton's "Regulæ Philosophandi"; and so scientific writers must invent two new words to express these two distinct notions, and not attempt to force a word of common currency out of its most extended meaning.

At the same time another rule might have been made —"The names of a thing must not be multiplied more than is necessary."

"Since the centre of inertia of body small enough to be handled coincides with its centre of gravity as defined in Statics, we shall denote it by the letter G" (p. 102).

And now we have three names, *centre of mass* (d'Alembert), *centroid* (Clifford), and *centre of inertia*, where the single name centre of gravity is sufficient for ordinary purposes. It is a pity to waste the expression "centre of inertia" in this way, as it may prove useful for designating a point distinct from the centre of gravity, in the case of non-rigid systems, such as a carriage on wheels, or a fish, bird, or projectile moving in its medium.

This brings us to the "Conception of a Rigid System" in § 114—

"If the particles of a rigid system continuously fill a surface, the system is a rigid body, and the surface is the surface of the body."

At this rate the ball-bearings of a bicycle constitute a rigid system, contrary to the function for which they are designed.

The bicycle has done wonders in familiarising our youth with dynamical sensations; and the machine itself can be used in a variety of ways to illustrate the theory of the pendulum and the gyroscope. When testing the wheels for friction and balance, the elliptic functions, defined in rather a condensed way in § 191, can easily be watched in their fluctuations; while the new drawing-room game of trying to walk round holding a revolving wheel serves to emphasise gyroscopic domination. With this stimulus the languishing study of elliptic functions may again become popular, and lead on to the dynamical applications of the hyper-elliptic functions, sketched out by Prof. Klein in his Princeton lectures, as required for the complete solution of the bicycle problem, especially as the Prize offered by the French Academy for this subject is still open.

The influence of wind will excite an interest in § 212, on the motion in a resisting medium. In this article the author could have simplified the treatment, by introducing the notion of "terminal velocity," as in ex. 155, p. 227.

The statement on p. 195, that the resistance of the air is better represented by the cubic law, is not valid, except for a very limited region in the neighbourhood of the velocity of sound; but, considering that the retardation

$$\frac{d^2s}{dt^2}$$

can be replaced by

$$\frac{d^2t}{ds^2}v^3,$$

Mr. Bashforth found it convenient, in the reduction of his screen records, to take out the factor v^3, and to measure carefully the other factor, $\frac{d^2t}{ds^2}$.

The Science of Dynamics does not consist in labelling certain physical quantities with letters, such as m, W, f, g, . . .; these letters really mean numbers, expressed each in its own unit. Mathematical Tripos questions unfortunately pay scant attention to the units involved, and our mathematical students learn to loathe all numerical applications, and so lose sight of the true meaning of these algebraical symbols for numbers. One reason for this dislike of numerical computation is the absurd system of using 7 figure logarithms, where, as in the case of the gravitation constant γ, upon which all Celestial Dynamics depend, the numbers do not warrant such refinement. A gigantic cheese-auger cannot be driven into the earth, to determine the density of the strata up to the centre, so we have to be content with the indication of the Cavendish experiment, which, even in the experienced hands of Mr. Boys, do not warrant the use of logarithms of more than 4 places.

The two papers on the theory of the oscillations of a ship, and of the stresses produced thereby, read recently before the Institution of Naval Architects by Captain Kriloff, Professor at the Naval Academy of St. Petersburg, are worth the attention of theoretical students in showing the numerical computations, given to 3 significant figures only, required in a complicated problem of Rigid Dynamics, and showing also the system of gravitation units invariably employed in such calculations.

The letters m and W are the modern dynamical equivalents of the θ and π, the θεωρητική and πρακτική, embroidered on the hem of the robe of the vision which appeared to Boethius in his dungeon, to inspire his *Consolation of Philosophy*.

Let the letter W still continue to denote the number of pounds of matter in the body, and let m denote the number of grammes; let us adopt the method of Prof. T. W. Wright's "Mechanics," reviewed by Prof. Perry, a new edition of which has just appeared, and employ the absolute system with Metric units only, so that the "poundal" is merely mentioned once to point out its uselessness. Now Prof. Perry can denote W ÷ 32·1912 by the letter M, so that the unit of M is a 32·1912 pound shot; and if he calls M the mass of the body, in opposition to Mr. Love, he is only following the custom which can be traced back through the treatises of Todhunter, Parkinson, Earnshaw, Whewell, Poisson, Lagrange, &c., up to Euler.

Thus M. de Freycinet writes, in his *Essais sur la philosophie des Sciences*:—

"Il ne suffit pas d'avoir la notion claire de la masse. Il faut aller plus loin. Pour les besoins de la Dynamique il est nécessaire de savoir *chiffrer* les masses.—Une quantité d'eau peu inférieure a 10 décimètres cubes, soit 9 litres, 8088, . . . le nombre habituellement désigné par la lettre g, voilà l'unité de masse."

With these writers we find that the gravitation unit of force alone is employed, and, contrary to Mr. Love's classification in § 294, the unit of mass is a *derived* unit, being that quantity of matter which will receive unit acceleration from the gravitational unit of force. The same method is employed in all engineering treatises, but we are inclined to agree with Mr. Love in thinking it might be abandoned with advantage, as being a mere lazy device to avoid writing $\frac{W}{g}$; and coming back to Euler, we find him explaining at length, in some six pages of his "Dynamics," 1760, that the acceleration $a = \lambda \frac{P}{M}$, due to a force P acting on a mass M, and that we must take $\lambda = 2g$, where g is taken by Euler to measure the distance a body falls from rest in one second.

Students will be grateful to the author for the two elegant and complete chapters on two-dimensional Motion of a Rigid Body, a great desideratum. A very large and valuable collection of illustrative examples are brought together, most of which are capable of experimental verification in our field of gravity; and in such cases it would increase the instructiveness to employ the gravitation measure of force, the only one capable of exact measurement.

"When, as in astronomy, we endeavour to ascertain (these) causes by simply watching their effects, we *observe;* when, as in our laboratories, we interfere arbitrarily with the causes or circumstances of a phenomenon, we are said to *experiment*" (Thomson and Tait).

In recording theoretical results of astronomical observation, absolute units are certainly appropriate, but they are all susceptible to the probable error in the determination of the gravitation constant γ.

The author has performed a useful service in § 277, in calling attention to the looseness of the ordinary school-book definitions, that "the weight of a body is the force with which it is attracted by the Earth."

But we must return to the charge again, and protest against the assumption that the addition of the word "weight" to "pounds" is required to connote the idea of force. Architects may measure the pressure on foundations in cwt/ft², but there is no such thing in existence as a pressure gauge graduated in lbs-wt/in²; it is always in lbs/in²; more than that, we doubt the existence of any gauge graduated in dynes/cm², or barads; and the stock of instruments at present in use is sufficiently large to resist this innovation. The centesimal measurement of time, required for the completeness of the metric decimal system, never came into use, if only because of the number of clocks, watches and chronometers in existence; so that the C.G.S. system is a mongrel one, involving the sexagesimal second of time.

In the careful examination of the ultimate axioms of Dynamics which he has set himself for reconsideration, the author has thrown down a challenge to the Metaphysicians, in the theory of the relativity not only of motion, of rotation as well as of translation, but also of time, matter, force, &c., which we trust will not pass unnoticed.

This minute survey of the foundations of Dynamics has, like a visit to the dentist, revealed so many unsuspected flaws, that it seems doubtful if Dynamics can remain an exact Science. Considering that the gravitation of a body varies with the velocity relative to the Earth, how are we justified in accepting the sacred definitions of the C.G.S. units, which may be affected by similar defects? A spirit of dynamical scepticism is in the air, as testified by the treatises of Mach and his disciples, Hertz, Boltzmann, and by Poincaré on Hertz in the *Revue générale des Sciences.* Maxwell's and Clifford's work does not appear to have influenced the author.

According to the Preface, "The foundations of Mechanical Science were laid by Newton"; but we think that the claims of Galileo are passed over, not to mention Archimedes. Galileo appears throughout this treatise as Galilei; both forms of the name are correct, according to the German student song—

"Auch ging er wohl mitunter
Zur Kirche als frumber Mann;
Doch beten und singen nicht kunnt er,
Schaut lieber zur Decke hinan:
Was sah er da in der Höhi?
Tschahi, tschaheia ho—
Die Ampel sah Galilei
Und auch der Galileo!" &c.

Some novelties in the way of nomenclature are welcome, such as "frame of reference" for "coordinate axes," "localised vector," "kinetic reaction" (due to Mr. Larmor, we believe) for d'Alembert's reversed effective force"; but when the writer proposes to upset the well-established use of common words, and teach us a new language of recent invention, he might as well set to work to change the names of the stars and planets; and we are compelled to protest, in the words of Biron,

"These earthly godfathers of heaven's lights,
That give a name to every fixed star,
Have no more profit of their shining nights
Than those that walk, and wot not what they are."

A. G. GREENHILL.

LONDON BIRDS.

Birds in London. By W. H. Hudson. 8vo. Pp. xvi + 339; illustrated. (London: Longmans, Green, and Co., 1898.)

As a writer on the habits of animals and their natural surroundings, and one, moreover, gifted with an unusually facile and interesting mode of expression, Mr. Hudson has already established such a reputation that any new work from his pen is almost sure of meeting with a favourable reception. And, in our opinion, the present volume is as full of interest as the nature of the subject permits; many of his descriptions bringing into prominent notice the amount of attraction to be found in the open spaces in and around London if only we go about with our eyes open, and can snatch a few half-hours of repose from the business and pleasures of the great city. Most of us, who either live in the country, or spend our holidays there, quite fail to realise how gladsome must be the sight of the bird-life in our London parks to those who have little or no opportunities of escape from the wilderness of bricks and mortar; and Mr. Hudson, in his enthusiasm for his subject, says that not only do such glimpses brighten the existence of our toilers, but that they are almost essential to such existence. Be this as it may, his description of the delight afforded to our poorer neighbours by the contemplation of the birds kept in the little enclosure at the eastern end of the Serpentine is quite pathetic reading, and affords full justification for all that is being done to encourage the feathered denizens of our parks to remain and multiply.

From a scientific point of view the work, it must be confessed, cannot lay claim to a high place; and it was doubtless not intended so to do. The decimation of the species that formerly lived in and around London, and the introduction, either natural or artificial, of extraneous kinds, preclude it being considered as a manual of the avian fauna of the district. Still even the scientific ornithologist ought to find some interesting matter in regard to the persistence of some species and the disappearance of others; and more especially so when he finds that in some cases it is the apparently hardier and bolder forms that have disappeared, and the more delicate that have remained. Still more remarkable is the recent colonisation of certain spots by such apparently shy and retiring species as the dabchick and moorhen.

In some ways, perhaps, the author is inclined to take matters a little too seriously; and, personally, we fail to assent to his strictures concerning the rearing of wild ducks on the Serpentine. If we read him right, he would have them partly, if not entirely, disestablished in favour of his pet species the crow. But, to our own thinking, it is a far more generally interesting, and certainly a far less common sight to watch the evolutions of the flights of duck on our park waters, than it would be to observe the sedate manner of crows and rooks, which most of us, if so disposed, can see elsewhere. Still more uncalled for are the author's strictures on the annual battue held to keep the numbers of the ducks within proper limits. Somebody must undertake the duty; and if the duty be also a recreation, surely the Ranger or his deputies should not be debarred from enjoying it. But apparently Mr. Hudson is of opinion that nothing but outdoor natural history is worth anybody's attention, since he goes out of his way (p. 80) to attack the Government for the purchase of the Blenheim pictures.

Although there may have been reasons for their removal unknown to the general public, our personal sympathies are, however, decidedly with the author over the felling some years ago of the elms in Kensington Gardens, and the consequent total disappearance of the rooks.

Even to summarise the contents of the book would largely exceed our limits to space, but attention may especially be directed to the chapters devoted to the open spaces on the outskirts of London, and to the two on the protection of birds in our parks, and on those most suitable for encouragement or introduction. In the last of these the author is strongly of opinion that water-fowl, if properly protected, will return to their assigned haunts to breed, adding: "I believe that our ornamental water-fowl ought never to be pinioned except in the cases of a few rare exotic species. When a bird is pinioned its chief beauty and greatest charm are lost; it is then little more than a domestic bird, or a bird in a cage." With this commendable sentence we take leave of a very pleasantly written and charmingly illustrated little book.

R. L.

OPTICAL ACTIVITY.

Das optische Drehungsvermögen organischer Substanzen und dessen praktische Anwendung. By H. Landolt, assisted by Drs. O. Schönrock, P. Lindner, F. Schütt, L. Berndt and T. Posner. Second Edition. Pp. xxii + 655. (Braunschweig: Friedrich Vieweg und Sohn, 1898.)

The first edition of this book, which appeared nineteen years ago, has since its publication been the standard work on the rotation of the plane of polarised light by active substances. Since 1879, however, the number of active substances known has increased from 300 to over 700, the methods of determining the rotation have been much improved, and considerable advances have been made in the theory of the asymmetric carbon atom, to mention only a few of the directions in which progress has been made. All this necessitated a thorough revision of the "Drehungsvermögen"; and in order to cope, in reasonable time, with the mass of material, the author has called in the assistance of the specialists above named in writing several of the chapters. The writers must be congratulated on the way in which they have welded the different chapters into a homogeneous whole, the disjointedness which so often arises from such joint-authorship having been most happily avoided. Comparing the present edition with the former one, the progressive broadening and consolidation of our knowledge of optical activity is very apparent. Twenty years ago the main outlines of the subject were already sketched in, and these remain practically unchanged; how much has been done in the interval, in filling in details, can best be appreciated by reading the present work.

The arrangement of the material remains very much the same as in the former edition, but the revision has been very thorough; so far as we have been able to judge, nothing of importance has been omitted.

The first part contains a classification of all active substances known, and a succinct account of the theory of Van 't Hoff and Le Bel. The properties of the active, racemic and inactive modifications of a substance are then contrasted, and the methods of converting them into and separating them from each other described. A chapter by Prof. Lindner, on the micro-organisms employed in splitting up racemic compounds into their constituents, should be helpful to chemists. In the third part the rotation is considered from the physical point of view, the chapter on the influence of solvents on rotation being especially interesting. Many of the phenomena observed are still unexplained, and it would appear that a study of these should be capable of throwing some light on the nature of solutions. After a discussion of Guye's hypothesis, which is found to be insufficient, the author remarks that it will probably be impossible ever to discover the numerical connection between chemical constitution and rotation.

One hundred and forty-two pages are devoted to a very excellent account, by Dr. O. Schönrock, of polarimeters and saccharimeters, the subsidiary apparatus connected with them, and the methods of using them. Dr. Schütt contributes Part 5, on saccharimetry and the determination of several other active substances of technical importance, and the book terminates with a collection of the rotatory powers of all active substances known, which is complete up to the middle of 1896, and includes some of the data published since that date. A good index is added. T. E.

OUR BOOK SHELF.

The Span of Gestation and the Cause of Birth. By John Beard. Pp ix + 132. (Jena : Gustav Fischer, 1897.)

COMMENCING with the assumption that there is a "critical period" in the development of every mammal "when the embryo is first beginning to look like the form whose offspring it is," Dr. Beard proceeds, in this monograph, to point out the close connection existing between the extent of time, or "critical unit," which elapses before the "critical period" is attained and the ovulation and total gestation periods.

Dealing shortly with the probability of an alternation of generations in mammals, which he has so ably advocated in earlier communications, he reaffirms now his previous conclusion that the attainment of the "critical period" is coincident with the completion of all the important parts of the sexual generation, and with the commencing degeneration of the asexual generation or phorozoon. The length of the "critical unit" is, therefore, the length of the life of the phorozoon, and when it is completed, in the more primitive forms, *e.g.* the marsupials, the birth of the sexual generation occurs.

Obviously the simpler conditions prevailing in the lower forms have been altered in the higher mammals, and at first sight the alterations have not occurred along definite lines, for the "critical unit" is not a fixed quantity; on the contrary, it varies in length from $7\frac{3}{4}$ days, in the opossum, to 47 days, in man. Dr. Beard is convinced, however, that the variations can only occur in conformity with some discoverable law, and he shows that the "critical unit" is either slightly less than one, or than two combined ovular periods, which he proposes to term "ovular units." He suggests that if ovulation was not previously restricted it became impossible when gestation was established, and could only recur, in the most favourable circumstances, shortly after birth, and thus the "critical unit" came to govern the "ovulation unit." But the intimate correlation between the critical and ovulation units is not closer than that which exists between the "critical unit" and the gestation period, for the latter is always some multiple of the former, and the greater the number of the "critical units" contained in the gestation period the greater is the stage of the development of the fœtus at birth; nevertheless, the completeness of the development of a fœtus at birth is not dependent merely upon the length of its gestation period, but upon the number of critical units in that period, for the "critical unit" has probably been doubled or trebled in certain cases, and the author believes that such lengthening is associated not with increase of the development, but only with increase in the size of the fœtus.

The points raised in this interesting memoir are clearly stated, the evidence in their support is well arranged, and the author is to be congratulated on having thrown light on some obscure problems. It is to be hoped that he will push his observations further, and that he will eventually succeed in demonstrating "the cause of birth."

ARTHUR ROBINSON.

A New Astronomy. By Prof. David P. Todd, M.A. Ph.D. Pp. 480. (New York, Cincinnati, Chicago: American Book Company.)

ASTRONOMY is pre-eminently a practical science, yet instruction in it, and especially in the branch which pertains to geography, usually consists of a course of study of text-books. This is not as it should be. It is far better to observe the apparent movements of the stars and planets than to learn that they are hundreds of thousands of miles away from us; and to note the annual movement of the sun among the stars is more instructive than to learn the dimensions of some sun-spots and prominences. In astronomy, as in other sciences, the only firm conceptions are those obtained from direct observation. Prof. Todd's book marks a new departure by showing how the fundamental principles of the subject may be studied with the aid of tangible objects, somewhat as in physics and chemistry. The result is most successful. No book with which we are familiar contains a clearer account of astronomical geography, and certainly none show so well how to observe celestial movements or illustrate astronomical phenomena with simple appliances. The pupil who learns astronomy through Prof. Todd's book will have a real idea of the motions and measurements of the heavenly bodies instead of abstract conceptions concerning them.

The practical presentation of what may be termed the geometry of astronomy only forms, however, one commendable feature of the book. Other characteristics which call for just as much praise are the large number of illustrations—well reproduced and well chosen—and the attention that is given to the advances made in recent years in all branches of celestial science. Throughout the book the endeavour has been to present the subject in a way which will induce the student to think for himself, and not merely commit facts to memory. In other words, Prof. Todd shows how astronomy may be given an educational value, instead of being presented as a collection of isolated and imperfectly connected facts. Fortunate is the pupil whose teacher instructs him in astronomy on the sound methods described in this book.

Lessons in Domestic Science. Part i. By Ethel R. Lush. Pp. viii + 88. (London: Macmillan and Co., Ltd., 1898.)

THIS instructive little book has been prepared for use by children in public elementary schools. It contains simple information on food, clothing, and personal hygiene, and is well adapted for the purpose for which it is intended. Wherever possible, the principles described are illustrated by experiment.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Liquid Hydrogen.

IN his letter published in your issue of the 9th inst., replying to mine published on May 26, Prof. Dewar does not question the accuracy of the following statements, which form the most important part of my letter: (1) That the combination which I described in that letter as constituting the self-intensive method of refrigeration was proposed by me at the Royal Institution to his chief assistant, Mr. R. N. Lennox, in November 1894; (2) that this combination had not been previously employed; (3) that it formed the chief novelty of Prof. Dewar's paper and experiments of December 1895; (4) that it is essential to the apparatus which has made the step from liquid air to liquid hydrogen. These facts make a sound claim on my part to the invention of the process and to recognition in historical or explanatory accounts of work which involves the use of the process. Prof. Dewar says: "My results would have been attained had Dr. Hampson never existed, just as they have been developed." On the other hand, at the Society of Arts (see *Journal*, March 11, 1898, p. 382), in speaking of Dr. Linde's process, which is admitted to be substantially the same as mine, Prof. Dewar said that "after some fourteen years' work he ought to know something about low temperatures, but he must confess that the practicability of such a mode of working had never struck him." In illustrating the paper of December 1895, after showing an apparatus in which my process is embodied, and which has since been manufactured and sold by a firm of which his assistant, Mr. Lennox, is a member, Prof. Dewar said in my hearing that the chief credit for persevering with the development of that apparatus to a successful issue was due to Mr. Lennox. In his account (published in your issue of May 19) of the hydrogen apparatus, which also employs my process, Prof. Dewar says that it was constructed by Mr. Lennox's firm, and afterwards, in recognising "the invaluable aid of Mr. Robert Lennox," says "it is not too much to say that but for his engineering skill, manipulative ability, and loyal perseverance, the present successful issue might have been indefinitely delayed." I must allow that it is unfortunate for Prof. Dewar that an assistant so very useful and helpful should have kept the source of his inspiration on the vitally important features of the new development from the knowledge of his chief, who, in discussing my paper of May 2 before the Society of Chemical Industry, stated that he had been quite unaware of my communication of plans and drawings to Mr. Lennox. He ought however, when he did learn the facts, to have done me justice; whereas he says in his letter of the 9th inst.: "My assistant has explained his position in the matter in letters addressed to *Engineering* within the last few weeks." I earnestly hope that all who care for the credit of science will read for themselves the series of letters to *Engineering* by "Arenel," Mr. Lennox, and myself, from March 25 to May 13, in which it will be difficult to find a satisfactory explanation of Mr. Lennox's position. As I fear, however, that few people will exert themselves to look up these letters, I shall be pleased to send a copy of the series to any one who writes for it to No. 20 Gower Place, W.C.

Prof. Dewar criticises my statement that I was the first in this country to liquefy air and oxygen without employing other refrigerants, on the ground that it had previously been done in experiments at the Royal Institution. Now Mr. Lennox has been given very great credit for the work in these experiments; and I do not admit that experiments by my method, developed in collaboration with a gentleman to whom I had explained the method embodied in them, and who had confessed that this method was a novelty to him, and had promised to help me to the appliances required to work it, can be quoted as anticipations of my own work; but to make my statement more correct literally, I will say that my method (as compared with that of Dr. Linde, which differs from it in details) was the first in this country to liquefy air and oxygen without employing other refrigerants.

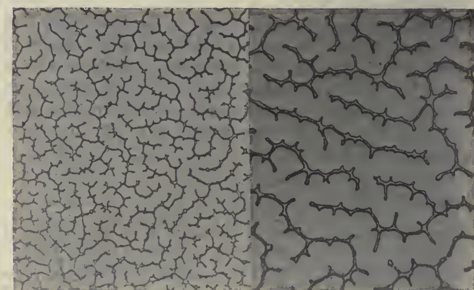
I may add that I mentioned my introduction to Mr. Lennox, not as an "excuse" for calling on him, a course which obviously needs neither excuse nor justification—but to show that I made my visit deliberately for a definite purpose, knowing that I was in possession of an invention of great value for work such as he was practically engaged in. W. HAMPSON.

June 11.

Dendritic Patterns caused by Evaporation.

I HAVE been much interested in Miss Raisin's Royal Society paper "On certain structures formed in the drying of a fluid with particles in suspension," of which an account appears in NATURE for June 2. In connection with this subject it may be worth while placing on record the fact that the presence of suspended particles is not essential for the production of dendritic forms.

Many years ago, when dabbling in microscopy, I mounted a number of objects in glycerine jelly, and was much troubled by the production of bubbles starting from the object and spreading in all directions, leaving a highly elaborate network of ramifications caused, no doubt, by the evaporation of water and consequent shrinkage of the jelly. Having called attention to this defect in a box of slides circulated by the Postal Microscopical Society, Mr. J. J. Wilkinson, of Skipton, very kindly sent me the two accompanying photographs taken with magnifications of 25 and 50 diameters respectively. An additional interest attaches to these from the fact that the slide from which they were taken belonged to the collection of the late Mr. Tuffen West. Needless to say, this slide was mounted for an entirely



× 25 × 50.

different object, and the specimen it contained was rendered worthless by the subsequent formation of these beautiful but troublesome vacuoles. It should be explained that it is the thin branches which are formed of the remains of the jelly, the air filling the broader species between them. G. H. BRYAN.

Bangor, June 10.

Iridescent Surf at Cromer.

CAN any of your readers account for what seems to me to be a singular phenomenon, as, although familiar with the beautiful sea-coast and clear green waves of many lands, I have never seen anything of the sort elsewhere.

The cliffs here, though fine when seen from a distance, are only composed of sand and earth, large quantities of which have been washed down by the recent rains, so that the sea is very dirty, each turning wave being dark with mud. This mud has apparently some curious property, which causes a very moderate surf to deposit long lines of foam all along the shore. Of this foam (which is in no hurry to disperse) each bubble is brilliantly iridescent, even on the dullest day of cold sea-fog, when there is not one gleam of sunshine to produce prismatic effects.

The inhabitants take this so entirely as a matter of course, that a lady whose attention I called to it, said that having always seen it, she had supposed it to be the natural condition of all sea-foam.

Beautiful in themselves as are these myriad rainbows of the shore, I am glad they are not universal, if they are only to be seen as compensation for a discoloured sea!

It would be interesting to learn what is the ingredient in the mud which, when combined with salt waves, produces such tints. CONSTANCE F. GORDON CUMMING.

Cromer, Norfolk, June 15.

Aquatic Hymenopteron.

IT may be of interest to some of your readers to know that, after years of unsuccessful search, I have at last bred *Prestwichia aquatica* (Lubbock) from eggs of Notonecta.

From one single egg there emerged no less than fourteen specimens, one male and thirteen females. This astonishing fact, besides proving that *Prestwichia* is an ovivorous parasite, beats all previous records of the number bred of allied species; but this record has since been put into complete shade. On Friday, from another egg, I bred six males and twenty-eight females; thirty-four parasites from a single egg.

After this astounding fact we must be prepared for something strange, now that the life-history of these marvellous ovivorous parasites is being worked out. FRED ENOCK.

13 Tufnell Park Road, N.

"A High Rainbow."

THE "rainbow" described by Mr. Moreland (in your issue of June 16) was evidently of the same character and origin as an inverted arc near the zenith, which occurred in connection with a mock-moon phenomenon at Birmingham, on May 31, 1895.

An illustrated description of this, by the writer, may be found in *Symons's Meteorological Magazine* for September 1895, p. 122. F. J. ALLEN.

Mason College, Birmingham, June 17.

THE ETIOLOGY AND PREVENTION OF MALARIAL FEVER.

THE study of the causes of intermittent or malarial fevers has received a marked impetus through the discovery by Laveran (*Traité des fièvres palustres*, 1884) of the presence in the blood of the affected persons of definite living bodies belonging to the protozoa. A large amount of important research has been carried on since, concerning these bodies or corpuscles of Laveran, which has yielded not only a clearer understanding of their morphological and biological characters, but has more accurately defined and placed on a firm basis the relation of these protozoa to the different known types of malarial fevers: febris quotidiana, tertiana, quartana—terms denoting the rhythm of the fever paroxysm. The researches of Laveran, of Marchiafava and Celli, of Golgi, of Celli and Guarneri, Grassi and Feletti, Councilman, Danilewsky, Mannaberg and others have definitely established that malarial fevers are characterised by and due to the presence, within the red blood discs of the patient, of parasites belonging to the group of protozoa known as sporozoa (gregarinida, coccidia and hæmosporidia); that is to say, of minute amœboid corpuscles, measuring not more than a sixth or an eighth or less of the broad diameter of a red blood disc, having entered into a blood disc pass their life cycle intraglobularly, growing in size at the expense of the blood disc, consuming the latter's substance till of the host nothing but a small mass of black pigment—the remnant of the blood pigment—is left. The final phase in the life-history of this plasmodium malariæ or hæmoplasmodium malariæ is reached when by a process of simultaneous fission its body produces a number of minute oval spores. These becoming free in the blood fluid are carried by the circulation into the different internal organs: marrow of bone, brain, and notably the spleen. Here at the proper time each spore germinates into an amœboid plasmodium, which passes as such into the general circulation, and, having invaded a red blood disc, goes through all the stages of its intraglobular growth and final sporulation. There is a good deal of evidence to show that the phase of sporulation and consequent dissolution of the central part of the parasite, not consumed by the spores themselves, is actually one of the direct causes of the fever paroxysm; at any rate, these events coincide with the commencement of the febrile attack. One of the most important amongst the many interesting facts elucidated is this, that the duration of the life cycle of the plasmodium malariæ stands in a direct ratio to, and determines the rhythm of the consecutive fever attacks in this way: in febris quartana the plasmodium finishes its cycle in seventy-two hours, in febris tertiana in forty-eight hours, and in febris quotidiana and perniciosa — so common and so virulent in tropical and subtropical regions—the whole process of development is very rapid, the plasmodia are conspicuously small and very numerous, very active, and sporulation takes place chiefly in the internal viscera, notably the spleen.

There are other details elucidated, by which the different types of plasmodium malariæ can be distinguished from one another; as by their size, the number of spores produced in each type, the character and intensity of the amœboid movement, &c., not the least important and fundamental detail being the artificial production by inoculation of the different types of fever: quartana, tertiana or quotidiana, according to whether for the inoculation one or the other or the third definite type of the plasmodium is employed. From all this it seems justifiable to assume that the different types correspond, if not to different species, at any rate to different well-defined varieties of the plasmodium malariæ. Whether or no these varieties have become "set" and permanent (form-constant), or whether they may in one or another generation, owing to alteration of the conditions of host, season, climate or other factors, undergo transition one into the other—as is maintained by some observers—remains to be seen. This, however, has become evident, that by careful microscopic examination of the blood the nature, type and severity of the fever paroxysms can be readily diagnosed and accurately determined. This is of particular value in those atypical and irregular forms of malarial fevers, where clinical diagnosis becomes difficult and indefinite, as, for instance, when there exist several generations of plasmodia in the same affected body, and when these different generations do not start at the same time, and do not finish at the same time their life cycle, as in quartana duplex and triplex.

Koch, in a recent lecture before the Colonial Society in Berlin, lays justly stress on the importance of systematic examination of the blood by experts, so as to determine the type and character of the parasite, because —and herein lies the chief burden of Koch's remarks— the accurate determination of the type of the plasmodium should guide the treatment of the case.

It is within common knowledge that the administration of quinine is invaluable in the treatment of ague, but it is equally known that in some cases its administration is either of no avail or has proved positively harmful.

Now, Koch insists on this, that since quinine has the power to arrest and inhibit the growth and development of the plasmodium, without killing it, the administration of the quinine should be so timed that it is capable of unfolding its effects at the proper phase in the life cycle of the plasmodium, that is about the time of sporulation—immediately before the onset of the fever paroxysm —or immediately after the germination of the spores into the plasmodia—that is immediately after the onset of the fever paroxysm. These phases can only be determined by accurate and systematic microscopic examination of the blood in each individual case.

Also in another direction Koch's remarks are of value, viz. in drawing renewed attention to the high probability of the view first expressed by Laveran, then maintained and expressed with ability by Dr. Manson, to the effect that, similarly to what has been proved in Texas fever of cattle for the tick, so also in human malarial fevers the mosquito (or gnat) plays an important part in the transmission and spread of the disease, being in fact the instrument by which natural inoculation is effected. Thus Koch mentions an island off the coast of German (malarial) East

Africa, in which the absence of the mosquito is associated with a conspicuous absence of ague. It would, however, be premature to sweep aside by such observations those of many previous writers, according to whom infection with the malarial poison occurs both by way of the alimentary canal (through drinking water) and of the respiratory organs (through air). However this may be, whether malarial infection under natural conditions is carried out to a large extent by way of inoculation through mosquitoes; whether the mosquito serves merely as the instrument of infection; or whether it is—as is maintained by Laveran, and notably by Manson—the host of the malarial plasmodium; whether artificial immunity against malarial fever is procurable and by what means, are some of the questions which, having a principal bearing on prevention, ought to receive an immediate answer.

It is for reasons of this kind that Koch's great authority and weighty opinion are welcome; they ought to stimulate to action those Governments whose possessions in tropical and subtropical countries impose on them the responsibility of better protecting the health and life of their civil and military subjects, a responsibility which hitherto, unfortunately, does not seem to have weighed heavily on them. Our own Indian Government has with laudable spirit initiated important work by appointing for specific research on malaria an able young military surgeon, Surgeon-Major Dr. Ronald Ross. While this is a beginning, it is small as compared with what is needed to meet the case; what is wanted is a staff of specialists, whose systematic and concerted work is required to elucidate the many problems connected with the subject. The Colonial Office also, with its sway over vast malarial territories in tropical and subtropical Africa, might do a great deal in the matter, considering that the health and life of their numerous civil and military servants is exposed continually in some of the most notorious hotbeds of deadly fevers to dangers which ought to, and with advancing exact knowledge might be prevented.

E. KLEIN.

THE UNIVERSITY OF LONDON COMMISSION BILL.

THE second reading of the University of London Commission Bill last week, without a division, should make its passage into law this Session certain. After the elaborate pains taken by the leaders of the irreconcileable graduates to personally instruct members of Parliament during the week preceding the debate, the feeble nature of the actual opposition came as something of a surprise. It is dangerous to treat Parliament as if it were a body of graduates with a vote to cast at a senatorial election, and methods suitable for the one kind of campaign are likely to fail in the other, as Sir John Gorst made plain, when he referred to the misstatements of fact which are inseparable from a contested election. But the danger is by no means altogether overpast. Having failed to persuade Parliament to reject the Bill, Sir John Lubbock and his friends are now preparing to do their best to wreck it and to ensure its passage in a form which will effectually prevent the University from adding to its present usefulness or doing anything to encourage learning and research. The member for the University has placed his name to two amendments, each of them, if accepted, calculated to stultify the labours of half a generation for the advancement of higher education in the metropolis. To begin with he proposes to abolish the thirty-mile limit, which is necessary if the reconstituted University is to be a seat of learning for London as well as of London. The effect of this would be to encourage those provincial Colleges at present unconnected with any University to apply for incorporation with London, to delay indefinitely the formation of a University for the Midlands—a foundation much to be desired, and to render impracticable the working of the Boards of Studies of the new University in London—a provision upon which a large part of its efficiency will depend. It would be difficult to imagine any single amendment which could reach further in its evil consequences, or be more destructive of the whole purpose of the Bill than this.

But Sir John is not content with making any unity of policy unattainable; he is anxious to ensure that as large a proportion as possible of the University scholarships and exhibitions shall help to maintain the students of other seats of learning. It has long been one of the anomalies of the present University that a large number of the scholarships are won by men and women who are studying elsewhere than in London, and very frequently at other Universities. Especially is this the case with mathematics, the rewards for which study are almost invariably taken by Cambridge men. In order to maintain and extend this condition of things, the member for the University proposes that external students shall be admitted to the examinations for internal students. Under the dual examination system which the Senate will have the power of establishing, by the terms of the Bill, should it seem advisable to do so, internal students will be admitted to the examinations for external students; and rightly, for these tests, like the present ones, will be open to all the world, irrespective of the manner or place of study. But this is no argument for reciprocity in regard to the internal examinations. Should an internal student win an external scholarship, the University funds will at least go to the encouragement of learning in London itself; but should an external student take an internal scholarship, the University chest will, in the large majority of instances, be depleted for the benefit of some other institution. And what is even more objectionable, this amendment would divest the internal degree of its chief value in the eyes of students and the public alike, the guarantee namely which it will give under the Bill as it stands, that its holders have undergone a definite course of training and study. This guarantee is far more valuable in the eyes of those who understand educational matters than the difficulty of the questions which a candidate may succeed in answering during a few days at the close of his studentship, under conditions which at best admit a large measure of chance.

It is hard to believe that the Colleges will consent to take a part in reconstitution on these lines, or that Parliament will play into the hands of the wreckers by accepting such amendments. The proposal to bind the hands of the Senate and force them willy-nilly to subject external and internal students to the same examination—a point to which so much attention was directed in the recent debate—is not worth serious argument; for apart from its inherent impracticability, the facultative dual examination was the basis of the compromise on which the present Bill rests, and to destroy this would be to render legislation ineffectual because unacceptable to all the teaching bodies interested.

THE SCIENCE AND ART BUILDINGS AT SOUTH KENSINGTON.

WE were able to print last week the text of the Memorial forwarded to the Government by the President of the Royal Academy, pointing out how disastrous it would be for the future of Art in this country if the new proposals regarding the buildings at South Kensington were carried out. As our readers will remember, the same course had already been taken by the President of the Royal Society with regard to the Science side of the question.

We are now enabled to give the names of those who have signed the Art Memorial.

NOTES.

IN the presence of a brilliant and representative gathering of citizens, the freedom of the City of Edinburgh was conferred upon Lord Lister on Wednesday, June 15.

GERMANY owes most of her success in the commercial and industrial world to her readiness to act upon the advice of her men of science. The German Emperor has just given further evidence that he understands the value of scientific opinion in matters affecting national welfare, and recognises the importance of technical education, by nominating Prof. Slaby, of the Technical College at Charlottenburg, Prof. Launhardt, of the Technical College at Hanover, and Prof. Intze, of the Technical College at Aachen, to be life members of the Upper House of the Prussian Diet. The *Times* correspondent at Berlin states that while Prof. Slaby was delivering his lecture at Charlottenburg on Wednesday, he was interrupted by the receipt of a telegram from the Emperor, which he proceeded to read to his class. It was in the following terms :—"In recognition of the importance which technical knowledge has acquired at the end of our century, and in profound respect for the exact sciences in general, I wish to confer upon the Technical College of Charlottenburg a seat and a vote in the Herrenhaus, and I nominate you as the most fit person to be its representative.—William, I.R." Prof. Slaby, addressing the students, expressed his sense of the significance of the step which the Emperor had taken in conferring upon the technical colleges the right of representation in the Upper House of the Prussian Diet, a privilege which the Universities had long enjoyed.

THE preliminary programmes of the sections of the American Association for the Advancement of Science are beginning to be published. Section A (Mathematics and Astronomy) announces twenty-five papers, and reports of five committees. Section C (Chemistry) announces that on Tuesday, August 23, under the auspices of the American Chemical Society, the morning session will be devoted to the subject of analytical chemistry, led by Dr. P. De P. Ricketts, of Columbia University; the afternoon to teaching of chemistry, Dr. F. P. Venable, University of North Carolina. On Wednesday, August 24, the Association will make an excursion to Salem as guests of the Essex Institute. On Thursday, August 25, the morning will be given to inorganic chemistry, led by Dr. H. L. Wells, Yale University; the afternoon to organic chemistry, Dr. Ira Remsen, Johns Hopkins University; and the evening to physical chemistry, Dr. T. W. Richards, Harvard University. On Friday, August 26 (Harvard Day), in one of the Harvard University rooms, the subject of physiological Chemistry will be opened by Dr. E. E. Smith, New York; President Eliot will deliver an address to the Association at large in the evening. On Saturday, August 27, the morning will be given to agricultural chemistry, led by Dr. H. A. Weber, Ohio University; and the afternoon to technical chemistry, Dr. N. W. Lord, Ohio University.

THE issue of the *Revue Scientifique* of June 11 contains an interesting critical notice of the Royal Society's International Catalogue scheme by M. Charles Richet, a well-known expert in such matters. M. Richet fears that the apathy which the public manifest towards all such enterprises may make it difficult to obtain the necessary funds from subscriptions. He cordially welcomes the proposal to issue the catalogue in two forms—as slips and in book form—but regards the preparation of slips of the character suggested as a work of great difficulty on account of its magnitude. Being an ardent advocate of the Dewey system, he naturally deplores the fact that it has been put aside; but yet finally expresses his conviction that all advocates of the system will rally, without hesitation, to the system proposed by the Royal Society, which, being advocated by such a body, has the greatest chance of success. Of the scheme as a whole, M. Richet writes: "C'est une belle œuvre à accomplir: et le plan est excellent, dans son ensemble. Nous espérons donc fermement que tous les savants de France et de l'étranger prêteront leurs concours actif à cette magnifique publication." If all receive the proposals in the same generous spirit of appreciation and self-abnegation, there can be little doubt of the success of the enterprise.

PROF. O. C. Marsh, Yale University, New Haven, has been elected a Foreign Member of the Geological Society.

PROF. B. GRASSI, M. Hippolyte Lucas, and Dr. August Weismann have been elected honorary members of the Entomological Society of London.

THE death is announced, at the age of seventy-two, of Sir James Nicholas Douglass, F.R.S., late Engineer-in-Chief to the Hon. Corporation of Trinity House. During his tenure of this post he carried out many important engineering works both at home and abroad, such as the Wolf, Longships, Great and Little Basses, Eddystone, and Muricoy lighthouses, and he effected numerous technical improvements connected with lighthouses and their illuminating apparatus, as well as in buoys and beacons. He was elected a Fellow of the Royal Society in 1883, and retired from his post at the Trinity House in 1892.

THE *Times* reports that the Norwegian Geographical Society gave a banquet last Saturday to the expedition under Captain Sverdrup, which is on the point of leaving for exploration along the north and north-west coast of Greenland. Several of the Norwegian Ministers were present, as well as the Presidents of the two Houses of Parliament, Dr. Nansen, Prof. Mohn, and other distinguished men.

AN international fisheries exhibition, together with an exhibition of Norwegian industry, agriculture, art and home industries, is now open at Bergen. The directors of the Society for promotion of Norwegian fisheries are of opinion that besides the many various meetings which will take place during the exhibition, an International Fisheries Congress ought, if possible, to be arranged. They therefore invite Norwegians as well as foreigners interested in fisheries to join in such a Congress, to be held in Bergen on July 18–21.

ACCORDING to a report of the French Minister at Stockholm, referred to in the *Board of Trade Journal*, the industry of textiles made from peat-fibre has just been introduced into Sweden. The fibres, produced from peat by a mechanical process, can be mixed in the proportion of 75 per cent. with pure wool, for the manufacture of yarn similar in appearance to common woollen yarn.

THE Pilot Chart of the North Atlantic Ocean, issued by the United States Hydrographic Office for the month of June, shows that the ice season has now set in on the Grand Banks, and that the amount of icebergs is equal to the average of past years. In addition to the ordinary useful information there is a sub-chart showing the distribution of atmospheric pressure and the prevailing winds in the South Atlantic, taken, with some modifications, from the Meteorological Atlas of the Deutsche Seewarte. It shows that a belt of high pressure extends east and west along the parallel of 25° S. To the southward the pressure diminishes rapidly and with great uniformity, and the decrease is continuous as far towards the pole as observations have been carried. Some useful general remarks are made as to the system of winds to which this high pressure area gives rise in various seasons of the year.

IN the last annual number of the *Journal of the Scottish Meteorological Society* (vol. xi.), Dr. Buchan has published a most important paper on the mean atmospheric pressure and temperature of the British Islands, with twenty-six coloured maps and tables of monthly and yearly values for forty years, 1856–1895. Fifteen years ago similar data for twenty-four years were published, but since that date a large number of stations have been added, the total now reaching 400, and a more satisfactory inspection of stations has been brought about, chiefly by the valuable aid rendered by the Meteorological Council, so that better averages are now obtainable. This monumental work teems with interesting and strictly trustworthy results, but we can only briefly refer here to one or two general remarks pointed out in the author's instructive discussion. The most striking feature is the down-curving of the annual isobaric lines as they cross the Irish Sea and St. George's Channel. Another distinct feature of the isobars is the influence of the land in increasing the barometric pressure, and the opposite influence of the sea in depressing the isobars. In the discussion of the temperature observations the author arrives at a conclusion of great importance for invalids, viz. that where a winter climate is sought, offering, in the highest degree the combined qualities of mildness and dryness, anywhere afforded by the British Islands, such a climate is to be found on the shores of the Channel, from about Dover to Portland.

MR. W. ERNEST COOKE, Government Astronomer of Western Australia, has forwarded to us particulars received from Captain Odman with regard to a remarkably severe storm experienced off the north-west coast of Australia between March 30 and April 3. Captain Odman was commanding the S.S. *Albany*, and evidently passed right into the "eye" of the storm. Strong north-east winds were met on April 1, and the barometer fell until 10 a.m. of the following day, when the weather became calm. An hour later the barometer rose quickly, and south-west winds were experienced. The following extracts from the log are instructive, as showing the characteristics of wind and atmospheric pressure in a rotary storm:—April 1, lat. 19·00, 12 a.m., barometer 29·58, strong N.E. winds and clear; 3 p.m., barometer 29·48, blowing N.E. gale with heavy rains; 11 p.m., barometer 29·42, wind N.E., blowing and raining, the force of the wind being indescribable, and continuing with fearful hurricane force up to 10 a.m. on 2nd. April 2, lat. 20·00, 10 a.m., barometer 27·80, suddenly and without warning it became calm; in fact, we could not feel a breath of wind, or tell from which direction it came. The barometer then stood at 27·80, and continued stationary till 11 a.m, when it suddenly rose to 27·90, and the wind could be heard roaring and the sea boiling before we felt it, when it suddenly struck the ship from S.W., in an entirely opposite direction to that previously experienced, and, with the rain, became almost as dark as night, and continued to blow at much greater hurricane force than it had done before, the barometer still rising. The gale still continued with violent force up to midnight, the barometer still rising and the wind decreasing from then. Captain Odman states as a positive fact that the men's dungaree suits and his own canvas one were blown to ribbons during the storm. The barometer fell an inch between 6 and 10 a.m. on April 2, and rose an inch again by 6 p.m. Mr. Cooke informs us that the storm struck the towns of Cossack and Roeburne, and almost demolished them. Cossack registered 15·42 inches of rain, Roeburne 14·66, and a place called Whim Creek had 36·53 inches. Mr. Cooke failed, however, to trace the storm inland. He expected it to work overland towards Eucla, at the head of the Great Australian Bight, but no traces of it were perceptible at the inland meteorological stations.

IT may be remembered that in May of last year Dr. Le Neve Foster, F.R.S., nearly met his death by carbonic oxide poisoning while investigating the circumstances attending an underground fire at the Snaefell Lead Mine, Isle of Man (see NATURE, vol. lvi. p. 58). A detailed report upon this mine accident has just been published in a Blue Book, and it is not merely a statement of facts as to the condition of the mine and the method of working, but a document containing information which will prove of service to persons exposed to the risk of carbonic oxide poisoning, and also be of scientific interest to physiologists. Dr. Foster points out that although the gas occurs occluded in certain rocks and minerals, it has never been found as a natural constituent of the atmosphere of mines. He had, therefore, to seek for some artificial source of the poison when investigating the accident, and he found sufficient evidence to justify the conclusion that the deaths of the twenty victims of the Snaefell disaster were due to carbon monoxide produced by timber burning in the mine. It is startling to find how small a quantity of timber need be burnt to pollute to a dangerous extent the passages of a mine. By the combustion of a cubic foot of larch, which was the kind of timber employed at Snaefell, enough carbon monoxide is produced to occupy 417 cubic feet of space at a temperature of 60° F., and a pressure of 30 inches. Twenty-five cubic feet of timber contain carbon enough to produce sufficient carbon monoxide to give an atmosphere with 1 per cent. of the noxious gas all through the mine, which proportion is quite sufficient to cause almost immediate loss of consciousness, followed speedily by death. Dr. Foster therefore recommends that the linings and fittings of all mine shafts and roadways in mines should be made fire-proof, or of fire-resisting materials, unless the shafts and roadways are decidedly wet or damp. The use of oxygen in restoring sufferers from carbonic oxide poisoning is referred to, and the suggestion is made that a supply of compressed oxygen should be available in every district, and also apparatus for penetrating into noxious gases. With Dr. Foster's report is a report by Dr. Miller upon physiological effects of carbon monoxide poisoning, and an appendix containing statements concerning the sensations, symptoms, and after-effects produced by breathing the gas.

DR. ISSATSCHENKO, of the bacteriological laboratory attached to the agricultural department of the Russian Government, has just made a preliminary communication on a new microbe pathogenic to rats which he has discovered. A disease, which assumed epidemic proportions, broke out amongst the rats kept for experimental purposes in the laboratory, and from the liver and spleen of affected animals a bacillus was isolated, which proved on inoculation to be extremely fatal as regards both rats and mice. Receiving food infected with this organism rats and mice invariably succumbed, the former after from eight to fourteen days, the latter after from four to eight days. Following Pasteur's example in the case of a bacillus similarly fatal to rabbits, attempts were made to turn this new microbe to practical account and utilise it as a living rat poison. The results so far have not been very encouraging, but further experiments are being made in this direction. It is apparently quite without effect upon pigeons and rabbits. As regards its artificial cultivation this microbe is very accommodating, growing luxuriantly upon all the customary culture media with the exception of potatoes. In microscopic appearance it varies, as is so often the case, according to the nature of the medium in which it has been previously grown. It is mobile, and is endowed with lateral flagella.

INCREASING attention is paid nowadays to the elevation and sub-soil by those who are in a position to choose their place of residence. It is true that many circumstances have to be taken into consideration in fixing upon a home, and not the least important is the construction of the house itself—more important, probably, than the question of a gravel or clay sub-soil. Elevation and surroundings, again, may confer advantages not to be had in a low-lying gravel area. To those, however, who are seeking for homes on particular sub-soils or in particular situations the handsome embossed model just published by Mr. E. Stanford, London, will prove an excellent general guide. If the more elevated regions of Shooter's Hill, Sydenham and Wimbledon, of Hampstead, Highgate and Harrow, appear to stand out in somewhat mountainous form, owing to the horizontal scale of one inch to a mile and the vertical scale of one inch to a thousand feet, the main features can nevertheless be readily grasped. The leading roads and railways are shown, the sub-soils are distinctly coloured, and along the margin of the model there are sections depicting the underground structure of the country. The model itself measures 2 feet by 1 foot 8 inches, including its frame, and it takes in Barking on the north-east, a part of Harrow on the north-west, Long Ditton on the south-west, and Orpington on the south-east. The model is made of tinned steel plate, enamelled in colours, and its price is 15*s*. It has been prepared by Mr. James B. Jordan, the geology being compiled from the maps of the Geological Survey, the work chiefly of Mr. Whitaker. House-hunters who consult it will see at a glance the advantages to be gained from certain localities, and also the districts that should, if possible, be avoided. For educational purposes in schools the model may prove of considerable service.

AN interesting address entitled "Types of Scenery and their Influence on Literature," recently delivered at Oxford by Sir Archibald Geikie as the Romanes Lecture, has been published by Messrs. Macmillan and Co., Ltd. The object of the address was to point out the leading types of scenery that distinguish the British Isles, and to show that it is possible to trace from each of them an influence upon the growth of English literature. For instance, Sir Archibald points out that the English lowlands have had a distinct influence upon our literature. They are washed by the sea along the whole of their eastern and northern borders. Moreover, the coastline is indented by numerous bays, creeks, and inlets, which furnish many admirable natural harbours. There can be no doubt that this feature in our topography has powerfully fostered that love of the sea which has always been a national characteristic. To the same cause may be traced that appreciation of the poetry of the sea so noticeable in our literature. For a century after Milton's time poetry became with each generation more polished and artificial. When at last a reaction set in, the impulse that led to the most momentous revolution in the history of English poetry came in large measure from the writings of three poets, each of whom drew his inspiration from lowland scenery—Cowper, Thomson, and Burns. The uplands, which include the border country of England and Scotland, produced the Border ballads, and the highlands of Western Argyleshire are portrayed in Macpherson's "Ossian"; while the Lake District, also mountainous, claims attention for its influence on the progress of national literature, for it was amidst its scenery that William Wordsworth was born and spent most of his long life. Towards the end of his interesting address Sir Archibald Geikie remarks:—"It is curious to remember that three of the poets whom I have singled out as illustrations of the influence of our lowland, upland, and highland scenery upon our literature have held up the geologist to ridicule. Cowper put that votary of science into the pillory among the irreligious crowd, about whose ears the poet loved to 'crack the satiric thong.' Wordsworth treated the geological enthusiast with withering scorn. Scott, with his characteristic good humour, only poked fun at him. It was reserved for a poet of our own day to look below the technical jargon of the schools, and to descry something of this wealth of new interest which the landscape derives from a knowledge of the history of its several parts. But Tennyson only entered a little way into this enlarged conception of nature. There remains a boundless field for some future poetic seer, who, letting his vision pierce into the past, will set before the eyes of men the inner meaning of mountain and glen."

THE twenty-sixth annual report of the Board of Directors of the Zoological Society of Philadelphia has been received. The number of visitors to the Gardens of the Society during the year covered by the report was 173,999. In addition to this, 125,000 free tickets were issued to the Board of Education for the admission of pupils of the public schools. The Society's collection of animals numbers 1019, of which 339 are mammals, 421 birds, 238 reptiles, and 21 batrachians. Among the additions to the collection were two young West Indian seals (*Monachus tropicalis*). Although the existence of a peculiar species of seal in the Caribbean Sea has been known for several centuries, no detailed description has been given of it until very recently, and no living specimens had been procured until a schooner was sent out last spring by a firm of merchants for the purpose of capturing some, which was finally effected on a small coral reef off the Campeachy coast of Yucatan. These animals were distributed among various zoological collections, and three were secured by Philadelphia. It was hoped that observations might be made upon the habits of this almost unknown species, but unfortunately, in all these cases, the animals were induced to take food with difficulty and in small quantity, and they lived only a short time. The genus *Monachus* includes the present species and one other found in the waters of the Mediterranean, these seals being the only ones belonging to the *Phocidæ*, or the group without external ears, which are found in subtropical regions of the Atlantic. Referring to the death of a male orang belonging to the Society, it is noted that though it has more than once been pronounced by high authority to be anatomically impossible for the orang to maintain an erect attitude without touching some means of support, this animal was repeatedly observed walking about his cage in an absolutely erect position without having his hands in contact with any fixed object.

WRITING in the annual volume of the *Sitzungsberichte der physikalisch medicinischen Societät in Erlangen*, Prof. E. Wiedemann and Dr. G. C. Schmidt give some noteworthy observations on the electric properties of gases. In the first of their papers the authors discuss the absorption of electric oscillations by gases, and arrive at the somewhat remarkable result that gases which are excited to incandescence by electric discharges will absorb electric waves falling on them, even when they would not do so if unexcited; but the dark space surrounding the kathode is only feebly absorbent of such oscillations, thus behaving like a non-conductor. Prof. Wiedemann and Dr. Schmidt also discuss the effects of Goldstein's rays ("kanalstrahlen") on electric oscillations, and find that the oscillations emanating from a Lecher condenser are absorbed by gases which have been excited by these rays.

IN a second paper, Prof. Wiedemann and Dr. Schmidt discuss the view that the conduction of electricity through rarefied gases is an electrolytic phenomenon. This view is negatived by their present observations. In some cases, as with chloride, bromide and iodide of mercury, no products of electrolysis appeared at the electrodes; in other cases, where decomposition did take place, the amounts liberated were found not to follow Faraday's Law. In a further communication to the same journal, Dr. G. C. Schmidt discusses the relation between fluorescence and photo-electric susceptibility; the results of these observations do not altogether favour the hypothesis of Elster and Geitel as to a parallelism between the two phenomena.

SOME of the catalogues published by many photographic firms, besides containing useful information on photographic lenses, cameras, shutters, &c., are really works of art of no mean merit. We have just received the fourth edition of Messrs. Newman and Guardia's catalogue, which quite falls into this category if one examines the series of illustrated specimens of the work done with their so-called "N. and G." cameras. The beauty of these reproductions will be fully appreciated by all who peruse this book, the half-tone blocks having been produced by the Swan Electric Engraving Company.—Messrs. Ross, Ltd., have also forwarded to us their catalogues for the present year, containing a mine of information about lenses, cameras, &c., of every conceivable kind, and many other optical instruments which this firm manufactures.

IN the *Bollettino della Società Sismologica Italiana* (vol. iii. No. 8) a list of earthquakes observed in Greece during the year 1897 (January–June) is given by S. A. Papavasiliou, in continuation of the catalogue compiled by the author before his retirement from the observatory at Athens. The number of shocks recorded during the six months is about 130. Other papers are:—A new contour-map of the central crater of Etna, by A. Riccò; seismoscope with clock, by C. Guzzanti, describing an arrangement for starting mechanically a clock, previously set at a known time; seismology and palæography, by E. Oddone; notices of earthquakes recorded in Italy (May 23–June 11, 1897), by G. Agamennone, the most important being the Ionian Sea earthquake of May 28–29, and earthquakes of distant origin on May 23–24, 24–25, and June 3.

A NEW part (vol. ii. Isopoda, part ix. x.) of Prof. G. O. Sars' monograph on the "Crustacea of Norway" has just been issued by the Bergen Museum. The Munnopsidæ are concluded in this new part, which also contains descriptions of members of the tribe of Oniscoida, four families of which are represented in the fauna of Norway.

THE second volume of the Cape Photographic "Durchmusterung," by Dr. David Gill, F.R.S., and Prof. J. C. Kapteyn, has just been published as vol. iv. of the *Annals of the Cape Observatory*. The arrangement of the stars in the catalogue is precisely similar to that of vol. i., recently reviewed in these columns (p. 513). The new volume contains the positions of stars in the zones $-38°$ to $-52°$.

MR. T. CHALKLEY PALMER has an interesting note in the *Proceedings* of the Academy of Natural Sciences of Philadelphia, on the peculiar movements of the diatom *Eunotia major*, which he considers to be connected with an actual process of assimilation or elimination of oxygen, and to be produced by special pseudopode-like organs; these he calls "coleopodia," and he believes them to be present also in other diatoms belonging to the Fragilarieæ.

THE fourth German edition of Dr. A. Classen's work on "Quantitative Chemical Analysis by Electrolysis" differs from the previous editions in several respects, among which may be mentioned the insertion of a section devoted to theory, and the addition of descriptions of various measuring instruments and electrolytic experiments. The revision was carried out with the assistance of Dr. W. Löb; and the authorised English translation of the revised and enlarged edition, prepared by Prof. W. H. Herrick and Dr. B. B. Boltwood, has been published by Messrs. J. Wiley and Sons (London: Chapman and Hall, Ltd.). The book is a more complete, scientific and logically arranged work than heretofore, and is altogether a useful manual on electro-chemical analysis. The illustrated account of the Electro-chemical Institute at Aachen, where Drs. Classen and Löb are at work, should lead to the foundation and equipment of similar institutions here for purposes of instruction and research in this most important branch of science. It should not be left to Germany to extend and apply the principles discovered by Davy and Faraday.

REPORTS of papers read before the Royal Society of Edinburgh regularly appear in the columns of NATURE shortly after the papers are read, so it is unnecessary to do more now than briefly refer to the papers which appear in their complete form in the *Transactions* of the Society for the sessions 1895–96, 1896–97. Among the subjects and authors of papers in the volumes are the following:—Observations on the phonograph, by Prof. J. G. M'Kendrick; the strains produced in iron, steel, and nickel tubes in the magnetic field, by Prof. C. G. Knott; the temperature variation of the magnetic permeability of magnetite, by Dr. E. H. Barton; the weather, influenza, and disease, by Dr. A. Lockhart Gillespie; torsional oscillations of wires, by Dr. W. Peddie; the meteorology of Edinburgh (two papers), by Mr. R. C. Mossman; some nuclei of cloudy condensation, by Mr. John Aitken (in this paper Mr. Aitken shows, by experiments on the effect of sunshine on the gases in the atmosphere, that it is possible for cloudy condensation to take place in the absence of dust); the fossil flora of the Yorkshire coal-field, by Mr. Robert Kidston; and the automatic linear transformation of a quadric, by Dr. Thomas Muir. The *Proceedings* of the Society (vol. xxii.) contain several papers by Lord Kelvin; notes on specimens of rock from the Antarctic Regions, by Sir Archibald Geikie; observations of instrumental disturbances at the Colaba Observatory during the Indian earthquake of June 12, by Mr. N. A. Moos; the velocity of graded actions, by Dr. James Walker, and other papers.

THE additions to the Zoological Society's Gardens during the past week include a Guinea Baboon (*Cynocephalus sphinx*) from West Africa, presented by Captain C. C. Wyatt; three Common Marmosets (*Hapale jacchus*) from South-east Brazil, presented by Colonel A. H. Maclean; two White-tailed Gnus (*Connochœtes gnu*, ♂ ♀) from South Africa, presented by Mr. C. D. Rudd; a Cape Zorilla (*Ictonyx zorilla*), a Little Ichneumon (*Helogale parvula*), a Spotted Eagle Owl (*Bubo maculosus*) from South Africa, presented by Mr. J. E. Matcham; two South African Kestrels (*Tinnunculus rupicolus*) from South Africa, presented by Mr. C. Southy; a Naked-footed Owlet (*Athene noctua*), European, presented by the Hon. Mrs. Barrington; two Senegal Parrots (*Pœocephalus senegalus*) from West Africa, presented by Miss E. L. Barford; four Fieldfares (*Turdus pilaris*), a Black Guillemot (*Uria grylle*) from Christiansund, North Norway, presented by Dr. R. B. Sharp; an Indian Python (*Python molurus*) from India, presented by Mr. Percival F. Tuckett; a Four-lined Snake (*Coluber quatorlineatus*), European, presented by Mr. J. W. Temple; twelve Algerian Skinks (*Eumeces algeriensis*) from Algeria, presented by Mr. Robert S. Hunter; a Malabar Squirrel (*Sciurus maximus*, var. *dealbatus*) from India, two Forster's Ceratodus (*Ceratodus forsteri*) from Australia, deposited; a Crowned Partridge (*Rollolus cristatus*) from Malacca, four Common Cormorants (*Phalacrocorax carbo*) from Holland, two Cereopsis Geese (*Cereopsis novæ-hollandiæ*), two Forster's Ceratodus (*Ceratodus forsteri*) from Australia, purchased; three Triangular-spotted Pigeons (*Columba maculosa*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMETS NOW VISIBLE.—Last week it was noted in these columns that Mr. Coddington had discovered a comet in the position R.A. 16h. 24m. 45·9s., and Declination (South) 25° 14′ 20″. Circular (No. 7) of the *Centralstelle* gives the elements and ephemeris of the comet, based on the positions observed on June 11, 13 and 15, and calculated by Prof. A. Berberich. The former are as follows:—

$$T = 1898 \text{ August } 4{\cdot}478 \text{ Berlin M.T.}$$

$$\left.\begin{aligned}\omega &= 206^\circ\ 8'{\cdot}5\\ \Omega &= 73\ 58{\cdot}7\\ i &= 76\ 48{\cdot}3\end{aligned}\right\}1898{\cdot}0$$

$$\log q = 0{\cdot}31850$$

As the comet is moving rapidly south, and has now a Declination (South) of about 32°, we do not give the ephemeris. This comet was independently discovered by Dr. W. Pauly in Bucharest on June 14.

We have received two telegrams from Kiel concerning another comet, Perrine (June 14). The former gives the observation made on June 14 at Lick mean time 15h. 16·0m., giving the position Right Ascension 3h. 29m. and Declination + 58° 36′, the latter showing the position to be Right Ascension 3h. 34m. 58s. and Declination + 58° 24′ 2″ at Lick mean time 14h. 12m. on June 15. A Circular (No. 5) from the *Centralstelle* gives us the elements and ephemeris calculated by Perrine and Aitken from the observations made on June 14, 15 and 16. These are:—

Elements.

$$T = 1898 \text{ August } 17{\cdot}40 \text{ Greenwich M.T.}$$

$$\left.\begin{aligned}\omega &= 196^\circ\ 46'\\ \Omega &= 260\ 6\\ i &= 69\ 42\end{aligned}\right\}1898{\cdot}0$$

$$q = 0{\cdot}7418$$

Ephemeris for 12h. Greeenwich M.T.

1898.	R.A. h. m. s.	Decl. ° ′	Br.
June 20	... 4 2 52	... +57 15	... 1·18
24	... 4 25 24	... 55 56	
28	... 4 48 48	... 54 20	
July 2	... 5 10 0	... +52 27	... 1·72

The comet will thus gradually brighten as July is approached, but takes a somewhat southerly course.

Another Kiel telegram, dated June 18, tells us that Perrine found Wolf's comet on June 16, at 15h. 5·3m. Lick mean time, in position—

R.A. 2h. 16m. 19s., and Declination + 19° 42′ 44″.

Still another and last telegram from Kiel, dated June 19, informs that comet Giacobini was seen on June 18 at 13h. Nice mean time in the position of Right Ascension 20h. 36m. 30s. and Declination − 21° 14′ 0″.

THE 40-INCH YERKES REFRACTOR.—Prof. Barnard, writing in the *Astronomical Journal* (No. 436) with respect to a series of measures of the satellite of Neptune, gives an interesting account of the behaviour of the Yerkes telescope. Actual observation was not possible until the best season was essentially over, but it was found that even a part of this unfavourable weather permitted the power of the telescope to be tested. On one or two occasions, when observing double stars, he was able to use powers of several thousand diameters, and on one date he employed a power of 3750 with good success. The object-glass he finds entirely free from any form of ghost, and the definition is at times very good, showing, as he says, that "this last great work of Alvan Clark is one of his noblest monuments." The driving clock moves the great tube with such perfect steadiness that he was astonished at the result, and so stable is the mounting of the instrument that the effect of the clock, rewinding itself automatically at periods of 1h. 48m., does not in the least interfere with micrometer work. Very satisfactory also are the electrical contrivances at the eye end for clamping and slow motion; the clock takes up the tube upon the application of the electric clamp in Right Ascension perfectly instantaneously, and the slow movement is so exact that a star can be brought from the edge of the field and stopped instantly behind the micrometer-wire, the motion being about 1′ in 8 seconds. Prof. Barnard further mentions the ease with which the instrument can be handled; as an instance, he says that he placed the telescope on the west side of the pier in position of + 50° declination, and by means of the electric motors he moved it on the other side of the pier to the same Declination in 1m. 50s. An important addition to the dome is the wind-break. This consists of two curtains working on endless chains, one rising from the base of the slit, and the other passing through the zenith from the rear. With these, excepting at low altitudes and right in the face of the wind, the tube is always perfectly protected even on the windiest nights.

VARIABLE STARS OF SHORT PERIOD.—Prof. E. C. Pickering describes in a *Harvard College Observatory Circular* (No. 29) a very simple means of detecting variables whose periods are short if the observer is provided with a telescope mounted equatorially and a fairly good driving clock. The method is so simple and complete that it has probably been tried before, although, so far as we know, no mention of it has come under our notice. The idea is to expose a photographic plate in a telescope, the clock of which is working somewhat fast, and at intervals of ten and fifty minutes to alternately expose and cover the lens by an electrical attachment. Prof. Pickering describes one of the plates so exposed. An 8 × 10 plate was exposed in a telescope with a Cooke anastigmatic lens, aperture 2·6 cm. and focal length 33·3 cm. and eight successive images of each star were obtained in the period of about eight hours, The plate covered a region of about 33° square, and a portion of it, shown in the *Circular*, indicates the variable intensity of the images of the star U Cephei, while those of the neighbouring stars show no such variations.

On this scale forty plates would cover the whole sky from north to south pole, and Prof. Pickering proposes to undertake this work as soon as the best method of taking the plates has been determined. By the above plan it is hoped to secure a complete list of all variable stars of short period brighter than the ninth magnitude at maximum, whose variation exceeds half a magnitude, and whose period is less than a day. In such a sweep, probably, many other variable stars of longer period, and stars of the Algol type will be discovered.

The beauty of the above method lies in the simple equipment that is necessary to obtain results of considerable value. It will be noticed that the method is a differential one, clouds passing across the field of view during an exposure affecting all the photographic images alike.

THE OXFORD UNIVERSITY OBSERVATORY.—The twenty-third annual report of the visitors of the University Observatory appears in a recent number (June 14) of the *Oxford University Gazette.* The report refers to the period from June 1, 1897, to May 31, 1898, and exhibits the state of the observatory on the last-named day. One of the main points referred to by Prof. Turner in the report, is that of the necessity of completing the observatory by attaching to it a residence. This, he points out, is urgent, since it is most imperative that the official staff should be as near their work as possible when both routine observational work and students have to be dealt with. Prof. Turner refers to a very curious accident that occurred to the level belonging to the Barclay transit circle that is used for time determinations, which is well worth repeating. "The striding level, weighing 19 lbs., which was suspended over the instrument by means of a cord, pulley and counterpoise, fell (from its usual position when not in use near the roof) a distance of three or four feet on to the instrument, owing to the snapping of the cord. It was found the next morning standing upright, with its feet on the pivot covers as if in position for an observation. The blow had thus been received by the pivot covers, and no other part of the instrument had apparently been damaged or even struck. The brass tube of the level itself was shattered, but the glass-tube inside was not broken!" Surely this is quite a unique accident?

The measurement and reduction of the plates for the Astrographic Catalogue seem to be proceeding apace, an average of 3951 measures of the star positions and magnitudes being made every week, the total number for the year being 205,443. The main result of the year's work is that the prospects of achieving the object aimed at are brighter than previously; this was, as Prof. Turner states, that by the middle of 1901 we may be ready to furnish, or demand, the positions and magnitudes of the brighter stars in zones $+24°$ to $+32°$ to the number of something like a quarter of a million. The speed at which these measures can be made, can be gathered from the statement that "whereas at first thirty or forty star-measures an hour was thought fair work, the more skilful can now measure 150 per hour or more." The new photographic transit circle has involved much experimental work, and is proceeding satisfactorily.

THE SUPPOSED VARIABLE Y AQUILÆ.—In the series of measures to determine the light curves of variable stars of short period north of $-40°$ Declination with the meridian photometer, the curve of the star $+10°$ 3787 was not found to be smooth. This star had previously been catalogued by Chandler as varying from 5·3 to 5·7 in a period of 4·986 days. It was also suspected by Gould, confirmed by Chandler 1894, and also by Yendell. Mr. Wendell has recently made some observations (*Harvard College Observatory Circular*, No. 30) with the photometer attached to the 15-inch equatorial telescope, on six nights in May last, eighty sittings being made each night, the comparison star employed being $+10°$ 3784. The mean of the differences of magnitude showed very little variation, and, as Prof. Pickering states, fails to show any evidence of variation, since deviations of a tenth of a magnitude may be ascribed to errors of observation. Since it is "impossible to prove that the light of a star never changes, this star may still be an Algol variable with a short time of variation, or the period may be entirely wrong."

COMPANIONS OF ARGON.[1]

FOR many months past we have been engaged in preparing a large quantity of argon from atmospheric air by absorbing the oxygen with red-hot copper, and the nitrogen with magnesium. The amount we have at our disposal is some 18 litres. It will be remembered that one of us, in conjunction with Dr. Norman Collie, attempted to separate argon into light and heavy portions by means of diffusion, and, although there was a slight difference[2] in density between the light and the heavy portions, yet we thought the difference too slight to warrant the conclusion that argon is a composite substance. But our experience with helium taught us that it is a matter of the greatest difficulty to separate a very small portion of a heavy gas from a large admixture of a light gas; and it therefore appeared advisable to re-investigate argon, with the view of ascertaining whether it is indeed complex.

In the meantime, Dr. Hampson had placed at our disposal his resources for preparing large quantities of liquid air, and it was a simple matter to liquefy the argon which we had obtained by causing the liquid air to boil under reduced pressure. By means of a two-way stopcock the argon was allowed to enter a small bulb, cooled by liquid air, after passing through purifying reagents. The two-way stopcock was connected with mercury gas-holders, as well as with a Töpler pump, by means of which any part of the apparatus could be thoroughly exhausted. The argon separated as a liquid, but at the same time a considerable quantity of solid was observed to separate, partially round the sides of the tube, and partially below the surface of the liquid. After about 13 or 14 litres of the argon had been condensed, the stopcock was closed, and the temperature was kept low for some minutes in order to establish a condition of equilibrium between the liquid and vapour. In the meantime the connecting tubes were exhausted, and two fractions of gas were taken off by lowering the mercury reservoirs, each fraction consisting of about 50 or 60 cubic cm. These fractions should contain the light gas. In a previous experiment of the same kind a small fraction of the light gas had been separated, and was found to have the density 17·2. The pressure of the air was now allowed to rise, and the argon distilled away into a separate gas-holder. The white solid which had condensed in the upper portion of the bulb did not appear to evaporate quickly, and that portion which had separated in the liquid did not perceptibly diminish in amount. Towards the end, when almost all the air had boiled away, the last portions of the liquid evaporated slowly, and when the remaining liquid was only sufficient to cover the solid, the bulb was placed in connection with the Töpler pump, and the exhaustion continued until the liquid had entirely disappeared. Only the solid now remained, and the pressure of the gas in the apparatus was only a few millimetres. The bulb was now placed in connection with mercury gas-holders, and the reservoirs were lowered. The solid volatilised very slowly, and was collected in two fractions, each of about 70 or 80 cubic cm. Before the second fraction had been taken off, the air had entirely volatilised, and the jacketing tube had been removed. After about a minute, on removing the coating of snow with the finger, the solid was seen to melt, and volatilise into the gas-holder.

The first fraction of gas was mixed with oxygen, and sparked over soda. After removal of the oxygen with phosphorus it was introduced into a vacuum tube, and the spectrum examined. It was characterised by a number of bright red lines, among which one was particularly brilliant, and a brilliant yellow line, while the green and the blue lines were numerous, but comparatively inconspicuous. The wave-length of the yellow line, measured by Mr. Baly, was 5849·6, with a second-order grating spectrum. It is, therefore, not identical with those of sodium, helium, or krypton, all of which equal it in intensity. The wave-lengths of these lines are as follows:—

Na (D_1)	5895·0
Na (D_2)	5889·0
He (D_3)	5875·9
Kr (D_4)	5866·5
Ne (D_5)	5849·6

The density of this gas, which we propose to name "neon" (new), was next determined. A bulb of 32·35 cubic cm. capacity was filled with this sample of neon at 612·4 mm. pressure, and at a temperature of 19·92° it weighed 0·03184 gram.

Density of neon ... ... 14·67

This number approaches to what we had hoped to obtain. In order to bring neon into its position in the periodic table, a density of 10 or 11 is required. Assuming the density of argon to be 20, and that of pure neon 10, the sample contains 53·3 per cent. of the new gas. If the density of neon be taken as 11, there is 59·2 per cent. present in the sample. The fact that the density has decreased from 17·2 to 14·7 shows that there is a considerable likelihood that the gas can be further purified by fractionation.[1]

[1] "On the Companions of Argon." By William Ramsay, F.R.S., and Morris W. Travers. Paper read at the Royal Society, June 16.

[2] Density of lighter portion, 19·93; of heavier portion, 20·01 (Roy. Soc. *Proc.*, vol. 60, p. 206).

[1] June 21.—After a preliminary fractionation, the density has been still further reduced to 13·7.

That this gas is a new one is sufficiently proved, not merely by the novelty of its spectrum and by its low density, but also by its behaviour in a vacuum-tube. Unlike helium, argon, and krypton, it is rapidly absorbed by the red-hot aluminium electrodes of a vacuum-tube, and the appearance of the tube changes, as pressure falls, from carmine red to a most brilliant orange, which is seen in no other gas.

We now come to the gas obtained by the volatilisation of the white solid which remained after the liquid argon had boiled away.

When introduced into a vacuum-tube it showed a very complex spectrum, totally differing from that of argon, while resembling it in general character. With low dispersion it appeared to be a banded spectrum, but with a grating, single bright lines appear, about equidistant through the spectrum, the intermediate space being filled with many dim, yet well-defined lines. Mr. Baly has measured the bright lines, with the following results. The nearest argon lines, as measured by Sir William Crookes, are placed in brackets:—

Reds very feeble, not measured.		
First green band, first bright line	5632·5	(5651 : 5619)
First green band, second bright line	5583·0	(5619 : 5567)
First green band, third bright line	5537·0	(5557 : 5320)
Second green band, first bright line	5163·0	(5165)
Second green band, second bright line ...	5126·5	(5165 : 5065) brilliant.
First blue band, first bright line	4733·5	(4879)
First blue band, second bright line	4711·5	(4701)
Second blue band, first bright line	4604·5	(4629 : 4594)
Third blue band (first order)	4314·0	(4333 : 4300)
Fourth blue band (second order)	4213·5	(4251 : 4201)
Fifth blue band (first order), about	3878	(3904 : 3835)

The red pair of argon lines was faintly visible in the spectrum.

The density of this gas was determined with the following results:—A globe of 32·35 c.c. capacity, filled at a pressure of 765·0 mm., and at the temperature 17·43°, weighed 0·05442 grams. The density is therefore 19·87. A second determination, made after sparking, gave no different result. This density does not sensibly differ from that of argon.

Thinking that the gas might possibly prove to be diatomic, we proceeded to determine the ratio of specific heats:—

Wave-length of sound in air	34·18
,, ,, gas	31·68
Ratio for air	1·408
,, gas	1·660

The gas is therefore monatomic.

Inasmuch as this gas differs very markedly from argon in its spectrum, and in its behaviour at low temperatures, it must be regarded as a distinct elementary substance, and we therefore propose for it the name "metargon." It would appear to hold the position towards argon that nickel does to cobalt, having approximately the same atomic weight, yet different properties.

It must have been observed that krypton does not appear during the investigation of the higher-boiling fraction of argon. This is probably due to two causes. In the first place, in order to prepare it, the manipulation of air, amounting to no less than 60,000 times the volume of the impure sample which we obtained was required; and in the second place, while metargon is a solid at the temperature of boiling air, krypton is probably a liquid, and therefore more easily volatilised at that temperature. It may also be noted that the air from which krypton has been obtained had been filtered, and so freed from metargon. A full account of the spectra of those gases will be published in due course by Mr. E. C. C. Baly.

University College, London.

ON THE STABILITY OF THE SOLAR SYSTEM.[1]

ALL persons who interest themselves in the progress of celestial mechanics, but can only follow it in a general way, must feel surprised at the number of times demonstrations of the stability of the solar system have been made.

Lagrange was the first to establish it, Poisson then gave a new proof; afterwards other demonstrations came, and others will still come. Were the old demonstrations insufficient, or are the new ones unnecessary?

The astonishment of these persons would doubtless be increased if they were told that perhaps some day a mathematician would show by rigorous reasoning that the planetary system is unstable. This may happen, however; there would be nothing contradictory in it, and the old demonstrations would still retain their value.

The demonstrations are really but successive approximations; they do not pretend to strictly confine the elements of the orbits within narrow limits that they may never exceed, but they at least teach us that certain causes, which seemed at first to compel some of these elements to vary fairly rapidly, only produce in reality much slower variations.

The attraction of Jupiter, at an equal distance, is a thousand times smaller than that of the sun; the disturbing force is therefore small; nevertheless, if it always acted in the same direction, it would not fail to produce appreciable effects. But the direction is not constant, and this is the point that Lagrange established. After a small number of years two planets, which act on each other, have occupied all possible positions in their orbits; in these diverse positions their mutual action is directed sometimes one way, sometimes in the opposite way, and that in such a fashion that after a short time there is almost exact compensation. The major axes of the orbits are not absolutely invariable, but their variations are reduced to oscillations of small amplitude about a mean value.

This mean value, it is true, is not rigorously fixed, but the changes which it undergoes are extremely slow, as if the force which produces them was not a thousand times, but a million times smaller than the solar attraction. One may, therefore, neglect these changes, which are of the order of the square of the masses. As to the other elements of the orbits, such as the eccentricities and the inclinations, these may acquire round their mean value wider and slower oscillations, to which, however, limits may easily be assigned.

This is what Lagrange and Laplace pointed out, but Poisson went further. He wished to study the slow changes experienced by the mean values—changes to which I have already referred, and which his predecessors had at first neglected. He showed that these changes reduced themselves again to periodic oscillations round a mean value which is only liable to variations a thousand times slower.

This was a step further, but it was still only an approximation. Since then further advance has been made, but without arriving at a complete definitive and rigorous demonstration. There is a case which seemed to escape the analysis of Lagrange and Poisson. If the two mean movements are commensurable among themselves, at the end of a certain number of revolutions, the two planets and the sun will be found in the same relative situation, and the disturbing force will act in the same direction as at first. The compensation, to which I have referred, will not any more be produced, and it might be feared that the effects of the disturbing forces will end by accumulating and becoming very considerable. More recent works, amongst others those of Delaunay, Tisserand, and Gyldén, have shown that this accumulation does not actually occur. The amplitude of the oscillations is slightly increased, but remains, nevertheless, very small. This particular case, therefore, does not escape the general rule.

The apparent exceptions have not only been dispensed with, but the real reasons of these compensations, which the founders of celestial mechanics had observed, have been better explained. The approximation has been pushed further than was done by Poisson, but it is still only an approximation.

It can be shown, in certain particular cases, that the elements of the orbit of one planet will return an infinite number of times to very nearly the initial elements, and that is also probably true in the general case; but it does not suffice. It should be shown

[1] Translation of a paper, by M. H. Poincaré, in the *Annuaire du Bureau des Longitudes*, 1898.

that these elements will not only regain their original values, but that they will never deviate much from them.

This last demonstration has never been given in a definite manner, and it is even probable that the proposition is not strictly true. The statement that is true, is that the elements can only deviate extremely slowly from their original values, and this after a long interval of time. To go further, and affirm that these elements will remain not for *a very long time*, but *always* confined within narrow limits, is what we cannot do.

But the problem does not take this form.

The mathematician only considers fictitious bodies, reduced to simple material points, and subject to the exclusive action of their mutual attractions, which rigorously follows Newton's law. How would such a system behave, would it be stable? This is a problem which is as difficult as it is interesting for an analyst. But it is not one which actually occurs in nature. Real bodies are not material points, and they are subject to other forces than the Newtonian attraction. These complementary forces ought to have the effect of gradually modifying the orbits, even when the fictitious bodies, considered by the mathematician, possess absolute stability.

What we must ask ourselves then is, whether this stability will be more easily destroyed by the simple action of Newtonian attraction or by these complementary forces.

When the approximation shall be pushed so far that we are certain that the very slow variations, which the Newtonian attraction imposes on the orbits of the fictitious bodies, can only be very small during the time that suffices for the complementary forces to destroy the system; when, I say, the approximation shall be pushed as far as that, it will be useless to go further, at least from the point of view of application, and we must consider ourselves satisfied.

But it seems that this point is attained; without quoting figures, I think that the effects of these complementary forces are much greater than those of the terms neglected by the analysts in the most recent demonstrations on stability.

Let us see which are the most important of these complementary forces. The first idea which comes to mind is that Newton's law is, doubtless, not absolutely correct; that the attraction is not rigorously proportional to the inverse square of the distances, but to some other function of them. In this way Prof. Newcomb has recently tried to explain the movement of the perihelion of Mercury. But it is soon seen that this would not influence the stability. It is true, according to a theory of Jacobi, that there would be instability if the attraction were inversely proportionate to the cube of the distance. It is easy by rough reasoning to account for this; with such a law, the attraction would be great for the small distances and extremely feeble for great distances. If therefore, for any reason, the distance of one of the planets from the central body were to increase, the attraction would diminish rapidly until it would not be capable of retaining the planet in its orbit. But that only takes place with laws very different from that of the square of the distances. All laws, near enough to that of Newton's to be acceptable, are equivalent from the stability point of view.

But there is another reason which opposes the theory that bodies move without ever deviating much from their original orbits. According to the second law of thermodynamics, known by the name of Carnot's Principle, there is a continual dissipation of energy, which tends to lose the form of mechanical work and to take the form of heat. There exists a certain function called entropy, which it is unnecessary to define here; entropy, according to this second law, either remains constant or diminishes, but can never increase. When once it has deviated from its original value, which it can only do by diminishing, it can never return again. as it would have to increase. The world consequently could never return to its original state, or to a slightly different state, so soon as its entropy has changed. It is the contrary of stability.

But the entropy diminishes every time that an irreversible phenomenon takes place, such as the friction of two solids, the movement of a viscous liquid, the exchange of heat between two bodies of different temperatures, the heating of a conductor by the passage of a current. If we observe, then, that there is not in reality a reversible phenomenon, that the reversibility is only a limiting case—an ideal case which nature can more or less approach but can never attain—we shall be led to conclude that instability is the law of all natural phenomena.

Are the movements of the heavenly bodies the only ones to escape? One might believe it by seeing that they move in a vacuum, and are thus free from friction. But is the interplanetary vacuum absolute, or do the bodies move in an extremely attenuated medium of which the resistance is extremely feeble, but nevertheless is capable of offering resistance?

Astronomers have only been able to explain the movement of Encke's comet by supposing the existence of such a medium. But the resisting medium which would account for the anomalies of this comet, if it exists, is confined to the immediate neighbourhood of the sun. This comet would penetrate it; but at the distances at which the planets are, the action of this medium would cease to make itself felt, or would become much more feeble. As an indirect effect, it would accelerate the movements of the planets; losing energy, they would tend to *fall* on the sun, and by reason of Kepler's third law the duration of the revolution would diminish at the same time as the distance to the central body. But it is impossible to form an idea of the rapidity with which this effect would be produced, as we have no notion of the density of this hypothetical medium.

Another cause to which I am now going to refer must have, it seems, a more rapid action. It had for some time been imagined, but was first more especially brought to light by Delaunay, and afterwards by G. Darwin.

The tides, which are direct consequences of celestial movements, could only stop if these movements ceased. But the oscillations of the seas are accompanied by friction, and consequently produce heat. This heat can only be borrowed from the energy which produces the tides—that is to say, to the *vis viva* of the celestial bodies. We can therefore foresee that, for this reason, this *vis viva* is gradually dissipated, and a little reflection will enable us to understand by what mechanism. The surface of the seas, raised by the tides, presents a kind of wave. If high tide took place at the time of the meridian passage of the moon, this surface would be that of an ellipsoid, the axis of which would pass through the moon. Everything would be symmetrical in relation to this axis, and the attraction of the moon on this wave could neither slow down nor accelerate the terrestrial rotation. This is what would happen if there were no friction; but in consequence of this friction, high tide is late on the moon's meridian passage; symmetry ceases; the attraction of the moon on the wave no longer passes through the centre of the earth, and tends to slow down the rotation of our globe.

Delaunay estimated that, for this cause, the length of the sidereal day increases by one second in a hundred thousand years. It is thus he wished to account for the secular acceleration of the moon's motion. The lunation would seem to us to become shorter and shorter, because the unit of time to which we ascribed it, the day, would become longer and longer.

Whatever we may think of the figures given by Delaunay, and the explanation which he proposes for the anomalies of the moon's movement, it is difficult to dispute the effect produced by the tides.

It is just this that may help us to understand a well-known but very surprising fact. It is known that the period of rotation of the moon is exactly equal to that of its revolution; in such a way that, if there were seas on this body, they would have no tides—at least, tides due to the attraction of the earth; because for an observer situated at a point on the surface of the moon, the earth would be always at the same height above the horizon. It is also known that Laplace tried to explain this curious coincidence. How can the two velocities be *exactly* the same? It is exceedingly improbable that this strict equality is due to mere chance. Laplace supposes that the moon has the form of an elongated ellipsoid; this ellipsoid behaves like a pendulum, which would be in equilibrium when the major axis is directed along the line joining the centres of the two bodies.

If the *initial* velocity of rotation differs slightly from that of revolution, the ellipsoid will oscillate about its position of equilibrium without ever deviating much from it. A pendulum which has received a slight impetus behaves in this way. The *mean* velocity of rotation is then exactly the same as that of the position of equilibrium round which the major axis oscillates; it is, therefore, the same as that of the straight line which joins the centres of the two bodies. It is therefore strictly equal to the velocity of revolution.

If, on the contrary, the initial velocity differs considerably from the velocity of revolution, the major axis will not oscillate any more round its position of equilibrium, like a pendulum which under a strong impulse describes a complete circle.

It suffices, therefore, that the velocity of revolution should be *almost* equal to the *initial* velocity of rotation, in order that it may be exactly equal to the *mean* velocity of rotation. A strict equality being no longer necessary, the paradox does not exist any more. The explanation is nevertheless incomplete. What is the reason of this approximate equality, of which the probability is no longer zero, it is true, but still very small? And, especially, why does not the moon undergo slight oscillations about its position of equilibrium (if we eliminate, of course, its numerous librations, due to other well-known causes)? These oscillations must originally have existed; they must have become extinct by a kind of friction, and everything tends to make us believe that the mechanism of this friction is that which I have just analysed with respect to the ocean tides.

When the moon was not yet solid, and formed a fluid in the form of a spheroid, this spheroid must have experienced enormous tides, by reason of the proximity of the earth and of its mass. These tides could only have ceased when the oscillations became almost entirely extinct.

It seems that Jupiter's satellites, and the two planets nearest the sun, Mercury and Venus, have also a rotation, the duration of which is the same as that of their revolution; it is doubtless for the same reason.

It might be thought that this tidal action has no connection with our subject. I have as yet only spoken of rotations, and in the studies relative to the stability of the solar system the movements of translation are only dealt with; but a little attention shows that the same action makes itself equally felt on the latter.

We have just seen that the attraction of the moon on the earth does not act exactly through the centre of the earth. The attraction of the earth on the moon, which is equal and exactly opposite, would not pass either through this centre; that is to say, through the focus of the lunar orbit. A disturbing force is the result, very small in reality, but sufficient to make the moon increase in energy. The active force of translation thus gained by the moon is evidently smaller than that of rotation, lost by the earth; because a part of the energy must be transformed into heat in consequence of the friction engendered by the tides. The period of revolution of the moon lasting about twenty-eight sidereal days, a very simple calculation shows that this body gains twenty-eight times less *vis viva* than the earth loses.

I have already explained the action of a resisting medium; I have shown how, by making the planets lose energy, their movements are accelerated; on the contrary the action of the tides, by increasing the energy of the moon, retards its movements; the month lengthens therefore as well as the day. Now if this cause acts alone, what is the final state towards which the system will tend? Obviously this action would only stop when the tides have ceased—that is to say, when the rotation of the earth would have the same duration.

This is not all: in the final state the orbit of the moon must have become circular. If it were otherwise, the variations of the distance of the moon to the earth would suffice to produce tides. As the movement of rotation would not have changed, it would be easy to calculate what angular velocity would be common to the earth and to the moon. One finds that, at the limit, the month, like the day, would last about sixty-five of our actual days.

Such would be the final state if there were no resisting medium, and if the earth and the moon existed alone.

But the sun also produces tides, the attraction of the planets likewise produces them on the sun. The solar system therefore would tend to a condition in which the sun, all the planets and their satellites, would move with the same velocity round the same axis, as if they were parts of one solid invariable body. The final angular velocity would, on the other hand, differ little from the velocity of revolution of Jupiter. This would be the final state of the solar system if there were not a resisting medium; but the action of this medium, if it exists, would not allow such a condition to be assumed, and would end by precipitating all the planets into the sun.

It must not be thought that a solid globe which was not covered by seas would, by the absence of tides, find itself free from actions analogous to those just mentioned, even by admitting that the solidification had reached the centre of the globe. This body, which we suppose solid, would not on that account be an invariable one; such bodies only exist in text-books on rational "mechanics." It would be elastic and be subject, by the attraction of neighbouring celestial bodies, to deformations analogous to tides and of the same order of magnitude.

If the elasticity were perfect, these deformations would occur without loss of work, and without the production of heat. But perfectly elastic bodies do not exist. There would be in consequence development of heat, which would take place at the expense of the energy of rotation and translation of the bodies, and which will produce absolutely the same effects as the heat engendered by the friction of the tides.

This is not all: the earth is magnetic, and very probably the other planets and the sun are the same. The following well-known experiment is one which we owe to Foucault: a copper disc rotating in the presence of an electromagnet suffers a great resistance, and becomes heated when the electromagnet is brought into action. A moving conductor in a magnetic field is traversed by induction currents which heat it; the produced heat can only be derived from the *vis viva* of the conductor. We can therefore foresee that the electrodynamic actions of the electromagnet on the currents of induction must oppose the movement of the conductor. In this way Foucault's experiment is explained. The celestial bodies must undergo an analogous resistance because they are magnetic and conductors.

The same phenomenon, though much weakened by the distance, will therefore be produced; but the effects, being produced always in the same direction, will end by accumulating; they add themselves, besides, to those of the tides, and tend to bring the system to the same final state.

Thus the celestial bodies do not escape Carnot's law, according to which the world tends to a state of final repose. They would not escape it, even if they were separated by an absolute vacuum. Their energy is dissipated; and although this dissipation only takes place extremely slowly, it is sufficiently rapid that one need not consider terms neglected in the actual demonstrations of the stability of the solar system.

ON THE USE OF METHYLENE BLUE AS A MEANS OF INVESTIGATING RESPIRATION IN PLANTS.

IT has long been known that methylene blue is capable of being decolorised by reducing agents, and the object of the present communication is to point out its use as a means of demonstrating in a striking manner the reducing power possessed either by living protoplasm or at any rate by substances intimately associated with the exercise of its vitality. Its employment is not new to animal physiologists, but botanists appear not to have recognised the possibilities latent in the method, perhaps because some ten years ago Pfeffer ("Oxydationsvorgänge in Lebenden zellen") stated that although fermenting yeast would decolorise the blue solution, green plants would not do so. Doubtless this was true under the conditions of Pfeffer's experiments, but nevertheless many green plants are, as a matter of fact, found to give admirable results.

If germinating seedlings of barley or peas be placed in test tubes filled with a 0·0005 per cent. solution of methylene blue, which has been boiled in order to expel air, it will be found that in the course of a few hours the liquid around them will have lost its colour. The most striking way of performing the experiment is to suspend the peas in the solution, then a decolorised zone is formed between the upper and lower parts of the liquid, each of which still retain its blue colour. Gradually the clear zone extends until the entire mass of the liquid, except just at the surface where it is in contact with the air, becomes decolorised. At first the radicles of the seedlings are strongly stained; they finally again become white.

If some of the decolorised liquid be drawn off by means of a pipette, and shaken up with air, the blue tint speedily returns. If some of the seedlings be removed from the now colourless liquid, and be rinsed in boiled water and then exposed to the air, they soon become blue, and the stain gradually extends into the internal tissues as these become gradually aerated. The "development" of the blue can readily be seen in sections, quickly made, under the microscope.

Cress seedlings are far more active than either barley or peas, just as would have been expected from the relations which they exhibit towards oxygen.

But perhaps the most remarkable results are those obtained from a plant like *Chara*. This alga is suspected to possess peculiar properties in regard to its connection with oxygen (*Annals of Botany*, vol. x. p. 288), and I have since ascertained in several ways that the plant is nearly as greedy for oxygen as are many seedlings. A branch of *Chara* placed in the methylene blue and *put in the dark*, will decolorise the surrounding liquid in a few hours; but if the tube containing it be exposed to the action of bright daylight the colour soon returns when the plant is alive, owing to the evolution of oxygen consequent on its splitting up the carbon dioxide which has been evolved by it, and which has been accumulating in the water, during the plant's stay in darkness. (Of course it is hardly necessary to state that the carbon dioxide is not itself the cause of the loss of colour in the liquid.) The experiment can be repeated several times with the same *Chara* plant, and we have succeeded in keeping it alive (as proved by the continuance of the protoplasmic movement) for four days. Naturally if the experiment is performed in continuous daylight no decoloration is effected.

Many other plants fail to give such quick results; thus *Elodea* requires about two days in darkness to obtain the reaction. All the plants experimented on give a result much more quickly if they have previously been starved of oxygen. And this indicates that under these conditions, as also under those of the experiments above described, the oxygen is not directly utilised either by the protoplasm, or some of the normal combustible bodies present in the cell, but by some dissociation product formed during the metabolic activity of the protoplasm. Of course decoloration of the blue does not occur when the plants are exposed to the action of free oxygen; this element can then be obtained more cheaply than by reducing the aniline dye. But this is not the place in which to discuss the meaning of the reaction or the nature of the substance which primarily reduces the methylene blue. The facts have been arrived at during an investigation, which is still proceeding, into the respiratory processes of plants. The method here detailed is, however, so simple, and seems likely to prove useful to teachers and others as a demonstration-experiment, that it appeared worth while to make it generally known. J. B. FARMER.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—In connection with the extracts printed last week (p. 165) from the reports of the delegates of the University Museum, referring to the want of accommodation and equipment for research in certain branches of science, it may be worth while directing attention to the leading article in *Literature* of June 11, regretting that little original work is being done in the domain of letters. The opinion is expressed that the Royal Commission which sat on the Universities rather more than twenty years ago, "made Oxford and Cambridge much more effective places for teaching and examining than they had been before, while at the same time it helped to ruin them as places for study." The leader concludes with the words:—"Englishmen are by nature somewhat too much inclined to look for an immediate advantage; to bring all things to a common-sense, even a commercial, test; to distrust theory; to despise action for an abstract end. One of the functions of a University is to keep alive a higher faith by giving an example of thorough and devoted work done without a commercial object. Our Universities, as they are at present managed, do no such thing."

The research degree of Bachelor of Science was conferred upon Mr. A. E. Tutton in Congregation on June 16. Mr. Tutton is the first recipient of a degree for research in natural science or natural philosophy, the only other research degree yet conferred being for mathematical work. In order to qualify for the degree eight terms must be kept, and one or more original theses presented. Mr. Tutton presented two theses—one his paper on the crystallography of the selenates of potassium, rubidium and cæsium, and the other on the new interference dilatometer exhibited by him at the recent conversazioni of the Royal Society. The B.Sc. research degree ranks with the B.C.L. immediately after the M.A. degree, and before the B.A. degree. It is hoped that, by requiring a high standard of qualification for the new degree, research will be encouraged, and the scientific work of the University will be increased in value and amount.

CAMBRIDGE.—Among the ten recipients of honorary degrees on June 15 were the Italian Ambassador (General Ferrero) and Mr. F. C. Penrose. General Ferrero early distinguished himself in mathematics, and, after an active military career, he became connected with the military and geographical Institute of Florence, editing all its publications from 1873 to 1893, and being at its head from 1885 to 1894. He organised the general topographical and cadastral survey of Italy, which led to the publication of important maps of the country, in the preparation of which valuable aid was derived from photography. In 1883 General Ferrero was made a Member of the Accademia dei Lincei, and in 1892 a Senator of Italy. Since 1874 he has taken an important part in the International Commission for the measurement of the earth's surface, and in this respect (amongst others) he has a European reputation.

Mr. Penrose has not only made valuable contributions to archæology, but also to astronomy, and his papers on the orientation of Greek temples exhibit the rare combination of archæological and astronomical knowledge.

The following are the speeches delivered by the Public Orator, Dr. Sandys, in presenting General Ferrero and Mr. Penrose for the honorary degree of LL.D. and Litt.D. respectively:—

Olim in hoc ipso loco Italiae legatum belli et pacis artibus illustrem salutavimus; hodie eiusdem adiutorem atque adeo successorem insignem non minus libenter salutamus. In Academia Taurinensi scientia mathematica excultus, et rei militaris et geographiae studiis deditus, Italiae toti accurate dimetiendae et describendae summa cum laude est praepositus. Huic imprimis debemus regionum Italiae tabulas depictas, partim lucis ipsius auxilio in lucem emissas; hunc non modo Linceorum Academia Romana sociis suis, sed etiam Italia tota senatoribus suis merito adscripsit; huius fama ultra patriae fines a se ipso tam diligenter descriptos etiam in alias Europae partes latissime diffusa est. Asiae regiones pulcherrimae (Vergilio si credimus) Italiae cum laudibus certare nequeunt; Europae gentes maximae Italiae legatum insignem certatim laudant. Belli certe et pacis artes feliciter consociatae sunt Italiae in legato illustri, ANNIBALE FERRERO.

Hodie reducem salutamus alumnum nostrum qui abhinc annos fere septem et quinquaginta Thamesis inter undas e certamine nautico cum Oxoniensibus commisso semel tantum victus, plus quam semel victor evasit. Olim Academiae nomine in Italiam et Graeciam missus, de Atheniensium templis opus egregium edidit, in quo Parthenonis et columnas et epistylium columnis impositum lineis non rectis sed leviter curvatis contineri primus omnium ostendit, et ordinis Dorici maiestatem artificio tam minuto adiuvari demonstravit. Idem nuper de templis Graecis ad stellas quasdam orientes conversis ingeniose disputavit. Illud vero felicitatis conspicuae documentum Nestori nostro contigit, quod et Athenis et Londinii architecturae studiis diu deditus, non modo Sancti Pauli ecclesiae cathedralis in culmine sed etiam Iovis Olympii columnarum in fastigio solus omnium mortalium constitit. Viro ad tantam altitudinem evecto non sine reverentia quadam in hoc templo honoris lauream nostram laeti decernimus.

Duco ad vos Collegii Magdalenae socium, Britannorum Scholae Archaeologicae Atheniensi et Regio Architectorum Instituto nuper praepositum, FRANCISCUM CRANMER PENROSE.

THE vote of 8,520,175*l.*, for public elementary education in England and Wales, was passed by the Committee of Supply of the House of Commons on Friday. To this sum of money, contributed towards elementary education by the Imperial Government, must be added the sums derived from voluntary subscriptions and the rates. Last year the former amounted to 845,000*l.*, and the latter to 2,325,801*l.* There is no reason to believe that in the coming year these sums will substantially decrease; therefore it may be assumed that in the coming financial year a total sum of no less than 11,690,762*l.* will be spent by England and Wales upon elementary education.

THE annual Commencement at Columbia University on June 8 was noteworthy as the first to be held in the new and permanent home of the University on Morningside Heights. The number of degrees conferred was greater than on any previous occasion, amounting to 485 in cause, and four honorary. An unusual feature was the presentation of the Loubat prizes for the best works on the history, geography, archæology, ethnology or numismatics of North America. These prizes, amounting to 1000 dollars for the first and 400 dollars for the second, are to be awarded every five years, beginning with the present year; and are not to be less than the amounts named, but may hereafter exceed those amounts. The first prize was awarded to William Henry Holmes, for his book on "Stone Implements of the Potomac-Chesapeake Tide-water Provinces." The second prize was awarded to Dr. Franz Boas, for his work on "The Social Organisation and Secret Societies of the Kwakiutl Indians." Honourable mention was made of work by Dr. Carl Lumholtz, Mr. Frank H. Cushing, and Mr. Walter Hoffman, of America; and Mr. Alfred P. Maudslay, of London.

SCIENTIFIC SERIALS.

American Journal of Science, June.—A theory to explain the stratification of the electric discharge in Geissler tubes, by H. V. Gill, S.J. The phenomenon of stratification is a form of Kundt's experiment in which the heaps of powder which accumulate at the nodes are replaced by the strata of molecules between which the discharge is taking place in a luminous form.—Orthoclase as a gangue mineral in a fissure vein, by Waldemar Lindgren. During the examination of Silver City mining district, in southern Idaho, a vein was encountered containing a gangue of unusual character, consisting of quartz and orthoclase, the latter sometimes preponderating. It occurs as large, irregular milk-white grains, intergrown with vein quartz. This occurrence, together with various other forms, demonstrates the aqueous origin of the mineral. The analysis indicates typical adularia. The artificial production of orthoclase in the wet way, by heating powdered muscovite with a solution of potassium silicate, has a direct bearing upon its natural occurrence. The reason why orthoclase is not more frequently found on mineral veins lies possibly in the abundant presence of carbon dioxide in thermal waters, which would rapidly attack orthoclase and form more stable compounds, such as muscovite or sericite.—Notes on rocks and minerals from California, by H. W. Turner. The rocks discussed include a peculiar quartz-amphibolite-diorite, a new amphibole-pyroxene rock, a quartz-alunite rock, gold ores containing tellurium, selenium, and nickel, and gravels containing zircons.—A psychrometer applicable to the study of transpiration, by Robert G. Leavitt. The psychrometer consists of four nickel-plated tubes which can be kept at various temperatures by a mixture of hot and cold water. The dew point is indicated immediately by noting which of the tubes bears a deposit, and by varying the temperatures within narrow limits it may be found within 0·1° C. The apparatus was employed to determine the effect of light on the transpiration of plants, and a decided fall of the dew point was noticed as accompanying a diminution of light.—Comments on *Bulletin* No. 21, "Solar and terrestrial magnetism in their relations to meteorology," by F. H. Bigelow. The *Bulletin* attempts to overthrow two positions held in terrestrial magnetism: (1) that the sun is not a magnetic body because it is too hot, and (2) that the variations of the terrestrial magnetic field can be accounted for by electric currents in the cirrus cloud region. The earth is immersed in an external magnetic field of such a direction and strength as to make the inference necessary that its seat is in the sun. Else it will be necessary to assert that the earth's changes are sufficiently strong to disturb the sun's state, which is absurd.

Bulletin of the American Mathematical Society, May.—Concise abstracts are given of nine papers read at the third regular meeting of the Chicago Section of the Society, held on April 9. At the afternoon meeting Prof. Michelson exhibited the workings of his new harmonic analyser, a description of which was published in the *Philosophical Magazine* for January 1898.—Prof. M. Bôcher finishes his paper on the theorems of oscillation of Sturm and Klein. In the present portion Prof. Bôcher proves two simple theorems of Sturm's, and uses these to throw Sturm's theorem of oscillation into a slightly generalised form; he then proves Klein's theorem in a very general form. He proposes, in a subsequent paper, to come back to some more general cases which do not seem to present any serious difficulty.—The construction of special regular reticulations on a closed surface, by Prof. H. S. White, was read, in part, at the January 1897 meeting of the Society, and in final form at the recent April (30) meeting. The reticulations here discussed are called regular for two reasons: the number of termini of edges (r) assembled in one vertex is the same for all vertices (V) of the reticulation, and the number of edges (s) in the boundary of a face (F) is the same for all faces. The writer remarks that the regularity of these reticulations is not the same as that defined by Dyck and Klein in function-theoretic investigations; the two definitions overlap, but neither includes the other. The points discussed are (1) the mutual derivations of two dual reticulations from each other (dual when r, s, V, F of the first are equal respectively to s', r', F', V' of the second, and when each face of the one corresponds to a vertex of the other in such a way that the succession of vertices about each face corresponds exactly to the succession of faces about the corresponding vertex). (2) Two processes for multiplying the number of vertices or faces; and (3) the dissection of a Riemann surface into a fundamental polygon.—Dr. L. E. Dickson, in systems of simple groups derived from the orthogonal group, continues previous work (*Bulletin*, February number).—A proof of the theorem $\frac{d^2u}{dxdy} = \frac{d^2u}{dydx}$ follows, by Mr. J. K. Whittemore (read at the April meeting). This is short and neat.—Miss Frances Hardcastle contributes an interesting article entitled, "Some observations on the modern theory of point groups," in which she indicates some of the converging lines of the German and Italian work. In her first section she discusses some of the technical terms, and in the second section she starts from the Riemann-Roch equations by the suggestion of certain lines of inquiry which may prove useful in the classification of algebraic curves. A useful bibliography is appended.—A note on contact transformations is intended, by Prof. E. O. Lovett, to correct some misapprehensions that a reader of a note in the *Zeitschrift für Mathematik und Physik* (vol. xxxvii., 1892) to a paper by Dr. Mehmke may carry away.—Dr. Staude's "die Focaleigenschaften der Flächung zweiter ordnung" is reviewed; and Mr. J. E. Campbell, in a note, admits the validity of an objection brought by Prof. E. O. Lovett (in the November 1897 *Bulletin*) against a statement in his paper (*Proc. L.M.S.*, vol. xxviii.—incorrectly xxiii. in the *Bulletin*—pp. 381–390), and expresses his meaning more clearly.—"Notes" and "publications" close the number.

Wiedemann's Annalen der Physik und Chemie, No. 5.—Susceptibility of water and aqueous solutions, by H. du Bois. Determinations of the molecular susceptibilities of the salts of some paramagnetic metals, such as the chlorides of Ce, Cu, Ni, Fe, and Mn, go to confirm the rule observed by Jäger and Meyer that the atomic susceptibilities of the metals Ni, Co, Fe, and Mn are in the ratios 2 : 4 : 5 : 6.—Magnetic after-effect, by C. Fromme. The "magnetic creeping" or after-effect diminishes when the reduction of the field to zero takes place rapidly. This may be explained by supposing that the molecular magnets are thereby thrown into a more violent commotion, and are better able to attain stable positions. A similar effect may be brought about by heat or mechanical stress.—Magnetisation of hollow and solid iron rings, by F. Kirstädter. To determine whether the outer parts of a rod or ring screened the inner portions against magnetisation, the author split a ring in two halves, and bored round holes so that on recombination a hollow ring was formed. By boring the holes larger and larger the surface of the ring was given various thicknesses. It was found that the inner layers acquired the same magnetisation as they would have done had they been exposed to the immediate action of the magnetising field.—The function of the condenser in an induction apparatus, by P. Dubois. There is a certain maximum spark length obtainable in any given induction coil circuit by means of a condenser. When the capacity of the condenser exceeds that maximum, the effect diminishes. For a resistance of some 200 ohms in the circuit, the maximum useful capacity for the condenser is 3 microfarads.—On the rays proceeding from thorium compounds and some other substances, by G. C. Schmidt. These rays differ from uranium rays in not being polarised by tourmaline, and from Röntgen rays in being refracted. But like uranium and Röntgen rays, they impart a temporary conductivity to air and other gases.—Potential gradients at electrodes discharged by X-rays, by C. D. Child. When the discharge passes between two plates with air between rendered conducting by means of X-rays, the gradient is steeper near the plates and less steep in the middle, as may be proved by a Kelvin water-dropping electrometer.—Proof of the existence of the thin Zenker's plates in colour photographs taken by Lippmann's method, by R. Neuhauss. The layers of metallic silver to which, according to Zenker's theory, the colour effects in Lippmann's photographs are due, have been actually seen and photographed by the author under a microscope magnifying 4000 times in a cross section of a film taken by a very good microtome and operator. The distance between the lamellæ for red light is, as postulated, equal to the wave-length of the light.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 26.—"Contributions to the study of 'Flicker.'" By T. C. Porter (Eton College). Communicated by Lord Rayleigh, F.R.S.

The first part of the paper describes experiments made to ascertain the exact relative rotations at which the flicker of a disc, half black, half coloured, vanishes in the different colours of the spectra of sun- and lime light, formed by a diffraction grating of 14,434 lines to the inch. The main precautions which must be taken are briefly stated, with a short discussion of the results, which may be summed up as follows.

The rate of rotation of the disc that the flicker may just vanish is highest for the yellow, decreasing for the succession of colours on either side of this one, being the same for the deepest visible crimson and full green; from the full green to the violet end of the spectrum the rate continues to fall off, till in the last visible rays it is very nearly one-half its maximum for the yellow.

When the intensity of the different spectra is varied, the greater the intensity the more rapid is the rate of rotation necessary for flicker just to vanish; thus, as the stimulus applied to the retina increases in intensity, the impression produced retains its maximum value for a shorter and shorter time. That a brighter illumination of the disc does produce a greater stimulus (*i.e.* that neither the contraction of the pupil, nor any other cause, overcomes the effect of brighter illumination) is proved by the fact that the brighter the light, the brighter on the whole is the disc, when flicker has just vanished. Research was made to discover in what way the rotation of a black and coloured disc must be varied for flicker to vanish, when the proportion of the coloured to the black sector varied by stages of 10° at a time, the experiments being carried out in each of the main colours of the lime-light spectrum.

Throughout this series of experiments the intensity of the illuminant was kept constant. The results are expressed in a series of rather remarkable curves, the rate of rotation rising rapidly with the instalments of 10° to the coloured sector, then remaining at its maximum, and constant within the errors of experiment, from a coloured sector of about 150° to one of about 240°, after which the rate of rotation falls off somewhat more rapidly than it rose when the coloured sector was small.

The remainder of the paper is devoted to the discussion of these curves, and it concludes by proving from a series of points, taken at random on one of them, that the duration of the impression on the retina undiminished is inversely proportional to the time during which the retina is stimulated. Some other conclusions of interest are arrived at; but for the reasoning and description of experiments necessary, we must refer to the paper itself: *e.g.* (1) When flicker has just vanished, the effective stimulus at any point of the retina is to the maximum stimulus the coloured sector can produce, as the angle of the yellow sector is to the angle of the whole disc (*i.e.* 360°), the illumination being supposed constant. (2) The coloured sector always requires a finite time in order to produce its maximum effect on the retina. (3) When the width of the white or coloured sector is increased in steps of 10° at a time, the increment in the apparent brightness in the rotating and flickerless disc follows, within the errors of experiment, the series of 1/0, 1/1, 1/2, 1/3, 1/4, &c., as it should. The paper is the first of a series on the subject.

"Aluminium as an Electrode in Cells for Direct and Alternate Currents." By Ernest Wilson. Communicated by Dr. J. Hopkinson, F.R.S.

This paper deals with the apparent great resistance which aluminium offers to the passage of an electric current when coated with a film and used as an anode in cells containing, for instance, such an electrolyte as alum in water.

Part i. deals with experiments made on aluminium-carbon cells with direct currents, the electrolytes used being alum solution, dilute sulphuric acid, and sodium hydrate in water.

After making a preliminary experiment in which an exploring electrode inserted between the plates was used to allocate the distribution of potential difference in the cell, the author describes a series of experiments made with a view to finding the effect of variation of current density and temperature upon the potential difference between the Al and C plates. Two cells were constructed and, during the forming process, which consisted of passing a current of ·005 ampere per square inch of the Al anode for forty-seven hours, one of them contained a dilute H_2SO_4, and the other a saturated potash alum solution. The apparent resistance was not nearly so marked in the H_2SO_4 solution cell as in the other.

The H_2SO_4 solution was then replaced by a saturated alum solution, and the two cells submitted to a further forming process for thirteen hours. The two cells were then experimented upon at approximately constant temperature, but the current density varied. The potential difference in the two cases rose from 1·89 to 34·5 volts as the current density varied from ·00006 to ·12 in the case of the H_2SO_4-formed plate, and from ·00011 to ·041 in the other. With about 39 volts directly applied to each the current rapidly increased in the two cells, accompanied by rapid increase of temperature from its final value of about 20° C.

The cell containing the alum-formed plate was next heated; the current density of the Al anode kept approximately constant at ·019 ampere per square inch, and the temperature raised from 13° to 70° C. The potential difference fell from 30 to 3 volts under these conditions.

The potential difference was not materially increased by cooling a cell in a freezing mixture of carbonic acid snow and ether.

One of these films was examined under a microscope and analysed by Mr. Herbert Jackson, of King's College, London, who states "that the skin over the plate is seen to be full of minute cracks, giving the impression of a dried gelatinous pellicle; not an unexpected appearance if the plate had been covered when wet with a thin coating of the gelatinous aluminium hydroxide. The analysis of the film over the metal shows it to consist of basic aluminium sulphate."

An experiment was made upon a film which was formed without the passage of current by first submerging a bright Al plate in alum solution, and then exposing it to the atmosphere. The author concludes that this film has the same effect as another formed during the passage of current.

Part ii. deals with alternate currents. Experimenting first with Al-C plates in potash alum solution, the frequency was varied from 16 to 98 periods per second, and the current density varied from ·0396 to ·583 ampere per square inch of the Al plate. The results show that small currents are accompanied by large phase difference; but the effect looked for, namely a large ratio between the maximum coulombs in the two halves of a period, has not time to properly develop at the frequencies tried.

The next set of experiments deals with a "rectifier" for alternate currents proposed by Graetz, in which Al-C cells are employed. It is shown that a uni-directional current can be produced by the Graetz arrangement, and the efficiency of such a system is discussed.

The concluding portion of these experiments deals with aluminium plates only for the purpose of forming the electrodes of a condenser for alternate currents. Soda, ammonia, and potash alums, both saturated and non-saturated, are employed as electrolytes. The frequency is varied from 7·5 to 100 periods per second, and the current density from ·0139 to ·6. The results show that phase differences of the order of 60° and 70° (360° = 1 period) can be obtained by a suitable choice of current density and temperature. Maximum phase difference develops with small currents at low temperature. With regard to frequency, both saturated and non-saturated solutions give a higher efficiency at the higher frequency. The conclusion is that the metal aluminium is suitable for use as the plates of condensers if due regard be given to current density and temperature.

Royal Microscopical Society, May 18.—Mr. E. M. Nelson, President, in the chair.—The President exhibited a simple form of student's microtome, suitable for cutting soft sections. It was made by Messrs. Reynolds and Branson, of Leeds, and was on the principle of the Williams microtome, but consisted only of a plate of glass and an adjustable casting carrying the razor. The chief point of interest was its low cost.—The President read three short papers which had been received from Mr. Jourdain. The first was on a new apochromatic objective constructed without the use of fluorite. This objective is made by the Bausch and Lomb Optical Company, who have promised to send examples to Mr. Jourdain for examination. The other papers by Mr. Jourdain were on a method of adjusting the sizes of coloured images yielded by the Cooke lens, and on the construction of the planar lens and its use in low power photomicrography.—The President read a note on the optics of photographic lenses.—A paper by Mr. F. W. Millett, which was a continuation of his "Report on the Foraminifera of the Malay Archipelago," being of a highly technical character, was taken as read.—There was a very interesting exhibition of microscopic aquatic life by members of the Quekett Microscopical Club and Fellows of the Society.

Anthropological Institute, May 24.—Mr. F. W. Rudler, President, in the chair. —Prof. E. B. Tylor, F.R.S., having exhibited lantern photographs of the great totem-post from Queen Charlotte's Island, sent over by Mr. Bertram Buxton, and now erected in the grounds of Fox Warren, near Weybridge, the residence of Mr. Charles Buxton, took this as the text for a critical examination of totemism in general, as regards both its real importance and the somewhat extreme ideas of its place in anthropology and theology, which have been gaining ground ever since J. F. McLennan brought it into notice in his "Primitive Marriage." This writer at first looked at it purely in its legal aspect, the group of clans named after animals—as Wolf, Bear, Tortoise, Snake, &c.—being used as a means of dividing tribes, so as to regulate their exogamy or marrying-out; a Wolf man, for instance, not being allowed to marry a Wolf, though he might marry a Bear. Later McLennan wrote papers on the worship of animals and plants in the *Fortnightly Review*, which he did not republish, but which have served to model public opinion since. As bringing the subject into scientific view, these papers were admirable; but they plunged into somewhat reckless theories which have held their own, notwithstanding incompatibility with evidence. Especially the word totemism, originally referring to exogamous human clans named from animals, was used in the large and complex sense of animal-worship, to only a fraction of which the totem-clans really belong. This discrepancy became serious when, for instance, in Fiji a god who embodied himself in serpents, was treated as if his worshippers formed a serpent-clan; in such a case the serpents being regarded as totems, and it being further supposed that the superior gods of the land were evolved out of such totem-animals. When this notion was later expanded in the works of Frazer and Jevons, it gradually produced a theory of totem-animals having been the origin from which a rude form of monotheism arose in the religion of mankind. As an instance how misleading such reasoning may be, it was pointed out that the great Heaven-god Tangalsa, whose veneration extends over the islands of the Pacific, is in Samoa incarnate in a species of snipes. According to this totemic theory of gods, the vast Sky-god would be a developed and exaggerated snipe. It was argued also that attempts to support Robertson Smith's doctrine of the Slain-god, with its further sacramental implications, by certain supposed piacular sacrifices of totem-animals to the totem-god, were not to be depended on, the few instances alleged being cases of animals put to death for reasons not necessarily sacrificial. As to the real meaning and origin of totemism, Prof. Tylor pointed out that modern information has thrown considerable light on the annuistic processes by which totems probably came into existence. The evidence of Wilken and Codrington, from the Malay and Melanesian region, shows the prevailing doctrine of transmigration of soul to convert an ordinary form of animal-worship into what hardly wants more than the name to become a totem. An influential native on his death-bed will announce to his family the animal into which his soul will migrate, perhaps a crocodile or shark by preference; taking him at his word, his kinsfolk will worship the creature —above all, not killing or eating it—and the crocodile or shark species becomes their protector. Such a family multiplying, and being called after sacred animals, will become crocodiles or sharks, clans whose totem is the crocodile or the shark.

Entomological Society, June 1.—Mr. R. Trimen, F.R.S., President, in the chair.—Mr. P. B. Mason exhibited a specimen of the rare *Lathridius filum* from his own herbarium. It had been previously taken at Edinburgh by McNab, and he understood that an example had been found in a sealed envelope containing *Marchantia* from Franz Josef Land.—Mr. J. J. Walker exhibited a singular blue variety of *Carabus monilis*, Fabr., resembling in colour *C. intricatus*, and taken at Iwade, Kent, in flood-rubbish in May.—Mr. F. Merrifield forwarded for exhibition from Riva on the Lago di Garda larvæ of the "Corsican form," var. *ichnusa*, of *Aglais urticæ*.—Mr. G. C. Champion called attention to Mr. A. Somerville's recently-published sheet of the county and vice-county divisions of the British Isles for biological purposes, and a discussion ensued thereon.—Papers were communicated by Sir G. F. Hampson, Bart., on "The Moths of the Lesser Antilles," and by Mr. J. H. Leech on "Lepidoptera Heterocera from Northern China, Japan, and Korea."

Chemical Society, June 2.—Prof. Dewar, President, in the chair.—The President announced the death of the Right Hon. Lord Playfair, the senior past President, and last surviving founder of the Society.—The following papers were read:—The boiling point and density of liquid hydrogen, by J. Dewar. Liquid hydrogen boils at about $-238°$ C., and its density at the boiling point, determined by measuring the gas obtained by evaporating 10 c.c., is about 0·07. Since the hydrogen occluded by palladium has the density 0·62, it cannot be associated with the metal in the liquid state.—The action of hydrogen bromide in presence of ether on carbohydrates and certain organic acids, by H. J. H. Fenton and Mildred Gostling. The formation of ethylic dihydroxymaleate by the interaction of the acid with dry ether and hydrogen bromide is generally applicable to the preparation of alkylic salts. On applying the reaction to carbohydrates and polyhydric alcohols, it is found that an intense purple or red coloration is sometimes obtained with ether and hydrogen bromide; the coloured matter produced resembles the metafurfurol of Stenhouse and others.—Production of some chloropyridinecarboxylic acids, by J. N. Collie and W. Lean.

Linnean Society, June 2.—Mr. Albert D. Michael, Vice-President, in the chair.—The Chairman announced that the President had nominated Messrs. William Carruthers, Frank Crisp, Albert D. Michael, and Dr. D. H. Scott to be Vice-Presidents for the ensuing year.—Dr. St. George Mivart, F.R.S., contributed a paper entitled "Notes on Lories." Referring to a recently published paper by Captain Hutton on the value of specific characters (*Linn. Soc. Journ.*, *Zool.* xxvi. p. 330) in which the writer had stated the results of his examination of a large number of pigeons belonging to the genus *Ptilopus*, and his reasons for concluding therefrom "that the specific characters of these species could not have arisen as 'recognition marks' or from any other mechanical mode of origin," Dr. Mivart adduced other examples in support of this view from the family *Loriidæ*, or brush-tongued parrots. From the facts collected he expressed his conviction that the cause of specific characters still remained an unsolved enigma, the solution of which would probably not be achieved until the higher psychological problems of biology were more widely understood, and the light thus gained had been reflected on questions of ordinary physiology.—Mr. E. S. Salmon read a paper entitled "A Revision of the Genus *Symblepharis*." This genus of mosses, he said, as founded by Montagne in 1839, had proved too narrow, through the limits imposed by certain peristome characters, and he was of opinion that Mitten's later emended description should be accepted.—Surgeon-Captain Cummins read a paper on the food of the Uropoda. The nature of the food of these mites, which belong to a highly specialised genus of the *Gamasinæ*, had long been a puzzle even to those who have paid particular attention to their organisation. From careful experiments and observation, the author of the paper had come to the conclusion that amongst the organisms on which the Uropoda live were many species of bacilli, including the potato bacillus and the earth bacillus. Wild yeast-cells were rapidly devoured, as also were *Micrococci*. He had little doubt that they consumed the gonidia of Fungi, for species of *Penicillium* and *Mucor* never appeared in the boxes which contained mites in large numbers; otherwise they were commonly present. Mr. A. D. Michael, in criticising the paper, pointed out the distinguishing characters of the Uropoda as compared with others of the *Gamasinæ*, and especially the peculiar form of the mandibles, which suggested a different mode of feeding to that adopted by other mites.—Mr. C. B. Clarke, F.R.S., gave a summary of a paper on the subdivision of biological areas in India, and in the course of his remarks mentioned some interesting facts in connection with plant distribution in the Indo-Oriental region. Dr. Otto Stapf, in commenting on the paper, expressed the opinion that the limits of the subdivisions proposed were natural, and might well be accepted by botanists.

Geological Society, June 8.—W. Whitaker, F.R.S., President, in the chair.—On the discovery of natural gas in East Sussex, by C. Dawson. Inflammable natural gas was first recorded by Mr. H. Willett in his thirteenth quarterly report of the Subwealden Exploration. Another discovery was in a deep artesian boring in the stable-yard of the New Heathfield Hotel. In 1896, at a site about 100 yards distant from the last-mentioned locality, a boring was put down by the London, Brighton and South Coast Railway Co., the details of which are given in the paper, together with those of the earlier Heathfield boring. From this boring gas has been escaping for the last eighteen months, with a pressure of not less than 15 lb. to the square inch, and at the rate of about 12½ cubic feet per hour (with a pressure of 20 tenths maintained), although the tube is stopped up, and is partially filled with water (see NATURE, vol. lii. p. 150). Though deficient in illuminating quality, the gas burns well when mixed with air, and gives a good bunsen-flame. The author considers that it is probably derived from the lower beds pierced, that is, the Purbeck strata, or by percolation from the still lower Kimeridge beds, which were not reached by the borings. The borings pierce the southern slope of the great anticline which runs from Fairlight into mid-Sussex, and is joined at Heathfield by another considerable anticline running through Burwash.—Note on natural gas at Heathfield Station (Sussex), by Dr. J. T. Hewitt. A sample of natural gas from the boring described above was taken in December 1897, and analysed with the following result: Methane, 91·9; hydrogen, 7·2; nitrogen, 0·9. Oxygen, carbon dioxide, carbon monoxide, olefines, and hydrocarbon vapours were altogether absent.—On some high-level gravels in Berkshire and Oxfordshire, by O. A. Shrubsole. The high-level gravels are divided by the author as follows, beginning with the oldest: (1) Pebble-gravel, composed very largely of flint or chert; (2) the Goring Gap gravel; (3) quartzose gravel, with only a small proportion of flint-pebbles; (4) quartzite-gravel, with purple and brown quartzite-pebbles; (5) local flint-gravels.—The *Globigerina*-marls of Barbados, by G. F. Franks and Prof. J. B. Harrison, with an appendix on the Foraminifera by F. Chapman. After a reference to previous publications on the island by one of the authors and Mr. Jukes-Browne, an account is given of the tectonic structure of Bissex Hill, on which the principal exposures of the *Globigerina*-marl occur. In the appendix a list of 146 species of foraminifera is given. Fifteen of these occur only in strata ranging from the Cretaceous to the Pliocene Period. The rocks bear some resemblance to the limestones and marls of Malta and to the *Globigerina*-beds of Trinidad; the recent foraminifera indicate that the deposit was formed at a depth of about 1000 fathoms and at some distance from land.

Zoological Society, June 7.—Dr. Albert Günther, F.R.S., Vice-President, in the chair.—Mr. L. A. Borradaile read the second part of a paper on Crustaceans from the South Pacific. In this part twenty-one species of *Macrura anomala*, examples of which had been collected in the islands of Rotuma and Funafuti by Mr. J. Stanley Gardiner, were enumerated, and notes were given on several of them. Under the head of *Petrolisthes lamarcki* the author proposed to unite a number of forms previously considered as specifically distinct.—A communication was read from Mr. A. E. Shipley containing an account of the gephyrea or unsegmented worms collected by Mr. J. Stanley Gardiner at Rotuma and Funafuti. These comprised examples of two species of Echiuroidea and twelve of Sipunculoidea. Of the latter group two new species were described, viz. *Sipunculus rotumahensis* and *S. funafuti*, and *Physcosoma varians* was recorded for the first time from the Pacific.—Mr. G. A. Boulenger, F.R.S., read a fourth report on the additions to the Batrachian Collection in the Natural History Museum, containing a list of the species of this class (115 in number), new or previously unrepresented, of which specimens had been added to the collection since November 1894. Eight new species were described in this paper.—Mr. G. A. Boulenger, on behalf of Count Peracca, gave an account of a new species of newt (*Molge italica*), recently discovered in Southern Italy, and exhibited some living specimens of it.—A communication was read from Mr. L. W. Wiglesworth, entitled "Theories of the Origin of Secondary Sexual Characters," which contained arguments in favour of the theory of the stimulation of parts to higher development through use or external violence or irritation, as observed in birds.—A communication was read from the Rev. O. Pickard Cambridge, F.R.S. It contained an account of a collection of Araneidea from Savoy, comprising examples of twenty-four species, one of which (*Gnaphosa molesta*) was described as new.

Mathematical Society, June 9.—Prof. E. B. Elliott, F.R.S., President, in the chair.—The President briefly noticed the loss sustained by the Society owing to the recent deaths of Mr. H. Perigal (elected January 23, 1868) and of the Rev. Dr. Percival Frost, F.R.S. (elected December 9, 1869) (see NATURE, No. 1493, p. 131).—The following communications were made: Point-groups in a plane, and their effect in determining algebraic curves, by Mr. F. S. Macaulay.—On a regular rectangular configuration of ten lines, by Prof. F. Morley.—On the conformal representation of a pentagon on a half-plane, by Miss M. E. Barwell.—On the general theory of anharmonics, by Prof. E. O. Lovett.—On the calculus of equivalent statements (eighth paper), by Mr. H. MacColl.—On a continuous group defined by any given group of finite order (second paper), by Prof. W. Burnside, F.R.S.—On certain regular polygons in modular network, by Prof. L. J. Rogers.

Royal Meteorological Society, June 15.—Mr. F. C. Bayard, President, in the chair.—A paper by Mr. R. C. Mossman was read on the frequency of non-instrumental meteorological phenomena in London with different winds from 1763-1897. In previous papers the author has discussed the secular and seasonal variation of various phenomena, and he now gives the results of an analysis of the direction of the surface winds observed during the occurrence of snow, hail, gales, thunderstorms, lightning, fog, and aurora. Snow is of most frequent occurrence with north and east winds, and least common with S.W. winds. Hail showers occur most often with W., N.W., and N. winds. Gales are most frequent with W. and S. winds. The greatest number of both summer and winter thunderstorms occurs with W. winds, although the values in summer are high with E., S.E., and S. winds. The greatest number of fogs are recorded on calm days, closely followed by days on which the wind blew from the east.—A paper, by Mr. A. L. Rotch, was also read on the exploration of the free air by means of kites at Blue Hill Observatory, Mass., U.S.A. After giving a brief account of the use of kites for scientific purposes from 1749 to the present time, the author describes the various forms of kites which have been employed at Blue Hill Observatory, viz. the Eddy, or Malay tailless kite; the Hargrave cellular or box kite; and the Lamson aero-curve kite. The highest flight was on October 15, 1897, when, by means of four kites having a combined lifting surface of 150 square feet, the meteorograph at the end of 20,100 feet of wire was raised vertically 11,080 feet above the hill. About 200 records from kites have been obtained in the free air at heights from 100 to 11,000 feet in all kinds of weather. Mr. Rotch maintains that the kite can be made of the greatest importance for meteorological investigation. At the recent meeting of the International Aeronautical Committee at Strassburg it was recommended that all central observatories should employ kites as being of prime importance for the advancement of meteorological knowledge.

EDINBURGH.

Royal Society, June 6.—Lord McLaren in the chair.—Prof. C. G. Knott read a paper on magnetic strains, being a continuation of a paper already published in the *Transactions*. Iron, nickel, and cobalt tubes of various dimensions were studied in detail. As a rule each was the subject of four distinct experiments. The change of length in the magnetic field was first measured; then the change of volume of the material; thirdly, the change of volume of the bore; and finally the change of external volume of the tube when plugged up at both ends. From these the coefficients of strain of an element at both the internal and external surface were calculated. Many details of interest were touched upon, and the general conclusion arrived at that the system of stresses required to maintain the complicated state of strain indicated could not be accounted for in terms of any of the recognised theories connecting magnetism and stress.—Dr. A. T. Masterman read a paper on the further anatomy and the budding processes of *Cephalodiscus dodecalophus*. Among the chief features dealt with may be mentioned the following. The pharynx has special adaptations for the separation of food and water currents, *e.g.* hyper- and hypo-pharyngeal grooves, the peripharyngeal groove, the pharyngeal clefts, &c. The notochord of the *Chordata* may be primarily derived from this source as a channel for cloacal water. The pedicle or ventral sucker has a ventral nerve cord and two ventro-lateral cords, a dorsal and a ventral blood sinus and complete inner layer of longitudinal muscles. The buds arise usually in pairs ventrally. The pharyngeal clefts arise as endodermal diverticula, which break through the ectoderm to the exterior. The sexual development commences in the egg capsule whilst attached to the inner wall of the cœnœcium, and results in the form of a larva segmented into two parts by an annular constriction.—Mr. Malcolm Laurie gave a description of a new Silurian scorpion from the Pentland Hills, the fourth that had been found in Silurian rocks. Regarding certain structures on the abdominal segments, the hypothesis was advanced that the new form was a water-breathing animal. A description was also given of some new Eurypterids, of which no fewer than twelve species had been found in this particular Pentland bed.—Dr. Masterman also communicated a paper on the theory of archimeric segmentation, considered in relation to the classification of the *Cœlomata*. This was a following up of a suggestion made in a recent paper that in the morphology of the *Cœlomata* there are two distinct types of segmentation: (*a*) a primitive or archimeric type, having in its constitution evidences of a radial origin, and (*b*) a secondary or metameric segmentation superposed upon the former, and bearing evidence of a bilateral origin.

Mathematical Society, June 10.—Dr. Mackay in the chair.—The following papers were read:—Notes on permutations, &c., by Mr. R. F. Muirhead.—Extension of the method of displacement-sequence, by Mr. R. F. Muirhead.—Converse theory of binomial theorem, by Mr. Sita Noth Chokrobarthy.—Elementary notes, by Mr. W. J. Butters.

DUBLIN.

Royal Dublin Society, May 18.—Prof. D. J. Cunningham, F.R.S., in the chair.—Dr. F. T. Trouton, F.R.S., communicated a method of measuring the surface tension of liquids which depends on the rate at which a column of liquid fills, or empties itself out of a tube of fine bore. The tube is placed horizontally and has one end bent downwards into a vessel of the liquid. By altering the level of the liquid it can be either arranged to measure the rate the tube fills, in which case the capillary forces draw the liquid up, or the rate it empties, the capillary forces retarding. Were the flow viscous the distance traversed would be proportional to the square root of the time. This was shown to be approximately true. Experiments were described using an inclined tube with a wide bent-down portion attached to the lower end. The rate of emptying could be made constant by making the height of the liquid in the wide part equal to the capillary elevation in the fine tube. Experiments were also described made with liquids such as soap solution, where surface tension varies with time.—The Rev. H. O'Toole exhibited and described a new hydrometer, which consists of a stem at the lower end of which is a weighted bulb, as in any of the common forms of hydrometer; higher up on the stem is another bulb, which causes the instrument to float, and at the top is a dish in which weights may be placed. Between the floating bulb and the dish there is another bulb, which may be called the standard bulb. The method of use is as follows: the apparatus is immersed in a given liquid, and weights added to make it sink to a marked point between the floating and standard bulbs; additional weights are then added to immerse the standard bulb to another marked point near the dish; these additional weights are evidently the weight of a volume of the liquid equal to the volume of the standard bulb. The weight of the same volume of water may be similarly found, and thus the specific gravity determined.—Prof. D. J. Cunningham, F.R.S., and Mr. Joseph Welland exhibited an apparatus for lantern-photography of microscopic objects. This is of interest as affording a means of using an ordinary optical lantern, with or without a microscopic projector, for making enlarged photographs of transparent microscopic objects, the precise degree of enlargement wished for being readily obtained. It has been employed chiefly for photographing large sections of the brain, and it is particularly well adapted for this purpose. Further, by means of this apparatus, transparencies reproducing the different colours of stained and injected tissues can be readily obtained by the Joly process. Slides showing a section through a kidney injected in two colours (red and blue) and a picrocarmine specimen of hair follicles were exhibited.—Mr. Richard J. Moss exhibited an apparatus for drying bodies *in vacuo* at various temperatures. Steam or other vapour is passed through a flat coil of pipe in an inverted bell-jar, closed with a glass plate and rubber ring, and attached to a water vacuum pump. A flat-bottomed platinum capsule containing the substances to be dried rests on the coil of pipe, and any desired desiccant is placed in a tray above it.

PARIS.

Academy of Sciences, June 13.—M. Wolf in the chair.—Liquid air, by M. d'Arsonval. An account of the Linde process of liquefying air. An expenditure of rather less than three horse-power gives a litre of liquid air per hour.—Spectroscopic researches on atmospheric air, by MM. H. Moissan and H. Deslandres. A sealed note deposited May 11, 1896.—Remarks by M. H. Moissan on the above.—On the direct measurement of a quantity of electricity in electromagnetic units; application to the construction of a current meter, by M. R. Blondlot. A coil in the form of a ring is hung on a vertical axis inside a long horizontal bobbin, the same current passing round both coils. The product of the intensity of the current into the time of oscillation, that is, the quantity of electricity which traverses any given section of wire during one swing, is a constant quantity, depending only on the construction of the two bobbins. By the application of a device for counting the vibrations of the small coil, a practical coulombmeter is obtained, which works equally well with continuous and alternating currents.—On differential equations of the second order at fixed critical points, by M. Paul Painlevé.—On the problem of integration from the point of view of real variables, by M. R. Baire.—On mixtures of gases, by M. Daniel Berthelot. A discussion of Dalton's Law of mixed gases. Starting with the assumption that the law of Avogadro is only true in the limiting case of infinite volume, an expression is developed for the constants in the Van der Waal equation to the mixture. The results found experimentally by MM. Leduc and Sacerdote are in perfect agreement with the theory.—On the study of the radiations of mercury and the measurement of their wave-lengths, by MM. Ch. Fabry and A. Perot. A comparison of the green line and two yellow lines of mercury with the cadmium lines by means of the interferential spectroscope described in previous papers.—On the electrical resistance of steel, by M. H. Le Chatelier. The steels were examined in the form of well annealed bars, 20 cm. long and 1 sq. cm. in section. The resistance increases with increasing percentage of carbon, and similarly with silicon, 1 per cent. of the latter having double the effect of the same amount of carbon. Steels containing manganese, nickel, chromium, tungsten, and molybdenum were also examined.—Entoptic vision, and sensibility in the yellow spot, by M. Aug. Charpentier.—On the atomic weight of nitrogen, by M. M. Vèzes. From the densities of nitrogen and its compounds M. Daniel Berthelot has deduced an atomic weight of 14·005 for nitrogen, whilst the figure given by Stas is 14·044. This discrepancy cannot be accounted for, as MM. D. Berthelot and Leduc have assumed, by the systematic error introduced by oxygen dissolved in the silver, as M. Stas has himself carefully reconsidered the whole of his work in the light of this objection of Dumas, and has shown that the effect is practically negligible, the atomic weight in question being only lowered from 14·044 to 14·040. The cause of the difference still remains to be explained.—On the atomic weight of tellurium, by M. R. Metzner. The tellurium employed in this research was prepared by the decomposition of tellurium hydride at 500°; it is certain that this metal must be free from antimony and bismuth. The reactions chosen were the conversion of the metal into its sulphate, and the reduction of tellurous acid with carbon monoxide. The mean result is 127·9.—Action of sodammonium in excess upon red phosphorus, by M. C. Hugot.—On the preparation and properties of a new carbide of tungsten, by M. Percy Williams. The carbide is produced by the interaction of tungstic acid, carbon, and iron at the temperature of the electric furnace. Its formula is WC, and is distinguished from the carbide W_2C, discovered by M. Moissan, in not being attacked by chlorine.—New method of separating geraniol and citronnellol, by MM. J. Flatau and H. Labbé. The essence is converted into phthalic ethers by heating with benzene and phthalic anhydride, and these separated by means of ligroin. The ethers are described in detail.—On the composition of fish, crustacea, and molluscs, by M. Ballard. Determinations of water, nitrogen, fat, extractives, and ash for a large number of fish, crustacea, and molluscs.—On the crystalline forms of quartz from Meylan, by M. Ferdinand Gonnard.—On the direct fertilisation in some plants in which the flowers would appear to be adapted to cross fertilisation, by M. C. Gerber.—On a remarkable fault between Brives, Périgueux and Angoulême, by M. Ph. Glangeaud.—On new sources of petroleum in the Caucasus, by M. Venukoff. Naphtha-bearing sand has been found near Anaclie, in the Eastern Caucasus.—

Atmospheric situation at the time of ascent of experimental balloons, by M. H. Tarry.—The registration of atmospheric electric discharges, by M. Ducretet. The registration was effected by the Hertzian waves set up; the recording instrument was a Branly radio-conductor.—International balloon ascent of June 8, by M. W. de Fonvielle. The ascents were made on the same day at Paris, Brussels, Strassburg, Vienna, Berlin, St. Petersburg, and Munich.—Short account of the results of the ascents of three captive balloons at Trappes, by M. L. Teisserenc de Bort.

NEW SOUTH WALES.

Linnean Society, April 27.—Mr. P. N. Trebeck in the chair.—Some new genera and species of fishes, by J. Douglas Ogilby.—On the affinities and habits of *Thylacoleo*, by Dr. R. Broom. The author reopens a much-debated question in the light afforded by the interesting little fossil marsupial recently described by him under the name *Burramys parvus* [P.L.S.N.S.W., 1895, p. 563]. This little form, which is evidently the representative of a sub-family of the *Phalangeridæ*, in most of its characters agrees with the phalangers, but it possesses the greatly enlarged and grooved premolars of the rat-kangaroos; and not only does it show evidence of a group which fills the only remaining gap between the kangaroos and the phalangers, but as a phalanger with the posterior premolars enormously enlarged, it comes nearer to *Thylacoleo* than does any extinct or living form hitherto discovered. The conclusions arrived at are—That *Thylacoleo* is descended from a phalangeroid form not very dissimilar from *Burramys*, and that it was almost certainly a purely carnivorous animal.—Descriptions of new Australian lepidoptera: with a note on the occurrence of *Deilephila livornica*, Esp., at Broken Hill, N.S.W., by Oswald Lower. The beautiful sphingid, *Deilephila livornica*, Esp., was noticed by the author to be common during the early part of March last, at the electric lights at Broken Hill. On one occasion individuals were literally swarming. The species occurs in Europe, Africa, and S. Asia. It was first recorded from Australia by Mr. Miskin from a Queensland specimen. It is also known from Adelaide, but has not yet been reported from Victoria, Tasmania, or West Australia; nor has it been recorded previously from New South Wales.—Descriptions of a new Australian grass, by Fred. Turner. The species of *Panicum* described is a capital forage plant from the Liverpool Plains, N.S.W., its nearest allies being *P. semitonsum*, F.v.M., and *P. antidotale*, Retz, from North Australia.—Mr. Hedley exhibited a specimen of fully developed *Gundlachia* recently taken by Mr. H. Leighton Kesteven from a pool in the Botanical Gardens, Sydney. This is the second instance of its occurrence in Australia, and the first in New South Wales. The genus has been treated of at some length in vol. viii. (2nd series) of the Society's *Proceedings*. Possibly no real *Ancylus* exists in Australia, and all those hitherto reported will ultimately be shown to assume occasionally and at rare intervals the Gundlachia form.—Mr. Ogilby exhibited the type of the new bathybial fish from Lord Howe Island, described in his paper as *Æthoprora perspicillata*, and remarked that it may be distinguished from the three Atlantic species by the presence of a pair of supernumerary photophores between the upper angle of the eye and the ante-orbital.

DIARY OF SOCIETIES.

CONTENTS.

THURSDAY, JUNE 30, 1898.

THE COLOURS OF INSECTS CLASSIFIED ACCORDING TO THE METHODS OF ART.

Observations on the Coloration of Insects. By Brunner von Wattenwyl. Translated by Edward J. Bles, B.Sc., King's College, Cambridge. Pp. 16, and 9 Coloured Plates. (Leipzig: W. Engelmann, 1897.)

THIS publication consists of a series of nine beautifully coloured plates containing 118 numbered figures, in addition to several others distinguished by letters. Accompanying the plates is a brief descriptive letter-press which explains the plan on which the illustrations have been selected and grouped, and the theoretical views of the author, the eminent orthopterist. The expense of the plates, which must have been very heavy, was aided by a grant from the Wedl Fund of the Imperial Academy of Sciences in Vienna.

The translation is, on the whole, extremely good, only a sentence now and then serving to recall the (to us) clumsy form of the original. Mr. Bles, in a cautiously worded translator's note, excuses himself from the acceptance of the author's philosophy.

The printing and general get-up are of the very highest character.

The views of the author upon mimicry, protective resemblance, &c., are already well known from his previous writings. Thus in 1883 he suggested (*Verh. der K.K. zool. bot. Ges. in Wien*, 1883, p. 247) the term "Hypertely" to express the supposed fact that resemblance to surroundings may be more perfect and detailed than is required by the struggle for existence. Thus Brunner could perhaps accept the view that resemblance to a leaf is useful for concealment from enemies, although likeness to a leaf which has been mined by larvæ went, he contended, too far, and transcended the limits of the useful. It was therefore of the highest interest to ascertain whether the criticism of so distinguished an entomologist was purely destructive—for "Hypertely" merely meant that he could not accept the explanation offered by natural selection—or whether he had not some alternative theory to explain the facts. Hence the expectant interest with which this publication will be received by all naturalists who are interested in theories which are supposed to account for evolution.

In the Introduction the author describes the plan of his memoir in these words: "The following work contains simple observations on the phenomena of coloration. I have attempted to classify these phenomena, and I have found laws which have no connection with the care for the preservation of the species." These "laws" consist in classifying a large number of the colours and patterns of insects according to their forms, and especially according to the relationship they bear to the various methods of decorative art as applied by man.

It must be regarded as a serious error that the author should have used a monograph of this kind for the burial, rather than the publication, of the description of a few new species.

The following groups are recognised and beautifully illustrated in the plates: (1) *Uniform and Rainbow Coloration*, the simplest and commonest of all; and next to it (2) *Stripes, Bands and Spots.* Under this head it is well shown that the stripes often persist over certain contours or surfaces of the body, regardless of the various anatomical features which are traversed; and also that the continuity of stripes can only be made out, in certain cases, by placing the insect in its position of rest. When an insect possesses a "single narrow band which extends, mostly in a straight line, over the different parts of the body, sometimes vertically, sometimes horizontally or obliquely," and when this band only becomes continuous in a certain position of the insect, Brunner calls it (3) *The Line of Orientation*, "because it indicates the position assumed by the insect in receiving its coloration." (The form of words used should be noted.) Numerous excellent examples of such lines are figured. The next group consists of (4) *Strokes and Dots*, a special form of pattern which gives "the impression of a simple pen-and-ink drawing." A certain West African Locustid (*Mustius Afzelei*) is "marked with a pen-and-ink design" in the form of rings round the antennæ, on the borders and tips of the wings in the position of rest, and on the ends of the feet. A detailed description is given by the author "in order to show that in this insect the pen-and-ink markings are, so to speak, the finishing touches to the coloration of the insect." (5) *Eye Spots.* A beautiful series of these striking markings has been selected and figured. The species belong to the Coleoptera, Orthoptera and Lepidoptera. (6) *Spirals.* Another very striking and remarkable form is found in many moths and in the Mantid family *Harpagidæ*, which, however, are described under Section 9. (7) *Splash Marks* are distinguished from the markings hitherto described by their irregularity and want of symmetry. In two species of *Aularches* from the Oriental region, "the effect of the whole is as though the insect with folded wings had been irregularly splashed with a body-colour." Splash marks when crowded may be modified into (8) *Clouded Markings*, although in this case the pigment is "not applied like a body-colour." The author, "speaking figuratively," prefers to "regard these markings [as in the fore-wings of *Œdipodidæ*] as produced by the impression of a thumb moistened with colour."

Up to this point coloration has been considered "as though produced by painting with a brush. Besides this, forms of coloration are met with which imply, when carefully considered, another method of application." The first of these are (9) *Stencil Patterns*, in which "the colour is perfectly uniform throughout with hard contours, like the wall paintings produced with the aid of stencil plates." "In many instances, various colours are laid on in different shapes, like in polychrome decorations." The examples are selected from dragon-flies and Orthoptera. The realistic manner in which the author follows up his own metaphor is well shown in his description of the marking on the fore-wings of the Harpagid (*Mantidæ*) *Pseudocreobotra ocellata* from Natal.

"One sees on the transparent, somewhat yellowish ground of the fore-wings, firstly, a green patch laid on as with a stencil. Then, in the middle of the green portion, opaque citron-yellow is laid on in the form of a spiral. The spiral is bordered with a heavy black line,

K

and in the centre of the spiral there is a round spot of the same colour. The black line obviously is meant to serve as a setting of the yellow spiral,"

but it is somewhat misplaced in the design, being shifted, together with the central spot, towards the base of the wing.

"We have, consequently, three colours stencilled on the glassy wings: first green (Fig. 70 *b*), then lemon-yellow (*c*), and, to complete the picture, a black body colour; the latter is somewhat misfitted, as it may also be at times in our coloured prints."

All the specimens examined were found to exhibit the same displacement of the black band, so that it is not "a mere chance occurrence in an individual." The author reaches the remarkable conclusion—"The species was ornamented *once for all*, and just as it emerged from this operation, so has it been transmitted by inheritance." Stencil painting also occurs in Lepidoptera, although it requires "a little good will" to find it. Indeed Brunner is inclined to look upon this as the primitive coloration, which has been in the Lepidoptera "frequently effaced by selection and by simply going to the bad."

The transparent patches which occur on the wings especially of Orthoptera and Lepidoptera are classed under (10) *Erosion.*

These ten groups of marks are followed by general Sections dealing with the alterations which occur in pattern as it is traced through a series of allied forms. In Section (11) *Changes of Pattern*, it is pointed out that unlike the *Pseudocreobotra*, described above, the outlines of spots and stripes and even their position are variable in Lepidoptera.

The author therefore compares

"the first method of coloration with colour printing, and the latter with hand painting; thus indicating the fact that on one hand we meet with undeviating similarity, and on the other with a certain freedom."

The methods by which the changes are effected are then considered in (12) *Enlargement and Diminution of Spots and Bands*, (13) *Dislocation*, the change in position which corresponding marking may undergo in allied species, principally illustrated from the *Hesperidæ*. (14) *Diminution of Patterns*, in which a "pattern remains unchanged and only diminishes in size." The fascination for metaphor which possesses the author leads him to say concerning diminution (as opposed to "the simple breaking down of a design"),

"We have a process before us, which is carried out physically when a magic lantern picture is diminished on the screen by manipulating the lenses."

The title of Section (15) is *Changes of Colour due to Adaptation.* Although the choice of these words seems to imply the recognition of natural selection, such an explanation is by no means congenial to the author. After alluding to his previous description of a Locustid from the Soudan which resembles an ant, the shape of the latter being indicated in black pigment on the body of the former of which all other parts are coloured with a pale tint, he inquires "is this imitation an accidental freak of nature?" Indeed throughout this section Brunner seems to doubt his own explanations. He gives numerous instances of insects living on plants "in which the leaves of the habitat or parts of them are doubtlessly imitated"; but follows the list, which is illustrated by eight figures, with the paragraph—

"With the aid of the imagination, one may recognise the most various figures in the arrangements of spots and ocelli, and if, perchance, these can be referred in any way to protective resemblance, your case of mimicry is established."

Apart from the fact that such a description is a caricature, exception must also be taken to the inconvenient confusion between protective resemblance and mimicry, two principles which, although bearing a close relationship to each other, are better kept separate.

(16) *Staining of Contiguous Parts.*—This Section contains the somewhat crude and entirely unsupported assertion that when an intensely coloured part of the body is of the same tint as other parts which are in contact with it, the latter have been stained by the former. Careful microscopic investigation at the time during which the pigments are developed would settle the matter, and without it no such assertion can be justified.

(19) *Fading in Covered Parts.*—In many instances the parts of wings which are covered in the position of rest are of a different tint from the exposed portions. From this well-known fact, and without the remotest attempt at proof, the author observes

"these facts convey the impression that the brighter colours are produced by daylight. If one exposes to the action of the sun and of the air several sheets of white paper of different sizes lying one upon the other, then, in a short time, the silhouette of the smaller pieces will stand out on the larger either in lighter or in darker tints. It is probable that the phenomena observed in Blattodea and Phasmodea belong to this category of light effects."

The author's method of dealing with natural selectionists may be fairly used against himself. If, perchance, it is possible to institute a crude comparison between the colour effects produced by physico-chemical forces upon dead matter, and the arrangement of tints in a highly organised being, you have probably established a valuable "law" which you can then place before the world, without troubling to inquire whether you have been misled by a resemblance which is purely superficial.

(18) *Colouring in Relation to Position.*—In this Section the patterns which pass over the body irrespective of its parts, and produce a "homogeneous" effect, are distinguished as *holotypic* from those *correlative* markings which are similar upon homologous parts, as in the repetition of ocelli upon the corresponding areas of fore and hind wing, &c. Numerous interesting and beautiful illustrations are given. It is common for the same insect to possess more than one holotypic pattern having reference to more than one position. This at least is the way in which a follower of natural selection, or indeed a Lamarckian, would express the facts, and he would then attempt to ascertain the meaning of the patterns in relation to the positions. Brunner expresses them very differently and in a manner which is significant of his views of creation. With him the position represents the attitude of the insect when the pattern originally fell upon it. Such a view is expressed again and again, the best example being contained in the next and last

Section (19) dealing with *Arbitrariness of Coloration* (viz. the fact that colouring often has no "reference to the somatic importance of organs"). He here speaks of a black Australian bug of the genus *Pirates*, in which the wings of the male and the abdomen of the wingless female are similarly striped and spotted with dirty yellow. "What, then, does this mean? When the pattern was produced, it fell upon the wings of the male, and in the female on the uncovered abdomen."

There is a conspicuous want of method and arrangement in the Sections recognised by the author. Thus the idea of a pattern which persists over the body surface independently of structural features but related to attitude, is the central conception of many of the Sections, and even those as widely separated as (3) is from (18) and (19). It is interesting to compare this point of view with that of the late Alfred Tylor, who ingeniously attempted to show that the true significance of pattern is to be found in its relation to underlying structure. Undoubtedly many patterns possess this relationship, and undoubtedly many others as conspicuously lack it. The facts on which both naturalists relied are certainly right, while their conclusions are as wrong as they are contradictory of each other—Brunner, that pattern is produced upon the organism by some power outside it, and caring nothing for its structural differentiation; Tylor, that there is some deep and significant bond between pattern and underlying structure, so that the former becomes the outward and visible sign of the latter.

The attempt has now been made to give the whole of the "laws which have no connection with the care for the preservation of species" which the author claims to have found. To the majority of naturalists these "laws" will appear to be the grouping of certain markings and patterns according to more or less superficial resemblances between them; and this being done, the real interest now begins—the attempt to ascertain their significance in the lives of their possessors. Much interest, too, awaits a minute investigation of many of the groups in order to make out whether they are based on superficial appearances, and therefore artificial, or whether they are real and natural.

To the author, however, it all means far more than this. As the memoir was being studied, the continual pursuit of detailed metaphor led to the belief that the author did not regard his imagery as metaphor only. In the brief Conclusion he speaks out on the question.

"In the above paper I have brought into a system the divergent facts of coloration. In so doing, simple principles have been formed which coincide in a remarkable manner with those of the human painters' arts. The agreement is so striking that one is tempted to use the terms of our own technique in descriptions. I speak of splashing, stencil-painting and brush-painting, also of the position of the insect when the colour was applied, of sketching in the pattern in different ways, &c."

"This is figurative language, but the uniformity of the phenomena forces one to the conjecture, that the process in nature is of a similar character; that is to say, a phenomenon which acts from without, independent of the biology of the animal coloured and in nowise connected with its structure."

When we inquire what this power can be, the author replies as follows:—

"The exact sciences have accustomed us to refer all natural phenomena to the action of definite, inviolable laws. In the coloration of insects, however, we meet with an *arbitrariness* striving to produce attributes without regard for their possessors and, therefore, obviously to be looked upon as the emanation of a Will existing above the universe."

Thus Brunner leads us back to a form of special creation. Paley was convinced by the argument of design; Brunner by the argument of want of design. Most of us, while rejecting both, will distinctly prefer the philosophy of the old theologian to that of the great orthopterist.

The "Will existing above the universe," the Will which Brunner supposes to work out "purposes in creation far more lofty than the mere preservation of the species," is mainly to be recognised by the resemblance of its handiwork to that produced by the methods of the craftsman, and especially by the remarkable likeness which it presents (as in the wrongly-placed stencil pattern) to a poor form of human art, at its worst.

The reasons given for rejecting the Darwinian explanation are indeed remarkable, but far more remarkable are the hypotheses which the objectors prefer to put in its place.

E. B. P.

BLANFORD'S BIRDS OF INDIA.

The Fauna of British India. Birds, Vol. iv. By W. T. Blanford. 8vo. Pp. xxi + 500. (London: Taylor and Francis, 1898.)

THE present volume completes the Vertebrates of the Indian Fauna, and the editor (in this case also the author) is to be congratulated on having thus far so successfully accomplished a very important and at the same time a very difficult task. The volume before us is, perhaps, the most generally interesting of the four devoted to birds, seeing that it treats of groups like the pigeons, the sand-grouse, the game-birds, and the ducks and geese, which claim attention from a wider circle of readers than is attracted by the perching birds and picarians. Since the author, in addition to his scientific qualifications, is also a sportsman who has shot a large number of the species he describes, his work can scarcely fail to prove as acceptable to his brother sportsmen as to scientific ornithologists. Limitations of space have necessarily curtailed the amount of matter devoted to the habits of most of the species, but within such limitations the notices leave little to be desired.

From its geographical situation, India, we need scarcely remind our readers, is visited during the cold season by vast swarms of game-birds and ducks of various kinds; and the fauna of these groups is consequently very much larger than might *à priori* have been expected. Sportsmen accordingly often experience considerable difficulty in identifying the species contained in their "bag," but with the publication of the present volume such difficulties should cease.

Turning to the more strictly scientific aspect of the book, it may be noted that the author is careful to state how much he is indebted to the British Museum Catalogue of Birds, certain volumes of which devoted to several of the groups he describes have appeared at more or less recent dates.

On comparing these volumes of the Museum Catalogue with the work before us, it will be found that in many instances Mr. Blanford has somewhat simplified the classification adopted. This is most markedly the case in the pigeons, the existing members of which were divided by Count Salvadori into five families; whereas Mr. Blanford, so far at least as Indian forms are concerned, admits but one. Although he has not to deal with the former on this occasion, he further suggests that the separation of the *Tetraonidæ* as a family apart from the *Phasianidæ* seems scarcely justifiable by the facts. And on turning to the minor groups, we find a similar wide and comprehensive view taken as to their respective limitations. Leaving out of consideration the very distinct demoiselle crane (*Anthropoides*), it may be noticed as an example of this feature that recent writers have assigned the three species of true cranes which visit India proper to as many distinct genera, respectively distinguished, mainly, if not entirely, by the comparatively insignificant character of the extent to which the head is clothed with feathers. All the three species are indeed structurally similar and essentially the same type of bird, and to many at least it will be a source of satisfaction to find them once again reinstated in the original genus *Grus*. Possibly a further improvement would have been to have placed the Burmese representive of the Sarus crane of India as a sub-species rather than a species, but this is a matter of detail.

In museum work (as in stamp-collecting) there seems to be an inevitable and inherent tendency on the part of specialists to go on refining and discriminating in the detection of small points of difference, and thus to raise the individuals or groups in which such minute points of difference occur to a higher and higher rank. And in consequence of this extremely natural ultra-refinement (due to a ripe knowledge of minuteness of detail), the mutual affinities of animals tend to become obscured or even lost, while the science is cumbered with an excess of more or less superfluous terms. It is therefore a distinct advantage when a man with the wide experience and knowledge derived from the study of other groups, possessed by the author of the present volume, sets himself the task of revising the classification of a group which has occupied the attention of a large number of specialists. And whatever may be the opinion from the specialist point of view, it can scarcely be doubted that to naturalists who desire to take a broad and comprehensive view of zoological affinities, Mr. Blanford's simpler arrangement is decidedly preferable to the numerous sub-divisions adopted by some of his fellow workers.

As regards the general classification adopted, it is gratifying to notice that it has not been considered necessary by the author that he should propose any new scheme; and the various major groups accordingly, for the most at any rate, appear under the old familiar names. In some instances, however, generic terms in common use have had to be rejected on account of priority or preoccupation, and a few birds consequently appear under unfamiliar titles. The horned pheasants, for example, figure as *Tragopan* in place of *Ceriornis*, but since the former name is often used as the popular title of these birds, the change in this case is less startling than usual. As in all those made by the author, this substitution was a necessity according to the rules of nomenclature.

The total number of Indo-Burmese birds regarded as entitled to rank as distinct species in the four volumes devoted to the group is given by the author as 1626. Years ago, from a much smaller area, Jerdon recognised 1016. In Mr. Hume's catalogue of 1879 a total of 1788 entries were recorded, but of these 106 were rejected as invalid, and 74 regarded as doubtful, thus leaving a total of 1608, or very nearly the same as the number admitted by Mr. Blanford and his fellow author Mr. Oates. Since a large number of new species have been described of late years, this indicates that due attention has been given on the part of ornithologists to the elimination of nominal ones. An exact estimation of the number of species of any group of animals inhabiting a particular country must, however, depend to a considerable extent on the personal equation of the describer. As the author well observes:—

"The precise number of species is naturally dependent on a personal factor, some writers being more liberal than others in admitting the claims to specific rank of races which are distinguished by small differences of plumage or measurement, or which are connected by intervening links with the typical form. Such races or sub-species, as they are called, have not, as a rule, been separately numbered and described in the present work, but they have received due notice and their characters have been explained."

From this it would appear that Mr. Blanford has not yet brought himself to accept the principle of trinomialism for birds, although his recent paper on the large Indian squirrel seems to show that he has already done so in the case of mammals; and the innovation would, to our thinking, be an advantage among the former.

As is always the case with the author's work, his descriptions are most accurately and concisely written, and they all bear the impress of having been drawn up afresh from the birds themselves, and not merely extracted and furbished up from the writings of others. In many of the groups described, and especially the game-birds, the females are so different in plumage from the males, as to require a description nearly as long as that devoted to the latter, so that the labour involved in the work is almost double that which might at first sight be supposed necessary. Equally exact, and at the same time important, are the details given in connection with the geographical range of the genera and species; a subject too often neglected by the earlier writers.

One thing we should like to suggest to the author, and that is that in future works he should give the reference to the place of publication of the generic names and their synonyms, instead of merely citing the author and date. The characters of the eggs in each genus might also have been added; while a few more details regarding the nesting habits of some of the more important species would, if space permitted, have added to the interest of the book.

Many books on Indian game-birds and the kindred groups are already in existence, and a new one on a small scale is now in course of publication; but it may be safely said that as a work of reference, embodying all the important information regarding these groups, the present volume will long remain the standard, both to the naturalist and to the sportsman. While lacking the advantage of plates, it has the compensations of portability, accuracy, and completeness; and it forms a worthy companion to its fellow volumes of the same series. R. L.

NAVIGATION AND CYCLONES.

Méthode pour abréger les traversées en utilisant les perturbations de l'Atmosphère. Par M. A. Fieron, capitaine de frégate. Pp. 91. (Paris: Imprimerie Nationale, 1891.)

THIS little book bears the date 1891, and is extracted from the *Annales hydrographiques* of that year. The object of the author, who was attached to the *Calédonien*, and thus had considerable experience of the Southern Seas and of the weather prevalent in those latitudes, is to indicate methods by which navigation may be facilitated and the duration of voyages, in sailing ships especially, diminished by taking advantage of the cyclonic and anticyclonic movements in the atmosphere. By so manœuvring that the violence of the storm is utilised in carrying the ship in the direction desired, it is contended that these destructive agents can be turned to useful account. It may be true, as the author asserts, that in every area of low pressure there is always one part which can be made useful—one sector in which favourable winds will be found. But careful navigators are rather prone to give these areas of disturbance a wide berth; and it speaks much for the trustfulness of the author, and of the calm confidence in which he reposes on scientific deductions, that he does not propose to avoid these dreaded cyclonic storms, but is prepared to steer into their midst and make their violence subservient to his ends. His system is based upon instrumental observations, chiefly of the barometer, from which may be learnt the direction and force in which the cyclone is moving. Experience teaches the behaviour of the atmosphere in a region of low pressure in different latitudes, and by the aid of a few rules, easily learnt and remembered, it is not difficult to perceive whether one be on the navigable or dangerous side of a cyclone, and arrange accordingly. The author therefore gives in very considerable detail, the condition of the weather, the direction of the wind, and the appearance of the sky, which may be expected in the various positions in which the ship finds itself relative to the centre of the storm.

We have practically to do with a system of weather forecasting, based upon knowledge which cannot always be exact or sufficient, and therefore it would seem must sometimes lead astray. But the author declares that he has never been in error, and that he has never had any hesitation in selecting the proper route which would enable him to find the most favourable wind to carry him most swiftly in the direction he desired to travel. He is, however, careful to add that his rules for observance apply only on the open ocean, where land masses do not interfere with the aerial current, and his success may be to some extent due to the employment of the system under the conditions of the greatest simplicity.

This work has been before the maritime public now some seven years, and presumably the procedure has been submitted to frequent test by those who have to navigate in those seas, which have been made the subject of study, but the testimony in its favour does not seem to be overwhelming. Several causes may be assigned to explain the indifference with which the practical suggestions contained in the book have been received by the mariner and the shipowner. The most evident is the steady decline in the tonnage of sailing vessels, and the tendency to convert many of these into floating warehouses containing grain. When a shipowner knows that he will have to pay rent for storage of the cargo on arrival, he is practically indifferent how long the voyage may last, and safety is of greater consideration than swiftness. The recognition of trade routes and the maintenance of particular lines of navigation pursued by vessels which can both steam and sail, forbid a haphazard, self-selected route, which, if it shorten the time of passage, increases the chances of collision. The author, it is true, considers his system particularly applicable to this kind of steamer, employing the steam to carry the vessel into a position in which it would enjoy favourable breezes. A few tons of coal would be well expended, he urges, if it enabled a skipper to bring his steamer alongside a friendly cyclone which would carry it along on a twenty-knot breeze in the coveted direction. We imagine that the few tons of coal would more frequently be expended in carrying the ship away from a region in which disaster is quite as likely to be encountered as material assistance to be rendered.

Possibly, knowing the destructive effects that these cyclones can work, our mariners have received them with too much distrust, and not sought to derive from them what little advantages they may offer. M. Fieron's book is directed towards creating a more favourable opinion of these atmospheric disturbances. The issue must be left to the expert, who has before his eyes Board of Trade inquiries and nautical assessors who may not share the hopeful views of the author. One very real source of danger on which the author does not appear to insist sufficiently is the swell which arises from the heavy seas, that accompany typhoons, tornadoes, &c. A well-found sailing vessel may withstand the force of the wind, after due precaution, but suffer grievously from heavy confused cross seas. This point and others of much importance are discussed in a pamphlet recently issued by Dr. Doberck, the director of the Hong Kong Observatory. The director has here incorporated the experience of many years' study gained in an observatory which exists mainly for the purposes of warning the mercantile marine against the dangers arising from the approach of typhoons and similar atmospheric disturbances. During the last thirteen years, the tracks of nearly 250 typhoons have been examined and discussed, from information supplied, either from ships at sea, or from fixed stations. The causes that produce variation from regularity, such as the geographical position of the origin of the storm, the presence of land masses in the path, the condition of the monsoon, &c., have been taken into account, with the result that successful prediction is generally secured, and rules for the management of vessels, under whatever conditions they are placed, have been formulated with scientific precision.

OUR BOOK SHELF.

Notes from a Diary, 1873-1881. By the Right Hon. Sir Mountstuart E. Grant Duff, G.C.S.I. Vol. i., pp. iv + 334; Vol. ii., pp. 394. (London: John Murray, 1898.)

THE only scientific interest which these volumes possess is due to the fact that a number of distinguished men of science are referred to in their pages, and occasional mention is made of botanical species found in the places visited by the author. Chatty reminiscences of this kind are always interesting, and they become much more so when they are related by a man with a wide circle of friends among leaders in many branches of intellectual and political activity. Almost all reference to the working-day part of the author's life has been eliminated, though during the whole period covered by the volumes the author was a member of Parliament actively engaged in political affairs. The volumes are concerned with the lighter and recreative side of the life of a public man, and as such contain notes on many amusing occurrences, as well as open expressions of opinions by distinguished men. Whether it is desirable to give a permanent form to stories told in private conversation, or to record casual opinions, may be doubted; but, by bestowing care upon the preparation of the notes for the press, Sir Mountstuart Grant Duff has been able to avoid publishing anything likely to give offence.

The volumes will provide after-dinner speakers with a wealth of capital anecdotes. In 1877 the author was shown an egg of the great auk, and was told that on account of its rarity it was worth 60*l*. Since then, a great auk's egg has been sold for nearly 300*l*. Referring to the auk the author says: "This was the creature whose name brought down on the ornithologist who used it at the Belfast meeting, the criticism of the lady who remarked—'He can't be an educated man, he speaks of the great 'awk!'" The following entry in the diary for March 24, 1878, is interesting:—

"At High Elms, Lyon Playfair, amongst others, being of the party. *A propos* of the Algerian conjurors, who apply hot metal to their bodies without suffering, he explained to us that, if only the metal is sufficiently hot, this can be done with perfect security; and told an amusing story of how, when the Prince of Wales was studying under him in Edinburgh, he had, after taking the precaution to make him wash his hands in ammonia, in order to get rid of any grease that might be on them, said: 'Now, sir, if you have faith in science, you will plunge your right hand into that cauldron of boiling lead, and ladle it out into the cold water which is standing by.' 'Are you serious?' asked the pupil. 'Perfectly,' was the reply. 'If you tell me to do it, I will,' said the Prince. 'I do tell you,' rejoined Playfair, and the Prince immediately ladled out the burning liquid with perfect impunity."

Several stories are told in connection with Darwin. The following is an entry on December 15, 1880:—

"Drove with my hostess to Liverpool. She told me that she had lately explained to Darwin the state of her sight, which is very peculiar. 'Ah! Lady Derby,' said the great philosopher, 'how I should like to dissect you.'"

The volumes are full of accounts of similar amusing incidents, and will serve to while away many leisure hours.

Elements of Descriptive Astronomy. By Herbert Howe, A.M., Sc.D. Pp. 340 + xii. (London: George Philip and Son, 1897.)

THIS is an elementary text-book which touches briefly upon the more important principles, facts, and theories of astronomy. In such a general treatment of a large subject, opinions are bound to differ as to what should be included and what omitted, but the author has on the whole made good use of his space. The arrangement of matter is only marred by the subordinate position given to the spectroscope and the principles of spectrum analysis. While the telescope is treated of in a separate chapter, the spectroscope is given a few paragraphs in a chapter on the sun, an arrangement which is apt to be misleading now that the astronomical applications of the latter instrument are as wide as those of the telescope.

The author wisely insists on the necessity for actual observations, even without instruments, and draws attention to the need for the cultivation of what is happily called the "geometric imagination." Each chapter is provided with a number of exercises which seem to be well adapted to assist the student. The illustrations, including a set of star maps, are, with one exception, admirable. Though the colouring of the plate of spectra is excellent, several of the details are inaccurate: for example, the spectrum of sodium is represented as consisting of a bright line and two dark ones, having no connection with the solar lines, and the hydrogen spectrum is quite unrecognisable.

In spite of the necessarily meagre character of much of the information, the book has many attractive features, and will give the student a good idea of the principal teachings of astronomy.

South American Sketches. By Robert Crawford, M.A. Pp. xx + 280. (London: Longmans, Green, and Co., 1898.)

THREE-FOURTHS of this volume consist of narratives of amusing and exciting personal experiences; the remainder contains general information on the natural history, climatology, and geography of Uruguay. The author resided in Uruguay for three and a half years, during which period he was engaged in the construction of a railway, and had good opportunities of observing the nature of the country and the manners of the people. The life of a railway engineer is never without its adventures, so it is easy to imagine that the author did not lack exciting incidents. Of course he witnessed a revolution, and experienced some of the discomforts suffered during periods of political disturbances in South America. The descriptions of these incidents of public and political life, and of perils by land and sea, are well worth reading. Referring to the change of character of streams in a few hours, Mr. Crawford says: "I have known a little stream that I have repeatedly jumped across on foot spread out to a width of more than a hundred yards, with a depth of from ten to fifteen feet, in five or six hours, and fall again as rapidly." The rivers, as well as the smaller rivulets and brooks, are affected in a similar way.

Though the volume is not expressly intended for schools, it contains enough adventures to interest young readers, and conveys at the same time a large amount of information concerning conditions of life in Uruguay.

The Making of a Daisy; "Wheat out of Lilies"; and other Studies in Plant-Life and Evolution. A Popular Study of Botany. By Eleanor Hughes-Gibb. Pp. 126. (London: Charles Griffin and Co., Ltd., 1898.)

UNDER a cumbersome title, we have here a half-dozen short papers containing elementary descriptions of the parts of a few common flowers and their functions. The object of the author has been "to help my readers to form some idea of the principles on which the classification of flowering plants are based, and at the same time to give a view of the chief divisions marked out upon these principles." There is, however, little novelty either in the plan or execution of the volume; and though a certain amount of instructive information may be extracted from its pages, it is garnished with too many platitudes to be interesting. For readers who like to draw moral lessons from natural processes, the book will be found attractive; but as a popular work on botany little can be said in its praise.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Liquid Air at One Operation.

IT is to be hoped that personal matters will not divert attention from the very interesting scientific questions involved. The liquefaction of air at one operation by Linde and Hampson is indeed a great feat and a triumph for the principle of regeneration. But it must not be overlooked that to allow the air to expand without doing work, or rather to allow the work of expansion to appear as heat at the very place where the utmost cooling is desired, is very bad thermodynamics. The work of expansion should not be dissipated within, but be conducted to the exterior.

I understand that attempts to expand the air under a piston in a cylinder have led to practical difficulties connected with the low temperature. But surely a turbine of some sort might be made to work. This would occupy little space, and even if of low efficiency, would still allow a considerable fraction of the work of expansion to be conveyed away. The worst turbine would be better than none, and would probably allow the pressures to be reduced. It should be understood that the object is not so much to save the work, as to obviate the very prejudicial heating arising from its dissipation in the coldest part of the apparatus. It seems to me that the future may bring great developments in this direction, and that it may thus be possible to liquefy even hydrogen at one operation. RAYLEIGH.

Terling Place, Witham, June 26.

Liquid Hydrogen.

I OBSERVE with some amusement that you still allow Mr. Hampson to embellish your columns with vain repetitions of accusations which he was compelled to withdraw when he met me face to face at the meeting of the Society of Chemical Industry.

It is idle to discuss any question with a man whose notion of argument is to restate in somewhat different language what has already been refuted, and then to assert that the accuracy of his propositions has not been questioned.

Mr. Hampson must be a singularly dull person if he fails to appreciate the magnitude of the draft he makes upon the credulity of the world. He asks men of the world to believe that he, being convinced of the general dishonesty of Royal Institution methods, and being in possession of a novel and valuable invention, fully completed but not protected by patent, came unbidden and unsought to reveal all the details to a man whom he knew to be my assistant.

He further expects the world to believe that having thus given himself away, he refrained from protecting his invention until the rival inventor had had ample time to profit by his childlike simplicity. But even this is not all; for the world is further asked to believe that after he had placed the Royal Institution in possession of full information concerning a finished invention, it took me more than a year to utilise his generosity, while in the interval Dr. Linde had published his method and apparatus. Does not all this amount to rather a large order?

But perhaps no one can answer Mr. Hampson so well as Mr. Hampson himself. At the meeting of the Society of Chemical Industry on May 2, Mr. Hampson expressed himself as follows (*The Journal of the Society of Chemical Industry*, No. 5, vol. xvii. p. 421):—"Prof. Dewar will do me the justice to say that I have nowhere published any statement that he had made use of anything I had communicated, or of what I had invented. I have, therefore, nothing to withdraw, since I have nowhere suggested that a communication had been passed on to him. . . . I am not to be understood as saying that my proposal was passed on to Prof. Dewar."

What is Mr. Hampson to be understood as saying in the letters you have published, if not the precise contrary of what he said when brought to book at the Society of Chemical Industry?

How otherwise is the "credit of science" involved?

It is worth noting that in March 1896, a year and a half after the famous interview with Mr. Lennox, Mr. Hampson threatened Messrs. Lennox, Reynolds, and Fyfe with legal proceedings on the ground that a lecture apparatus made for my Chemical Society paper of 1895, and subsequently advertised by them in NATURE, was an infringement of his patent. They replied that he might take any action he pleased. He has never taken any.

Mr. Hampson's extract from my speech at the Society of Arts, reported in the *Journal* for March 11, 1898, is so completely isolated from the context as to convey a totally wrong impression. When Mr. Hampson made it, he had before him my statement that "although this regeneration system had been carried by Dr. Linde to the acme of perfection, no one who constructed low temperature apparatus rejected the cool gas without utilising it; the great advance was that Dr. Linde did so completely."

If all that Mr. Hampson wants is "recognition in historical or explanatory works" of his claim to be the inventor of a general claim to intensive refrigeration, he will find Solvay, Dr. Linde, and Prof. Onnes obstacles quite as serious as myself. Further, this attempt to justify going behind my back in his relations with a member of the staff of the Royal Institution, is a too transparent subterfuge to require further comment.

JAMES DEWAR.

The Spectrum of Metargon?

IN the account given by Prof. Ramsay of his researches on the "Companions of Argon," he has omitted to draw attention to a very curious similarity between the spectrum of his new gas "metargon" and the ordinary spectrum of carbon, with which every student of spectrum analysis is familiar.

The following comparison of wave-lengths will make the similarity apparent.

		Ramsay's metargon.	Carbon (Angström and Thalén).
Citron band	1	5632·5	5633·0
	2	5583·0	5583·0
	3	5537·0	5538·0
Green band	1	5163·0	5164·0
	2	5126·5	5128·0
Blue band	1	4733·5	4736·0
	2	4711·5	4714·5
Indigo band		4314·5	4311·0

There are three of Ramsay's bands not included in this list, but these are nearly coincident with known bands in the cyanogen spectrum.

It seems hardly credible that Prof. Ramsay has not guarded against the possibility that all these bands may be due to carbon, and not to a new gas; but some explanation seems required, for though the coincidences in the two sets of bands is not complete, there is no case known in which two different elements have spectra so nearly alike as those of carbon and metargon seem to be. ARTHUR SCHUSTER.

Anatomy of the Swallows.

MY friend Dr. R. Bowdler Sharpe, of the British Museum, has favoured me with a copy of his recent and very useful memoir upon the swallows (*Hirundinidæ*), and we find the group treated under the several heads of (1) an introduction; (2) geographical distribution; and (3) the literature of the Subject. In the last, the author of this contribution has evidently intended to present a very complete list of the titles of works that have been written about swallows, extending between the years 1731 to 1894 inclusive; while in the introduction he makes the statement that "The Swallows appear to us to be such a well-marked and isolated Family of Passeres, that, in the absence of any detailed account of their anatomy and general structure, which, so far as we know, has not been attempted, there remains little for us to say." As one, perhaps, who has had occasion to keep a little better track of the literature of hirundine morphology, permit me to invite the attention of this distinguished systematist to a memoir published by me in the *Journal* of the Linnean Society of London for 1889 (vol. xx. pp. 299–394, with 39 lithographic figures); he will find in it, under the title of "Anatomy of the North-American Hirundinidæ," not only a complete account of the pterylography of every species of swallow in the United States, but myological descriptions of the same; with references to their visceral anatomy; and an entire chapter devoted to the osteology of all the United States genera. Not only this, but on the plates, illustrating the same memoir, Dr. Sharpe will find very accurate figures of the skulls (nat. size) of *Progne subis*, *Chelidon erythrogaster* and *Tachycineta thalassina*—all important forms of swallows, of which the "anatomy and general structure" are very well known. In that paper he will also see that I have attempted to compare the anatomy of all our swallows, with the structure of the American swifts, and with *Ampelis*, and a great many other birds. This paper of over one hundred pages, and numerous plates, is not found in Dr. Sharpe's works upon the life-history and structure of swallows find no place "Literature" of the *Hirundinidæ*. Numerous other important works upon the life-history and structure of swallows find no place in Dr. Sharpe's bibliography of this group. In this connection, then, it may be said that our author distinguishes but *twelve genera* of swallows in the world's avifauna, and of these I have carefully compared, illustrated and published full accounts of the anatomy of no less than *six* genera, or in other words fifty per cent. of those known at present to science. And, as *Stelgidopteryx* was included among these, I very much question that any very marked anatomical differences will be found to exist among the unexamined types.

Further, as has been the case with not a few other anatomists, I have treated the subject of the systematic position of the swallows in numerous places, but more particularly in my "Contributions to the Comparative Osteology of the Families of North American Passeres," in which the skeletons of all the passerine birds in the United States were, in a comparative way, passed in review, the swallows with the rest. This is another formal work dealing with the *Hirundinidæ*, overlooked by our bibliographer of this family of birds. R. W. Shufeldt.

2508 University Place, Washington, U.S.A., June 11.

Rotifers in Lake Bassenthwaite.

It may be of some interest to readers of Nature to call attention to the fact that during the warm days of June 16–18, the beautiful Rotifer *Asplanchna priodonta* was to be found in the surface waters of Lake Bassenthwaite, Cumberland, in very great abundance. After dragging a small tow-net through the water from a row-boat for twenty minutes, the water collected in the bottle attached to the end of the net was perfectly turbid with the multitude of these animals, interfering very materially with the observation of the other constituents of the plankton. Observations taken by Mr. Ashworth in different parts of the lake in the early morning, mid-day and the evening, proved that they were not present merely in a localised cloud, but distributed in immense numbers all over the lake, from the surface to a depth of ten feet or more.

The observation is of interest, as the "Lakes" are not given in the great work on Rotifers, by Hudson and Gosse, as a locality for this genus, nor is there mention made of its occurrence in such great numbers. Perhaps some of your readers may be able to inform me if this phenomenon has previously been recorded in England. Sydney J. Hickson.

The Owens College, Manchester.

Lion-Tiger Hybrid.

Some of the readers of Nature who have the opportunity of visiting the exhibition at Earl's Court may be interested to know that one of the members of the "Happy Family" now on show there is evidently a hybrid between a lion and a tiger. The animal appears to be about two years old. By artificial light the ground colour closely resembles that of a lion, being tawny rather than reddish yellow; but the tiger-stripes, though faint, are quite visible, especially on the tail. Such stripes might perhaps be mistaken for unusually strong cub-markings of the lion retained for an unusual length of time. But apart from the stripes, the tiger-strain comes out strongly in the blackness of the corners of the mouth, the hairs of the lips in this place being jet black in the tiger, white in the lion. R. I. Pocock.

Natural History Museum, June 22.

Transference of Heat in Cooled Metal.

J'ai l'honneur de vous envoyer pour votre si intérressant journal, une remarque qui pourra intéresser peut-être quelques lecteurs de Nature.

Il s'agit d'un phénomène certainement bien connu et qui n'a peut-être pas attiré l'attention des physiciens, comme il semble le mériter. Prenons dans la main l'extremité d'une barre de métal et chauffons l'autre extrémité aussi fortement que possible, mais pourtant de manière à pouvoir tenir la barre sans se brûler par la première extrémité. Cela étant, refroidissons brusquement l'extremité chauffée, soit en la plongeant dans l'eau, soit au moyen d'un jet d'eau. *Nous constatons alors que la température de la partie non chauffée monte et que nous sommes obligés de lâcher la barre, si nous ne voulons pas nous brûler.* C'est ce que savent très bien, tous ceux qui ont travaillé à la forge ou qui ont fait des soudures de petites pièces métalliques tenues à la main. Les ouvriers disent que la chaleur est *repoussée* par le froid vers la partie non chauffée. Le phénomène a-t-il été étudié scientifiquement et connait-on sa cause? Henry Bourget.

Astronome adjoint à l'observatoire de Toulouse, juin 14.

Parker and Haswell's "Text-book of Zoology."

In reply to Prof. Ray Lankester's references to me in his review of Parker and Haswell's "Text-book of Zoology" in this journal for May 12th, I should like to state as follows:—(1) That I had nothing to do with correcting the "final revise" of this book. (2) That the new English edition of Prof. Wiedersheim's "Comparative Anatomy of Vertebrates" is not a translation, but an "adaptation." (3) That the assertion with regard to the ossification of parts of the skeleton in Elasmobranchs in the latter work is not the same as that to which Prof. Lankester objects in the "Zoology," whether the latter be right or wrong. (4) That Götte in 1878 distinctly stated that true bone is undeniably present in the vertebral centra of several Elasmobranchs the histology of which he describes, and that all kinds of intermediate stages between calcified cartilage and true bone occur in these centra. (5) That in the fourth edition of Marshall and Hurst's "Practical Zoology" true bone is said to occur in the centra of *Scyllium*, and that this statement does not appear in previous editions of the book. (6) That in the fourth German edition of Wiedersheim's "Grundriss der vergleichenden Anatomie," which was published a week or two ago, the centra of Elasmobranchs are described as being "kalkknorpelige resp. knöcherne." W. N. Parker.

SOME RESULTS OF MY RESEARCHES ON OCEANOGRAPHY.

By Albert, Prince of Monaco.

The devotion that has been quite lately given to the new science called "oceanography," has decided me to dedicate some of the strongest efforts of my life to its advancement. I set about my work in 1885 with a small sailing schooner of 200 tons, the *Hirondelle*, and I explored the Atlantic as far as the coast of Newfoundland, and as deep as 1600 fathoms, without any power greater than the arms of my fourteen sailors. Later on I built a steam vessel of 560 tons, better fitted for such rough work; this was the first *Princess Alice.* Now I

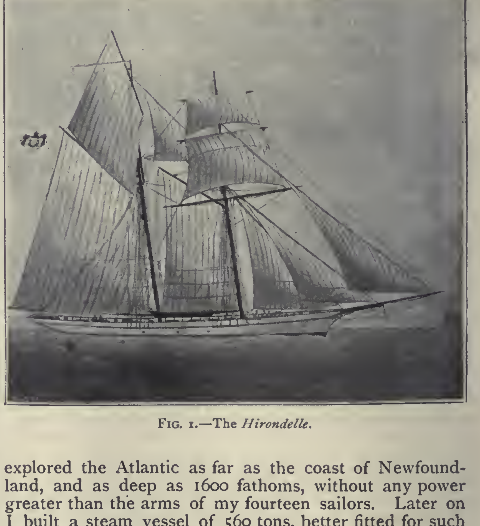

Fig. 1.—The *Hirondelle.*

have just built another one still more powerful, of 1400 tons, also called *Princess Alice*. Thus the love of science, and the successful combat of the difficulties met with in its employment in researches at sea, enlarges constantly the horizon and demands more powerful means.

I began by trying to find out experimentally how the currents moved on the surface of the Atlantic, and for this purpose I dropped, in three different cruises, 1675 floats between Europe and North America. These floats were mostly a strong glass bottle protected by a sheet of brass, ballasted so as to keep just at the level of the surface, and containing a document written in several languages to invite the finders to return it with particulars as to place and date.

Out of these, 226 had been returned to me up to the year 1892, when I drew, by working scientifically the course that each of them had probably been following, a definite map of the currents. And I may add that this result is certainly very near the truth in its general lines, because the elements employed have always been numerous for each region.

Fig. 2.—The second *Princess Alice*.

The floats have landed on almost all the shores of the North Atlantic, from the North Cape to the south of Morocco, along Central America, and on the islands of Canaries, Madeira, Azores, Antilles, Bermudas, Shetlands, Hebrides, Orkneys and Iceland. Not one has appeared as far south as the Cape Verd islands.

They show an immense vortex which begins towards the Antilles and Central America with the Gulf Stream, which issues from the Gulf of Mexico, and with the equatorial current; passing the banks of Newfoundland at a tangent, it turns to the east, approaches the European coasts, and runs southward from the Channel to Gibraltar, after having sent a branch which runs along the coast of Ireland and the coast of Norway as far as the North Cape.

It then returns to the west, encircling the Canaries. Its centre oscillates somewhere to the south-west of the Azores.

My observations enabled me also to establish a very good average for the speed at which these floats have been travelling in the different sections of the vortex, and for every twenty-four hours.

Between the Azores, France, Portugal and the Canaries: 5·18 miles.

From the Canaries to the Antilles, the Bahamas, and as far as the Bermudas: 10·11 miles.

From the Bermudas to the Azores: 6·42 miles.

The mean speed for the North Atlantic is 4·48 miles. These values being under rather than over the truth.

When I began to work on the bottom of the sea to study animal life, as constant sounding is required for that purpose, I found that most of the sounding machines in use were defective, and I had one constructed according to my own ideas. It is completely automatic in all the details of its action, so as to allow a single man to take a sounding at any depth; the line that I have used for four years is no longer a steel wire, but a steel cable made up of many very thin wires; it is, therefore, stronger and more pliable. It is paid out at the required speed, hauled up again, dried, greased, and regularly rolled up on a drum by an automatic guide. The brake is a powerful spring.

Among the observations for which this machine is wanted, I will mention those concerning the temperature of the water at different levels. I am using, to obtain them, a thermometer designed for my cruises by Mr. Chabaud, a French instrument maker. It is very much like Negretti and Zambra's pattern, but the part of the tube containing the mercury reservoir is recurved so as to prevent the mass of this metal forcing itself by its own weight through the constricted angle which serves to break the column; and such an accident used to happen now and then.

When I went into the study of the density of the water, I found that Buchanan's bottle was the best for collecting samples of the stratum nearest to the bottom. But to obtain samples at any intermediate depth, Dr. Jules Richard, chief of my laboratory, has designed a thoroughly trustworthy instrument with which we have been able to study the gases contained in these samples, and to demonstrate that they are not dissolved in the depths at any other pressure than they are at the surface. This instrument can be shortly described by saying that it is a bottle filled with mercury, and inverted with its neck dipping into a dish also full of mercury. In this position it is sent along a steel cable as far as the required depth, where it meets a platform, and where a mechanical action raises the neck of the bottle over the mercury of the dish. The mercury of the bottle then runs out into the dish, and water takes its place. Soon after this, a messenger sent from the ship reaches the instrument, and acts so as to dip again the neck of the bottle into the dish containing the whole of the mercury. In this last position the instrument can be hauled up without any risk of the sample of water being mixed with outside water; and if there was any gas dissolved in it at a high pressure (which was not the case in my observations), it would gather on the surface of the sample, as this pressure would diminish as the instrument came nearer to the surface of the sea. This research led Dr. Richard to announce in 1895 the presence of argon in the swimming bladder of certain fishes.

Very soon after this, I had the satisfaction of presenting the French Academy of Science with very interesting observations made by M. Knudsen during the cruises of the Danish steamer *Ingolf*. This investigator proved by analyses of samples of water made *in situ* that predominance of animal or vegetable life in any part of the sea causes the variations in the amount of contained oxygen or carbonic acid.

One of the most difficult questions to investigate is the penetration of light in the depth. Photographic plates turned towards the heavens have been exposed by Hermann Fol, and impressed as deep as about 200 fathoms. I have myself used, as far as about 90 feet, an instrument invented by Dr. Regnard for my experiments; it is a cylindrical box with a narrow slit in the direction of its length. Inside is a sensitive paper, which is made to pass slowly under the slit by means of clockwork, capable of running for twenty-four hours. If there is any light falling on it, it is shown on the paper when developed, and with the increasing or the decreasing power before or after noon. But by this method one obtains no absolute information, as some more sensitive matter may be discovered any day.

FIG. 3.—*Photostomias Guernei.*

Indeed, light exists everywhere in the depths: where the rays of the sun do not reach themselves, numbers of animals furnish it by special phosphorescent organs which are real accumulators of light. Besides, I have found animals with perfect eyes at every depth; and science teaches us that an organ always atrophies or disappears when the conditions are such as to prevent its use.

Among the special circumstances created by the statical and dynamical conditions of this space, organic life presents itself under aspects which appear strange to those who are accustomed to its appearance near the surface. I endeavoured to obtain from all the levels of the sea as many samples of the species belonging to them as it was possible, but I had to find other apparatus than the old trawl used for the former scientific cruises, which can only get animals fixed on the bottom of the sea, or hiding in the mud, or possessing very slow means of progressing. Of course I have used it a great deal, because no other instrument can collect for us a certain fauna; but when it occurred to me that there must be in the deep waters some nimble animals able to escape such a net as a trawl, I first built a trap of a special shape and very large, in order to attract these supposed animals, when properly baited. The trap is lowered to the bottom with a steel cable, and hauled up again after having been left there for a day or two attached to a buoy.

The handling of this was very difficult in the beginning, and required several years' practice to be brought up to positive rules, but it has given most brilliant results, animals quite unknown coming into my hands perfectly well preserved against shocks, frictions and other causes of damage to which they would be liable in a trawl.

One interesting fact they have shown is the enormous numbers in which some animals exist in certain places. As an example, I obtained one day in a trap that had been lying on the bottom at 700 fathoms depth for twenty-four hours, 1198 fish called *Simenchelys parasiticus*, which was only known by one or two samples in a more or less imperfect state. I have succeeded in sending these traps as low as three thousand fathoms with complete success.

On another occasion my trap brought up a new crab,

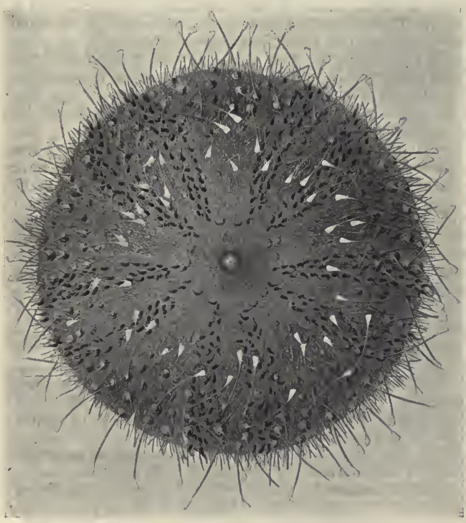

FIG. 4.—*Sperosoma Grimaldii.*

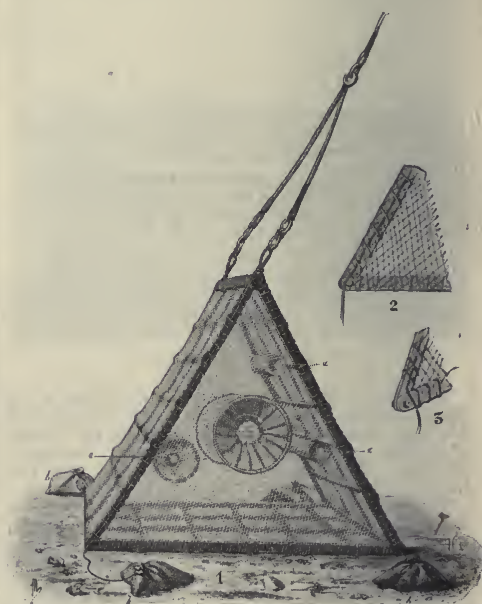

FIG. 5.—Deep-sea trap.

one of the largest ever known, *Geryon affinis*, and there were sixty-four specimens of it. Curiously enough, several of them, which had not yet found the entrance of the trap when it was hauled up, made the whole voyage of many hundreds of fathoms, clinging voluntarily to the outside of the trap.

Another time, again (and this was of a special interest because the event took place in the great depths of the Mediterranean, where previous investigations with trawls had led to the supposition that life was almost absent), a trap returned with over eighty sharks called *Centrophorus squamosus*.

For two years I have been trying to use in great depths a net which is very good when used on inshore fishing grounds. This is the trammel; but its use has proved to be exceedingly difficult because of its frailty and its size. Still, I have already obtained with it results which prove how useful it can be. I worked it as low as 1500 fathoms.

The most difficult regions to explore in the sea are the intermediate depths between the surface and the bottom, because the animals living there are very active and very suspicious, and have ample space where they can escape easily, and where they find abundant prey for their food. Besides, the apparatus used must be built in such a manner that they show at what level animals have been caught, or else the scientific conclusion can not be made complete; therefore such an apparatus must be so as to be lowered shut to the determined region, there open and work, and lastly shut again before leaving the region.

Many instruments have been devised for this purpose, but I know only one of them offering complete safety; this is a net invented by Prof. Giesbrecht, which has been slightly altered by Dr. Richard and myself. But it would be difficult to make it of a large size; therefore we get only specimens of very small species.

Lately I have obtained a certain number of large animals living in those intermediate depths and belonging to the very interesting group of cephalopods, by examining the stomach of several cetaceans who feed upon them. Since this interesting fact, I added to the scientific gear of my vessel a complete whaling arrangement. This new method has given me the most remarkable animals of my whole collection; one especially, the *Lepidoteuthis Grimaldii*, can be classified in no actually known species, genus, or even family of his order. It was vomited in 1895 during the dying struggles of a sperm whale, but had unfortunately lost its head by the last adventures of its life. The fragment is about one yard in length, and the complete animal must have measured over seven feet; adding the arms, we get a monster of colossal strength. Its most remarkable feature is a cuirass of large prominent scales which cover its visceral bag; these are quite unknown with animals of that order.

The vomitings of the same sperm whale, who covered two acres of the sea with his blood, contained another immense cephalopod, a Cucioteuthis with arms as strong as a man's, and carrying suckers armed with claws as powerful as those of a tiger; this animal is furnished with luminous organs.

In 1897 another large cetacean, that I was attacking with my whale boats, vomited a large fragment of a cephalopod which was peculiar in being of viscid substance not unlike glycerine; no net could retain it, and we only secured it by "dipping" it up with a large tub as well as the mass of water in which it was floating.

But it will be convenient to remind the reader that cetaceans divide themselves into two principal groups. One, to which belongs the right whale or other marine mammals chased by whalers, and who feed upon very small animals that they absorb simply by moving about with their mouths open. They have no teeth, but a sort of sieve made of what is called whale bone.

Another group, to which belongs the sperm whale, is armed with powerful teeth, a single one weighing sometimes as much as six pounds. They live upon big preys, mostly cephalopods, as aforesaid. These cetaceans are ferocious, while the others have a much milder temper, and some of them, as the *Orca Gladiator*, can be very dangerous to attack. Two years ago I chased a school of three of these, just off the Monaco rock, and very soon one was struck by my whaler's harpoon. While it was ending with violent struggles, the two others came alongside the whale boat and seemed willing to fight for their companion. They swam round and round, sometimes so close that the men touched their enormous backs with their hands. I had to release at once that boat, and for an hour we were (seventeen men and three boats) engaged in a most grand wrestling. The result was that a second orque was killed by a spear stroke.

On the previous day we had caught a grampus, also a cetacean; so we returned to the harbour of Monaco with three of these monsters captured within fifteen miles of that place.

The orques are black and white, much like a magpie, and these were 16 and 18 feet long. They seem to feed exclusively on porpoises. My two, when opened, contained each of them a dozen pieces of porpoise in its stomach like heaps of paving-stones: they had just taken a meal when they were struck.

Tail. Lower jaw. Head.

FIG. 6.—Sperm whale being broken up.

Among many remarkable facts that I have observed during my studies of the ocean, one has especially called my attention because of its practical consequences; that is, the intensity of life appearing on the surface at certain hours.

Almost in every region of the North Atlantic where I have carried on my investigations, I have ascertained the existence of large tunny fishes which morning and evening chase smaller fishes whose shoals cover sometimes the sea on such a large area that we sail or steam hours and hours across them.

Then, if we sight some wreckage—as a log or a barrel—we always find under it or near it fishes of a good size and of different species that never seem to abandon this guide that they have chosen, and that takes them across the Atlantic. They are very easily caught with a fish spear, and the tunny fish are hooked with a tow-line baited with a rough imitation of a squid.

I once speared in that way fifty fishes weighing 300 pounds altogether, which were following a log on the Atlantic; and their number seemed not to have been much lessened by such a breach. Another day, while I was alongside a log, very anxious to make a good bag, because I had just picked up the crew of an English vessel, the *Blue and White*, sunk under my eyes, and we were already short of provisions, I was disturbed in this occupation by a large shark, who was himself living about the log, and who, after having looked at me with his cruel eyes, stuck himself under my dinghy. His head and his tail projected beyond the ends of this boat, and the friction of his back against the keel gave a rather uncomfortable feeling. Therefore, after I had made a few catches of the usual fishes, which gave him some excitement, I left the log and returned on board, escorted for some distance by the disagreeable wanderer.

On the other hand, we have on many occasions caught dozens of tunny fishes in a day by simply using the aforesaid tow-line.

Thus I can state that many sailors wrecked on the Atlantic, and abandoned for days and weeks on its apparently uninhabited wilderness, have died of hunger among a most abundant and attainable food, and that they could have been saved had they simply known it, and possessed the very simple gear required. Therefore I think that all the principal boats of a ship ought to be permanently provided with a few lines and hooks and with a fish spear.

There is no very obvious explanation of the fascination which any floating or drifting object seems to have for marine animals of various sorts. Even turtles, which are very stupid, and sperm whales or other cetaceans, which seem intelligent, are attracted by a buoy or by a ship, and any kind of apparatus brought up from the depth, even a cable end, is often accompanied by single fish or small companies, which get hopelessly bewildered when the object disappears out of the water.

REPRODUCTION BY PHOTOGRAPHIC PROCESSES.

IT is not difficult to understand the survival and general adoption of those photographic methods in which the light, by shining upon the sensitive surface, produces shading or blackness. Although the first product, as obtained in the camera, by such a process is itself useless as a photograph, the lights and shades being reversed; this "negative," as it is termed, becomes a means of reproduction, as by laying the negative over a sensitive surface more or less similar to that first used, and allowing the light to shine through it, any required number of prints or copies in true light and shade may be obtained. Such a process is necessarily slow, as in working upon this system the production of each individual print or photograph involves an exposure to light, and the rapidity of reproduction is limited by the chemical intensity of that light which is available, and also by the sensitiveness of the material used.

Another system of reproduction, and one which is month by month becoming of greater industrial importance, evades the necessity of a special exposure to light for obtaining each individual print or copy, this being effected by the production of a printing surface or plate from which copies may be printed by mechanical means. Prints obtained by a special exposure to light for each copy are often called solar prints, or true photographs, while those prints which are printed mechanically from a plate or surface which itself is photographically produced, are now so generally called process prints, that the title of "The Process Year-Book"[1] is by no means ambiguous in its meaning to those who are current with the technological phraseology of the day. "The Process Year-Book" well represents the present state of process craft, not only by giving numerous representative illustrations, but by articles from the leading authorities in such matters. The articles are, however—as should be in a work of this kind—written rather for the expert than for the comparative outsider, and we shall give our readers a better general idea of the development and present condition of reproduction by the photo-mechanical processes if we drift away from our text, than if we confine our remarks to the matter before us in Mr. Gamble's volume.

It is interesting to note that the early experiments of Nicéphore Niepce, which were commenced as far back as 1813, were undertaken with the view of obtaining printing surfaces by photographic agency, so the history of photographic process work includes the first chapter in photographic history. Niepce coated lithographic stones or metal plates with a varnish the solid material of which tends to become insoluble in its menstruum where exposed to light. There are many such varnishes, and as an example we may mention a solution of bitumen in a volatile oil like that of turpentine. Those portions of the film which are still soluble after exposure are next dissolved away, while the insoluble portions form a ground, or resist against the etching fluid, which is next used. A heliographic etching on metal by Niepce, made about 1824, is still extant, and in 1827 he brought several specimens to England; but very little attention was given to photographic matters until, in 1839, the daguerreotype was introduced with its perfect rendering of the most delicate degrees of light and shade, and this by a very short exposure in the camera.

Considering that the daguerreotype image is of the nature of a deposit on a smooth metal surface, the idea of moulding by the electrotype process so as to produce an intaglio printing plate, naturally presented itself; as also that of etching the metal, in the hope that the image on the surface might serve as a local resist. Grove, Chevalier, Claudet and others made experiments with the view of obtaining printing plates from the daguerreotype by such methods, but most etchings were wholly unsatisfactory; and although the electrotype casts of the plate were perfect as reproducing in intaglio every tone of the original, the plate had neither that grain nor that depth which are essential to the satisfactory printing of a photo-engraved plate.

Mr. Fox Talbot, whose Calotype or Talbotype process on paper was made public practically at the same time as the daguerreotype, was one of the first to produce satisfactory intaglio printing plates, and his method is specially interesting as being the basis of that process of intaglio photogravure which is most in use at the present time. Talbot coated the metal plate with a wash or film of gelatine made sensitive to light by the addition of bichromate of potassium, and he exposed under a transparent positive. Where the light acted to the full, the gelatine became impervious to aqueous fluids; but where protected from the light, the film allowed such fluids to pass readily, and between these extremes were all degrees of intermediate resistance to the passage of the aqueous etching fluid. Talbot used such saline etching materials as platinic chloride or ferric chloride, and from time to time he suggested and used various methods of producing an ink-holding grain, such as a resinous dust, a network, or a kind of aqua-tint ground formed by the evaporation of a solution of camphor and common resin in chloroform. The chief present-day method of photogravure is Herr Klic's modification of the Talbot method, the chief differ-

[1] "The Process Year-Book, a Review of the Graphic Arts." Conducted by William Gamble. (London and Paris: Penrose and Co.)

ence being that the film of chromated gelatine, hardened by the action of light, which forms a resist to the etching fluid, is transferred to the metal plate after being exposed; a proceeding which affords one very important advantage. The gelatine, which remains soluble or unaffected by light, can under these circumstances be washed away by warm water, leaving on the metal plate a resist of graduated thickness. The frontispiece of "The Process Year-Book" for last year is a very fine example of photogravure by the Talbot-Klic process, the work of Mr. Horace Wilmer; a specimen interesting as showing that, in process work, the amateur may stand fully level with the professional. The frontispiece of the current issue (1898) is a good specimen of similar work by Dr. E. Albert of Munich.

Printing by hand from the intaglio plate is a very slow process, especially in the case of the finer class of work; and although we gather from "The Process Year-Book" that very much progress has recently been made in the rapid printing of intaglio plates by machine, the chief or general aim of the process-worker now-a-days is the rapid production of plates or blocks which can be set up with a forme of type, and printed together with the type and without any complication of the method of printing.

Methods of making such photo-typographic blocks are very numerous, but according to that system of working which is now most general, the first and most delicate task is to obtain a negative in which the degrees of transparency are rendered by the increasing size of minute windows ranged in regular order all over the subject; but where the negative is most opaque the size of each of these windows may be reduced to *nil*, and where the negative is most transparent the windows may run into each other and give an area of virtually clear glass. Such a negative is obtained if a glass plate or screen, closely ruled with opaque cross-lines, is set in the camera a little way in front of the sensitive plate, each window in the screen forming a pin-hole image of the aperture of the lens. The question of the best use of the ruled screen and the most suitable kind of ruling is a very complex one, as evidenced by several very recondite articles in "The Process Year-Book." The screen-negative having been obtained, an impression is made on a metal plate coated with a sensitive resist, which sensitive resist may be bitumen, sensitive albumen, or, more often in practice, the highly soluble and almost gum-like gelatine sold as fish glue. Each window of the screen negative makes an insoluble spot of corresponding size on the sensitive film, after which the soluble portions of the film are dissolved away, and the insoluble spots of graduated size form the resist in the next stage: etching the plate. When sufficiently etched, the plate is ready for being printed from, and it naturally gives an impression in which each window of the screen-negative is rendered by a dot of printing ink of corresponding size.

There are many other methods of photographic process reproduction in use, and still more methods which have been worked out experimentally but have not yet obtained any commercial status. As regards the application of three-colour heliochromy to process work, we need say no more than to remark that any method of process reproduction may be applied to the formation of the triad of printing surfaces from which it is necessary to print in true register with appropriate pigments; and the question of the successful application of heliochromy to process work depends rather on the colour-sensitising of the negative films, the use of appropriate colour-screens and of suitable printing pigments, than on the purely process side of the work. Those wishing to learn more, or to see representative examples of results, cannot do better than to obtain "The Process Year-Book."

T. BOLAS.

THE FORTHCOMING MEETING OF THE BRITISH ASSOCIATION.

THE following epitome of the programme of the forthcoming Bristol meeting of the British Association has been prepared by the Local Secretaries. We have already given a provisional list of the excursions, and shall supply our readers with further details as soon as the routes are finally settled and the arrangements complete.

Tuesday, September 6.—The Cabot Tower, on Brandon Hill, will be opened at 3 p.m. by the Marquess of Dufferin and Ava, K.P., G.C.B.

Wednesday, September 7.—Drill Hall Exhibition opened at 3 p.m., by the Marquess of Dufferin and Ava, K.P., G.C.B. Address by the President, Sir William Crookes, F.R.S., in the Colston Hall, at 8 p.m.

Thursday, September 8.—The Biological Exhibition at the Zoological Gardens, Clifton, will be opened at 3 p.m. by Sir John Lubbock, Bart., M.P. Garden party given by Mr. and Mrs. W. M. Roscoe, at Crete Hill, Westbury-on-Trym, 3.30 to 6 p.m. (200). Garden party, given by Mr. E. P. Wills and Miss Wills, at Hazlewood, Sneyd Park, 3.30 to 6 p.m. (200). Conversazione, at Clifton College, given by the Chairman of the Council (the Lord Bishop of Hereford), the Head Master and Mrs. Glazebrook, 8.30 to 11.30 p.m.

Friday, September 9.—Garden party, given by Mr. and Mrs. Frank Jolly, at Rockwell, Henbury, 3.30 to 6 p.m. (100). Garden party, given by Mr. Lewis Fry, M.P., and Miss Fry, at Goldney House, Clifton, 3.30 to 6 p.m. (300). Garden party, given by Mr. J. Colthurst Godwin and Miss Godwin, at Ellenthorpe, Stoke Bishop, 3.30 to 6 p.m. (200). Lecture by Prof. W. J. Sollas, F.R.S., on "Funafuti: the Study of a Coral Island," in the Colston Hall, at 8 p.m. "Symposium," in honour of the President, Sir William Crookes, F.R.S., at the Merchant Venturers' Technical College, at 10 p.m. (limited to 250).

Saturday, September 10.—Excursions. Lecture to working men, by Prof. E. B. Poulton, F.R.S., "The Ways in which Animals Warn their Enemies and Signal to their Friends," in the hall of the Young Men's Christian Association, at 8 p.m. Public banquet, arranged by the President and members of the Bristol Chamber of Commerce, at the Colston Hall.

Sunday, September 11.—Special sermons by the Lord Bishop of the Diocese (Cathedral, 11 a.m.), Prof. Bonney (Redcliffe Church, 6.30 p.m.), and Rev. D. Richards, 11 a.m., and Rev. John Gerard, S.J., 6 p.m. (Pro-Cathedral, Park Place, Clifton). The band of the Royal Artillery (mounted) will perform a selection of music at the Drill Hall, at 3 p.m.

Monday, September 12.—Garden party, given by the headmaster and assistant masters of Clifton College, 3.30 to 6 p.m. Lecture by Mr. Herbert Jackson, on "Phosphorescence," in the Colston Hall, at 8 p.m.

Tuesday, September 13.—Garden party, given by Mr. and Mrs. Edward Robinson, at The Towers, Sneyd Park, 3.30 to 6 p.m. (200). Garden party, given by Mr. and Mrs. G. A. Wills, at Burwalls, Leigh Woods, 3.30 to 6 p.m. (200). Conversazione at the Colston Hall, given by the Local Committee, 8.30 to 11.30 p.m.

Wednesday, September 14.—Concluding general meeting, in the Lecture Theatre, Bristol Museum, at 2.30 p.m. Garden party, given by Mr. and Mrs. Herbert Ashman, at Cook's Folly, Sneyd Park, 3.30 to 6 p.m. (200).

Thursday, September 15.—Excursions.

Friday, September 16 to 20.—Excursion through Devonshire, extending over five days. Exeter, Torquay, Dartmouth and Plymouth have taken up the matter very warmly, and kindly offers of hospitable entertainment have been received from them.

The Committees of the leading Clubs in Bristol and Clifton have consented to grant the privilege of honorary membership to visiting members of the Association during the meeting.

NOTES.

THE centenary of the Paris Conservatoire des Arts et Métiers was celebrated on Friday last. The Priory of Saint-Martin-des-Champs, where the collections of the Conservatoire are installed, contains fourteen thousand exhibits. Seventeen professors hold evening classes in the building, and there are eight laboratories, one of photography and photometry being a recent addition. The Academy of Sciences has on several occasions presented objects of scientific interest to the museum of the Conservatoire, among them being its collection of machines, physical apparatus, and part of the contents of Lavoisier's laboratory.

THE programme of the fourth International Congress of Zoology, to be held at Cambridge in August, has been issued. The meeting will open on Monday, August 22, with a reception at the Guildhall by the Mayor of Cambridge. On the following day, the formal opening of the Congress and election of officers will take place in the morning, and the Sections will meet in the afternoon. The Sections will be: (*a*) General Zoology; (*b*) Vertebrata; (*c*) Invertebrata (except the Arthropoda); (*d*) Arthropoda. On Wednesday, August 24, there will be a general meeting of the Congress to discuss the position of sponges in the animal kingdom. The discussion will be opened by Prof. Yves Delage, of Paris, and Mr. Minchin, of Oxford. On Thursday a general meeting will be held to discuss the origin of Mammals. The discussion will be opened by Prof. H. F. Osborn, of New York, and Prof. Seeley, of London. The Sections will meet on Friday, August 26, and on Saturday a general meeting will be held to settle the time and place of the fifth International Congress.

WE notice with regret the announcements of the deaths of wo distinguished botanists: Prof. Anton Kerner, Ritter von Marilaun, professor of systematic botany in the University of Vienna, and Prof. Ferdinand Cohn, professor of botany in the University of Breslau.

THE tenth Congress of Russian Naturalists and Physicians will be held at Kieff on August 21–30, under the presidency of Prof. J. Rachmaninow.

M. E. A. MARTEL, whose researches in underground caverns have often been referred to in these columns, has been created a Chevalier of the Legion of Honour.

AT the annual general meeting of the Royal Statistical Society, held on Tuesday, it was announced that the subject of the essays for the Howard medal, which will be awarded in 1899, with 20*l.* as heretofore, is "The Sentences on, and Punishments of, Juvenile Offenders in the Chief European Countries and the United States." The essays should be sent in on or before June 30, 1899.

A DESTRUCTIVE earthquake was experienced in some parts of Italy on Monday night. The shock was felt all along the Antrodoco valley, and several buildings were thrown down in the commune of Santa Rufina. The disturbance was felt at Rieti shortly after midnight.

CAPTAIN SVERDRUP'S polar expedition on board the *Fram* left Christiania on Friday morning.

A REUTER telegram from Tromsö reports that Mr. Walter Wellman, the American explorer, left on Monday on board his ice steamer *Frithyof* for the North Polar regions. Just before his departure from England Mr. Wellman gave to Reuter's representative an account of his expedition, in which he said that his aim was to reach the North Pole, and also to explore the still unknown northern parts of Franz Josef Land. The party consists of Prof. James H. Gore, Columbia University, a geodesist; Lieut. Evelyn B. Baldwin, who was on the Greenland ice cap with Lieut. Peary; Dr. Edward Hofma, naturalist and medical officer; and Mr. Quirof Harlan, physicist, from the United States Coast and Geodetic Survey. Norwegians experienced in Arctic work make up the remainder of the party of ten. Mr. Wellman proposes to reach the Pole by a sledging expedition over the pack ice.

THE Geologists' Association have arranged an excursion to Birmingham from July 28 to August 3, under the direction of Prof. C. Lapworth, F.R.S., Prof. W. W. Watts, Mr. W. J. Harrison, and Mr. W. Wickham King. A sketch of the geology of the Birmingham district, with special reference to this excursion, will be given at the meeting of the Association to-morrow, July 1.

MR. WALTER E. ARCHER, Inspector of Salmon Fisheries under the Fishery Board for Scotland, has been appointed Chief Inspector of Fisheries to the Board of Trade, in succession to Mr. A. D. Berrington, who has retired. On Mr. Berrington's retirement, the Fisheries Department and the Harbour Department of the Board of Trade have been combined into one department, which will be called the Fisheries and Harbour Department, and will be under the charge of the Hon. T. H. W. Pelham, as Assistant Secretary.

THE death is announced of Dr. Charles E. Emery, the well-known American engineer. Dr. Emery was a member of the Institution of Civil Engineers, and received a Watt medal and Telford premium for a paper in which he described the plant constructed by him at New York for the house-to-house distribution of steam raised in a central boiler. He was a prominent member of the principal American engineering societies, and was president of the New York Electrical Society in 1896-97. He also held the post of non-resident professor of the Cornell University.

THE Committee appointed to consider the present state of the law with regard to the storage, transport, and sale of petroleum have decided to recommend Parliament to raise the legal flash-point of oil from 73° F. to 100° F. It is believed that comparatively few lamp accidents will occur when the use, as an illuminant, of oil with a flash-point below 100° F. is forbidden; but unless the suggested legislation also provides against the construction and sale of lamps with glass reservoirs and of faulty design, the raising of the flash-point of the oil burned in these lamps will only partly prevent the accidents.

THE annual general meeting of the British Institute of Preventive Medicine was held on Friday, June 24, at Chelsea. The meeting was attended by the Duke of Westminster, Earl of Feversham, Lord Lister, Dr. Pye-Smith, Dr. Thomas Bridgwater, and others. The Report states that during the year the work of the Institute has been marked by progression and expansion. The internal fittings of the new building are in an advanced state, some departments are already in full operation, and it is confidently anticipated that all will be fully equipped in the early autumn. The demand for diphtheria and streptococcus serum has increased, and there has also been an increased demand for mallein and tuberculin. The Institute has rented laboratory accommodation to the Local Government Board for the purpose of preparing glycerinated calf lymph. The volume of *Transactions*, published by Messrs. Macmillan and Co. on behalf of the Institute, contained nine original contributions by members of the staff. A number of fresh investigations have been conducted and completed during the year; some of these are published, and others are on the eve of publication. There are also other investigations in progress, and the laboratories continue to attract research workers. The Institute has endeavoured to encourage the periodical examination of water and water supplies, and several local authorities have requested the Institute to undertake this systematic examination on their behalf. Bacteriological work has also been undertaken for several additional sanitary authorities. In the new building every facility is being provided for the furtherance of bacteriological research. The Institute will require, however, a considerable addition to its funds to enable it to carry out adequately the objects for which it was founded.

THE preliminary programme of the sixteenth Congress of the Sanitary Institute, to be held in Birmingham, from September 27 to October 1, has now been issued. The President of the Congress is Sir Joseph Fayrer, Bart., K.C.S.I., F.R.S. Dr. Christopher Childs will deliver the lecture to the Congress, and Dr. Alex Hill, Master of Downing College and Vice-Chancellor of Cambridge University, will deliver the popular lecture. Excursions to places of interest in connection with sanitation will be arranged for those attending the Congress. A conversazione will be given by the Right Hon. the Lord Mayor (Councillor C. G. Beale), and a garden party, at the Botanical Gardens, Edgbaston, will be given by members of the Sanitary Committee. It appears from the programme that over three hundred authorities, including several County Councils, have already appointed delegates to the Congress, and, as there are also over two thousand members and associates in the Institute, there will probably be a large attendance in addition to the local members of the Congress. In connection with the Congress, a Health Exhibition of apparatus and appliances relating to health and domestic use will be held as a practical illustration of the application and carrying out of the principles and methods discussed at the meetings; which not only serves this purpose, but also an important one in diffusing sanitary knowledge among a large class who do not attend the other meetings of the Congress. The Congress will include three general addresses and lectures. Three Sections will meet for two days each, dealing with (1) Sanitary Science and Preventive Medicine, presided over by Dr. Alfred Hill; (2) Engineering and Architecture, presided over by Mr. W. Henman; (3) Physics, Chemistry, and Biology, Dr. G. Sims Woodhead. There will be five special conferences: Municipal Representatives, presided over by Alderman W. Cook; Medical Officers of Health, presided over by Dr. John C. McVail; Municipal and County Engineers, presided over by Mr. T. de Courcy Meade; Sanitary Inspectors, presided over by Mr. W. W. West; Domestic Hygiene, presided over by Mrs. C. G. Beale (the Lady Mayoress). The local arrangements are in the hands of an influential local Committee, presided over by the Right Hon. the Lord Mayor of Birmingham, with Prof. A. Bostock Hill, Mr. W. Bayley Marshall, and Mr. J. E. Willcox as Honorary Secretaries.

DR. G. VAILATI, writing in the *Bolletino di Storia e Bibliografia Matematica*, has brought to light an obsolete book of Euclid dealing with balances and the principle of the lever. This work has become known through an Arabic translation by Ibn Musa in the National Library at Paris, an account of which was given in 1851 by Woepke in the *Journal Asiatique*, but seems to have been overlooked by mathematicians. Euclid's reasoning is based on the two axioms: (1) that if a loaded lamina balances about a horizontal axis, it will continue to balance when the weights are displaced parallel to the axis; (2) if a lamina balances horizontally about two intersecting axes in its plane, it will also balance about their point of intersection. From these axioms, Euclid deduces a proposition *practically* equivalent to a special case of the theorem that three equal weights placed at the vertices of a triangle will balance about a median. Then by the first axiom a second proposition is proved, virtually amounting to the statement that a single weight on one side of a lever will balance two equal weights on the opposite side if the distance of the first from the fulcrum is equal to the sum of the distances of the second and third. By the superposition of such sets of equilibrating systems, and the removal of pairs of weights symmetrically placed on opposite sides of the fulcrum, Euclid arrives at the conditions of equilibrium on a lever whose arms are in the ratio of two whole numbers by a method closely analogous to that adopted by Archimedes.

DR. ADRIEN GUÉBHARD, of St. Vallier-de-Thiey, sends us a number of papers dealing with the supposed photographic representation of currents emanating from the human body, concerning which much appears to have been said in France a few months ago, when the subject was brought into prominence by the announced discoveries of Dr. Baraduc and the late Dr. Luys. Briefly told, when a slightly fogged photographic plate is developed in a shallow bath, and the experimenter presses his fingers on the plate during the process, streaks are observed to radiate from the parts touched. So far from the effect being due to "animal magnetism," or any of the other occult influences with which spiritualists are wont to deal, Dr. Guébhard shows that the lines are simply caused by convection currents produced by the warmth of the operator's finger. If for the latter there be substituted a small india-rubber ball filled with warm water, exactly the same impressions are produced. Similar results are obtained with a body cooled below the temperature of the developer, and in each case their intensity is greater the greater the difference of temperature. In some of Dr. Guébhard's figures the lines closely resemble the lines of flow due to sources and sinks, or the lines assumed by iron filings in the presence of magnets; as representations of the lines of flow of convection currents, these figures may interest the physicist.

WE have received a copy of the observations made at the Blue Hill Meteorological Observatory, Massachusetts, during the year 1896, forming Part i. vol. xlii. of the *Annals* of the Astronomical Observatory of Harvard College, containing results of observations made at three stations as in former years. The primary station is the observatory on the summit of Great Blue Hill, at an elevation of 640 feet above mean sea-level, and the two secondary stations are situated northwest of it, one being at the base of Blue Hill. In addition to the usual meteorological tables and hourly cloud observations and measurements of heights and velocities recommended by the International Meteorological Committee, the work contains an interesting study of special cloud forms and their relations to cyclones and anticyclones, as well as to other phenomena, by A. E. Sweetland. One of the principal features of the work of the observatory is the exploration of the air by means of kites. A full description of the methods employed is given by S. P. Fergusson, and a valuable discussion of the records by H. H. Clayton. This exploration was begun in August 1894, and is, we believe, the most thorough study of the lower strata of free air ever made, and occasionally very high altitudes are also attained. We are glad to see that the continuance of the useful observations at Blue Hill, now maintained by the liberality of Mr. A. L. Rotch, has been assured by the leasing of the land around the observatory by Harvard College, and that it is expected that the work will ultimately become a part of that carried on directly by that University.

VARIOUS schemes have from time to time been suggested for utilising the power of the tides and waves as a motive force, and ingenious models have been constructed showing the various methods proposed. The plans consist generally either of a system of reservoirs for storing the water at high tide and using it by means of water-wheels or turbines as the tide falls, or else by compressing air in a chamber and making use of its expansion in working an engine. None of these schemes have, however, so far been carried into practical effect. On one or more tidal creeks in this country there have, however, existed water-wheels for grinding corn worked by the tides. Across the creek self-acting doors are placed which open to let the tide flow up, and automatically close as soon as it begins to recede. For several hours each tide there is thus afforded a supply of water with sufficient head to work a water-wheel which turns the machinery. Recently, at Los Angeles, an attempt has been made to make use of the waves. At the end of a pier 350 feet long, three floats were constructed acting on hydraulic air compressors connected with storage tanks holding water situated at different levels. By means of the compressed air the water is driven from a lower into a higher tank, which affords the head required to work a water motor. The waste water from the motor flows back again into the lower tank, to be again raised by the compressor. The varying effect of the waves is compensated by this arrangement of air and water pressure. The experiment is said to have proved sufficiently satisfactory to warrant the extension of the system so as to develop 200 horse-power.

It is seldom that military operations afford much opportunity for scientific research, but the Ashanti expedition of 1896 was fortunately an exception. Upon the recommendation of Kew, Surgeon-Captain H. A. Cummins accompanied the expedition as a member of the medical staff, and he succeeded in bringing back a collection of about two hundred species, including nine which were new, and one new genus. A list of these plants, with their geographical distribution and descriptions of the new species, and notes on the physical and botanical characters of the country traversed by Surgeon-Captain Cummins, appears in the latest issue of the *Kew Bulletin* (Nos. 136–137). The economic products of the region from Cape Coast Castle to the Moinsi Hills, which are 150 miles inland, are numerous. "Plantains are largely grown, and form the principal food of the inhabitants. Indian corn is extensively cultivated and grows freely. Sugar-cane is grown in many of the villages. Pineapples are found all over the country in such a way as to lead persons who have travelled far inland to believe them indigenous. Cola, rubber and gum trees grow plentifully in the forest region, and are reported to be more numerous in the districts around Kumassi." In addition to these plants, there are many trees producing valuable wood in great quantity. The country is unhealthy, but Surgeon-Captain Cummins states that if a railway penetrated the forest zone, establishing a rapid means of communication with the healthy mountainous interior, trade in the vegetable and mineral products of the country could be carried on without the present limitations.

Another interesting article in the *Kew Bulletin* is a brief account of the principal botanical museums in Belgium and Holland, by Mr. J. M. Hillier, assistant in the museums of the Royal Gardens. A noteworthy preservative solution, consisting of alcohol with the addition of two per cent. of hydrochloric acid, was found in use at the University Botanic Garden, Ghent. The object to be preserved is placed in this solution for a few weeks according to discretion, after which it is put into methylated spirit for permanent preservation. In the Commercial Museum at Brussels scientific names are not as a rule attached to the products, but useful details are given on the labels with regard to prices, &c. Mr. Hillier describes Prof. Errera's process for preserving flowers and other objects in their natural colours. "The specimen to be preserved is placed in a conical-shaped paper bag, the narrow diameter resting in the mouth of a glass jar. The bag is carefully filled up with finely sifted sand, after which the jar, together with its contents, is kept at a warm even temperature for two or three weeks, at the expiration of which time the sand is carefully removed and the dried specimen placed in a stoppered jar. The stopper must be hollow and filled with unslaked lime, the latter being kept in position by a thin piece of leather tied over the portion of the stopper which is inserted into the mouth of the jar. The lime absorbs all moisture, and so preserves the specimen from deterioration by damp."

Mr. Frank Finn, Deputy Superintendent of the Indian Museum, contributes a number of interesting notes on natural history to the *Proceedings* of the Asiatic Society of Bengal. Much remains to be done in the observation of living birds, even when these belong to quite common and well-known species. Mr. Finn's notes on peculiarities of attitude, &c., of various birds are, therefore, very useful contributions to ornithology. In a note on the position of the feet of the "Picarian" birds and of parrots in flight, he concludes from his experiences that "supposing the same habit of carrying the feet to run through a family, the forward position of the feet in flight probably characterises hoopoes, woodpeckers, and barbets, and the backward one certainly obtains among kingfishers, rollers, hornbills, cuckoos, and parrots." In other notes Mr. Finn describes various species of Grebes, with especial reference to the power of walking and digestion possessed by these birds; brings forward an instance which confirms the common belief in India that the whip-snake has a propensity for deliberately striking at the eye; and shows that the Indian Gossander can walk like other ducks, and does so in the same attitude. Such notes as these, on imperfectly known points in the habits and economy of birds, are of distinct service to students of avian classification.

Messrs. W. Wesley and Son, Essex Street, Strand, have issued a Catalogue (No. 131) of works on gardening in all its branches, reaching to 714 publications.

We have received the reports, for 1896 and 1897, of the Botanical Department of the Indiana Agricultural Experiment Station, by Mr. J. C. Arthur, State botanist, including an account of experiments on the cultivation of various agricultural crops and garden flowers.

From the Government Laboratory, Antigua, we have received a report of the results obtained on the Experimental Fields, at Skerrett's School, 1897. It refers almost entirely to the cultivation of the sugar-cane, especially to the relative values of different varieties, and to the diseases to which the cane is subject, and the remedies for them.

Messrs. Sealy, Bryers, and Walker, of Dublin, announce for early publication Mr. H. Chichester Hart's "Flora of Co. Donegal, with Introduction on Topography, Geology, Geographical Distribution, &c., and Appendices on Plant Names and Plant Lore and Climate."

The Department of Agriculture, Victoria, has issued a brochure of additions to the fungi on the vine in Australia, by Mr. D. McAlpine, Government Vegetable Pathologist, assisted by Mr. G. H. Robinson. It includes a very full account of twenty-three species, fourteen of which are parasitic and nine saprophytic fungi, ten of them being new to science. The report is very copiously illustrated.

In *Bulletin* No. 1 of the Geological Survey of Western Australia, Mr. A. Gibb Maitland, Government Geologist, gives a bibliography of the works, papers, reports, and maps bearing upon the geology, mineralogy, mining, and palæontology of the Colony. The publications are arranged in alphabetical order under authors' names.

THE tenth issue of "The Wealth and Progress of New South Wales," by Mr. T. A. Coghlan, bringing the affairs of the Colony up to the end of 1897, has just been distiibuted by the Agent-General for New South Wales. The volume contains more than a thousand pages, and is filled with accurate information of service to persons who are engaged in the active life of the Colony, and not without interest to those who are not concerned about the details of local affairs. It would be to the credit of all our Colonies if they published such admirable life-histories as the one for which Mr. Coghlan is responsible.

THE first volume of a second edition of a useful directory of German makers of optical instruments, and other instruments of precision, has been published by the firm of F. and M. Harrwitz, Berlin. This "Adressbuch" is edited by Herr F. Harrwitz, the editor of the journal *Der Mechaniker*, and has been greatly enlarged. It contains the names and addresses of German mechanicians, opticians, glass instrument makers, and allied callings, arranged alphabetically according to names of firms, towns, and specialities. How numerous these makers of scientific instruments are in Germany may be judged from the fact that the directory just issued contains nearly four hundred pages.

THE number of the *Journal of the Royal Microscopical Society* for June contains a reference by the President, Mr. E. M. Nelson, to an old book on optics, Zahn's "Oculus Artificialis," published in 1702. The following figures, taken from the work, are reproduced in the *Journal*:—A telescope-sight for a musket and a cannon, with the legend: "Bombardae et omni genere balistarum ac tormentorum bellicorum tubum opticum sive telescopicum aptare, quo visus ad scopum exactè dirigi poterit." A sunshine recorder or "Organum heliocausticum," with the legend "Horas Luce Sono tibi sphaerula Vitrea monstrat, ignis nil mirum Coelicus urget opus." A series of mirrors for a telescope called "Catoptrico dioptrica telescopica." The same number of the *Journal* contains a lengthy abstract of Dr. A. Clifford Mercer's important paper on "Aperture as a Factor in Microscopic Vision," delivered as a presidential address to the American Microscopical Society; also an abstract of Mr. E. M. Nelson's paper on "Microscopic Vision," read before the Bristol Naturalists' Society; and the commencement of a series of papers by Mr. Fortescue W. Millett on recent Foraminifera of the Malay Archipelago, collected by Mr. A. Durrand, illustrated by plates.

AMONG the volumes lately published by W. Engelmann, Leipzig, in Ostwald's valuable series of reprints and translations of scientific classics (*Klassiker der exakten Wissenschaften*) is a translation, with notes, by Herr W. Abendroth, of Newton's first book on optics, dealing with reflection, refraction, and colour, Four of Ernst von Brücke's papers on plant physiology, published between 1844 and 1862, are reprinted in No. 95 of the series; and a paper, translated from the Swedish of Eilhard Mitscherlich (1821), on the relation between the chemical composition and crystalline form of salts of arsenic and phosphorus, forms No. 94. The article on crystallography and crystallometry, contributed by J. F. Christian Hessel to Gehler's *Physikalische Wörterbuche* in 1830, appears as a reprint in Nos. 88 and 89, edited by Herr E. Hess. Prof. Ernst von Meyer edits No. 92, containing a paper by H. Kolbe (1859) on the natural connection of organic with inorganic compounds, and its bearing upon the classification of organic bodies. No. 90 is a translation from the French of a geometrical paper (1848) by A. Bravais; and No. 91 is a German edition of a paper by G. Lejeune Dirichlet (1839-40) on various applications of infinitesimal analysis to the theory of numbers.

THE value of the Reports of the U.S. National Museum has been so often referred to in these columns, that the announcement of the publication of a new volume containing a report upon the condition of the Museum and the work accomplished in its various departments, is sufficient to convey to all who are familiar wlth the Smithsonian Reports the fact that a large amount of information has been added to the pabulum of scientific readers. The Report just issued runs into 1080 pages, is lavishly illustrated, and is full of interesting matter. In an elaborate paper, Dr. Franz Boas describes and illustrates the collections of the Museum referring to the social organisation and secret societies of the Indians of the coast of British Columbia. His paper is based upon personal studies made during a series of years, and forms a very valuable contribution to the ethnology of the Kwakiutl Indians. Many brilliant reproductions of photographs taken during the performance of native ceremonies are given, and also the transcriptions of a series of phonographic records of songs belonging to the ceremonials. "The Graphic Art of the Eskimos" is dealt with by Dr. W. J. Hoffmann in another long and well-illustrated essay, which will interest archæologists as well as anthropologists. In addition to the researches in pictography, the paper contains much information upon the gesture language of the various tribes studied. A comparison of the pictographs, and various painted records found in different parts of the United States, with the Eskimo work, show the latter to be superior to the former, especially in faithful reproduction of animal forms and delicacy of artistic execution. The remaining papers in the volume are much shorter than the two already mentioned. Among the subjects dealt with are the tongues of birds, taxidermical methods in the Leyden Museum, and the antiquity of the Red Race in America.

SINCE the memorable researches of Humphry Davy on the decomposition of the alkaline earths, many methods have been suggested for preparing the metal calcium in the pure state. M. Moissan, in the current number of the *Comptes rendus*, after showing that none of these yield a pure metal, describes two ways of preparing crystallised calcium containing less than one per cent. of impurities. The first of the methods depends upon the property possessed by calcium of dissolving in liquid sodium at a dull red heat, and separating out in crystals on cooling. By treating the mass cautiously with absolute alcohol the sodium is removed, and the calcium is obtained in the form of brilliant white hexagonal crystals. Similar white crystals of calcium can be obtained by the electrolysis of fused calcium iodide. It is noteworthy that calcium has usually been described by previous workers as a yellow metal; doubtless owing to the presence of impurities.

THE additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albigularis*, ♀) from West Africa, presented by Miss Gladys Carey; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Miss Stankowski; a Brush-tailed Kangaroo (*Petrogale penicillata*, ♂) from Australia, presented by Mr. C. J. Leyland; two Red-backed Pelicans (*Pelicanus rufescens*) from the River Niger, presented by Mr. H. S. Bernstein; a Black Hangnest (*Cassidix oryzivora*) from the Amazons, presented by Mr. R. Phillipps; two Yellow-cheeked Lemurs (*Lemur xanthomystax*), two Madagascar Tree Boas (*Corallus madagascariensis*) from Madagascar, a Banded Ichneumon (*Crossarchus fasciatus*), an Angulated Tortoise (*Testudo angulata*) from Africa, a Blue-fronted Amazon (*Chrysotis æstiva*) from Brazil, six Algerian Tortoises (*Testudo ibera*) from Algeria, deposited; a Great Ant-eater (*Myrmecophaga jubata*), a Tamandua Ant-eater (*Tamandua tetradactyla*) from South America, a Green-winged Trumpeter

(*Psophia viridis*) from the Amazons, two White-necked Storks (*Dissura episcopus*) from Africa, two Dusky Francolins (*Pternistes infuscatus*) from British East Africa, a Madagascar Tree Boa (*Corallus madagascariensis*) from Madagascar, purchased; two Red and Yellow Macaws (*Ara chloroptera*) from South America, received in exchange; a Hybrid Zebra (between *Equus caballus*, ♂, and *Equus burchelli*, ♀), a White-tailed Gnu (*Connochætes gnu*, ♂), two Thars (*Hemitragus jemlaica*, ♂ ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JULY:—

July 3. 8h. 57m. Partial eclipse of the moon. Magnitude 0·934.
4. Wolf's comet due at perihelion.
13. Venus 1° north of α Leonis (Regulus).
15. Venus. Illuminated portion of disc 0·765.
15. Mars. ,, ,, ,, 0·904.
15. Jupiter. Polar diameter, 31″·9.
15. Saturn. ,, ,, 16″·6.
16. 6h. 31m. to 9h. 25m. Transit of Jupiter's Sat. III.
18. 8h. 7m. Annular eclipse of the sun invisible at Greenwich.
18. Wolf's comet 27′ distant from Mars.
19. Saturn. Outer minor axis of outer ring, 17″·89.
26. 22h. 0m. Mercury nearly occults α Leonis (Regulus).
28. 12h. 49m. Moon in conjunction with α Scorpii (Antares).
28. Many meteors from Aquarius and Perseus.
30. 7h. 31m. to 8h. 41m. Occultation of λ Sagittarii (mag. 3·1) by the moon.

COMETS THAT ARE NOW VISIBLE.—There is plenty of cometary news in the three most recent numbers of the *Astronomische Nachrichten* (3498–3500). As regards comet Coddington-Pauly, which has a declination too southern for the ephemeris to be of any use in this column, Prof. Berberich publishes some new elements (*Astr. Nach.*, No. 3500) based on other observations than those previously used by him, which differ somewhat from the values given in his first computation. The comet has a southerly movement, so that it will not be visible in our latitude.

Comet Perrine (June 14), on the other hand, has a great northerly declination, and is increasing in brightness very rapidly. The elements and ephemeris of this comet have been computed by Perrine and Aitken, and also by Berberich. The elements obtained by the former we published last week, but they differ slightly from those calculated by Berberich, these being as follows:—

$$T = 1898 \text{ August } 4{\cdot}7473 \text{ Berlin M.T.}$$

$$\left.\begin{aligned} \omega &= 235^\circ\ 16'{\cdot}77 \\ \Omega &= 252\ \ \ 2{\cdot}34 \\ i &= 72\ \ 11{\cdot}43 \end{aligned}\right\} 1898{\cdot}0$$

$$\log q = 9{\cdot}44405$$

The ephemeris for the current week, according to these values, is:—

Ephemeris for 12h. Berlin M.T.

1898.	R.A. (app.) h. m. s.	Decl. (app.) ° ′	log r.	log Δ.	Br.
June 30	5 4 3	+52 57·9			
July 1	9 56	52 23·3	9·9817	0·2061	2·34
2	15 46	51 46·9			
3	21 34	51 8·7			
4	27 19	50 28·7			
5	33 1	49 46·7	9·9415	0·1904	3·03
6	38 40	49 2·7			
July 7	5 44 15	+48 16·7			

The new comet discovered by Giacobini is gradually decreasing its southern declination, but the elements at present calculated are described as uncertain. With a diameter of 2′, an excentric condensation, and of about the 10th magnitude (June 21), the comet is not an easy object. Those wishing to observe it will find the following positions useful.

Ephemeris for 12h. Berlin M.T.

1898.	R.A. (app.) h. m. s.	Decl. (app.) ° ′	Br.

THE FIRST SATELLITE OF JUPITER.—In two early numbers of *Astronomy and Astrophysics* (November 1894 and May 1893) our readers may remember that Prof. W. H. Pickering contributed an account of a very interesting series of observations on the shapes of the satellites of Jupiter, and the conclusions he arrived at were that the discs were by no means round, but assumed very decided irregularities as they performed their rotations. These satellites have been further minutely examined by Mr. A. E. Douglass during last year, and in the *Astronomische Nachrichten* (No. 3500) he describes what knowledge has been gained by the observations of the first satellite. These were made in Mexico, from February 18 to March 28, with the Clark 24-inch, and in Flagstaff from May 16 to June 9. We must confine ourselves to a very brief summary of this paper, and refer our readers to the original for the minute details given both in the text and accompanying plate.

Although the markings on the satellite were sometimes well seen, the observations were not numerous enough over a long period of time to effectively map and determine the period of rotation by tracing the succession of detail. Mr. Douglass adopted Prof. Pickering's method of observing the changes in the elliptical form of the satellite's disc. After an elaborate trial of several periods he was led to deduce a period of 12h. 25·8m. for the year 1897, a value not very different from that found by Pickering in 1892, namely 13 hours. Most peculiar are the markings on this satellite. Assuming the axis of the satellite to be perpendicular to the plane of its orbit, they appear to extend from about + 60° to − 60° in latitude, and they take roughly the form of lines directed either to the north or south pole. Their general distribution can be best described and their symmetry best illustrated, as Mr. Douglass says, "by saying that they nearly form portions of five great circles passing round the satellite."

The micrometer measures for determining the elliptical form of the disc gave indications of a large ellipticity. Mr. Douglass thinks that this flattening is real, and not due to the presence of surface markings near the limb. The following brief table shows the values of the ellipticity and period of rotation for the periods observed since 1892:—

Date.	Ellipticity.	Period. h. m.	Obs.	Telescope
Dec. 1892 ...	100–110 ...	13 3	... Pickering ...	13 inch
Oct. 1894 ...	108–120 ...	13 3	... ,, ...	18 inch
March 1895 ...	104–120 ...	(?)	... Douglass ...	,,
March 1897 ...	115–130 ...	12 25·8 ...	,, ...	24 inch

The indications of an increase in the ellipticity and decrease in the period of rotation led Mr. Douglass to investigate the question of whether a decrease in the size of the disc had been observed. An examination of the existing measures showed that such a change has probably taken place, but the values cannot be relied on for certain. If this decrease in size be an actual fact, then the increase in rotational velocity and increase in mean polar compression would naturally follow.

THE METEOR SHOWER OF NOVEMBER 13, 1897.—Those who intend to systematically observe or photograph the meteor shower next November, will find in the account of the arrangements made last year at the Harvard College Observatory (*Annals*, vol. xli. No. 5) many interesting suggestions. Prof. W. H. Pickering, as will be gathered from his description in the above-mentioned *Annals*, made arrangements for a combined attack on the night of the 13th at various stations connected with the observatory. To present an idea of the scale in which such work is undertaken in America, in addition to visual observations, we give the number of plates exposed and instruments used. Three plates were taken with the Draper 11-inch telescope, with two objective prisms of 15°. Fourteen plates with the 8-inch, with two objective prisms of 6° each. Twelve plates with the 6-inch, with objective prism of 6°. Eight plates with a Voigtländer 5-inch, with an objective prism of 6°. Three plates with a Ross rapid rectilinear lens of 1·5 inch, angle of prism 15°. With such a collection of fine instruments at work, it was only too disappointing that the meteors were so few and faint;

but it is consoling to think that the experience gained that night will undoubtedly be used to render the work at the time of the next November meteor shower more efficient. As regards the best form of lens to employ, Prof. Pickering advocates "a portrait lens of the kind formerly used by photographers." The plates should be exposed for half an hour, and at the end of this time the camera should be again pointed to the region fifteen minutes preceding the radiant point. At the Solar Physics Observatory, at Kensington, the methods employed were to fix a camera on the tube of a large equatorial (near the object-glass end), and also on the hour-angle circle of a siderostat, both cameras being moved by the clock-work of each instrument. Other cameras were fixed and oriented towards the radiant point and other directions. The 9-inch equatorial with objective prism was also used, but no bright meteor, unfortunately, passed across the field. May the meteorological conditions be such that the meteor shower of November 1898, will be well observed and successfully photographed!

HIGH SPEED TELEGRAPH TRANSMISSION BY MEANS OF ALTERNATORS.

ALTHOUGH, at the present day, high speed transmission is much more limited in its application than at an earlier period in the history of telegraphy, owing to the commercial aspects of the question having been unavoidably altered, attempts have been made from time to time to produce improvements in this direction; but until lately the admirable system invented by the late Sir Charles Wheatstone, and considerably improved by the British Post Office Telegraph Administration, has been the best available method of automatic high speed signalling.

The speed at which a series of waves can be passed over a given line depends primarily and inversely upon the product of the total resistance into the total capacity, the form of the wave having a considerable influence on the speed where any measurable capacity is present.

In the ordinary Wheatstone automatic fast speed system of telegraphy, the letters are formed by waves of different duration, a dot being produced by a short wave, a dash by a longer one. This renders it necessary to charge the line longer for a dash than for a dot, which is a grave defect in fast speed working; but the condenser compensation, introduced and employed by the British Post Office, practically doubles the speed attainable on any given line by, in some measure, equalising the line charges. That is to say, the condenser used is always of a capacity which admits of a full charge during the time interval of a dot, and a current of the duration of a dash does not give the condenser any higher charge. Indeed condenser compensation has such a beneficial effect, that the defect of unequal impulses is almost overcome, inasmuch as the increase of speed obtained by this arrangement and equal impulses, is only 5 per cent. greater than that obtained with currents of unequal duration. Again, although the signals be made equal in this system, another difficulty presents itself; that is, the waves that are sent through the line are the results of the sudden applications of the full E.M.F. used (in practice 100 volts), and consequently a reversal means a sudden change of 200 volts, *i.e.* from 100 volts positive to 100 volts negative. The form of the current wave with such a system depends almost entirely on the nature and form of the circuit. It is easy to produce correspondingly sudden and complete changes in the current when the circuit possesses only resistance, but when capacity, &c., is present, the form of current wave is vastly different to the impressed E.M.F. wave; for example, take the letter "A," the actual current curve on a land line without condenser compensation is shown in Fig. 1, while Fig. 2 represents the effect of shunted condenser compensation.

Prof. A. C. Crehore, of Dartmouth College, U.S.A, in conjunction with Lieut. G. O. Squier, of the United States Artillery, have, however, been led to make some experiments with alternators, and have suggested a mode of high speed signalling which, although presenting some mechanical difficulties, has recently been tried by the inventors of the Post Office telegraph lines in England, under the direction of Mr. Preece, and found to produce a distinct increase of speed.

Fig. 3 shows an ordinary sine wave as produced by an alternator, and it is this form of wave that Messrs. Squier and Crehore use in their so-called "synchronograph" system of fast speed telegraphy.

The signals are obtained by the omission of certain complete cycles or semi-cycles, the message being read by means of the blanks in the regular succession of recorded dots; or signals can be recorded on chemically prepared paper.

This system is to some extent a synchronous one with this great advantage over the many well-known synchronous systems, that the synchronism is not required between the transmitter at one end and the receiver at the other end of a line, but between the alternator and transmitter at the sending end of the line. This is easily obtained by driving the transmitter from the generator shaft. The transmitter itself is exceedingly simple, and consists of a wheel the circumference of which is one continuous conductor, presenting a smooth surface for the brushes to bear upon. If the periphery of this wheel be divided into forty equal parts, and be geared to run at one-fourth the speed of the armature of a ten-pole alternator, clearly one of these equal parts will correspond to one semi-cycle of E.M.F. produced by the alternator. Upon the surface of the wheel bear two

FIG. 1.

FIG. 2

brushes, carried by an adjustable brush-holder. One brush is joined to the generator, and the other to the line, so that the current entering one brush from the generator passes across the transmitting wheel to the other brush, and thence out to the line.

Now if a piece of paper $\frac{1}{40}$ of the circumference of the wheel be fixed thereon in such a position as to pass under one of the brushes, one semi-cycle or half-wave of current will be omitted in every twenty complete waves, and by means of a suitably prepared paper ribbon, or "slip," any combination of signals can in this simple manner be transmitted. The brushes are adjusted so that the periods of disconnection and connection coincide with the zero points of E.M.F. The transmitter may, however, have only one brush joined to line, and the wheel itself may be made the connection to the generator. With this mode of signalling much higher E.M.F.s may be used, and connections and disconnections made almost without spark at the brush contacts.

The speed of the transmitting wheel with respect to the generator shaft is immaterial, the essential being that its circumference should contain an integer number of times the arc which a point fixed with respect to the field would describe on such circumference during one semi-period of current.

FIG. 3.

Complete control of every semi-cycle of current thus permits the maximum speed of transmission of signals with a given frequency. If the transmitter does not act in synchronism with the generator, the "make" and "break" of the circuit occurs when the current is not naturally zero, and considerable interference results; care is, therefore, taken to ensure that the "slip" admits of the line connections being made at the proper times only.

Athough the received signals were originally intended by Messrs. Squier and Crehore to be recorded on chemically prepared paper, they have also devised a very ingenious massless receiver, although at present it is not in a practical form. It is based on the well-known discovery of Faraday that a beam of polarised light may be rotated by means of a magnetic field, the direction of rotation of the ray being the same as the direction of the current producing the field; the rotary power depends upon the intensity of the magnetic field, and the total amount of rotation upon the length of the rotary medium in which this magnetic field exists and through which the ray passes.

The method adopted is to pass a beam of light through a

Nicol's prism, thence through a long tube with plane glass ends containing liquid carbon bisulphide, and afterwards through a second Nicol's prism. The ray of light is received on a screen having a sensitised surface, which is carried forward at an uniform speed; a long coil is wound round the tube containing the carbon bisulphide, the prisms being adjusted so that no light passes through the tube when no current is flowing through the coil, the source of light being an arc lamp.

The passage of a current rotates the polarised ray within the tube, and the light then falls on the sensitised screen, and is thereby recorded.

As neither of these methods of reception are suitable for everyday use, the British Post Office undertook, in conjunction with the inventors, a series of valuable and interesting experiments over the departmental lines under more practical conditions. The existing departmental records of capacity, resistance and mileage, compiled for the whole country, proved invaluable by supplying exact data for each of the experiments performed, and enabled reliable tables and curves to be constructed. The experiments consisted of determinations of the highest limits of speed for the Wheatstone automatic, as well as the synchronograph system on various lines, the following combinations being specially compared:—

(1) Ordinary Wheatstone automatic with condenser compensation as is used at present.

(2) The synchronograph sine wave transmission system with chemical receivers.

(3) A combination of the synchronograph sine wave transmission with Wheatstone receivers.

The alternator used for these experiments consisted practically of several separate alternators on one shaft, each being independent of the remainder, and so constructed that, with the same speed of revolution, different frequencies or wave speeds could be obtained, transformers being used in those cases where it was desirable to maintain the E.M.F. unaltered.

Careful estimations were made not only of the force employed, which is about 50 per cent. higher than that ordinarily used on Wheatstone circuits, but also of the wave speed, and its equivalent value in "words per minute" in each case.

On a line from London to York and back, mainly composed of copper, having a total mileage of 431½, and a K.R. equal to 33,000, a speed of 540 words per minute was attained with Wheatstone receiver and Crehore-Squier transmitter (synchronograph), although the maximum limit was not reached. The speed obtainable with this K.R. being only 360 when ordinary Wheatstone automatic was used.

From London to Aberdeen and back, with a total mileage of 1097½ and a K.R. of 261,000, a speed of 135 words per minute was obtained by the Crehore-Squier Wheatstone combination, as compared with 46 words per minute on the ordinary Wheatstone automatic with the best compensating arrangements.

These two cases are typical of the whole series of observations, which enabled the comparative wave speeds of the different systems to be estimated as follows:—

Wheatstone automatic alone	1
Crehore-Squier transmission and Wheatstone receiver ...	2·9
Crehore-Squier transmission and chemical receiving ...	2·9

In the first two cases the number of waves necessary for each word is of course the same, but in the last-named case, where chemical receiving is employed, a further gain is obtained by using fewer waves for each word, making the word speed in the three cases bear the ratio 1, 2·9 and 7.

Chemical receiving is by no means so convenient as ordinary Wheatstone, and the most pressing practical requirement at the present day is not higher speeds for short distances, but higher direct working speeds over long lines where at present intermediate "repeaters" are necessary.

It is satisfactory to note that the maximum wave speed attainable by synchronograph transmission with the chemical receiver or with the Wheatstone receiver is exactly the same on any circuit where the speed is limited by the line itself and not by the receiving apparatus.

On the Wheatstone system shunted condensers are necessary to compensate for two distinct effects—the unequal duration of the signals, and the inductance of the receiver. Where the synchronograph transmission is employed on short cables or open lines, no line compensation is required, and a fixed condenser can be shunted across the receiver coils so as to compensate for the inductance of the receiver for any given speed. In connection with this question the inductance of the Post Office receiver was carefully verified, and was found to be 3·46 Henrys, the necessary condenser compensation depending solely on the speed of transmission (or wave-frequency) and the arrangement of the receiver coils, and in no instance having any direct or complicated relation to the line capacity.

On an artificial cable, equal to about 200 miles of ordinary submarine cable, where condenser compensation is used at both ends, the increase of wave speed obtained by the synchronograph was only 50 per cent. instead of 190 per cent. as in the case of open wires. It would therefore appear that with further experiment some line compensation might be found to be necessary for cable working.

The experiments show that where the capacity of the line is not great, as in the case of aerial lines, the transmission of the current in sine waves produces the best results, and leaves the factor of the inductance of the receiving instrument to be dealt with separately, and consequently in a more exact manner.

The principal difficulty in the application of the system is the necessity for the use of a new code of signals, or a reduction in the speed value to admit of conformity with existing codes. The existing Wheatstone automatic instruments are also light, portable, and adapted for use in outlying districts at short notice, where the synchronograph would probably be found to be less suitable. The perforator at present in use for the preparation of the transmitting "slip" has also, by a process of evolution, become extremely convenient, and equally suitable for hand working in confined spaces, or where power is available.

A suitable and easily manipulated perforator for the synchronograph has yet to be devised. Messrs. Squier and Crehore, however, deserve great credit for the discovery, with limited means of experiment, of an improved and promising system of high speed transmission.

OBSERVATIONS ON STOMATA.[1]

THE method described depends on the fact that in adult leaves transpiration is stomatal rather than cuticular, so that, other things being equal, the yield of watery vapour depends on the degree to which the stomata are open, and may be used as an index of their condition. In principle, it is the same as the methods of Merget (*Comptes rendus*, 1878) and Stahl (*Bot. Zeitung*, 1894). These observers used hygroscopic papers impregnated with reagents which change colour according as they are dry or damp, and Stahl, who employed paper soaked in cobalt chloride, has obtained excellent results. In my laboratory I have used, for some years, a hygroscope for demonstrating cuticular transpiration, in which evaporation is indicated by the untwisting of the awn of *Stipa pennata* (Darwin and Acton, "Practical Physiology of Plants," 1st edition, 1894); my present instrument is of the same general type, but the index is made of "chinese leaf," *i.e.* shavings of pressed and heated horn.[2] If a strip of horn is placed on a dry substance, *e.g.* the astomatal surface of a leaf, it does not move, but on the stomatal surface it instantly curves strongly away from the transpiring surface. In the hygroscope the degree of curvature is read off on a graduated quadrant, and in this way a numerical indication of the condition of the stomata is obtained.

The instrument makes no claim to accuracy, but has proved extremely useful when used comparatively to indicate and localise small changes in the transpiration of leaves, and therefore, by implication, changes in the condition of the stomata. By observing under the microscope the uninjured leaf of *Caltha palustris*, and comparing the variations in the size of the stomata with the variations in the readings of the hygroscope, it is easy to convince one's self of the value of the method. It must be especially noted that though a fall in the hygroscope readings corresponds with a narrowing of the stomatal opening, it does not follow that zero on the hygroscopic scale means absolute closure of the stomata. This want of sensitiveness has one advantage, namely, that cuticular transpiration has no effect on the horn index, so that any movement of the index

[1] A paper by Francis Darwin, F.R.S., read at the Royal Society, June 16.
[2] I also use the epidermis of a *Yucca*—a material which I owe to the kindness of Mr. Thiselton-Dyer.

must depend on a stomatal transpiration. The hygroscope indicates well the gradual "closure"[1] of the stomata that occurs as a plucked leaf withers. It is generally stated that marsh and aquatic plants do not close their stomata under these circumstances. I find that, although the phenomenon is much less marked than in terrestrial plants, yet that, in many species, partial closure of the stomata undoubtedly occurs in the aquatic class.

The most interesting fact observed in withering leaves is that in many cases the "closure" of the stoma is preceded by temporary opening, which may occur almost simultaneously with the severance of the leaf from the plant. Thus the hygroscope readings rise at first, and subsequently sink to zero. The interest of this fact is the demonstration of the interaction between the guard cells and the surrounding epidermis. The phenomenon is best seen in plants with milky juice, but is not confined to this class. The preliminary opening of the stomata occurs in the early morning, but not in the evening—a fact which is of importance in relation to the mechanism of the nocturnal closure of the stomata.

A diminution of the stomatal transpiration can also be brought about by compressing the stem of the plant in a vice, a process which is known to diminish the water supply (F. Darwin and R. Phillips, *Camb. Phil. Soc. Proc.*, 1886). The stomatal closure is here probably an adaptive response to the lowering of the water-supply of the leaf, but this is not quite certain.

A series of experiments were made on the comparative effect of moist and dry air, from which it is clear that the stomata "close" before any visible signs of flaccidity occur in the leaf. When leaves are exposed to air dried by H_2SO_4, "closure" is preceded by a remarkably prolonged opening of the stomata—a phenomenon which requires further investigation.

Baranetzky (*Bot. Zeitung*, 1872) showed that slight degrees of disturbance affect transpiration. The hygroscope gives no evidence of increased transpiration when the disturbance is slight. When the plant is violently shaken the leaves become flaccid and the stomata "close," and in some cases the closure is preceded by increased transpiration, no doubt due to temporary opening of the stomata, induced by the guard cells being released from epidermal pressure before they have lost their own turgor.

N. J. C. Müller (Pringsheim's *Jahrbücher*, vol. 8, 1872) showed that stomata may be closed by electric stimulation; my experiments show that while a strong shock narrows the stomata, a weaker one opens them, no doubt owing to the temporary loss of epidermal pressure.

Some experiments on poisonous gases and vapours were made. Chloroform and ether slowly "close" the stomata, which finally reopen in a normal atmosphere. Pure CO_2 also slowly closes the stomata.

The hygroscope is well fitted to demonstrate the fundamental facts in relation to light. The fact that the stomata are widely open in sunshine is well known; the difference between bright and less bright diffused light is not so well known, nor the fact that in dark stormy weather the stomata may be nearly closed by day, even in summer. The effect of difference of illumination is well shown in certain leaves having stomata in both surfaces, *e.g. Iris*, *Narcissus*, and the phyllodes of *Acacia cyclopis*. In these the stomata on the illuminated surfaces are much wider open than on the less brightly illuminated sides; and when the plant is reversed in position in regard to light, the stomata rapidly accommodate themselves to the change in illumination.

The most interesting fact in regard to the effect of artificial darkness is that it is more effectual in producing closure in the afternoon than in the morning; and, conversely, illumination opens closed stomata more readily in the morning than later in the day. These, together with other observations, tend to show a certain amount of inherent periodicity in the nocturnal closure of the stomata. Another fact of interest is that in darkness prolonged for several days the stomata gradually open. This last observation is used in the section on the mechanism of the stoma as an argument against the prevalent view that the stoma closes in darkness, because in the abeyance of assimilation the osmotic material, on which the turgor of the guard cells depends, ceases to be manufactured.

Schellenberger (*Bot. Zeitung*, 1896) has striven to uphold this view by showing that in the absence of CO_2 the stomata close as though they were in darkness. My experiments on plants deprived of CO_2 lead to absolutely contrary results, namely, that the stomata remain perfectly open even during prolonged deprivation of CO_2.

It is a vexed question (Leitgeb, *Mittheilungen aus dem Bot.*, Inst. zu Graz, 1886) whether or no the majority of plants close their stomata at night. My conclusion is that in terrestrial plants (excluding nyctitropic plants) a great majority show some closure at night; the horn hygroscope stands at zero on the stomatal surface of by far the greater number of ordinary plants. On the other hand, the hygroscope shows widely open stomata on most aquatic plants at night. Stahl (*Bot. Zeitung*, 1897) concludes that nyctitropic plants are remarkable for not closing the stomata at night; this fact I somewhat doubtfully confirm; but the question is not so simple as it seems, owing to the varying behaviour of the stomata at night in different temperatures.

Since the hygroscope gives numerical readings it is possible to represent graphically the daily opening and closing of the stomata. The curve begins to leave the zero with the morning light; it rises rapidly at first, and afterwards more slowly. In some cases it runs roughly horizontally until a rapid fall begins in the evening. In other cases there is a slow rise up to the highest point, which occurs between 11 a.m. and 3 p.m. The hygroscope generally sinks to zero within an hour after sunset.

The effect of heat has not been fully studied, but enough has been done to confirm previous observers who find that heat opens the stomata. As regards the visible spectrum, I find that the red rays are decidedly most efficient, but I am not able to find any evidence of a secondary maximum in the blue, such as Kohl (*Bieblatt zur Leopoldina*, 1895) describes.

The biology of the nocturnal closure is a subject which can hardly be discussed in a condensed manner. It is suggested that the gaseous interchange of assimilation may require widely open stomata, whereas respiration may be carried on with comparatively closed apertures. If this is so, the stomata might be to a great extent shut at night, and an economy in the use of water effected, without detriment to metabolism. Observations are given to show that quite another effect is brought about by nocturnal closure. As long as the stomata are open, the transpiring leaf is considerably cooler than the dry-bulb thermometer, but at night it has almost the temperature of the air. In this way a saving of heat is undoubtedly effected—but it is not easy to say whether it is sufficient to be of much practical importance to the plant. I am inclined to believe, from Sachs' (*Arbeiten*, 1884) experiments on the depletion of leaves, that all saving of heat must be valuable, by preventing the checking of translocation which he observed.

The mechanism of the stoma is another subject which does not lend itself to condensed treatment. I have tried to point out that the stoma has been neglected in the modern reorganisation of plant physiology from the point of view of irritability. Some observers insist on the preponderant influence of the guard cells, while Leitgeb in the same way exaggerated the importance of epidermic pressure, whereas the two factors should, as far as possible, be considered as parts of a whole and as correlated rather than opposed in action. I have also attempted to show how the stoma, like other parts of the plant, may be supposed to react adaptively to those signals, which we usually call stimuli. The attempt which I have made to rank the problem among the phenomena of irritability, is very tentative in character. I have ventured to put it forth because I am convinced that it is in this direction that advances will be made.

[1] I use the word "closure" to mean such a narrowing of the stomatal aperture as corresponds with zero on the hygroscope.

A NEW PHOTOGRAPHIC PRINTING PAPER.

ACTING as agents for the Nepera Chemical Co., New York, Messrs. Griffin and Co., of Garrick Street, have for some time been issuing a new sensitised paper under the name of "Velox," which for ease of manipulation and perfection of results promises to take a firm hold on public favour. From its advent, something more than a year ago, there has been ample opportunity to test the most desirable quality of a photographic paper, viz. its permanence under varying conditions, and, at the least, it can be relied on as much as any *silver* sensitised paper.

Full instructions for the manipulation of the paper for various purposes are given with it, and they do not greatly differ from those employed in the use of other bromide papers. The special advantages claimed for this paper is that the several difficulties involved in the working of ordinary papers are removed. The chief simplification is in the fact that a dark room may be entirely dispensed with, all operations being performed in an ordinary room lit in the usual manner. The paper is described as being coated with a chloro-bromide emulsion, and it is owing to the extreme slowness of this that a special non-actinic illumination is unnecessary. Of course, care is wanted, and *direct* light should not be allowed access to the print; but in an ordinary room, lit by two windows at middle of day, perfectly clean whites may be obtained by turning the back to the window, and developing in the shade thus produced.

Again, no great amount of apparatus is required, not even a printing frame; development is very efficiently performed on a sheet of glass, applying the developer with a pledget of cotton-wool or a mop camel-hair brush.

The exposure for contact printing from an average negative varies from 1-3 seconds for diffused daylight, to 30-120 seconds to a gas-burner at 6 inches distance. A point that might with advantage be added to the instructions for use, is the great convenience of magnesium ribbon as an illuminant. This is being brought forward by many leading plate and paper makers, and deservedly so. The light of burning magnesium is one of the most intense illuminants at present known; and as a great part of the light is concentrated in the blue and violet regions of the spectrum, the parts most effective on a silver emulsion, this gives the light a high efficiency. From 1-3 inches of ribbon, burnt at from 8-12 inches distance, will be found to give satisfactory exposures. Another point in favour of using magnesium is the ease of firing it, all the extra articles needed being a box of matches.

It might be worth while to make the gelatine, &c., which forms the basis of the emulsion, more insoluble than it appears to be from the samples tested, as many people find it convenient to dry prints quickly, and if the paper has not been specially treated, there is danger of blisters or of complete melting of the film. The paper is obtainable in several varieties of surface and suitability for different purposes.

Another suggestion, not mentioned in the circular issued, may perhaps be made as likely to extend its popularity. It is that the paper may be toned with any of the usual toning baths for bromide paper, the one made with copper sulphate and potassium ferricyanide, giving reddish-brown tones, being very suitable.

One of its good qualities is the ease of maintaining pure whites; and this will no doubt lead to its extensive use for copying purposes, as both the negative and positive may be made on the paper. For scientific workers, as well as pictorial photographers, the paper will doubtless prove a great boon.

From its extreme simplicity of manipulation, moderate price, and general high quality, the paper ranks high among silver emulsion printing papers.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. RICHARD ABEGG, privat-docent in physical chemistry at Göttingen, has been promoted to the rank of professor; Dr. Oswald Lohse, observer in the Potsdam Astrophysical Observatory, has also been promoted to a professorship; Dr. Böhmig, privat-docent in zoology at Gratz, has been appointed assistant professor; Prof. Kalkowsky, of the Technical High School in Dresden, has been appointed director of the geological and prehistoric museum there.

ON Wednesday in last week, the Duke of Devonshire opened the new Christie Library at the Owens College, Manchester, and laid the foundation of the Whitworth Hall, another addition to the college buildings. The library is the gift of Mr. R. C. Christie; and the expense of erecting the Whitworth Hall will be met by the sum of 50,000*l*. received by Mr. Christie as one of the residuary legatees of the estate of the late Sir Joseph Whitworth, and since paid by him to the Treasurer of Owens College.

IT is but rarely that an issue of *Science* appears without the announcement of one or more gifts to educational and scientific institutions in the United States, or for the advancement of learning. The following are among the donations recently announced:—By the will of the late Dr. Elizabeth H. Bates, of Port Chester, N.Y., the University of Michigan will receive 125,000 dollars, the income from which is to be used in establishing a chair for the diseases of women and children, to be known as the Bates professorship.—The will of the late Mrs. Annie S. Paton, of New York, leaves 100,000 dollars to Princeton University, subject to an interest for life of her two sons. The bequest is to found a fund for an endowment for Paton lectureships in ancient and modern literature.—It is said that Mrs. Phœbe Haarst will erect a building for mining engineering for the University of California at a cost of 300,000 dollars.—A building for the College of Agriculture of Ohio State University has been completed during the present year at a cost of 70,000 dollars.—The will of the late Mr. Felix R. Bonnet, of Pittsburg, Pa., provides that, upon the death of his widow, 300,000 dollars shall go to the Western Pennsylvania University for the endowment of scholarships.—A donor, whose name is withheld, has subscribed 25,000 dollars for Barnard College in case the 100,000 dollars needed to liquidate the debt on the College are subscribed by October 3. 23,000 dollars had previously been subscribed.—Hobart College, Geneva, N.Y., has received 6000 dollars for a scholarship by the will of Mrs. Augusta M. Williams.—Mr. Philip D. Armour has given an additional endowment fund of 500,000 dollars to the Armour Institute of Technology, Chicago. He had previously given the Institute an endowment of 1,500,000 dollars.—Mr. Washington Duke has given 100,000 dollars to Trinity College, Durham, N.C., which makes the total amount of his gifts to the College 425,000 dollars.—Dr. D. K. Pearsons, who has assisted so many smaller colleges, has offered to give the Salt Lake College, of Salt Lake, Utah, 50,000 dollars, on condition that its officers raise 100,000 dollars more within a year.—Dr. George W. Hill has been appointed lecturer in celestial mechanics in Columbia University, Miss Catherine W. Bruce having given 5000 dollars for this purpose.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 26.—"On the Kathode Fall of Potential in Gases." By J. W. Capstick, M.A., D.Sc., Fellow of Trinity College, Cambridge. Communicated by Prof. J. J. Thomson, F.R.S.

Hittorf and Warburg have shown that when an electric current passes through a tube containing a gas at a pressure of a few millimetres, the fall of potential along the greater part of the tube varies with the pressure of the gas and the current strength, but in the immediate neighbourhood of the kathode there is a fall which is constant in amount provided the negative glow does not cover the whole electrode, or extend to the walls of the tube. It seems likely that this kathode fall will prove to be connected with other constants of the gas, and the aim of the present investigation was to find such a connection by measuring the kathode fall in a compound gas and its constituent elementary gases. The gases used were water vapour, ammonia, and nitric oxide and their constituents.

No difficulty was experienced in measuring the fall in the elementary gases, and the separate readings for any one gas showed good agreement. It proved, however, a very difficult matter to get a constant current to pass through the compound gases. Many months were spent in a fruitless attempt to find what conditions determine the constancy of the current, and since the kathode fall is not constant when the discharge is intermittent, very few measurements could be made on the compound gases.

The values in volts ultimately found for the kathode falls were as follows:—

Hydrogen	298
Nitrogen	232
Oxygen	369
Water vapour	469
Ammonia	582
Nitric oxide	373

Warburg had previously determined the fall in hydrogen and nitrogen. For the former, he found 300. For atmospheric nitrogen containing argon, he found 232. The present experiments were made on nitrogen prepared from ammonium nitrite, whence it appears that the presence of argon does not affect the kathode fall.

The value found for nitric oxide is of very doubtful validity. The appearance of the discharge showed that the gas is rapidly decomposed, and the fact that the kathode fall is nearly the same in nitric oxide. air and nitrogen with a trace of oxygen, points to the oxygen being the sole carrier of the electricity in each case.

If we leave nitric oxide out of account, it appears that the kathode fall is an additive quantity, and hence a property of the atoms rather than of the molecules.

Assuming that the conduction in gases is electrolytic, the analogy of the electrolysis of liquids suggests the possibility that the kathode fall is a measure of the heat of dissociation of the gas. If this be the case, the experiments might be taken to support J. J. Thomson's view that the carriers of the current are provided by the disintegration of the atoms into much smaller particles.

June 9.—"Experiments on Aneroid Barometers at Kew Observatory and their Discussion." By C. Chree, Sc.D., LL.D., F.R.S.

The paper deals with two species of data. The first consists of particulars derived from the records of Kew Observatory as to the errors in aneroid barometers subjected to the ordinary Kew test, which consists in lowering the pressure to which the aneroid is exposed inch by inch to the lowest point required, and raising the pressure in a corresponding way to its original value. Readings are taken at each inch of pressure during both the fall and the recovery, and a table of corrections is obtained by reference to a mercury gauge.

The second group of data are the results of special experiments made at Kew Observatory during the last three years.

The aneroid is an instrument exhibiting elastic after-effect. When pressure is lowered and then maintained constant, the reading continues to fall, and when pressure is restored to its original value, the aneroid reads at first lower than it did originally, but exhibits a tendency to recover. The most characteristic features were discussed thirty years ago by Dr. Balfour Stewart. They have also been the subject of a pamphlet by Mr. Edward Whymper, who gives the results of a number of interesting long period experiments.

The present paper treats of how the differences between the readings with pressure descending and ascending in a normal pressure cycle, such as the Kew test, varies throughout the range, and how the sum of these differences varies from one range to another. It investigates how the error, as pressure is reduced, varies with the rate of fall of pressure (when uniform), how the fall of reading at a low stationary pressure increases with the time, depends on the pressure, and varies with the rate of the previous fall of pressure, and how the recovery after a pressure cycle progresses with the time, and is modified by the nature of the previous pressure changes. The influence of subsidiary stoppages is investigated, and experiments are discussed showing the influence of temperature.

The opportunity is taken of considering the secular change of zero, and also changes in the elastic and the after-effect properties.

Algebraic and exponential formulæ are obtained for such phenomena as the variation of the differences of the descending and ascending readings throughout a pressure cycle, the dependence of the sum of such differences on the range, the fall of reading at the lowest pressure and the final recovery. A theory, to some extent empirical, is built up, leading to mathematical results, depending on only three arbitrary constants, for the behaviour of an aneroid in the ordinary Kew test over any range.

The large differences brought to light between different aneroids show that the means of markedly raising the average are already at the makers' disposal. The present inquiry shows clearly how the effects of tentative improvements may be ascertained.

Physical Society, June 24.—Mr. Walter Baily in the chair.—Prof. Carus-Wilson exhibited an apparatus to illustrate the action of two electric-motors coupled in such a way as to admit of their rotating at different speeds. The two shafts are placed in line, and each is fitted with a bevel-wheel, gearing into an intermediate wheel. The axis of the intermediate wheel is at right angles to the line of the motor-shafts, and is free to rotate in a plane at right angles to that line. The motors can be made to rotate at different speeds by altering the strength of the magnets of either or both. The motion of the intermediate wheel depends upon the difference of the two speeds, or upon their mean, according to their relative directions of rotation. A simple graphic construction enables the action to be predetermined for any given load on the intermediate wheel. Calling the two motors A and B, and the intermediate wheel C, lines can be drawn on a base of current to represent the speeds and the torques for each motor. If the motions of A and B are in the same direction, the load or torque is the same on each, and of similar sign. Hence, as the load on the wheel C is increased, the speeds of A and B tend to become equal (if A had been running faster than B); and for a certain load on C the speeds of A and B will be equal. If the load on C is further increased, B will run faster than A. Also, there will be a certain value for the load on C at which the motion of A will reverse. A further increase of the load on C will bring C to rest, A and B then rotating at equal speeds in opposite directions. When the load on C is nothing, let the motors rotate in opposite directions, A running faster than B. The motion of C now depends upon the difference of speeds of A and B. When a load is put on C, the motion of A is retarded, while that of B is assisted, hence B takes less current, and A takes more. The torques on the two motors, due to the load on C, are now of equal amount, but of opposite sign. As the load on C is increased, the speed of A is reduced, and that of B increased, until the two are equal, and C comes to rest. B is now acting as a generator, and sending current into A. If the load on C is simply that due to friction, the process cannot be carried further. But if the load on C is reversed, the speed of B becomes greater than that of A, and the motion of C is reversed. In the steering gear designed by the Union Electricitäts Gesellschaft, the intermediate wheel is made to actuate a rudder by differential action. The motion is reversed by making the speed of one motor greater or less than that of the other.—Mr. Quick then exhibited Weedon's apparatus for the measurement of the expansion of solids. This method is claimed to be independent of knowledge of optics on the part of the student. The expansion is read directly by means of a pair of micrometers. Precautions are taken to prevent errors due to radiation. Mr. Lehfeldt asked what precautions were taken to prevent the movement of the micrometer supports. Mr. Stansfield described a form of apparatus in use at Chelsea Polytechnic; it was a simple contrivance, in which changes of length were measured by a micrometer. Mr. Quick, replying, thought the instrument referred to by Mr. Stansfield pre-supposed a knowledge of optics.—Mr. Lehfeldt then read a paper by Dr. Donnan on the theory of the Hall effect in a binary electrolyte. In 1883 Roiti investigated the subject of a possible Hall effect in electrolytic solutions. He failed to obtain any positive result. Recently the question has been examined by Bagard, who noticed certain effects in aqueous solutions of zincic and cupric sulphates. Meanwhile, negative results have been observed by Florio. The author therefore discusses what effect might be expected by theory, on somewhat the same lines as those of Van Everdingen, jun., taking a more general case. So far as the present discussion goes, the author's theory is wholly in favour of the negative results of Roiti and Florio. It would appear that Bagard measured a phenomenon not contemplated by the theory as stated in the present treatment. Van Everdingen originally supported the positive results of Bagard; but his work, unfortunately, was rendered incorrect by the accidental omission of a numerical factor. He has since discovered the slip in his calculations, and now agrees with the author's conclusions.—The Chairman proposed votes of thanks to the authors, and the meeting adjourned until October, this being the last of the session.

Linnean Society, June 16.—Dr. A. Günther, F.R.S., President, in the chair.—Prof. J. B. Farmer and Mr. W. G. Freeman demonstrated the action of germinating peas, cress, and barley in causing the deoxidation of a watery solution of methylene blue to a colourless liquid on shaking up the latter with air, while on adding a drop of hydrogen peroxide the blue colour was restored. Green plants placed in the solution were found to act in a manner precisely similar to the seedlings, though the action may be modified by assimilation in sufficient light (see p. 185).—Mr. F. Enock exhibited and made remarks on the eggs of an hemipterous insect containing living parasites (*Prestwichia aquatica*), of whose life-history and habits he gave a detailed account (see p. 175).—Prof. Herdman, F.R S., exhibited some dissections, microscopic preparations, and drawings to illustrate the presence of modified pedal muscles in the oyster. It was shown that there was reason to believe that these muscles, the insertion of which into the shell had been noticed in the American oyster by Ryder and Jackson, were the representatives of the *protractor pedis* of other Pelecypoda. But, as the oyster has no foot in the adult, the muscles have been modified in their distribution and have acquired a new function.—Mr. Miller Christy read a paper entitled "Observations on the seasonal variations of elevation in a branch of a horse-chestnut tree."—A paper was read by Mr. G. W. Carpenter on *Pantopoda* collected by Mr. W. S. Bruce in Franz-Josef Land, in which he recorded the existence of eleven species, one of which he described as new. Of this, *Nymphon piliferum*, a detailed description was given, as of a new variety *Nymphon piliferum* var. *abbreviatum*.—A paper was read by Mr. J. E. Duerden on the morphological relationship of the Actiniaria and Madreporaria.—Dr. C. Forsyth-Major communicated a paper on some fossil Leporines, an abstract of which was given by Prof. Howes. The author's investigations are based on the description of Miocene fossils collected by himself in Sardinia, France and Italy, and on specimens preserved in the Museum of Natural History.

PARIS.

Academy of Sciences, June 20.—Centenary of the foundation of the Conservatoire des Arts et Métiers, by M. Laussedat.—Actinometry in experimental balloons, by M. J. Violle.—On the study of the upper atmosphere, by M. L. Cailletet. An account of an experimental balloon ascent of June 8. The balloon was fitted with self-recording instruments, the lowest reading of the barometer, 118 m.m., corresponding to a maximum height of 13,700 metres.—On the boiling point of liquid ozone, by M. L. Troost. The temperature was determined by means of an iron-constantin couple, previously standardised in ice, boiling methyl chloride, nitrous oxide, ethylene, and oxygen. Several measurements were taken, the ozone always boiling steadily at − 119° C.—Preparation of crystallised calcium, by M. Henri Moissan. After a historical review of previous work on the subject, two methods are described which furnish calcium in white, hexagonal crystals (see p. 209).—On the classification of the Tunicates, by M. Edmond Perrier.—New gases in atmospheric air, by MM. Ramsay and Travers. An account of the discovery of neon and metargon.—On the Rubiaceæ of the Madagascar flora, by M. Emm. Drake del Castillo.—Comet discovered at the Observatory of Nice, by M. Giacobini.—Provisional elements of the Perrine comet (June 14, 1898).—Observations of the Coddington comet, Perrine comet (June 14), and the Giacobini comet, made at the Observatory of Toulouse with the Brunner equatorial, by M. F. Rossard.—Observations of the new Perrine comet (June 14) made at the Observatory of Paris, by MM. G. Bigourdan and G. Fayet.—Observations of the Coddington comet (June 11, 1898) made with the large equatorial at the Bordeaux Observatory, by M. L. Picart.—Application of interference fringes to the study of micrometers, by M. Maurice Hamy. A half-silvered lens of very slight curvature is fixed to the body of the micrometer, and a mirror to the moving portion of the instrument, the whole is illuminated with monochromatic light, and the method of fractional excess applied to the Newton's rings thus produced.—The equivalence group and kinematic bases, by M. Jules Andrade.—On the stability of equilibrium, by M. L. Lecornu.—On an apparatus called the anemotrope, by M. Maillet.—An optical method for measuring lengths up to several decimeters, by MM. A. Perot and Ch. Fabry.—Influence of tempering upon the electrical resistance of steel, by M. H. Le Chatelier. The resistance of steel is not influenced by tempering at temperatures below 710°, the temperature of recalescence. The resistance after tempering at 850°–1000° is about double that of the untempered metal. Some chrome and tungsten steels were also studied. At high temperatures chromium exaggerates the increase of resistance produced by tempering. Tungsten makes practically no difference.—On the rectification of alternating currents, by M. P. Janet.—On the paradoxical multiplication of a discharge derived from a condenser, by M. R. Swyngedauw.—Electrical resistance of the human body, by M. Dubois. The body acts as a condenser with liquid dielectric, of a capacity of about 0·165 microfarad. Under the action of continuous currents the resistance of the body may fall from 51,500 to 3030 ohms. But at any stage of this variable state, if the resistance be measured by a condenser method, with discharge through a ballistic galvanometer, the resistance is found to be invariable, about 400 ohms.—On the thioantimonites of the metals of the alkaline earths, by M. Pouget. The thioantimonites of barium, strontium, and calcium, of the form $R'_3.Sb_4S_9$, are described.—Pyridine bases, by M. Marcel Delépine. Thermochemical data are given for pyridine, piperidine, chloropiperidine, dipiperidine and δ-amidovaleraldehyde.—On some bases derived from piperidine, by M. G. André.—On some bromine derivatives of morphine, by M. H. Causse.—On some new aromatic diurethanes of piperazine, by MM. P. Cazeneuve and Moreau.—Action of chlorine upon ethylene chloride in presence of aluminium chloride. Chlorination of acetylene, by M. A. Mouneyrat. Ethylene chloride heated alone with $AlCl_3$ gives acetylene and hydrogen chloride. If chlorine is passed into the mixture, $CHCl_2.CHCl_2$ and $CH_2Cl-CCl_3$ can be isolated from the product. Chlorine and acetylene combine together quietly if all traces of oxygen are excluded.—Synthesis of symmetrical tetramethyl glutaric acid, by M. E. E. Blaise.—On a crystalline compound of acetylene with cuprous chloride, by M. Chavastelon.—On the cuticle of the palm of the hand and its evolution, by M. A Cannieu.—Classification of the Molgulideæ, by M. Antoine Pizon.—On the proboscidian nervous system of the Glyceræ, by M. Ch. Gravier.—On the first origin and development of nephridia in Annelids, and on the parallelism of their regenerative and embryonic ontogeny, by M. A. Michel.—On the buccal apparatus of the Acarina, by M. A. Brucker.—Study of the defensive glands in some Coleoptera, by M. L. Bordas.—On the oligocene formations occurring in Algeria (Constantine), by M. E. Ficheur.—The micro-organisms of lignite, by M. B. Renault. Micrococci are found in abundance in lignites.—On the use of manures in horticulture, by MM. Alexander Hébert and G. Truffaut. Plants treated with suitable manures showed on analysis the same composition as similar plants grown without the addition of fertilising materials, but the final weight in the former case was double that in the latter.

MUSEUMS.

Essays on Museums and other Subjects connected with Natural History. By Sir William Henry Flower, K.C.B., &c. Pp. xv + 394 (London: Macmillan and Co., Ltd., 1898.)

SIR WILLIAM FLOWER'S name is so intimately associated with the subject of museum management and organisation, that all naturalists who have been accustomed to look to him as their guide in this direction will be glad to have his writings collected into one volume for reference. The fact that the twenty essays and the four biographical notices have already been published elsewhere in no way detracts from their value, since the utterances of acknowledged leaders always possess historical interest, apart from the influence which they may have exerted upon contemporary thought.

Although the present volume deals with museums in the first place, there are altogether four sets of essays—the first treating of museums, the second of general biology, the third of anthropology, and the fourth consisting of biographical sketches of Rolleston, Owen, Huxley and Darwin. This arrangement, although upsetting the chronological order in which the various essays appeared, is very convenient for the reader and to some extent—but not wholly—compensates for the absence of an index, an omission to which we feel bound to call attention in these days of overwhelming scientific literature, when writers on scientific subjects are expected as a solemn duty to the reading public to give every facility for reference to the contents of their volumes. We are afraid, moreover, that the author himself is likely to suffer from this omission; for there is so much in his writings that one desires to remember and to quote, that unless notes are made as the pages are perused, the busy worker in science is likely to be put to endless trouble in endeavouring to find a passage which may have struck him at first reading as worthy of selection for future use. It is true that the various essays have their contents set forth at the commencement of the volume, but it is generally admitted that such tables of contents are very poor substitutes for a good index. In calling attention to this defect we are in reality paying the author the compliment of recording the opinion, which will be generally endorsed, that his writings have more than an ephemeral interest.

Of the leading ideas which run through Sir William Flower's essays on museums, the importance of such establishments as educational institutions is more than once dwelt upon and cannot be too strongly emphasised. At the present time, especially when County Council Technical Instruction Committees are wavering in their policy with respect to the endowment of museums, it is of interest to read the following passage given in an address to the Museums Association in 1893:—

"One cannot help considering how much might have been done if only a moderate portion of that large sum of money obtained a few years ago by the tax on brewers, and handed over to the County Councils to spend in promoting technical education, had been used for erecting museums, which might have taken a permanent place in the education of the country. Every subject taught, in order to make the teaching real and practical, should have its collection, and these various collections might all have been associated in the county museum under the same general management. The staff of teachers would assist in the curatorial work, and thus a well-equipped central college for technical education might have been formed in every county, sending out ramifications into the various districts in which the need of special instruction was most felt, and being also the parent of smaller branch museums of the same kind wherever they seem required" (pp. 34-35).

Some few of the counties have assisted in maintaining their local museums, but these are exceptions. In districts which are rural and agricultural, and where such institutions would be particularly valuable, little or nothing has been done. Those counties which have adopted the frittering-down policy of decentralisation have left themselves without adequate funds for the purpose. It may be doubted whether the sporadic instruction in those hardy perennial subjects of cookery, dressmaking and ambulance, which come sufficiently near the definition of technical instruction to entitle local committees to claim their share of the beer money, is ever likely to be of such lasting value to the welfare of the country as the foundation of educational museums. At any rate the present writer has no doubt on this point, whatever the attitude of County Councillors may be, and it is tolerably certain that in the present state of public opinion no auditor would be likely to challenge the expenditure of the technical instruction grant for such a purpose.

Another idea which Sir William Flower constantly urges is the importance of competent curatorship. Again and again has he insisted, during many years, upon the necessity for high scientific attainments on the part of those entrusted with the care of museums. In 1893, for example, in the same address as that from which we have already quoted, he told the museum curators then assembled that they were not, as a class, properly appreciated by the public. As to the qualifications he said:—

"Now, a curator of a museum, if he is fit for his duties, must be a man of very considerable education as well as natural ability. If he is not himself an expert in all the branches of human knowledge his museum illustrates, he must be able to understand and appreciate them sufficiently to know where and how he can supplement his own deficiencies, so as to be able to keep every department up to the proper level. His education, in fact, must be not dissimilar to that required for most of the earned professions" (p. 35).

Again, in the third essay of the present volume, based on statements made in 1891 and 1895 on the subject of local museums, he says:—

"You might as well build a church and expect it to perform the duties required of it without a minister, or a school without a schoolmaster, or a garden without a gardener, as to build a museum and not provide a competent staff to take care of it.

"It is not the objects placed in a museum that constitute its value so much as the method in which they are displayed, and the use made of them for the purpose of instruction" (p. 55).[1]

1 In this essay Sir Wm. Flower, speaking of the desirability of preserving, as an interesting survival, the parish stocks where they are still in existence, says that he knows of only one—in the village of Dinton, near Aylesbury. The writer knows of others at Brading (Isle of Wight), and Abinger, near Dorking.

L

Closely connected with the high qualifications which should be possessed by curators is the question of their remuneration and the inducement which such a career offers to men of scientific training. The author's remarks on this point may appear despondent, but they are, unfortunately, only too justifiable.

"In a civilised community the necessities of life, to say nothing of luxuries (which we do not ask for), but the bare necessities of a man of education and refinement, who has to associate with his equals, and bring up his children to the life of educated and refined people, involve a certain annual expenditure, and the means afforded by any occupation for this necessary expenditure give a rough and ready test of the appreciation in which such occupation is held" (p. 35).

Judged by this standard the museum curator stands very low in public estimation. Some consolation, however, may be derived by this class of scientific workers from the consideration that their position is not very different from that of the scientific enthusiast who devotes his life to research in any branch of pure science which has no immediate market value. The consolation is confessedly a very poor one, but the person with the necessary "scientific qualifications" who accepted the munificent stipend of 50*l.* per annum (with rooms, coal and gas) as resident curator, meteorological observer and caretaker of the museum and library in a certain town—of which the only redeeming feature appears to be that it was less wealthy than another town which offered 125*l.* to its museum curator—may find his case paralleled by looking at the advertisements for science teachers which occasionally appear in these columns or elsewhere, where men having an expert knowledge of several branches of science are invited to accept appointments in technical institutes, where their duties are irksome and heavy and their responsibilities great; where their time is taken up in drudgery which crushes enthusiasm and destroys originality, and for which they are offered a stipend that many a butler in a wealthy family would look at with contempt. The position of museum curators is all of a piece with the position of other workers in pure science; and until the so-called "practical man," in whose hands the administration of the technical instruction money has been placed, has been educated off the face of this country or superseded by legislation, there is very little hope of amelioration. It is instructive to note that in 1853 Prof. Edward Forbes said of museums[1]:—

"In most cases they are unassisted by local or corporate funds, and dependent entirely upon the subscriptions of private individuals. Indeed, any attempt to favour the establishment of public museums and libraries through the application of local funds is opposed with a horrible vigour more worthy of a corporation among the Cannibal Islands than within the British Empire. The governing bodies of too many of our towns include no small proportion of advocates of unintellectual darkness."

The writer could put in evidence certain local newspapers—published in a town not thirty miles from London—where an attempt to found a public museum and library was met, only last year, in the very same spirit which Prof. Forbes described in the above paragraph nearly half a century ago. So little have we advanced in this direction in fact in the rural districts, and even in many of the provincial towns, that the remarks on local museums made by Forbes in 1853 read like the precursors of Sir William Flower's observation on the same subject in the volume under notice:—

"It so happens, however, that the value and excellence of almost every provincial museum depend upon the energy and earnestness of one, two, or three individuals, after whose death or retirement there invariably comes a period of decline and decay" (Forbes, 1853).

"Voluntary assistance is, no doubt, often valuable. There are many splendid examples of what it may do in country museums, but it can never be depended on for any long continuance. Death or removals, flagging zeal, and other causes, tell severely in the long run against this resource" (Flower, 1895).

The history of too many local museums is unfortunately comprised in these paragraphs, and the writer has vividly in mind some very pregnant remarks in this strain made by Sir William Flower at Chingford in 1895, at the opening of that excellent little local museum founded by the Essex Field Club. We can only add that every one of the seven essays on museums reprinted in the present volume deserves most careful perusal, and all who are interested in the subject will do well to study them.

The eight essays on general biology, which follow those on museums, abound with interesting topics. Although, no doubt, many readers of these columns are quite familiar with these addresses, it is refreshing to have brought before us again the views of the author on the development of the Ungulata (Royal Institution lecture, 1873), his remarks on classification and nomenclature (Address to Section D, British Association, 1878), and the two lectures on whales delivered, respectively, at the Royal Institution in 1883 and at the Royal Colonial Institute in 1895. Throughout all these biological essays runs the leading idea of evolution, of which doctrine Sir William Flower has always been a consistent and temperate advocate. The perusal of some of these essays induces feelings akin to those with which the old soldier recounts his past campaigns. The arguments with which hostile criticism had to be met in the early days may now have lost their point, but the younger reader must never forget that the great battle of evolution has been fought and won since Sir William Flower entered the field, and a calm consideration of the contents of the present volume will show that no insignificant part in this struggle has been borne by its author. In fact, one of the most prominent episodes in the history of the spread of the new doctrine beyond the circle of workers in science was the memorable address on "Recent Advances in Natural Science in relation to the Christian Faith," given at the meeting of the Church Congress at Reading in 1883, and reprinted as the ninth essay of the present volume. If the consideration of these biological essays calls forth any feeling of regret on the part of those who are now actively engaged in carrying on the work of research, it must be that their distinguished author was unable by virtue of his official duties to enter into the later controversies which have divided the school of evolutionists. Sir William Flower's essays read like very "orthodox" Darwinism; yet there are few whose opinions on such topics as heredity and

[1] "The Educational Uses of Museums." (Introductory lecture, Session 1853–54; Museum of Practical Geology.)

the transmission of acquired characters, and the bearing of the teachings of Prichard, Galton and Weismann on the original theory of Darwin and Wallace would have been of greater value to the present generation of workers. On one point which has from time to time been raised in connection with the theory of evolution, viz. the rate of modification of organisms in past time, the author has recorded his view in the following terms :—

"There is no proof whatever that the laws of variation and natural selection, if such be the laws which lead to the introduction of new forms and the extinction of old ones, were ever more potent than they are at present" (p. 109).

The section on anthropology comprises five essays of which the last, "Fashion in Deformity," is familiar to our readers as one of NATURE Series. There are two presidential addresses to the anthropological section of the British Association, viz. York, 1881, and Oxford, 1894. The presidential address to the Anthropological Institute on "The Classification of the Varieties of the Human Species" was delivered in 1885, and the lecture on "The Pygmy Races of Men" at the Royal Institution in 1888. It is now familiar history that Sir William Flower was among the pioneers who in this country helped to raise anthropology to its present position among the natural sciences. It is strange that the science of man should have made less progress than that of the other subjects dealt with in these essays. The author says in the preface :—

"Upon the third subject, the main point of which is the advocacy of a more systematic study of Anthropology in this country, there has been, as it seems to me, less advance than in either of the other two ; and in putting forth its claims for greater recognition I felt for a long time as one crying in the wilderness."

Among recent signs of progress the author notes with satisfaction the establishment of a professorship of anthropology in the University of Oxford, a fitting place for such a chair being that University which gave a home to the first systematically arranged anthropological collection brought together and presented by another great pioneer in this field of research, General Pitt-Rivers.

In concluding this notice we can only say that while giving expression to the widely felt regret that the author should have been compelled to withdraw temporarily from active administrative duties, it is a matter of congratulation that he has been enabled to turn his enforced leisure to such useful account as the publication of the present volume. R. MELDOLA.

CLERK MAXWELL'S INFLUENCE ON MODERN PHYSICS.

James Clerk Maxwell and Modern Physics. By R. T. Glazebrook, F.R.S. Pp. viii + 224. The Century Science Series. (Paris and Melbourne: Cassell and Company, Ltd., 1896.)

THE sketch of Clerk Maxwell's life and work which Mr. Glazebrook has written well illustrates the immense influence which Maxwell has exerted on modern physics. Of his work it can be said, in a truer sense than of much that has been accomplished, that it lives after him. Its vitality is apparent in all kinds of ways, and in nearly every region of physical inquiry. In a certain measure the developments of his great scientific generalisation, though they do not yet lie in perspective before us in the same way, recall those of Newton's theory of gravitation. There is the same kind of power of intuition displayed in arriving at the general theory, the same kind of partial development, by the methods most ready to hand, of its consequences, and, to a certain extent at least, the same kind of presentation of the whole subject by methods which were not quite those of discovery. Now we have other workmen with tools of keener edge and finer temper, perhaps, adding here and taking away there to improve its symmetry and remedy its occasional want of logical consistency, and, what is of far more importance, extending the scope of its results, until electric wave-theory and experiment threatens to become a subject almost too great for any single investigator to intelligently follow in all its ramifications.

It is remarkable how quickly, sometimes, the natural philosophy of a science is built up, when observation and classification have been carried sufficiently far. At the right moment, when in a sense everything has been prepared, the genius arrives, and the chaotic elements spring into relation with each other and to life at his touch. Not that there is nothing really to be done ; on the contrary, the task is one which only genius could accomplish. Much has been achieved by other workers, who have spent laborious lives in research ; indeed, the actual toil by which the data have been collected and classified, and their relations traced, has been spread over centuries, and the actual work of those who unite all in a general theory is small in comparison. But how great the result is, is immediately made known by its fruits.

The present state of the science of electricity and magnetism is due to advances of this kind made by a close succession of men of genius, of whom one of the greatest is happily still with us. The natural philosophy of electricity, which may be said to have begun with Oersted and Ampère, is due in no small measure to the experimental researches and truly philosophical ideas of Faraday. The first consistent statement of it was given by Thomson, who expressed in mathematical language Faraday's ideas of lines of force, and deduced by a dynamical process the consequences of Faraday's experimental discoveries. Thomson's theory was at bottom one of action in a medium, and from it he obtained by deduction and experimental verification important discoveries of his own. Upon this quantitative philosophical discussion Maxwell to a great extent based his form of the theory, the essence of which is its dynamical character, and its explicit transference of the phenomena from the conductors and magnets and circuits to the electromagnetic field. The theory of light, though far from being the end, is the crown of the whole work.

The manner of scientific progress was traced very clearly by Comte, but the distinction between the observational and classificatory stage of a science and its natural philosophy stage, and the importance of the latter, have not been so well appreciated by other writers. It was said, as many people know, by a celebrated philosopher, that the theory of gravitation was really contained in the laws of Kepler, to whom therefore, and not to Newton, the discovery of gravitational attraction was due. The utterance was a remarkable one for a philosopher who always contended that the object of philosophy was, as no doubt it is, to find unity in diversity. It only shows that even divine philosophy does not always suffice to lift a man above national iealousy and prejudice. The law of gravitation was the one uniting principle, the unity which explained the whole range of planetary motions, brought into one view the motion of the moon and the fall of a stone, enabled the motions of the heavenly bodies to be computed, and the places of the bodies predicted for a long range of future time, and gave the keynote for those great investigations of the future and the past of the solar system, and of our own terrestrial system within it, which have been carried out since Newton's time by his followers. Some of the greatest of these researches —we may well be proud of the fact—have been carried out by scientific men of our own country, whom this age has either seen or still possesses.

Like Maxwell's electrical theory the Newtonian gravitation raised, as does every really science-making theory, questions which it did not answer. There is the further problem of the *rationale* and mechanism of gravitation, and questions of its application to close aggregates of particles, and our minds are suddenly turned from the stars in their courses to the structure of molecules and the nature of inter-molecular action. The new problems bristle with difficulties far greater than those which have been surmounted, the new standing ground attained has only disclosed steeper heights to be scaled.

So it has been in the electromagnetic theory of light. The conception of a plane wave of light as a propagation of a disturbance in which there is electric, and at the same time magnetic, intensity varying as a simple harmonic function of the time, and its minute verification by Hertz and his pupils, and by others, has opened whole vistas of problems we cannot hope to solve for many a day. There are the primary questions, whether the theory of the ether, according to which light vibrations are transmitted as waves of distortion in a medium for which the ratio of the rigidity modulus to the density is enormous, has any foundation in fact, and, if so, what is the relation of the varying electric and magnetic forces to the material vibrations; how do these electric and magnetic forces arise, and how are they maintained in the ether: in short, how does matter act upon ether and ether uopn matter. In these are involved others of perhaps a more limited or special nature, the mode of localisation of energy in fields in a steady state, and the mode of flow of energy in cases of transference. The complete solution of these would yield the secret of voltaic action, and, it might be, reduce the voltaic cell to a magneto-electric machine, and tell us in what magnetic and electric induction themselves consist.

That Mr. Glazebrook's book can be of great interest, even to those who are more or less familiar with Campbell and Garnett's life of Maxwell, we can fully testify. It is true that most of the early reminiscences given in the biographical sketch are to be found in the life; but there are personal recollections of Mr. Glazebrook's, and several other touches here and there, which give this part of the work a charm and value of its own. This is followed by one or two specimens of the verses which Maxwell from time to time threw off, sometimes in a serious mood, sometimes in a gay, but always with a grace of expression and originality (and at times a quirkiness amounting almost to caprice) of thought peculiarly his own. The specimens chosen are the inimitable parody in verse of Tyndall's Belfast Address, the verses on "Molecular Evolution," written on the same occasion, the verses addressed "To the Committee of the Cayley Portrait Fund," and the song of the Rigid Body. A few more might have been included without giving too much illustration of this side of Maxwell's versatile nature. The rapidity and ingenuity of his verse composition were extraordinary. The writer well remembers seeing on a sheet of the article "Elasticity," written by Lord Kelvin for the ninth edition of the "Encyclopædia Britannica," a copy of verses which Maxwell had jotted down before returning the proof. It began:

> "Vex not my ears, ye crystal spheres,
> Your harmony's insipid, O.
> But play again that tuneful strain,
> My parallelepiped, O."

And so on,

> "Finding great fun in twenty-one
> Elastic moduluses, O!"

for six or eight verses, with marvellous rhymes for the numerous, and for purposes of verse somewhat intractable, technical terms with which a mathematical discussion of the elasticity of an æolotropic solid abounds.

His letters also were very beautiful, and serve as a comforting reminder that if letter-writing is a lost art, it survives still in some men of playful fancy and lightness of touch as a natural gift. Of these only a few specimens are given by Mr. Glazebrook, and hardly more could have been included within the limits of space at his disposal.

The rest of the book consists of a sketch of Maxwell's work in Colour Vision, Molecular Theory of Gases, and Electricity. This we need not review. Suffice it to say that it is thoroughly clear and trustworthy, and will well repay perusal by the physicist already acquainted with later developments of Maxwell's work. Mr. Glazebrook has also found room for a valuable concluding sketch of the work of Hertz and his followers, which was founded on Maxwell's theory, and afforded its experimental verification.

There are one or two misprints. At p. 68, the Don referred to oddly enough turns a *watch*; and there is another, near the beginning of the foot-note on p. 131. The biographical reference to George Green, of Nottingham, on p. 158, is not quite accurate.[1]

[1] It is strange that the ninth edition of the "Encyclopædia Britannica" should contain no biography of Green. He was undoubtedly a great genius, and made an impression, not merely on mathematical physics, but on pure analysis, which will never be effaced. It has been said in jest, but with considerable truth, that applied mathematics is made up of continual applications of Green's theorem. Of this enormously powerful theorem a more lately discovered relation, which is very fundamental in the theory of functions of a complex variable, and which is generally quoted as Riemann's theorem, is only a particular case.

Green's career was certainly very remarkable: but Mr. Glazebrook is in error as to his original occupation. Up to the year 1829 he assisted his father, who was in business first as a baker in Nottingham, and afterwards as a miller in the neighbouring village of Sneinton. In that year, when Green was thirty-six years of age, his father died, and not long after Green

Mr. Glazebrook is to be congratulated on having produced an attractive and useful book. The only fault of the sketch is that it is too small for the subject, but for that the author is not responsible. And after all the time has hardly yet come for a complete appreciation of Maxwell's influence on modern science. A. GRAY.

FUNAFUTI.

The Atoll of Funafuti, Ellice Group: its Zoology, Botany, Ethnology, and General Structure, based on Collections made by Mr. Charles Hedley of the Australian Museum, Sydney, N.S.W. (*Memoirs Australian Museum, Sydney*, No. iii. Parts 1–6, 1896–1898.)

THE Pacific Ocean is divided into basins by a series of island chains and submarine ridges. The most conspicuous chain begins in Malaysia, crosses New Guinea, and, sweeping round parallel to the eastern coast of Australia, runs past New Caledonia and Lord Howe Island to New Zealand. The islands of this chain all rise from the Melanesian plateau, and they are continental both in structure and in the characters of their recent and fossil faunas. Outside this series is another, which Hedley calls the Marshall-Austral chain, including the Ellice, Phœnix, Marshall, Gilbert and Samoan archipelagoes, and perhaps represented still further to the south-east by the great Patagonian platform that projects north-westward from the coast of South America. All but one of the members of this chain are oceanic in structure and inhabitants; the exception is Samoa, where the chain crosses the line of elevation that passes from the Tonga Islands, through Samoa, and on northward towards the Sandwich Islands. In the angle between this line and that of the Austral-Marshall series is one of the deep open basins of the Pacific. A belt of apparent subsidence lies on each side of the Tonga-Sandwich line, marked amongst other points by the decreasing size of the atolls as the two belts are approached. It is the atolls that border these two belts of subsidence that offer the best chance of settling the great coral island controversy. Funafuti, as one of the easternmost of the Ellice Islands, is in as good a position for a test boring as could be selected; for it is near the depression between the Ellice Archipelago and the Tonga-Sandwich Island line, and is on the south slope of one of the deep open basins of the Pacific. The mechanical difficulties, however, proved too serious at the first attempt. But the expedition of 1896 was valuable not only from the lessons taught as to the methods of boring in coral reefs, but as it afforded the opportunity for a detailed study of the island. Captain Feild worked out the submarine contour, and the naturalists collected materials for a detailed study of the fauna and ethnology. Monographs of various types of Indo-Pacific islands are greatly to be desired before the primitive characters have been lost. We must therefore welcome the valuable monograph on Funafuti, based on the extensive and systematic collections of Mr. Hedley, which have been promptly worked out by the officials of the Sydney Museum. Six parts of the monograph have been received, amounting to 368 pages, and illustrated by twenty-two plates. Mr. Hedley contributes a general introduction, in which he clearly states the geomorphological position of the island, and describes its geological structure and its people. It is interesting to notice that, in spite of the slight depth reached by boring in 1896, Mr. Hedley infers from the general characters of the atoll that its structure supports the Darwinian theory. Mr. Hedley also contributes a series of most interesting notes to the other articles, and shows in them that he is as competent a naturalist as he is a keen collector.

The second part begins the description of the fauna with the account of the insects and Arachnida by Mr. Rainbow, of the Crustacea and Echinodermata by Mr. Whitelegge. The third part contains Mr. Waite's report on all the Vertebrates except the birds, which are described by Mr. J. North in the first part, and also some of the Alcyonaria and Enteropneusta. The accounts of these two groups are concluded in the fourth part, which also contains the report on the sponges. Mr. Hedley himself contributes the ethnological section, which forms the fifth part. The sixth section, the last we have received, contains one of the contributions of most interest at the present time—Mr. Whitelegge's account of the corals. Mr. Hedley tells us that the chief impression the coral reefs of the island made upon him was their poverty both in individuals and species. More genera and species can be collected, he tells us, in a single tide on the reefs of Queensland, New Guinea and New Caledonia than he could find at Funafuti in several weeks' search. Nevertheless, Mr. Whitelegge finds forty-seven species in Mr. Hedley's 170 specimens, and divides into distinct species corals which Mr. Hedley had especially collected to illustrate different forms of the same. But Mr. Whitelegge only adds two new species, which for corals is an unusual act of moderation.

In a series of memoirs such as this, it is of course inevitable that the standard varies. One factor that has a marked influence on the merit of the articles is the size of the group concerned. Mr. Waite's note on the indigenous mammal is a complete monograph, and its accuracy is apparently unimpeachable; but when we come to the sections on the Arthropods we find that Mr. Rainbow has to describe all the insects, including representatives of the orders Coleoptera, Hymenoptera, Lepidoptera, Diptera, Hemiptera and Orthoptera, and also that he has to describe the Arachnida. It is therefore Mr. Rainbow's misfortune, not his fault, that his determinations cannot hope for the same degree of finality as those of his colleagues who deal with smaller groups. But Mr. Rainbow's contribution is no less useful; only it must be judged as one of those preliminary descriptions which record the general constituents of a fauna, and thus sort it out ready for criticism and revision by the specialists. The specialists are few and insects are many. The specialist monographers cannot keep pace with the collectors. Hence if the work had waited until the

disposed of the business in order to obtain more leisure for his studies and researches. His entering at Gonville and Caius College in 1833 at the age of forty, and his obtaining the fourth place in the mathematical tripos of 1837, the year of Griffin, Sylvester and Gregory, are better known facts. His University career, whatever else it may have done, apparently did not tend to make his earlier work more generally known, and he died in 1841 without that scientific recognition which was his due. That came later when William Thomson (Lord Kelvin), who was the first to recognise the tremendous importance of Green's work, obtained in 1850 the republication in *Crelle's Journal* of the famous "Essay on the Application of Mathematical Analysis to the Theories of Electricity and Magnetism" [*Crelle* 40, 44, 47 1850, 1852, 1854)], originally published in 1828.

collection had been distributed and described by the experts, the account of the arthropod fauna would not have been available until the present interest of Funafuti had passed.

OUR BOOK SHELF.

Weather Lore. A Collection of Proverbs, Sayings and Rules concerning the Weather. By Richard Inwards, F.R.A.S. Third edition. (London: Elliot Stock, 1898.)

MR. INWARDS is to be congratulated on the fact that his industry, exhibited in the collection of quaint sayings concerning the weather, has been rewarded by the demand for a third edition of his book on weather lore. If this popularity indicates a greater taste for an acquaintance with unscientific rules to be applied for the purposes of weather prediction over long periods, than an appreciation for the forecasts made on sound principles but for shorter intervals, it would imply a retrograde movement in meteorological education; but we imagine the demand for the book arises rather from the curious information it contains, and the old-world wisdom it exhibits, than from its scientific teaching and character of guide to weather prophecy. This edition is apparently much increased in size, and some features of a distinctly scientific value have been added. We notice a frontispiece in which the typical forms of cloud are well illustrated, and the average height at which these clouds float is marked by the marginal introduction of well-known mountain summits, calculated to bring home to us a correct notion of the elevation at which these clouds circulate. Cloud study is deserving of much more attention than it generally receives, and we welcome any attempt to induce more regular examination of the forms and motions of the familiar spectacle clouds present.

Then the section on the average dates for the first flowering of plants and appearance of migratory birds, which is either new or has been enlarged, should lead to more accurate observation of familiar phenomena. Such sections interest us much more than the proverbs and sayings which go to make up the bulk of the book. The arrangement of these proverbs seems to be much the same as in the first edition. Of the value of these, apart from their literary character, perhaps it is as well to say nothing. We follow the author or compiler in calling these rules proverbs, but the term is scarcely a happy one. A proverb has been defined as the wisdom of many and the wit of one, but in some cases, here preserved, it is difficult to recognise either the wit or the wisdom. They may give some evidence of national customs or of local manners, and sometimes display shrewd observance on the part of the authors; but this mass of endless detail, collected by many generations of weather-wise people, may become somewhat wearisome if taken in large doses. Yet, if we understand Mr. Inwards correctly, he implies that the persevering labour and continuous observation bestowed on weather signs have resulted in securing some insight into meteorological phenomena, and he recommends us to imbibe the general spirit of these rules and adages, and try to find where similar results have followed similar indications. This would lead to the detection of a number of coincidences no doubt, but it is not easy to see how true science would be advanced thereby.

First Stage Magnetism and Electricity. (The Organised Science Series.) By R. H. Jude, M.A., D.Sc. Pp. 350 + xv. (London: W. B. Clive, 1898.)

ALTHOUGH there are several books on these subjects prepared specially to cover the syllabus of the elementary examination of the Science and Art Department, the one before us has some peculiarities which renders the treatment different in many respects. The chief difficulty which the author has attempted to overcome is the conception of electrical potential, which so often forms a stumbling-block to the beginner. This he has introduced much earlier than usual, leading appropriately up to it. In this, the first part of the book, the author has further expounded in a simple manner the conceptions of the ethereal theory, thus bringing it within reach of the beginner. The second two parts deal with magnetism and electrodynamics, the main points of treatment being the emphasis of fundamental principles, the omission of the disputed points in the theory of the voltaic cell, and, as the author states, "a liberal use of the conception of potential gradient." Numerous illustrations are inserted in the text, and a great number of examples and examination questions are added.

As a first course on magnetism and electricity the book should prove serviceable.

Problems of Nature. Researches and Discoveries of Gustav Jaeger, M.D. Selected from his published Writings. Edited and translated by Henry G. Schlichter, D.Sc. Pp. ii + 261. (London: Williams and Norgate, 1897.)

THIS small volume has been formed by collecting together a number of Jaeger's brief essays on various important subjects. They are classified under three headings as Zoological, Anthropological, and Varia. The essays are highly ambitious, and lay down the law upon matters of the deepest difficulty with commendable brevity. Thus the fourteen zoological essays range from "The Origin and Development of the First Organisms" and "The Origin of Species" to "Inheritance," "The Animal Soul," and "The Development of the Vertebrate Type," and altogether occupy eighty-three pages. The essays classed as anthropological deal chiefly with the author's pronounced views on physiological processes, infection, immunity, constitutional strength, &c.

The author is apparently a man with an active original mind and a great respect for his own opinion. Subjects of such intricacy and difficulty are not to be handled so boldly except by those who have not been able to study, or have not cared to study all that has been said about them. Allowing for the dictatorial and peremptory style of the author, much that is suggestive and interesting will be found in many of the essays, as indeed we should expect from the writings of a man who was one of the first, if not the first, to suggest the continuity of the substance of the germ cells of parent and offspring as the biological basis of heredity. A letter, written to the author by Charles Darwin in 1869, and a second in 1875, are printed, and the latter also reproduced in facsimile. Both are very characteristic in their high appreciation of the work of another.

The book is well translated and edited. The printing is good, but the few illustrations are not well executed, the representation of a nerve-cell (after Max Schultze) on p. 9 being especially bad. E. B. P.

Medical Missions in their Relation to Oxford. By Sir Henry W. Acland, Bart., K.C.B., F.R.S. Pp. 92. (London: Henry Frowde, 1898.)

THIS is an address, with a series of notes, delivered by Sir Henry Acland to the Oxford University Junior Scientific Club at the beginning of last December, with the object of showing the valuable work which can be accomplished by men with scientific knowledge acting in connection with foreign missions, either as coadjutors or as appointed religious teachers, as medical practitioners, or as health officers. The needs of India for such men are especially referred to, and it is shown that the prevention of disease, or the care of the public health among various races under different conditions of climate, life, and character, as well as the treatment of disease under the same conditions, should be an essential object of foreign missions. The establishment at Oxford of a department where the complicated subjects bearing on the public health of India can be taught is warmly advocated.

It was with the idea of securing such means of study that Sir Henry Acland resigned his office into the hands of the Regius Professor of Medicine, Prof. Burdon-Sanderson, but, unfortunately, the University is not able to carry out the scheme, and it remains for some wealthy person to grasp the great importance of the various questions involved in the public health of India, and assist the University to provide the means required.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Protective Mimicry.

I HAVE read, with special interest, both Sir George Hampson's remarks on certain cases of pseudo-mimicry and Mr. Ed. Poulton's answer to the same (NATURE, vol. lvii. pp. 364 and 389).

Now, as I am the person that was consulted on the subject by one of Sir G. Hampson's correspondents in India, I think myself entitled, and in a way even bound, as far as possible to remove some of the misgivings that seem to have crept into Mr. Poulton's appreciation as to the true bearing of the facts under discussion.

Though he agrees, on the one hand, with Sir G. Hampson as to the fact that "this and other like cases of mimicry are quite destructive of any interpretation of resemblance based on Bates' theory," he yet maintains, on the other, that "they do not similarly affect the Müllerian theory."

But this is precisely what I contend is contradicted by the facts in question. To make this clear, I shall only use Mr. Poulton's own statements and admissions.

"The Müllerian theory," he says, "supposes that a common type of appearance among distasteful insects in the same locality acts as a common advertisement to enemies, so that the loss of life which must ensue during the time in which each generation of enemies is being educated to avoid the owners of a particular type or pattern and colouring is shared between the species instead of being borne by each independently."

The theory, thus understood, seems to Mr. Poulton to be rather exemplified and confirmed than contradicted by the facts in question, and he therefore continues: "It is probable that *Teracoli* are on the whole avoided by birds; and if this is also true of the *Abraxas*, the resemblance may well be advantageous, in spite of the difference in station, even granting that the 'good round sum' of 6000 feet is an absolute barrier to the *Teracoli* below and the *Abraxas* above. But future investigation may show that they approach much nearer than this."

First of all this reasoning, which is openly all about admitted facts, looks rather as a running away from those facts to some wished-for possibilities. Besides Mr. Poulton grants, after all, that unless both types occur in the same locality and be exposed to the same enemies, no possible training of young birds can be conceived, and consequently no advantage can be supposed to accrue.

But what are the facts? For here, of course, I do not pretend to discuss what might take place in any possible supposition, nor even to find fault with the logical slip so very common among natural selection evolutionists, which consists in so confounding the simple admission that similarity of colour exists, or even is useful, as to conclude from it that it is therefore the result of usefulness.

Now, so long as we keep to facts, whether we consider the two species of butterflies themselves or their respective enemies, the conclusion is the same, and they both require distinct climatic conditions and distinct "habitats."

Willingly or not, we must resign ourselves to see the "good round sum" of 6000 feet, or rather the difference in climatic conditions and other "surroundings" represented by this difference in elevation in our regions of Southern India remain as an insuperable barrier between the above-named species of butterflies, and to much the same extent also between their enemies.

Far from coming into contact, therefore, they are thus kept by their habits apart from one another, and put under conditions quite different from those required for the possible application of even the Müllerian theory.

Finally, both from the evidence of these and many like facts and, as Mr. Plateau has so well demonstrated, from the trifling importance of colouring in the selection of insects by their enemies, it is, to say the least, difficult to see how the facts of similarity in colour, shape, &c.—which for shortness sake we may even call "mimicry"—can be interpreted or explained by any possible theory based on simple natural selection. And I would, in conclusion, remark that I distrust all such theories not, as Mr. Poulton seems to believe, "on the ground that the evidence is not demonstrative," but because, far from offering an intelligible and possible explanation of facts, they simply stand in contradiction with them and mislead us as to their real meaning.

J. CASTETS, S.J.

St. Joseph's College, Trichinopoly, India, June 8.

I DO not propose to deal with Mr. Castets' objections to natural selection in general. They have often been met before. As to the special case under discussion, he feels that his knowledge of the distribution of the two species is exhaustive enough to give him safe warrant for the assertion that they are invariably separated by a height of 6000 feet. If this conclusion is well founded, it is an important contribution to the facts of the case under discussion. Nevertheless neither this nor the climatic differences need affect the Müllerian theory if the barrier which separates the one form from the other is crossed by the enemies of both. The *Teracolus*-like appearance of the moth is remarkable, and separates it very sharply from its allies. It occurs on an elevated district surrounded by lower country in which the *Teracolus* abounds. The approximation is sufficient to render the Müllerian theory a probable explanation in view of the immense number of similar relationships accompanying a closer approximation in other parts of the world, and considering the complete absence of any other explanation; unless, indeed, Mr. Castets intends to imply, by so constantly dwelling upon one aspect of the environment, that the *difference* in climate is responsible for the *agreement* in appearance.

Oxford, June 30. E. B. POULTON.

Epidemics among Mice.

REFERRING to a paragraph in your issue of June 23 (p. 179), relative to the discovery by Dr. Issatschenko of a new microbe pathogenic to rats, I would call attention to some articles by Prof. F. Loeffler on epidemics among mice, &c., in the *Centralblatt für Bacteriologie und Parasitenkunde*, Band xi. pp. 129–141 (February 10, 1892), and Band xii. pp. 1–17 (July 5, 1892), which will be found translated in a Blue Book entitled, "Report of the Departmental Committee appointed by the Board of Agriculture to inquire into a Plague of Field-Voles in Scotland, with Minutes of Evidence and Appendices and a copy of the Minute appointing the Committee" (1893). Translations of the above papers form Appendix vi. of this Report; and Prof. Loeffler's second paper relates his successful efforts to employ the "Bacillus typhi murium" to destroy field-voles in Thessaly.

It would be interesting to know whether the microbe discovered by Dr. Issatschenko is the same as that described by Prof. Loeffler, or a different species. W. F. KIRBY.

Chiswick, June 25.

Remarkable Hailstones.

ON Sunday, June 26, a district to the south of Manchester was visited by a thunderstorm, which was remarkable for its accompaniment of heavy hail. The storm came from the same quarter as the cool surface wind, viz, north-east, and reached its height about 2.15 p.m.

Preceded by a lull in the heavy rain, hail, accompanied by lightning, began to fall, and continued to do so for five minutes.

The most noticeable fact was the peculiar shape of the hailstones. These were conical in shape, about $\frac{1}{2}$ inch long, and $\frac{3}{8}$ broad in widest part. In longitudinal section they showed (*a*) opaque white bands; (*b*) clear, colourless bands; (*c*) semi-opaque bands, dotted with more opaque portions.

All of those examined agreed in possessing transparent portions at the *vertex* and *base*. On making a transverse section through one of the opaque bands, it was seen to consist of (*a*) narrow clear channels intersecting the surface; (*b*) opaque masses, many of an uniform size, separated by the above-mentioned clear, transparent channels.

The general appearance of this transverse section inclined one to regard the stone as built up of a number of conical spicules, with their vertices pointing towards the vertex of the stone.

This was confirmed by the fact that one of the stones, whilst melting, was squeezed between the thumb and finger, and immediately fell apart into three distinct spicules.

Samuel N. Player.

126 Burton Road, West Didsbury, Manchester.

Dendritic Patterns caused by Evaporation.

I was glad to see the note (with illustrations) published in Nature (June 23) on this subject. Among the specimens which I did not mention in my paper are two microscope slides similar to those described by Prof. G. H. Bryan. They are botanical slides from the collection in my laboratory at Bedford College, and as they were bought specimens, I was not certain that they had been mounted in glycerine jelly, although I believed it was probably the medium used. I therefore laid them aside for future work, and am now pleased to find the probability confirmed. I wished also to make further experiments on the relation of the structure to the included specimen.

I should like to point out, however, that although the medium does not contain recognisable particles in suspension, we may look upon the jelly as representing material in an extremely fine state of division, as it were, so that the principle of formation may be similar to that in the other slides described.

July 1. Catherine A. Raisin.

Solar Halo of July 3.

In case it may interest your readers, I write to say that there has been a magnificent halo round the sun, lasting almost without interruption from 4 p.m. to 6 p.m.

It varied in intensity during the time of its visibility, and also in colour. When at its best it was distinctly bluish at its outer margin, shading through yellow to red; the more decidedly green and pink tints of the rainbow seemed to be wanting. But the most conspicuous feature of the apparition was the comparative darkness of the sky within the ring. The halo appeared as if fringing a dark storm-cloud; but that this was not really the case, was evident from the sun's appearance.

All day, in fact for several days past, the sky has been exceptionally much decorated with fantastic cirrus clouds, and this afternoon, at the time of the halo, veils of cirrus concealed almost all the blue; while a lower layer of cumulus clouds drifted up from the west and gradually obscured the sun, halo and all, for a time.

I do not know if the halo formed a complete ring round the sun, as trees partly concealed my view; but I was able to trace it for fully three-quarters of its circumference.

Bradfield, Reading, July 3. Catharine O. Stevens.

A Monochromatic Rainbow.

A curious rainbow was observed here on Friday evening last. Heavy rain falling in a dark southern sky formed the lower portion of one limb of a bow, extending about 10° directly towards the zenith. The red band alone was visible, and lasted *after sunset* (which occurred at 8.40 for our horizon, and some ten minutes earlier below the Howgill Fells), for a full quarter of an hour. A. J. K. Martyn.

Sedbergh, July 3.

CAST METAL WORK FROM BENIN.

Among the spoils, interesting to ethnologists, brought back from Benin by the punitive expedition under Admiral Rawson, was a large number of elaborately carved elephant's tusks, some of them of remarkable length; various smaller objects in ivory; profusely ornamented wooden panels forming doors and looking-glass frames, and hundreds of objects of great multiplicity of design cast in metal, both in the round and in high relief. The wonderful technical skill displayed in the construction of the metal objects, their lavish ornamentation, much of which is deeply undercut, and in nearly every case the high artistic excellence of the completed subject, have been a surprise and a puzzle to all students of West African ethnology. If they have now begun to recover from their surprise that work of such excellence, indicating skill born of long experience, should have come to light from among so barbarous a race, and that no whisper of its existence should have reached Europe, notwithstanding its great abundance (as attested by the numerous pieces exposed in London and provincial auction rooms, in addition to the hundreds of plaques and figures sent to the British Museum); there has, at all events, been as yet no elucidation of the mysteries—who were its manufacturers, where and when was it executed, and whence did they derive the knowledge of this art?

Although the city has been described as being, in the middle of the seventeenth century, "of greater civility than to be expected among such Barbarous People," none of the travellers who, within the past two or three hundred years, have left accounts of their visits to Benin, have described this metal work as a special feature of interest there. If the amount that has already found its way to Europe had been displayed in the king's or chiefs' houses, or in their public buildings, it could not surely have failed to attract attention and remark. The artificers and their appliances for the manufacture of works, on so large a scale, could hardly also, one would suppose, escape notice, or be passed over in silence, if observed. More than one traveller mentions seeing blacksmiths at work and turning out good workmanship, "considering the appliances they have"; but no foundry work or modellers in clay or wax are referred to.

Tusk-holders in the form of human-headed vases have certainly been alluded to; and the nearest approach to a description of the plaques is the "melted copper whereon are Ingraven their Warlike Deeds and Battels, kept with exceeding curiosity," mentioned in Ogilby's collection of African travels. Few, however, if any, of the plaques brought to Europe display warlike deeds or battle scenes. The accompanying illustrations are taken from examples lately acquired by the City of Liverpool, and described by Dr. Forbes in vol. i. No. 2 of the *Bulletin* of the Liverpool Museums—a recently established periodical, intended to make known the contents of the Derby (or Zoological) and the Mayer (or Ethnological) Museums, and the results of the investigations carried on in the laboratories attached to them.

Fig. 1 represents a small plaque, used as a lid of a box, or perhaps as a pendant, in which the king or some high personage is shown, supported by two slaves; while in Fig. 2, is illustrated one of the human-headed vases which sat on the altar in the king's principal Juju-house, supporting a carved elephant tusk. The head-dress of this figure is a network of coral strings with pendants, set off on both sides by rosettes of larger beads of a different sort. Encircling the neck as high as the lower lips are thirty-one coral ropes, forming the collar, which is the insignia of a high dignitary.

On the face may be observed his tribal marks, consisting of three raised weals over the outer corners of each eye, and of two long perpendicular lines running down the front of the forehead above each inner corner. These last probably represented ordinary tattoo marks on the brow, as they are represented by bands of iron, ingeniously let into the metal during the casting. In the same way the pupils of the eye are formed by round discs of iron. The whole figure has been very carefully chiselled over; and when it was newly finished, there is little doubt that the steel-blue tattoo lines and the glistening pupils gave to the face and eyes a very life-like appearance.

The projecting circular flange of the base has depicted on it a series of most interesting symbolic and fetish emblems. From its centre in front, the different symbols follow each other in the same order round both halves of the circumference. The central symbol is a bullock's head; then, in succession, a stone neolithic celt; an arm excised at the shoulder (with a tripod-like ornament covering the termination, and in its hand a three-pointed object); a frog; a fish, with protruding eyes, which seems to resemble more nearly than any other the curious mud-hopping *Periophthalmus koelreuteri*, so common on the brackish margins of West African rivers, or, possibly, it may be intended for—though very unlike—the electric fish (*Malapterurus*), which is a powerful fetish on different parts of the coast, because of the "quaking and trembling it produces in the arm"; then follows another bullock's head, which, with a second neolithic stone axe, completes the series.

The bullock's head, which occupies the central position among the symbols, is doubtless a fetish emblem. The

FIG. 1.

Beni have large herds of black and white cattle, as described by Burton; and bullocks form one of the chief sacrifices, human beings being the other, when the king is making "country custom" for his father and dead ancestors. The same emblem was much in evidence also in Dahomey, when, "during the customs," as Commander Forbes records, "a party carrying the fetish gear is headed by a man in a huge coat of dry grass, wearing a large bullock's head. As he passes, all the boys follow crying 'Soh, soh!' This is the representative of the god of thunder and lightning." One of these actual masks formed part of the Benin loot, and is now in the National Collection.

The next emblem to this, on each side, is the representation of an undoubted neolithic celt. These implements, which occur in the ground in many parts of Africa, are, among the Yorubas, considered to be "thunderbolts which Shango or Jakuta, the thunder god, cast down from heaven, and are venerated as sacred relics. Among the negroes in Tobago, in the West Indies, where they disinter similar neolithic axes, from time to time, in digging holes for sugar-canes, the stone is often boiled, and the water drunk to cure various kinds of ailments. The tusk-holders that have been secured for the Liverpool Museum must be of great antiquity, for they are overlaid with a very rich patina, the result of long exposure.

The little statuette (Fig. 3) is very interesting. It represents a native soldier or hunter, standing with a flint-lock in his hand. The upper part of his body is clothed in a garment ingeniously made of the two halves of a headless leopard's hide. A short pleated kilt-like garment encircles his loins. He wears a bandolier, a short sword, a hunting-knife, and a powder-flask made

FIG. 2.

of elephant tusk. The most interesting detail of this statuette is undoubtedly the flint-lock, as it serves to fix the period anterior to which this casting could not have been made, *i.e.* 1630 to 1640, the date of the invention of flint-locks.

The elaborate details on the plaques, statuettes and tusk-holders prove that whoever the artist was who designed these objects, he was, or had become, well acquainted with the religious or fetish feelings and ideas of the people, their ceremonies and customs, and with the minutest details of their various garments, ornaments and accoutrements, and was no passing visitor. His skill and patience are beyond question.

The material of which these various objects is composed is not bronze, as has been generally stated in most of the accounts of them, but a copper-lead-zinc compound, in which the proportions of the three elements vary very much. Its analysis has consequently thrown little light on the source whence the metal was obtained.

The process of manufacture was undoubtedly that known as *Cera perduta*, in which the object is first modelled in very fusible wax. The model is then overlaid with finely levigated clay, and built up to a sufficient thickness. Through an orifice, afterwards made in the clay, the wax is melted out, and the molten metal run into the vacuity. By this process each article requires a model for itself, and only one casting can be made from one mould.

FIG. 3.

As the present natives of Benin are incapable of producing, at the present day, any works approaching these plaques and statuettes, it may be that the art was brought to the West Coast Hinterland by some European trader, prisoner or resident, who, observing the skill of these people in the modelling of clay figures, such as the Fantee women fashion, may have instructed them how to do the same in wax, and how by overlaying the model with clay to finally reproduce it in metal.

It is possible, on the other hand, that their knowledge of founding was derived from purely African sources. The ancient Egyptians knew how to cast in bronze, in which there was, however, no zinc. The Benin upper classes are not negroid, their features are regular, and their skin olive-coloured. It seems not improbable, therefore, as another explanation of the presence of such high works of art in Benin, that many centuries ago the city may have been occupied by an offshoot of the same central Soudan race, with the leaven of Abyssinian or Egyptian influences among them, as now occupies Nupe, a few hundred miles further north; but that through intercourse with the debased coast tribes, they became demoralised and degenerated into their present low civilisation. The metal work discovered in the city may, therefore, be the relics of a former higher civilisation; or they may, as Commander Bacon has suggested, have been the spoils of some campaign, kept as fetishes. When, however, their full history is elucidated, an interesting and unsuspected chapter in the history of West Africa will undoubtedly be brought to light.

THE PROPOSED UNIVERSITY FOR BIRMINGHAM.

THE movement started in Birmingham fifteen years ago for the establishment of a University in the Midlands has been growing so steadily in energy and in volume that the promoters feel justified in taking definite steps for the accomplishment of their object. The first stage of operations was reached last year, when the College founded by Sir Josiah Mason in 1880 was incorporated by Act of Parliament under a new constitution, and received the new name of "Mason University College." An important step forward was taken last week, July 4, when the first public meeting in favour of the proposal to create a University was held in the Council House, under the chairmanship of the Lord Mayor of Birmingham, and was attended by Mr. Joseph Chamberlain, M.P., and an influential gathering. The proceedings must have been in the highest degree satisfactory to the promoters, for not only were some interesting speeches delivered and much enthusiasm displayed, but a very substantial proof of the earnestness with which the scheme is being taken up by the inhabitants was afforded by the announcement of promised donations to the requisite funds of about 96,000*l*. The next step will be the issue of a public appeal for further donations; and it is confidently expected that the sum of 250,000*l*., which it is estimated is necessary to complete the equipment of the College, to found new chairs, to supply additional buildings, and to provide for the administrative machinery of the University, will before long be subscribed.

The proceedings at the recent meeting included the resolution, "That in the opinion of this meeting it is essential that in the interest of the city and the Midland district generally, a University shall be forthwith established in Birmingham." Mr. G. H. Kenrick, who moved this resolution, is a manufacturer at West Bromwich, employing a large number of men; and is himself a donor of 10,000*l*. to the fund. He has for many years taken a prominent and honourable part in promoting elementary and technical education in the city; and his opinion on such a question, whether as a man of business or as a school manager, is entitled to respectful attention from his fellow citizens. After referring to the influence which the existence of the University would have upon the training and education of teachers, Mr. Kenrick went on to give his view as to the intimate relation which must be established between the University and the industries of the district; and it is to be hoped that both parties, the professors on the one hand and manufacturers on the other, will be careful to note the very sensible observations of the speaker upon this topic.

No man can now stand up and say that industry can get on very well without science. That idea has been almost given up, but a more dangerous one has arisen in its place.

Some manufacturers know quite well that their industries are dependent upon scientific knowledge; but they have got into the way of saying that they do not want people around them knowing too much, and that when they want a scientific man they can send for him. But a man of science called in on such occasions is not always able to prescribe the exact remedy for the particular disease concerning which he is consulted. This is not to be wondered at, considering that industry has done her best so long to keep science at a distance, that science has pursued her own path independently with small direct reference to the needs of industry.

Prof. Tilden seconded the resolution, and took the opportunity of pointing out that, though in the past there had been much prejudice in the minds of British manufacturers against a University training, because they had been disposed to regard it as all very well for clergymen and schoolmasters, but useless in practical affairs; nevertheless a University rightly organised and rightly conducted might be made a most practical kind of thing.

He urged upon the meeting the importance of noting what is being done in other countries, especially the United States of America and Germany, and pointed to the fact that in these countries not only are Universities numerous, but are influential and richly endowed; while the directors, managers, and even foremen in manufacturing concerns are almost entirely men who have received a complete scientific education, and have taken a degree in one of the Universities, or if not in the University in one of the polytechnics or technical schools. The polytechnics of London and the municipal technical schools in this country are institutions which have done, and are doing, good service; but there are indications that the public do not realise how different they are from their prototypes on the Continent, partly in consequence of the inferior quality of the teaching staff, and partly by reason of the fact that the instruction given in such institutions in this country is only partial, and does not demand the devotion of the whole time and energy of the student. As to the influence of the Universities in England, it was obvious that the ancient Universities, though perhaps partly alive to the question, are incapable of providing what is wanted by industry. A great opportunity is now at hand for creating a University of a new type, in which all that is best of the old and the new can be associated together; not merely a large public school, but a place for men and women, a place for study and also eminently a place for research, and a place where that predominance of examinations which unfortunately prevails so generally in most British universities would be got rid of. In constituting her University Birmingham would do well to emphasise the claims of science in its application to industry by establishing a faculty of "technics" in which "applied science" should be put on an equality, so far as honours and rewards are concerned, with the faculties of arts and of pure science. Mr. Chamberlain supported the motion in a speech which passed in review the course of events which had led up to the movement then inaugurated, and made a strong and effective appeal to local patriotism which had done so much in the past, which had made Birmingham what it was, and which he believed would now set the crown upon their educational work.

The Bishop of Hereford, in moving for the formation of a general committee, made an interesting speech which was listened to with all the more attention that the Bishop of the diocese had endeavoured to throw cold water on the scheme by pointing to the spiritual destitution of the district, and indicating his opinion that this ought to be remedied before other schemes were brought forward. The Bishop of Hereford, however, pointed out that not only was it impossible to put a stop to a great tidal movement which arose out of civic patriotism, but that the work in which they were engaged was actually more likely than any other to help the growth of that spirit in every denomination in the city which would never rest till the spiritual needs of the community were adequately supplied. The Bishop in concluding referred to Bristol and its University College, of which he is President.

At one time it seemed probable that the Birmingham project would take the shape of a federation of colleges among which Bristol would be included. That idea seems now to be abandoned. But the success of movements of this kind seems to be dependent chiefly upon financial support; and if Birmingham brings her scheme to completion it may be hoped that this will serve as a stimulus to other cities to follow her example, so that at some future, not far distant, time, not only will London have a University worthy of her great position, but every large centre of population will be occupied by a seat of learning at once the guide and helper of local industry and a focus of the light and culture of the world.

THE NATIONAL MUSEUM OF NATURAL HISTORY.

THE imminent retirement of Sir William Flower after his long and extremely efficient service as Director of the Natural History Museum, is an event of very serious importance to the progress of natural science in England. At one time the national collection, like any little country museum, was a jumble of curiosities and antiquities, the stray result of capricious generosity. As knowledge grew, the various departments became specialised, and in the middle Victorian period, thanks to the prescience of Owen, and the active interest of the Prince Consort, a prodigious dichotomy was effected. The collections relating to what are called by a well-known if illogical term, the Natural Sciences, were separated from the sculptures of Assyria and Greece, from the papyri and coins, the remains of the arts and manufactures of earlier civilisations, and were lodged in the magnificent palace in South Kensington. They were placed under the care of a small army of specialists—zoological, botanical, geological and mineralogical—and these were directed by a single controlling general, directly responsible to the nation through the Trustees and the Treasury. The great abilities of Owen, and the coordinating genius of Sir William Flower, rapidly made the British Museum of Natural History an institution of world-wide importance. Scientific men from provincial England, from Scotland and Ireland, from the Colonies and from other nations, came to regard it more and more as the greatest of centres for the elaboration of all knowledge in natural science depending on the presence, classification, and display of material specimens. As the reputation of the Museum has grown, so also has grown the work done and to be done in it. Collectors from all parts of the world lavish on it or offer to it for sale the best of their specimens; naturalists bequeath to its care their treasured collections from a thousand sources, and so material for scientific work accumulates. The members of the staff become specialists of extraordinary knowledge; many of them, junior and senior, are experts of European reputation in their own departments. Among all the activities of our great nation, the scientific activity of the Natural History Museum takes a great and increasingly great place.

It is obvious that as this organism grows in activity and specialisation, the position of its Director becomes more arduous and important. The Director of the Natural History Museum should be the leader of the natural sciences in the Empire. He has the opportunity of influencing both society and the Legislature by personal contact and intercourse. He should be the channel through which the scientific workers of the nation make known their needs and aspirations. He should have attainments of the widest possible description, and scientific sympathies that are wider than possible attainments. Not only is such a man advisable for the general advancement of science—he is necessary for the particular post. An almost inevitable association with specialisation is limitation of outlook, and as the various members of the staff of the museum become more efficient in their own departments, they require more and more the assistance of a controlling and coordinating chief. Precisely as they become more distinguished in their own branches of exact knowledge, it becomes more necessary that an officer in whose wide powers they have the fullest confidence, and for the dignity and responsibility of whose post they have the highest respect, should be at their head.

There is no possible mode by which the election of a person with these high qualifications may always be secured, but at least it is certain that he should be sought for in the widest field. Britain and the Colonies, the whole Empire should be passed in review before choice is made of one to hold this arduous, dignified and supreme post. We need not doubt that the Trustees will rise to the level of their responsibilities, and we are glad to know that the President of the Royal Society is numbered among them.

NOTES.

IN honour of the centenary of the establishment of the Physical and Agricultural Society at Königsberg, Dr. Walter Simon has given the Society the sum of four thousand marks to be offered as a prize for a work on the subject of plant or animal electricity, presenting either fundamentally new aspects, or dealing with the physical cause of organic electricity, or its importance upon life in general, or upon certain functions. The competition is open to every one. The works presented may be printed or written in German, French, English, or Italian, and must be sent in before December 31, 1900. Works which are published before the end of next September will not be admitted to the competition, as the intention is to give the prize for works which are comparatively recent at the time of the award. Should no work of sufficient merit be presented the prize may be withheld, or two prizes of five hundred marks each may be awarded. The Committee appointed to make the award consists of Profs. W. Pfeffer, B. Frank, W. Kühne, E. Hering, and L. Hermann, with power to add to their number. Further information concerning the prize may be obtained from the President, or the Secretary, of the Physikalisch-ökonomischen Gesellschaft, Königsberg.

THE fourteenth annual general meeting of the Marine Biological Association was held on June 28; Prof. E. Ray Lankester, F.R.S., President, being in the chair. The Report of the Council dealt largely with the work done at the Plymouth Laboratory during the year. Reference was made to Mr. Garstang's investigations of the habits and migrations of the mackerel, to Mr. Holt's researches on the reproduction and development of fishes living in the neighbourhood of Plymouth, and their distribution at different ages, as well as to the experiments with floating bottles for determining the surface drift in the English Channel, and to the systematic investigation of the dredging and trawling grounds between the Eddystone and Start Point. Twenty-two naturalists and eight students were reported as having worked at the Laboratory since the last annual meeting, in addition to the members of the regular staff. The following were elected members of Council for the year:—President, Prof. E. Ray Lankester; Hon. Treasurer, J. A. Travers; Secretary, E. J. Allen. Council: F. E. Beddard, Prof. Jeffrey Bell, G. C. Bourne, Sir John Evans, G. H. Fowler, S. F. Harmer, Prof. Herdman, Prof. Hickson, J. J. Lister, Sir John Murray, P. L. Sclater, D. H. Scott, Prof. C. Stewart, Prof. W. F. R. Weldon.

ON June 30 the Senate of the Dublin University conferred the honorary degree of Sc.D. on Mr. R. H. Scott, Secretary to the Meteorological Council. In a humorous Latin speech the Public Orator referred to the fact that many people believed the recipient to be not only the interpreter, but also the author of the weather. Last year the French Government conferred on Mr. Scott the Order of Officer of the Legion of Honour, in recognition of valuable services rendered during many years to the French Marine, by the transmission of timely notices of impending bad weather.

MR. JOHN MILNE, writing from Shide, Isle of Wight, says:—At 6h. 48m. 37s. p.m. on June 29, preliminary tremors with a duration of nine minutes heralded the commencement of a large earthquake. The movements extended over three hours. The maximum change in inclination of the surface of the ground was between nine and ten seconds of arc. From an open diagram the period of the E.W. movements which were the most pronounced was thirteen seconds. Assuming a velocity of 2·5 km. per sec., then the length of the earth-waves would be about 32 km., and their height about 30 cm. Records were obtained at Kew, Laibach, and probably at all observing stations in the world.

THE annual general meeting of the Society of Chemical Industry will be held in Nottingham on July 13-15.

THE latest *Verhandlungen* of the Berlin Geographical Society (1898, Nos. 5 and 6) contain the addresses delivered at the special meeting held at the end of May to celebrate the seventieth anniversary of the foundation of the Society. The medals presented at the meeting were as follows:—The Humboldt medal to Dr. Nansen; the Karl Ritter medal to Dr. E. von Drygalski, for his work in Greenland and the monograph upon it; the gold Nachtigal medal to Dr. G. Schweinfurth, for his explorations in Africa; and the silver Nachtigal medal to Captain Ramsay, for his geodetic and cartographic work in German East Africa. Prof. W. M. Davis, Prof. G. K. Gilbert, M. A. de Lapparent, and Prof. Mohn were elected honorary members; and the following were elected corresponding members of the Society:—Dr. Sven Hedin, Lieut. Johansen, W. Obrutschew, Dr. Fritz Sarasin, Dr. Paul Sarasin, Captain Sverdrup, and Dr. Eduard Freiherr von Toll.

FOR several years the Royal Geographical Society, latterly in co-operation with the Royal Society, has been making strenuous efforts to influence the Government to equip an expedition for the exploration of the Antarctic, the greatest unknown area on the face of the earth. It will be within the recollection of our readers that at an enthusiastic meeting held at the Royal Society last February, at which Dr. Nansen and Prof. Neumayer, besides many distinguished British men of science, were present, the great value of the results to be derived from an Antarctic expedition was clearly explained. Previous to this, in October last, the President of the Royal Geographical Society wrote to the Prime Minister urging that an Antarctic expedition should be undertaken either by Her Majesty's Government or with the aid and sanction of the State. The President pointed out in strong terms that it was the duty of England to undertake the further exploration of the greatest unknown region of the globe, and so complete the work done by Ross fifty years ago. The reply received at the time was sympathetic and gave reason to hope that the final reply, which was to be sent at a later date, would be favourable. The final reply has just been received from Lord Salisbury, and in it "his lordship expresses his regret that he is unable, under existing circumstances, to hold out any hope of Her Majesty's Government embarking upon an undertaking of such magnitude." Moreover, it is stated in the reply that at the recent conference of Premiers held at Melbourne in March last, it was resolved that the Australasian Colonies should take no joint action in the matter of Antarctic exploration. In these circumstances, the Council of the Royal Geographical Society have decided to endeavour to obtain the funds for an expedition to be sent out under the Society's auspices. They have authorised the President to take steps to obtain subscriptions to the amount of not less than 50,000*l.*, and the Society itself will contribute 5000*l.* It is much to be regretted that the Government has been unable to give practical support to the enterprise, both in the interests of science and from the point of view of our national credit, but it will be still more lamentable if the expedition has to be abandoned altogether on account of want of funds. The amount required to equip and despatch the expedition is not excessive, and we trust it will soon be raised, so that the Antarctic area may be efficiently surveyed from many scientific aspects.

THE proposed removal of the Museum of Practical Geology from Jermyn Street to South Kensington, recommended by the Committee of the House of Commons on the Museums of the Science and Art Department, has met with adverse criticism from geologists and others. A circular inviting signatures to a memorial to the President and Council of the Geological Society, setting forth the reasons against the transference of the Museum to South Kensington, was recently sent to all Fellows of the Society resident in Great Britain and Ireland. The memorial pointed out that the Museum at present occupies a convenient central position, easy of access for engineers, architects, and others who make use of its collections, in proximity to most of the learned societies, and adjoining the offices of the Geological Survey. The Council of the Geological Society was therefore asked "to impress upon Her Majesty's Government that the suggested discontinuance of occupation and removal of the collections would seriously impede the progress of science, especially on its economic side." The memorial has been signed by about five hundred Fellows of the Society and was presented to the Council, a resolution passed at the recent meeting of the South-Eastern Union of Scientific Societies, and having the same object, being considered at the same time. Though the Council did not see their way to comply with the request of the memorial, they expressed the opinion that the question of the removal required more consideration than it appeared to have received. The memorial and the facts of the case were then brought to the notice of Lord Salisbury, who has promised to give attention to the whole question. There the matter at present stands, but it is to be hoped that no final decision will be arrived at until it has been given most careful consideration and more evidence taken with reference to it than has yet been laid before the Select Committee, in whose report the removal of the collections is suggested.

IT has already been announced that the Society of Arts' Albert Medal for this year has been awarded to his Excellency Dr. Robert Bunsen, the veteran professor of chemistry at the University of Heidelberg. At the annual meeting of the Society held on Wednesday of last week, the work of this eminent investigator was referred to by the Council in the following words:—Amongst the numerous and important scientific discoveries which have rendered the name of Bunsen famous wherever science is valued, perhaps the most striking is the one in which he was associated with his distinguished colleague, Prof. Kirchhoff, viz. spectrum analysis, a discovery which has shed a new and unexpected light on the composition of terrestrial matter, and has enabled us to obtain a distinct knowledge of the chemical composition of sun and stars. The contributions which Bunsen has made in the application of chemistry and physics to the arts and manufactures are of the utmost value, and their importance may be measured by two out of many instances. The Bunsen battery was, until the introduction of the dynamo, the cheapest source of electricity; the Bunsen gas-burner, by which a non-luminous, smokeless, but highly heated flame is obtained, is now not only indispensable in all laboratory work, but is used for heating purposes in thousands of houses and manufactories, and for illumination, by the incandescent system, in millions of lamps. Beyond these Bunsen's contributions to the sciences of chemistry and physics have been of the highest importance; but, perhaps, the greatest benefit which he has conferred through a long life devoted to the advancement of science, has been the influence which he has exerted as a teacher.

THE Paris correspondent of the *Chemist and Druggist* makes the following announcement:—"The gift of 2,000,000 francs (80,000*l.*), made by Baroness Hirsch some time ago to the Pasteur Institute, or rather about two-thirds of it, is to be devoted to building and fitting up a large model biological institute in the rue Dutot, Paris, opposite the Pasteur Institute. The interest of the balance of the money will be devoted to working expenses, though additional money will be required for the latter purpose. The ground on which the new building is to be erected was left as a legacy to the Pasteur Institute by another lady a few years ago. The plans for the Biological Institute have been drawn up by the directors and professors of the parent establishment with the aid of their architect. A hospital will be attached to it, where patients attacked by maladies to which Dr. Roux gives special attention will be treated. M. Duclaux will be the director of the new institute, in addition to that bearing Pasteur's name, while the laboratories of biological chemistry will be under the care of M. Gabriel Bertrand. It is hoped to have the building ready by 1900, and most likely the lectures, &c., connected with biology will in due course be transferred to the rue Dutot from the Sorbonne."

IT has been agreed by the Executive Committee that ladies attending the fourth International Congress of Zoology at Cambridge in the company of a member may become Associates on the payment of 10*s.* This payment will entitle them to attend the general and sectional meetings, and the receptions held during the meeting of the Congress at Cambridge.

THE septic treatment of sewage, to which reference was made in NATURE of November 4, 1897, has so far received the sanction of the Local Government Board, that they have authorised the borrowing of the money required for extending the experimental tanks at Exeter. The Board, however, do not yet seem to be satisfied that this system is capable of producing a thoroughly satisfactory effluent, as it has been required that the minimum area of land usually allowed shall be provided for the completion of the purification. From an article in *The Engineer* of June 17 it appears, however, that this system has been in successful operation in this country for several years, and that for an original outlay of 300*l.* and an annual cost of 50*l.* the sewage from the town of Winsford, in the Salt District, containing 12,000 inhabitants, has been sufficiently purified to flow into the river Weaver without causing any pollution. Under all the existing systems that are in operation, one of the chief difficulties is the disposal of the sludge which is left in the settling tanks, but under the septic treatment this difficulty disappears. The process at Winsford is simplicity itself. The works were constructed about twenty years ago, and have been in continuous operation ever since. They consist of a series of tanks containing about seven feet of ashes and clinkers, through which the sewage flows. Each set of tanks is used for a week, and then allowed a rest. The sludge settles in the first tank, and, owing to the action of the microbes, the residue, when taken out and placed on the banks, cannot be distinguished from ordinary soil. The quantity is so small that, although none has been removed, there is no accumulation at the present time. The water in the river Weaver, into which the effluent flows, has from time to time been analysed, but no traces of pollution have been detected, and there is no discoloration.

THE Deutsche Seewarte, in connection with the Danish Meteorological Institute, has issued daily synoptic weather charts for the North Atlantic Ocean and adjacent continents, for a year ending November 1893. These charts give a complete representation of the state of the weather existing at 8h. a.m. each day, and clearly show the movements of the low-pressure areas and the positions of the barometric maxima, compiled from all available data from land and sea. Synoptic charts for the above district have now been regularly issued (including those for the same district, issued by our own Meteorological Office for 1882–3) since the latter part of 1873, and contain the most necessary materials for elucidating weather changes and for improving weather predictions. The charts are accompanied by a separate *Quarterly Weather Review* explaining the various conditions, and illustrated by charts relating specially to each period during which any particular system was maintained, and clearly exhibiting the tracks of the various storms or low-pressure areas from west to east, or north-east. Great credit is due to the German and Danish Institutes for the persistency with which this most important work is carried on, as, although some copies are sold, there must be a considerable expense thrown upon them, both as regards the production of the charts and their subsequent discussion; but the value of the work to meteorological science is beyond question.

THE Director of the Madrid Observatory, Sr. M. Merino, has published the results of the meteorological observations made there during thirty-five years (1860–94). The tables, which have been very carefully prepared and arranged by Sr. F. Cos, show *inter alia* the monthly and yearly values of all the principal elements and the daily means for each five years. This long and laborious work is the continuation of that published in 1893, which contained the results of thirty years' observations. The absolute maximum temperatures of the various years range from 98°·6 to 111°·7, and the absolute minima from 25°·5 to 9°·5. The average yearly rainfall amounts to 16·5 inches, but the quantity varies very considerably in different years.

THE study of the mathematical theory of electricity would appear to be becoming popular in Japan, to judge from the *Kiji* of the Tōkyō Mathematico-Physical Society. In two numbers now before us (vol. viii. parts 1, 2) we find no less than three papers on this subject: one by H. Nagaoka, on the strain of an iron ring by magnetisation; one by E. Sakai, on the distribution of electricity on two excentric cylinders; and finally an essay by Dr. S. Kimura, on the magnetisation by induction of a rotating sphere or spheroid under a solenoidal distribution of magnetic force.

"THE disruptive discharge in air and liquid dielectrics' forms the subject of a dissertation by Mr. T. W. Edmondson, of the University of New York (*Physical Review*, vi. 2). From experiments with different sized spheres immersed in different liquids, Mr. Edmondson finds that the curves representing the relation between the potential difference and the sparking distance are in general approximately hyperbolas becoming practically straight lines for spark-lengths of over 3 mm. While a smaller difference of potential is necessary to produce a discharge through a given distance for large spheres than for small ones when the spheres are close together, for longer distances the dielectric is electrically stronger for large than for small spheres. Mr. Edmondson gives a table of the dielectric strengths of various substances; those for air, obtained with spheres, being considerably higher than that obtained by Macfarlane for planes. Both electrostatic and alternating discharges are considered.

A USEFUL summary of the present state of knowledge of the properties of Becquerel rays, in relation to Röntgen rays, is given by Mr. Oscar M. Stewart in the April number of the *Physical Review*. With reference to these radiations from various chemical substances, it is concluded: "As these rays can be reflected, refracted and polarised, there can be no reasonable doubt that they are transverse ether waves. Interference alone is left to be established to confirm this, but owing to the extreme feebleness and short wave-length it is doubtful whether it can be shown. . . . These rays, like X-rays, are not homogeneous. They have all the properties that X-rays possess, such as photographic action, exciting fluorescence, making gas conductors, and exciting thermo-luminescence. . . . The similarity in the behaviour of the X-rays and Becquerel rays certainly presents a strong argument in favour of the theory that X-rays are short transverse ether waves." In connection with this subject, it should be mentioned that the articles which have appeared on the subject of the discharge of electrified bodies by X-rays are briefly reviewed by Mr. Clement D. Child in Nos. xxiii. and xxix. of the *Physical Review* (1897), and supplemented with some results of his own upon the effect on the rate of discharge produced by a variation in the density of the air surrounding the electrified body.

PAPERS on miscellaneous results of recent work of the Division of Entomology of the U.S. Department of Agriculture appear in *Bulletin* No. 10 (new series). The articles are of interest to economic entomologists, and of importance to agriculturists and fruit-growers. Among the general notes is one on a lead-boring insect. Examination of a lead tank which had leaked showed that the metal had been pierced with holes by the larvæ of some species of beetle of the genus Lyctus. This is the third case which has come under Dr. L. O. Howard's notice of insects which bore into lead. In one case a Cossus larva bored its way through a large leaden bullet, which was embedded in an oak tree in which the larva was living; and in another, a coleopterous larva bored its way through a piece of lead piping.

AN important memoir, containing the results of a detailed craniological investigation, has just been published in the *Transactions* of the Wagner Free Institute of Science of Philadelphia (vol. v.). The memoir is the last of the late Dr. Harrison Allen's many contributions to the knowledge of organic forms and their modifications, and entitled "A Study of Hawaiian Skulls." The concluding remarks express clearly the scope of the contents; they are as follows:—"In the study just completed I have described a new graphic method of collating measurements. I have endeavoured to establish the proposition that the difference between the crania called here the 'cave and the coast crania' are not due to race but to methods of living, and in some degree to differences of mental strength in individuals. The cave series represents the dominating and superior type, and the coast series the weak and conquered type. I have suggested that some of the contrasts that obtain in the proportions of the face of the crania after European contact may be traced to the impress made upon the individual by the action of the exanthematous diseases. I remain of the opinion that the interest attached to the study of the human skull is not confined to attempting to limit race, but to the study of the effects of nutritive and even morbid processes upon the skull form." Dr. D. J. Brinton prefixes a short appreciative note to the memoir, and points out that the conclusion as to the influence of methods of living in producing differences between crania is most important.

"A CATALOGUE of Earthquakes on the Pacific Coast, 1769 to 1897," by Dr. E. S. Holden, forms No. 1087 of "Smithsonian Miscellaneous Collections," vol. xxxvii. In compiling this catalogue, Dr. Holden had in view the determination of the general facts as to distribution of earthquake shocks, as to topographic areas, as to time, intensity, &c., and also the characteristics of particular shocks. The result is a history of earthquakes on the Pacific Coast, the disturbances being arranged chronologically and briefly discussed in an introduction. As many of the earthquakes of California are very local phenomena, which depend upon local causes for their production, no very definite conclusions can be found with reference to them. An arrangement of the shocks according to seasons shows that for California, Oregon, and Washington at large, shocks occur with about equal frequency in the wet and in the dry seasons. The records indicate, however, that in San Francisco and San José shocks are more frequent in the rainy season than in the dry. Dr. Holden suggests that, in any future study of California earthquakes, special regions ought to be selected for examination, with the object of determining the origin of the local shocks. The data he has obtained seem to indicate that the greater number of California earthquakes have been the result of faulting in underlying strata, rather than due to volcanic causes directly. With regard to damage to life and property caused by the earthquakes recorded, it is concluded that the earthquakes of a whole century in California have been less destructive than the tornadoes or floods of a single year in other parts of the States.

WE have received the Summary Report of the Geological Survey of Canada for 1897, by Dr. George M. Dawson, Director, and it is interesting to note that there is a great and increasing demand for the Survey publications. It is, of course, not surprising to learn that the report on the Yukon district is practically exhausted, and that the text and maps will be revised and reprinted. Gold mining was first attempted in the Yukon region in 1880, and in 1887 Dr. Dawson conducted an exploration of it; his forecast of the mining prospects has been amply verified by the recent discoveries in the Klondike district. The work of the Survey has so increased that there is great need of new, fireproof, and more spacious quarters; but at present the economic and scientific value of the collections and records does not appear to be fully appreciated by the Canadian Parliament. A quotation is made from an article in NATURE, written by a geologist who attended the meeting of the British Association in Toronto, and this pointed out how well the work of the Survey is appreciated by the people for whom it is primarily intended. The results of experimental borings carried out by the Survey in Northern Alberta in search of mineral oils are duly recorded. There are useful notes on the occurrence of corundum, and of observations on it by Mr. W. F. Ferrier. Coal, peat-bogs, building-stones and various metals come in for a share of attention, as well as the soils and agricultural prospects. Various analyses and assays have been made. The purely scientific aspects of geology are by no means neglected, and we have accounts of the igneous origin of fundamental gneiss, and of various formations of all ages up to the glacial drifts and recent accumulations. Reports on the palæontologica work are furnished by Mr. Whiteaves. During the year nineteen new maps were published; so it is evident that the Survey is prosecuted with vigour and enthusiasm, and we only hope that Dr. Dawson's desire for a more appropriate establishment may be granted.

THE seventeenth annual Report of the United States Geological Survey, recording in full the work done under the direction of Mr. C. D. Walcott during the period 1895–96, has lately reached us. It is divided into three parts, which are published in two bulky and two smaller volumes, and together these comprise lxviii and 2998 pages of letter-press. The information, as usual, is of the most varied character. There is the general report of the Director; an account of magnetic declination in the United States, by Henry Gannett; further contributions to the geology of the Sierra Nevada, by H. W. Turner; a geological reconnaissance in North-western Oregon, by J. S. Diller; and a discussion of the faunal relations of the Eocene and Upper Cretaceous on the Pacific Coast, by T. W. Stanton. In addition there are reports on the coal and lignite of Alaska, on the Uintaite or Gilsonite (a variety of asphalt) in Utah; on the brick-clays of Rhode Island; on the gold-quartz veins of Nevada city; on the geology of Silver Cliff and the Rosita Hills of Colorado; on the Tennessee phosphates; and on various underground and artesian waters. The mineral statistics are full and elaborate, and it is interesting to note that Fuller's earth has been discovered in Florida, Georgia, Virginia, and South Dakota. The illustrations are many, and include figures of Eocene and Upper Cretaceous Mollusca, maps, sections, pictorial views, and plates showing structure of ores, eruptive and metamorphic rocks.

THE following important additions to our knowledge of the flora of the American continent and of Australia have reached us:—Contribution No. 3 to the coastal and plain flora of Yucatan, by D. C. F. Millspaugh, from the Field Columbian Museum, Chicago; Contributions from the Gray Herbarium of Harvard University (No. 13), by Mr. B. L. Robinson, comprising a revision of the North American and Mexican species of *Mimosa* (67 species), and of the North American species of *Neptunia*; five instalments of Contributions to the flora of Queensland, by Mr. F. M. Bailey (these, not being numbered, are difficult of reference).

TOURISTS who are contemplating a visit to the north of Ireland should procure a copy of the Official Guide to the Belfast and Northern Counties Railway, Giant's Causeway, and Antrim Coast. The volume is a handy and exceptionally interesting guide-book, containing, in addition to the usual information, a section upon scenery and geology in County Antrim, by Prof. G. A. J. Cole, botanical notes by Mr. R. Lloyd Praeger, notes on the antiquarian remains of Antrim, by Mr. W. Gray, and numerous reproductions of photographs.

THE initiation ceremonies of natives of Australia have in recent years received the attention of a number of anthropologists. The latest paper upon the subject deals with the initiation ceremonies of the Arunta tribe, Central Australia, and is by Prof. Baldwin Spencer and Mr. F. J. Gillen. (*Proceedings* of the Royal Society of Victoria, vol. x., issued May 1898). It may be recalled that an account of the Engwurra ceremony as performed by the Arunta tribe appeared in NATURE a year ago (vol. lvi., p. 136). The Engwurra is not passed through until probably the native has reached the age of at least twenty-five or even thirty; but this final and impressive ceremony is preceded by others, beginning at about the age of ten or twelve, through which practically every Australian native has to pass before he is admitted to the secrets of the tribe and regarded as a fully-developed member of it. It need hardly be pointed out that authentic records, such as are given in the present paper, of ceremonial rites of aboriginal tribes are of increasing scientific value, even though the significance of the rites is not understood. Among other subjects of papers in the volume of *Proceedings* referred to above are:—Entropy meters, a method of determining the specific heat of a liquid; the geology of Coimaidai, with appendices on the marsupial bones of the Coimaidai limestone and the graptolites of the district; the structure of an Australian land leech (*Philæmonpunge*, n.s.); and a catalogue of the marine shells of Victoria.

IN the current number of the *Berichte*, J. H. Aberson describes a very interesting substance, which appears to be a new isomeride of malic acid. This compound occurs in many species of Crassulaceæ, and has the composition, molecular weight and chemical composition of malic acid, $C_4H_6O_5$, but differs from this very markedly in its behaviour when heated. Ordinary malic acid under these circumstances yields water and fumaric acid or maleic anydride, whereas the new isomeride is converted into a volatile double anhydride or malide, $C_8H_8O_8$, formed from two molecules of the acid, small quantities of fumaric and maleic acids and other products being also formed. The new acid is, moreover, more strongly dextro-rotatory than ordinary malic acid, and yields salts which differ from the malates in several important particulars. The author considers that the new compound is geometrically isomeric with ordinary dextro-malic acid, but that in it the free rotation of the two carbon atoms has in some way been arrested, so that the atoms and groups attached to these are not in that "most favoured" position, by the aid of which Wislicenus has been able to formulate so clearly the production of fumaric and maleic acids from the ordinary acid. It has not, however, been hitherto found possible to convert the new acid into the better-known modification, although the author promises to describe at an early date a method for its synthetical production. If this new form of the acid really has the configuration assigned to it, further research will no doubt reveal the corresponding lævo-rotatory and inactive (racemic) acids, the number of isomeric malic acids being thus brought up to six.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*, ♂) from India, presented by the Lady Tichborne; a Pig-tailed Monkey (*Macacus nemestrinus*, ♀) from Java, presented by Mr. J. Ratillon; two Rhesus Monkeys (*Macacus rhesus*, ♂ ♀), a Bonnet Monkey (*Macacus sinicus*, ♀) from India, presented by the Parks Committee, Tynemouth; a Lioness (*Felis leo*) from Somaliland, presented by Mr. Henry S. H. Cavendish; a Mouflon (*Ovis musimon*, ♂) from Corsica, presented by Mr. H. Brinsley Brooke; a Jackal Buzzard (*Buteo jacal*) from South Africa, presented by Mr. J. E. Matcham; a Royal Python (*Python regius*) from West Africa, presented by Mr. W. G. Woodrow; a Chimpanzee (*Anthropopithecus troglodytes*, ♀) from West Africa, a Brush Turkey (*Talegalla lathami*) from Australia,, a Glaucous Macaw (*Anadorhynchus glaucus*) from Paraguay, a Yellow-crowned Penguin (*Eudyptes antipodum*), a Thick-billed Penguin (*Eudyptes pachyrhynchus*) from New Zealand; six Argentine Tortoises (*Testudo argentina*) from Patagonia, a Nilotic Trionyx (*Trionyx triunguis*) from North Africa, a White-throated Monitor (*Varanus albigularis*) from South Africa, four Wagler's Terrapins (*Hydraspis wagleri*) from Brazil, deposited; a Lesser Koodoo (*Strepsiceros imberbis*, ♂), a Beisa Antelope (*Oryx beisa*, ♂), two Hagenbeck's Jackals (*Canis hagenbecki*) from Somaliland, three Japanese Teal (*Querquedula formosa*, ♂ ♀ ♀) from North-east Asia, two Black-winged Pea-fowl (*Pavo nigripennis*) from Cochin China, a Rufous Rat Kangaroo (*Æpyrymnus rufescens*, ♂) from New South Wales, purchased; two Bennett's Wallabies (*Macropus bennetti*, ♂ ♀), a Brush-tailed Kangaroo (*Petrogale penicillata*, ♀), a Japanese Deer (*Cervus sika*, ♀), born in the Gardens, five Upland Geese (*Chloephaga magellanica*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMET PERRINE (JUNE 14).—The following is a continuation of the ephemeris from last week. The comet is rapidly decreasing its northern declination and becoming brighter.

1898.	R.A. (app.) h. m. s.	Decl. (app.) ° ′	log r.	log Δ	Br.

LATITUDE VARIATION IN A RIGID EARTH.—In an article contributed to the *Physical Review* (vol. vi. No. 3), Prof. Henry Crew discusses the movements of the earth's axis in terms of elementary dynamics, and calls attention to the "beautiful, but much neglected, top which Maxwell first spun at Edinburgh some forty years ago." Besides giving an excellent illustration of the top itself, Prof. Crew adds also an account of the adjustments that are necessary for its accurate working, and describes the various phenomena which it will illustrate, such as nutation and precession, statical stability and dynamical instability conferred by rotation, variation of latitude, and effect of polar ice-caps. In the mathematical treatment above referred to, Prof. Crew recalls the fine illustration employed by Maxwell, that the motion of the earth is practically that of a circular hoop rolling, but not slipping, on a stick of circular cross section, the word "practically" being used as the earth, in sections parallel to the equator, is not circular but elliptical. The theory here expounded shows that this hoop does represent the motion of a freely rotating rigid solid fixed at its centre of mass. Prof. Davidson's extensive and accurate series of observations (*Astr. Journal*, No. 323) receive here due attention.

CONFERENCE OF ASTRONOMERS AT HARVARD.—In consequence of the great success of the conference of the astronomers held last year at the Yerkes Observatory, it is proposed to hold a second meeting this year, and further to continue them annually. As the American Association for the Advancement of Science will meet in Boston on August 22, on the occasion of the fiftieth anniversary of its foundation, it has been decided to hold the conference at the Harvard College Observatory on August 18, 19 and 20. The circular, which we have received from Prof. E. C. Pickering, tells us that the proposed plan will enable visiting astronomers to attend this meeting, and those who are members of the Association can avail themselves of the special rates which have been obtained from hotels and railroads. Those who intend to go are requested to send in their names, and titles of papers if they intend to read any. Besides showing the work of the various departments of the observatory, excursions will be planned to various neighbouring scientific institutions, including the Blue Hill Meteorological Observatory, the Massachusetts Institute of Technology, the laboratories of Harvard College, &c.

A FINE COLLECTION OF METEORITES.—There has just been published a most interesting and valuable catalogue and guide to the collection of meteorites in the Paris Natural History Museum. Prof. Stanislas Meunier, who occupies the chair of Geology, tells us in his preface that in 1861 they only possessed 64 meteorites, and the first published catalogue comprised 86 falls. In 1864 the number rose to 160, and in 1889 the list consisted of 367 distinct meteorites. Since that date the museum has obtained possession of numerous new additions, and the present catalogue deals with 463 distinct falls. The catalogue itself is very well arranged. We have first a list of the different types which up to the present are known and exhibited in the museum, sections of which are copiously illustrated; we next come to the arrangement of the individual meteorites, followed by an excellent bibliographical index. The final list is arranged chronologically, and gives the date and locality of fall, type, weight, and other interesting data.

THE AMERICAN ASSOCIATION.

THE preliminary programme of the fiftieth meeting of the American Association for the Advancement of Science, to be held at Boston August 22–27, has just been issued by the local committee.

Some changes have been made in the officers of the Association by death and resignation. The revised list is:—President: Frederick W. Putnam. Vice-Presidents: Section A (Mathematics and Astronomy): Edward E. Barnard. Section B (Physics): Frank P. Whitman. Section C (Chemistry): Edgar F. Smith. Section D (Mechanical Science and Engineering): Mortimer E. Cooley. Section E (Geology and Geography): Horace L. Fairchild. Section F (Zoology): Alpheus S. Packard. Section G (Botany): W. G. Farlow. Section H (Anthropology): James M. Cattell. Section I (Social and Economic Science): Archibald Blue. Permanent Secretary: Leland D. Howard. General Secretary: James McMahon, to fill vacancy caused by the death of David S. Kellicott. Secretary of the Council: Frederick Bedell.

The meetings will be held at the Massachusetts Institute of Technology, the Harvard University Medical School, and the Boston Society of Natural History. Association headquarters will be at the Rogers Building of the Institute of Technology (named after Prof. Wm. B. Rogers, last president of the Society of American Geologists and Naturalists, from which the American Association was organised fifty years ago). The hotel headquarters will be at the Copley Square Hotel.

The general programme begins with the meeting of the Council on August 20. The first general session of the Association will be held on Monday, August 22, at 10 a.m., at Huntington Hall in the Rogers Building. The retiring president, Prof. Wolcott Gibbs, will introduce the president-elect, Prof. F. W. Putnam, of Harvard University. Addresses of welcome will be delivered by Governor Roger Wolcott, of Massachusetts; Mayor Josiah Quincy, of Boston; and President James M. Crafts, of the Massachusetts Institute of Technology. President Putnam will reply. The several sections will then commence their sittings.

The addresses of the several vice-presidents will be given on Monday afternoon as follows:—

At half-past two o'clock: Vice-President Whitman, before the section of physics, "On the Perception of Light and Colour"; Vice-President Cattell, before section of anthropology, on "The Advance of Psychology"; Vice-President Farlow, before section of botany, on "The Conception of Species as affected by Recent Investigations on Fungi."

At half-past three o'clock: Vice-President Barnard, before section of mathematics and astronomy, on "Development of Astronomical Photography"; Vice-President Blue, before section of social and economic science, on "The Historic Method in Economics"; Vice-President Packard, before section of zoology, on "A Half-century of Evolution with Special Reference to the Effects of Geological Changes on Animal Life."

At half-past four o'clock: Vice-President Smith, before section of chemistry (subject to be announced); Vice-President Fairchild, before section of geology and geography, on "Glacial Geology in America"; Vice-President Cooley, before section of mechanical science and engineering (subject to be announced).

The address of the retiring president, Prof. Wolcott Gibbs, on Monday evening, will be "On some Points in Theoretical Chemistry," after which will be a reception to the Association and invited guests.

The meetings of the several sections for the reading of papers will be held on Tuesday and Thursday, morning and afternoon; and some sections will also hold meetings at Cambridge on Friday. Sections F and H will meet on Tuesday evening at the Harvard Medical School, when Dr. Thomas Dwight will lecture on "Variations in Human Bones."

Wednesday will be "Salem Day," and will be devoted to an excursion to Salem, where the museum of the Association is located. On the return, in the evening, lectures will be given in Huntington Hall on the Boston Park System and the Metropolitan Water Supply and Sewerage System.

Friday, Cambridge Day, will be spent at Harvard University, and an address will be made in the evening at Sanders Theatre by President Charles W. Eliot.

The general closing session will be held on Saturday morning at 10 o'clock; and the concluding meetings and adjournment of the sections in the evening.

Besides the excursions to Salem and Cambridge, an excursion will be made on Tuesday afternoon, under the auspices of the American Forestry Association, to Middlesex Fells; on Thursday afternoon to the Arnold Arboretum and the Blue Hill Meteorological Observatory; and on Saturday a choice between (*a*) Wellesley College, (*b*) Concord and Lexington.

On the following Monday, August 29, excursions will start to the following places:—White Mountains, Plymouth, Provincetown (ocean excursion to Cape Cod), Wood's Holl (the Marine Biological Laboratory and the United States Fish Commission), Newport, Clinton (the new Metropolitan Water Supply), Lawrence Experiment Station (of special interest to chemists, biologists and students of public hygiene).

The foreign guests at the Boston meeting will be entertained by the City of Boston. The officers of the committee on foreign invitations are Dr. Henry P. Bowditch, chairman; Mr. A. Lawrence Rotch, secretary.

The local secretary for the Boston meeting is Prof. H. W. Tyler, of the Massachusetts Institute of Technology, to whom all correspondence should be addressed.

Meetings of affiliated societies will begin on August 18, including American Forestry Association, Geological Society of America, American Chemical Society, Society for the Promotion of Agricultural Science, Association of Economic Entomologists, Botanical Club of the Association, American Mathematical Society, Society for the Promotion of Engineering Education, American Folk-Lore Society, National Geographic Society, Botanical Society of America, and conference of Astronomers and Physicists.

FOLK-MEDICINE IN ANCIENT INDIA.

"THE most primitive witchcraft," says Sir Alfred Lyall, "looks very like medicine in the embryonic state." This is pre-eminently the case in ancient India, where it is not difficult to trace the history of medical science—such as we find it in scientific works on medicine, like the *Charaka* or *Susruta*—back to its early beginnings in the charms and witchcraft practices of the *Atharva-veda*, the most ancient compendium of sorcery.

In India, as elsewhere, the general doctrine of disease prevails that all abnormal and morbid states of body and mind are caused by *demons*, who are conceived either as attacking the body from without, or as temporarily entering the body of man. The consequence is that primitive medicine consists chiefly in chasing away or exorcising these hostile spirits. This is done, in the first instance, by *charms*. The spirit of disease is addressed with coaxing words and implored to leave the body of the patient, or fierce imprecations are pronounced against him, to frighten him away. But these charms, powerful as they are (in fact, there is nothing more powerful to the primitive mind than the human *word*, the solemn blessing or curse), are yet not the only resource of the ancient physicians or magicians.

From the earliest times people had become aware of the curative power of certain substances in nature, especially of herbs. This knowledge was first gained by experience, and, after it had once been obtained, people began to ascribe similar curative power to plants, as well as to animal and mineral substances for various other reasons. Analogy or association of ideas serves to explain not only many of the practices of primitive medicine, but also accounts in many cases for the belief in the curative power of certain substances. The principle that *similia similibus curantur* prevails throughout the whole range of folk-medicine. Thus dropsy is cured by water. A spear-amulet is used to cure colic, which is supposed to be caused by the spear of the god Rudra. The *colour* of a substance is of no small importance in determining its use as a medicine. Thus turmeric is used to cure jaundice. Red, the colour of life-blood and health, is the natural colour of many amulets used to secure long life and health. A black plant is recommended for the cure of white leprosy. But even the *name* of a substance was frequently a reason for ascribing to it healing power. One of the most powerful medicinal or magical plants is called in Sanskrit *apāmārga* (*Achyranthes aspera*), and it owes its supposed power essentially to its etymological connection with the verb "apamarj," meaning "to wipe away," and in Hindu charms the plant is constantly implored to wipe away disease, to wipe out demons and wizards, to wipe off sins and evils of all kinds.

To wipe a disease away, is a very common and a very natural means of getting rid of it. This seems to be the meaning also of that ancient method of curing disease by *the laying on of hands*, which is already mentioned in the *Rig-veda*, though it is also possible that it was intended to press the disease down by means of the hands, in order to make it go out of the body. Some of the charms used with the laying on of hands point to still another explanation. As the priest had to *touch* the person for whom he was offering prayers and sacrifices, so it was thought that the imprecations could only have effect on a person if there was an actual connection between the medicine-man and the patient. There is a striking similarity between this ancient Hindu custom and the modern practices of faith-healing, in which, after all, prayer has merely been substituted for the ancient charms.

The two chief resources of folk-medicine, then, are charms and magic rites, the principal object of the latter being to bring the body into contact with some supposed curative substance. These substances are frequently applied in the shape of amulets or talismans.

The most ancient collection of charms is that found in the *Atharva-veda*, an excellent translation of which, with extracts from the ritual books, has just been published by Prof. Bloomfield in the "Sacred Books of the East" (vol. xlii., 1897). In the medical charms of the Atharva-veda the diseases are always personified. It is only our way of speaking when we say that diseases are supposed to be *caused* by demons. As a matter of fact the diseases themselves are addressed as personal and demoniacal beings. Thus *Fever*—"the king of diseases," as it is called in the "Susruta," the great work on Hindu medicine—is addressed as a demon who makes men sallow and inflames them like a searing fire. He is implored to leave the body, threatened with destruction if he does not leave it, and yet at the same time worshipped as a superhuman being. "Having made obeisance to the Fever, I cast him down below." This is a very characteristic way of dealing with evil spirits, which we find among all primitive people. The healing power, too, is addressed as a supernatural being, and invoked to destroy the demon of disease. Thus the plant Kushtha (*Costus speciosus*), which was always considered by the Hindus as one of the most potent remedies against fever, leprosy, and other diseases, is addressed with such words as: "O plant of unremitting potency, drive thou away the Fever that is spotted, covered with spots, like reddish sediment." In some of the charms against fever, we meet with vivid descriptions of all the symptoms of malarial fever. We read in one charm: "When thou, being cold, and then again deliriously hot, accompanied by cough, didst cause the sufferer to shake, then, O Fever, thy missiles are terrible: from these surely exempt us!" And the Kushtha plant is again implored: "Destroy the Fever that returns on each third day, the one that intermits each third day, the one that continues without intermission, and the autumnal one; destroy the cold Fever, the hot, him that comes in summer, and him that arrives in the rainy season!"

The frequency of fever during the rainy season probably accounts for the belief that lightning is the cause of fever, as well as of headache and cough. A very symbolical cure of fever consists in making the patient drink gruel made of roasted grain, the dregs of the gruel being afterwards poured from a copper vessel over the head of the patient into fire, which must be taken from a forest-fire. A forest-fire is supposed to have originated from lightning, and that the cure of a disease is effected by that which causes it, is an almost universal belief. Both the roasted grain and the copper vessel are symbolical of the heat of fever. Here we have the rudiments of homœopathy. Another magic rite is intended as a remedy against cold fever. By means of a blue and a red thread a frog is tied to the couch on which the patient reclines, and a charm is recited in which the fever is invoked to enter into the frog. The frog represents the cold element, and the cold fever is expected to pass into the cold frog. A very similar charm is met with in Bohemia, where the peasants, in order to cure chills of fever, catch a green frog, sew it into a bag, and hang it around the neck of the patient.

The cure of a disease by making it enter into some animal, is one of the most general devices of medical witchcraft both in India and elsewhere. According to Jewish law, a living bird is "let loose into the open field with the contagion of leprosy." Jaundice is cured, in parts of Germany, by making it pass into a lizard. In ancient India, jaundice was cured by seating the patient on a couch beneath which yellow birds were tied. The yellow disease was expected to settle on the yellow birds.

The principle of curing a disease by something similar to its cause or symptoms is also apparent in the cure of excessive discharges by means of water. Dropsy—the disease sent by *Varuna*, the god of the sea and of the waters—is naturally cured best by the use of water. A very simple cure of dropsy consists in sprinkling water over the patient's head by means of twenty-one (*three times seven*) tufts of sacred grass (*Poa cynosuroides*), together with reeds taken from the thatch of a house. The water sprinkled on the body is supposed to cure the water in the body.

But there must have been many other reasons, too, which pointed to *water* as a great healing power. To the present day the Hindus look upon rivers as divine beings, or as the abode of spirits. And we may credit even the ancient Hindus with a certain knowledge of medicinal springs. Nor is it surprising that in a tropical climate the rain waters were hailed as "divine physicians." And it may be that actual experience of the beneficent influence of water on health suggested the eulogy found in a Vedic charm: "The waters verily are healing, the waters chase away disease, the waters cure all diseases."

That dropsy is ascribed to Varuna, one of the great gods of the Hindu pantheon, is quite exceptional. For, as a rule, diseases are caused by godlings rather than by gods. More especially, all such diseases as mania, fits, epilepsy, convulsions, &c., are ascribed to possession by Rakshas (devils) and Pisāchas (goblins). Even in the scientific works on medicine, *e.g.* in the "Charaka-samhitā," assaults of evil spirits and possession by demons are enumerated among the causes of disease. In the *Atharva-veda* we find a special class of charms, the so-called "driving-out charms," which are considered as most effective remedies against possession.

But the most powerful enemy and destroyer of all devils is the *Fire*. "Slayer of fiends" is one of the most common epithets of Agni, the god of fire. Hence we find that Fire is invoked in charms against mania to free from madness him who has "been robbed of sense by the devils." Sacrifices to the god of fire, burning of fragrant substances, and fumigation are among the principal rites against possession by demons.

Besides the Rakshas and Pisāchas (devils and goblins) whose special province it is to cause all kinds of mischief, we find in ancient India also the world-wide belief in *incubi* and *succubi*, who pay nocturnal visits to mortal men and women. These are the Apsaras and Gandharvas of Hindu mythology, who correspond to the elves and nightmares of Teutonic belief. They are really godlings of nature. Rivers and trees are their natural abodes, which they only leave in order to allure mortals and injure them by unnatural intercourse. To drive these spirits away the fragrant plant *ajasringi* "goat's horn" (*Odina pinnata*) is used, and certain charms are pronounced. According to Teutonic belief also fragrant herbs (*e.g. Origanum antirrhinum*, *Hypericum perforatum*, and especially thyme) are excellent means for frightening away devils and witches, as well as nymphs and elves.

That the spirits of trees and waters are occasionally identified with the spirits of disease, may to some extent account for the healing power ascribed to water and trees. In fact, the far-spread custom of transferring diseases to trees seems to have originated from a desire of infecting the *spirit* of a tree with a disease which may have been caused by the same or an allied spirit. Amulets as a protection against diseases, hostile sorcery, evil eye, and other calamities are frequently taken from trees. Thus, an amulet consisting of splinters from ten kinds of holy trees was considered by the ancient Hindus as a potent remedy against hereditary disease, and also against possession by demons. Nine kinds of wood are used for a similar purpose in German folk-medicine.

As these malevolent spirits are the sworn enemies of mankind, it is only natural that they should be most anxious to injure the new-born infant, and even the embryo. Numerous, therefore, are the charms and rites concerned with the protection of mother and child against the attacks of evil spirits. Hence the custom of keeping a fire or a light burning in the lying-in room—a custom found among tribes of the Malay Peninsula, prescribed in the sacred books of the Parsis, and still practised in Germany, as it was in ancient Rome. In ancient India, the rule was to keep a fire burning near the door of the lying-in room, in which mustard-seeds and rice-chaff were sacrificed every morning and evening for ten days. Visitors, too, were requested to throw mustard-seeds and rice-chaff into the fire before entering the room.

The chapter of children's diseases is as large in medical witchcraft as in modern medical science, and in the Hindu charms we find numerous names of demons to whom the various diseases of children are ascribed. One of these demons is called the "Dog-demon," and is said to represent epilepsy (though the barking dog would remind us rather of whooping-cough). When a boy was attacked by the dog-demon he was first covered with a net, and a gong was beaten, or a bell rung. Then the boy was brought into a gambling hall—not, however, by the door, but by an opening made in the roof; the hall was sprinkled with water, the dice cast, the boy laid on his back on the dice, and a mixture of curds and salt poured over him, while again a gong was beaten. To drive evil demons away by means of loud noises, such as the beating of a gong, was a device frequently resorted to in ancient Hindu rites, and bells and drums are still used in India as scarers of demons. Interesting is the practice of bringing the child into the hall through an opening in the roof—that is, *not by the door*. To enter a house by any other opening but the door seems to be a means of escaping the demons who are haunting the threshold. Thus, according to a German superstition, it is conducive to the health of a child to lift it out of the window when it is taken to church to be baptised.

Of course, the ancient Hindus knew that some maladies and derangements of the human body were not caused by any mysterious power; they knew that wounds were inflicted by weapons—they knew something about the effects of poison, and had an idea that certain diseases were caused by animals, such as *worms*. But in ancient India, as well as in German folk-medicine, the term "worms" includes all kinds of reptiles, and snakes and worms are not kept very distinct. Moreover, all kinds of diseases were ascribed to worms. And both worms and snakes are actually considered as a kind of demoniacal beings. The imprecations against worms are, therefore, not much different from the charms against the demons. Thus we read in a charm against worms in children: "Slay the worms in this boy, O Indra, lord of treasures! Slain are all the evil powers by my fierce imprecation. Him that moves about in the eyes, that moves about in the nose, that gets to the middle of the teeth, that worm do we crush." This fierce imprecation is accompanied by a rite symbolical of the destruction of worms in the patient. An oblation of black lentils, mixed with roasted worms and with ghee, is offered in the fire. Then the sick child is placed on its mother's lap, and, with the bottom of a pestle heated in the fire and greased with butter, the palate of the child is warmed by thrice pressing upon it. Then a mixture of the leaves of a horse-radish tree and butter is applied, and twenty-one (*three times seven*) dried roots of *Andropogon muricatus* are given to the child upon whom water is poured.

The words of the charm leave no doubt that not only intestinal diseases, but also pains of the head, the eyes, &c., are ascribed to worms. Thus, German folk-medicine knows of a "finger-worm" as the causer of whitlow (*Panaricium*), and even spasm in the stomach is ascribed to a worm, the so-called "heart-worm" (*Herzwurm*). As the Hindu charm mentions a worm "that gets to the middle of the teeth," so worms are believed to be the cause of toothache almost in every part of the world. "If a worm eat the teeth," says one of the prescriptions in an English "Leech Book," "take holly rind over a year old and root of carline-thistle, boil in hot water, hold in the mouth as hot as thou hottest may." In Madagascar the sufferer from toothache is said to be "poorly through the worm."[1] In a French charm against toothache it is said: "Si c'est une goutte de sang, elle tombera, si c'est un ver, il mourra." In Germany a sufferer from toothache will go to a pear-tree, walk three times round it, and say: "Pear-tree, I complain to thee, three worms sting me, the one is grey, the other is blue, the third is red—I wish they were all three dead." A young Hindu friend of mine (now a student at Oxford) tells me how he remembers the witch coming to his father's house (in Calcutta) to cure persons suffering from toothache, and how after some hocus-pocus she would point to some cotton threads she held in her hand, saying: "Look, here are the worms which I have taken out from your teeth."

In the Buddhist scriptures we read of an extremely clever physician, Jīvaka, who performed many marvellous cures. Once upon a time, we are told, there lived in the capital of Magadha a rich merchant who had been suffering for seven years from a disease in the head. Many renowned physicians came to see him, received much money, and went away without effecting a cure. At last the physicians agreed that the merchant must die; some said on the fifth day, others on the seventh day. Now Jīvaka, the physician in ordinary to the King of Magadha, was sent for, and he promised to cure the merchant if he would give him a good fee. "All that I possess shall be yours, doctor, and I will be your slave," said the merchant. "Well, my good householder, will you be able to lie down on one side for seven months?" asked the doctor. The merchant said he would. Would he be able to lie down on the other side for seven months, and on his back for another seven months? The patient thought he would be able to do so. Upon this the doctor ordered him to lie down, tied him fast to his bed, cut through the skin of the head, drew apart the flesh on each side of the incision, pulled *two worms* out of the wound, and, showing them to the people, said: "See, sirs, these two worms, a small one and a big one. The doctors who said that the patient would die on the fifth day had seen the big worm, those who said he would die on the seventh day had seen the small worm." Then he stitched up the skin of the head, and anointed it with salve. But after seven days the merchant said he could not lie down any longer on one side. Jīvaka ordered him to lie down on the other side for seven months. Again, after seven days, the patient said he could not bear it any longer. The doctor ordered him to lie down on his back for seven months, but he could bear this for seven days only. Then the doctor told him that he was quite well now, and that he knew beforehand the patient would be well in *three times seven*[1] days, but if he had told him so at the outset he would never have lain down even for so short a time.

This Jīvaka was a respectable man, an esteemed friend of Buddha himself, and a pious Buddhist. That the science of medicine had reached a comparatively high stage of development at the period when the Buddhist scriptures were compiled (say about 350 B.C.) is proved by the chapter on medicaments found in the "Vinayapitaka,"[2] and by the various stories told of Jīvaka. Yet there are traces even in these stories showing that physicians were considered as a class of uncanny creatures. "The physicians are cunning people," says King Pajjota, one of Jīvaka's patients. In the ancient Hindu, *i.e.* Brāhmanic, law-books, a very low social position is assigned to the physicians. They rank with temple-priests (who are in attendance to some popular idol), sellers of meat, hunters, usurers, women of bad character, outcasts, thieves, and eunuchs. They are not admitted to funeral meals and sacrifices, they receive no hospitality from members of the highest castes, and no orthodox Brāhman is allowed to accept food from a physician.

This degraded position of the medical profession in ancient India is, no doubt, due to the fact that in India, as in other countries, the physician is the direct descendant of the wizard and sorcerer. And although I do not believe that Sir Alfred Lyall[3] has succeeded in proving witchcraft to be "the aboriginal and inveterate antagonist of *religion or theology*"—the witchcraft practices of the ancient Hindus, and of all primitive people, rather prove an intimate connection between witchcraft and popular religious belief—yet I think he would be right if he had said only "*theology*" instead of "*religion or theology*." Witchcraft is always opposed to theology, and there is a natural rivalry between the wizard and the priest. And, as in India, the Brāhmans, the professional theologians, became the most dominant class, their antagonists—the wizard and his descendant, the physician—were naturally degraded and excluded from the higher ranks of society.

This antagonism between witchcraft and theology is the same as that between science and theology in more recent times. For the witch who depends not merely on supernatural agencies, but on actual observation of natural phenomena and on some sort of reasoning (which may not be *logical*, but can always be justified on *psychological* grounds) is, after all, the humble precursor of the man of science. To quote again Sir Alfred Lyall, "he is just touching, though he may only touch and let go, a line of thought which points, albeit vaguely and most crookedly, towards something like mental independence." It is this historical connection between witchcraft and science that gives an intrinsic scientific interest to the study of folk-medicine.

M. WINTERNITZ.

GUTTA-PERCHA AND INDIA-RUBBER.

BOTANISTS who are interested in the cultivation of *Sapotaceæ* on a commercial scale, are beginning to realise the consequences of the careless methods that have denuded the Indo-Malayan regions of Taban trees. Cable-manufacturers complain very seriously of the great falling-off in quality of gutta-percha during the past few years, and the small hope of obtaining better supplies in future. This degeneration of the cultivating industry is beginning to make itself felt in the Treasury Reports of the gutta-percha producing countries; not so much in the quantity annually shipped, as in the prices paid for a given weight each year.

For instance, the Sarawak (Borneo) Treasury Report of revenue and expenditure for 1897 gives comparative figures relating to the condition of supply and demand of gutta-percha and india-rubber; the following table, drawn up from the Report, shows the fall in prices of gutta-percha during the four years 1894–1897, inclusive, and indicates a corresponding degradation of quality. (The "picul" is, for our purpose, taken as 133⅓ lbs., and the Sarawak dollar as 1*s.* 11*d.*)

Gutta-percha exported from Sarawak.

Year.	Quantity.		Value.		Average price per picul.	
	Piculs.	Tons.	$	£ s. d.	$	£ s. d.
1894	1937	115·3	162,233	15,547 6 7	83·75	8 0 6¼
1895	2782	165·6	194,120	18,603 3 4	69·77	6 13 8¾
1896	2820	167·9	190,939	18,298 6 5	67·70	6 9 9
1897	2867	170·7	185,532	17,780 3 0	64·71	6 4 0½

With this may be compared the increased demand for, and steady value of india-rubber throughout the same period.

India-rubber exported from Sarawak.

Year.	Quantity.		Value.		Average price per picul.	
	Piculs.	Tons.	$	£ s. d.	$	£ s. d.
1894	1259	74·9	85,775	8,220 2 1	68·12	6 10 6¾
1895	1392	82 8	95,493	9,151 8 3	68·60	6 11 5¾
1896	1624	96·7	108,813	10,427 18 3	67·00	6 8 5
1897	2130	126·8	146,229	14,013 12 3	68·65	6 11 7

From another source we are able to give the total weights of gutta-percha landed in England, from all gutta-percha producing countries, since 1895.

Total Weight of Gutta-percha landed in England.

Year.	Tons.
1895	716
1896	318
1897	396
January to April 1898	626

The present year shows a very marked rise in the demand for gutta-percha; this is more apparent when it is remembered that the 626 tons was all landed between January 1 and April 30, and that the quantity landed in April alone was 149 tons.

We may sum up the condition of the gutta-percha cultivation industry in a few words: there is an increasing demand, a degeneration of quality, and an almost total disregard of the future. Experimental efforts have, we believe, been made to produce a steady supply of high-quality gutta-percha, but so many years are required to establish the scheme on a profit-earning basis, that it is almost beyond the powers of private enterprise to make it a success.

TREATMENT OF THE SURFACE OF MEDALS.[1]

SILVER.

IN this country medals have been issued for centuries with the tables or flat surfaces smooth and mirror-like, while a more or less frosted texture has been given to the portions in relief. This is especially the case in medals which have been struck as specimen pieces, for after highly-polished dies have been used for a certain time the difference between the appearance of the tables and the parts in relief becomes less and less marked. As is well known, medals with polished surfaces rapidly tarnish, and even blacken, by exposure to the ordinary atmospheric influences. In France a different system has long been adopted concurrently with the one just described. Unpolished dies are employed, and care is taken to impart to the medals struck from them a dead or frosted surface by rubbing them with fine pumice. Recently, at the French Mint, medals have been subjected to the process known as "sand blasting" by the aid of an appliance which projects against the surface of the medal a small jet of air, carrying with it fine sand, and having a velocity of about 180 feet per second. When thus treated the surface of the medal becomes minutely granular or frosted, and may then be further treated in several ways. Sometimes the surface is darkened by exposure to an aqueous solution of a sulphide, followed by rubbing with very fine pumice, which removes the dark layer of sulphide from the portions in high relief, and leaves dark lines in the more deeply-cut recesses. It is, however, preferable to cover the medal with a layer of platinum, and this is effected by immersing it in an alcoholic solution of chloride of platinum until a blackened surface is produced. Subsequent rubbing with a brush and very fine pumice changes the blackened surface to a delicate grey; and if this operation is conducted skilfully, graduated shadows may be left wherever the artist considers their presence to be desirable. The beauty of medals so treated, and the fidelity with which the details of the design are revealed, are beyond question; but it may be doubted whether the surface of the medal is permanently protected. A medal with a frosted platinised surface has, however, a great advantage over one with a polished table, as the platinised medal is merely deepened in tone by exposure to the atmosphere, and, unlike medals which have been struck in the ordinary way, does not become disfigured by blotches of tarnish. The frosted platinised medal may be restored to almost its original freshness by careful rubbing with a soft leather; while a polished silver one cannot be so renovated, as the tarnish attacks the surface and destroys the polish.

During the past year, for the first time in the history of the Mint, medals have been issued with frosted and platinised surfaces. More than 27,000 large silver medals were platinised by a slight modification of the above method. It became necessary, therefore, to provide an appliance for producing the sand blast, and this, together with a small 1 H.P. motor for driving it, has been fitted up in the basement of the Assay Department.

BRONZE.

Medals of bronze differ considerably from those of silver, as their surfaces are far more liable to be influenced either by the slow operation of the constituents of the atmosphere or by the more rapid action of chemical agents. Ancient silver coins, for instance, which have been long buried in the earth, do not show anything like so wide a range of colour in their patina or crust, as is revealed on coins of brass, bronze or copper, which have been hidden in the same way. This is due to the fact that silver is far less affected than copper by the chemical action of the constituents of soils, or by atmospheric influences. The patina acquired by an ancient coin or medal often constitutes no small part of its value. "You would laugh at me," said Philander, in Addison's charming dialogues upon the usefulness of ancient medals, "should I make you a learned dissertation on the nature of rusts; I shall only tell you that there are two or three sorts of them which are extremely beautiful in the eye of the antiquary, and preserve a coin better than the best artificial varnish." The object of the medallist is accurately expressed in the above sentence, for he endeavours to protect the surface of all medals in which copper is the main constituent, by a patina or film of oxide, so as to preserve the medal from further change. This may be effected in various ways. The medals of the Italian Renaissance were not struck, but cast by the method of *cera perduta*, already described in these Reports,[1] and much of the beauty of the medal was due to the "skin" or pellicle of oxide which the medal acquired during casting. The skill of the artist in arranging the composition of the bronze, and fixing the temperature at which it was cast, was revealed in the texture of the medal's surface.

In modern times most medals to which the name of bronze is given are really of copper, "bronzed" or coloured artificially on

[1] From a memorandum by Prof. Roberts-Austen, C.B., F.R.S., in the Twenty-eighth Annual Report of the Deputy Master and Comptroller of the Mint, 1897.

[1] Sixteenth Report (1886), pp. 24, 49; Seventeenth Report (1886), p. 15.

the surface. The process by which this colouring is effected has long been employed, and is thus described in an old receipt. Apply with a brush to the surface of the medal common crocus powder, jewellers' rouge, previously made into a smooth paste with water. When dry, expose the medal over a clear fire for about one minute; lastly, when the medal is sufficiently cold, polish it with a plate brush. The exact composition of the superficial layer of oxide which is formed, has, I believe, never been ascertained; but it is well known that the tint varies greatly from light brown to deep chocolate, according to the particular variety of oxide of iron which is used.

With a view to ascertain whether this old method could not be replaced with advantage, it was natural to turn to the work of Japanese artists, who are masters in the art of giving protective surfaces of varied tints either to copper in its pure state or to copper alloys. I have shown elsewhere[1] that in conducting such operations the Japanese employ dilute boiling solutions of certain salts of which verdigris and sulphate of copper are the more important.

The following solution[2] has been found to answer fairly well, even when the ordinary European verdigris, which is a basic acetate of copper, is employed:—

Verdigris	87 grains
Sulphate of copper	437 ,,
Nitre	87 ,,
Common salt	68 ,,
Sulphur	233 ,,
Water	1 gallon

In Japan, however, "verdigris" is made by the action of plum-juice vinegar on plates of copper which contain certain metallic impurities. Such native verdigris has consequently a very complex constitution. It is called "Rokusho," and cannot be procured in this country; but I am indebted for a sample of it to Mr. W. Gowland, formerly technical adviser to the Japanese Mint at Osaka. He obtained it from a famous maker of verdigris at Osaka, who persistently refused to give any information respecting its mode of manufacture. Mr. Gowland also gave me an elaborate description of the method of employing this verdigris in the colouring of copper medals, a method which has only been adopted in Japan as the result of a long series of experiments. Guided by an analysis which was made of this "Rokusho," a mixture was compounded which produced quite as fine patina on copper as the native "Rokusho," though its action was less certain and less rapid. The series of tints which may be obtained by slight variations in the composition of the "Rokusho" is truly remarkable. These tints range from golden yellow through deep brown to bright red, the colour mainly depending on the relative amounts of malate, urate, and chloride of sodium which are present.

The quality of the copper also exerts a very great influence on the tint of the patina; the difference, for instance, between ordinary "best select" copper of the smelter and "electro" copper, is very marked, as the former becomes dark brown and the latter golden yellow when boiled in the same solution of "Rokusho." Since the close of the year 1897, over 5000 medals have been treated by the method which has just been described. Apart from the mere tint of the medal, the Japanese artists attach much importance to producing a sheen or damascening which shows through a transparent patina. This is effected by developing the crystalline texture of the copper by a preliminary treatment of the medal before it is boiled in the solution of "Rokusho."

In France, medals of true bronze containing much zinc are struck, and although the colour is heightened by superficial oxidation, produced by gentle heating, no true patination is effected.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

By the will of the late Mr. Edward O. Bleackley, the Owens College, Manchester, receives 500*l.* for "Bleackley Scholarships."

We have more than once in these columns called attention to the views expressed by Prof. Meldola and others concerning the futility of occasional instruction in miscellaneous subjects as carried on at great cost to the county by many Technical Instruction Committees, more particularly in rural districts. An advocate of these views has now been found in the person of the Countess of Warwick, who, acting on the advice of Prof. Meldola, has established a small school of science at Bigods, near Dunmow in Essex, on her own estate. The school at present contains about sixty pupils of both sexes, and by way of a beginning it is proposed to select twenty of the most highly qualified for instruction under the "School of Science" curriculum of the Science and Art Department. Lady Warwick deserves every encouragement in this praiseworthy effort to bring systematic instruction within the reach of a class of the community more in need of such assistance even than the inhabitants of large towns, and we learn that the Essex County Council has wisely determined to co-operate in the movement. The experiment is one in every way deserving of success, and the results will be watched with interest all over the country. One of the weakest points in modern technical education schemes has been the lack of such institutions in the thinly-populated agricultural districts, and the county of Essex has done well in taking part in an experiment which cannot but lead to results of the greatest importance. Mr. E. E. Hennesey, of the Royal College of Science, has been appointed principal of the school, which is provided with laboratories, lecture and class rooms, a workshop and laundry, garden plots, &c., and is situated in a most pleasant and secluded corner of the county, about a mile and a half from Dunmow railway station. The mansion adjoining the school has been handed over by the Countess for the use of the staff and of boarders, and the neighbouring farm is available for field demonstrations.

SCIENTIFIC SERIAL.

Symons's Monthly Meteorological Magazine, June.—Lightning conductors, by A. W. Preston.—The author refers to a theory put forth by some architects that old churches which have never been struck by lightning do not require conductors, as the probability is they never will be struck. The editor of the *Magazine* will be glad to receive any evidence upon the subject.—Results of meteorological observations at Camden Square, London, for forty years. These show that the mean of all the highest readings was 78°·1, and of all the lowest 33°·8; the average rainfall is 1·92 inches, against 2·26 inches in the present year.—Summer rainfall, by A. B. MacDowall. Based upon the rainfall at Greenwich Observatory since 1841, the author finds (1) that in the first five years after sunspot minimum years, there have always been more dry summers than wet, and (2) that in each group of five consecutive years ending with a sunspot minimum year, there have been (with one exception) more wet summers than dry. These facts point to a tendency for a wet summer this year.—This number contains a long, if not unique, well record, containing the approximate height (in feet above Ordnance datum) of the top of the water in Mr. L. Wood's well at Chilgrove, near Chichester, since 1836.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 9.—"On the Heat dissipated by a Platinum Surface at High Temperatures." By J. E. Petavel, 1851 Exhibition Scholar. Communicated by Lord Rayleigh, F.R.S.

The first part of the paper refers to the emissivity of a bright platinum surface in air, hydrogen, carbon dioxide, and in other gases.

In the case of each of the above gases the values of the emissivity are given at three distinct pressures; namely, 6, 76, and 228 centimetres of mercury.

The temperature measurements are based on the researches of Callendar and Griffiths, confirmed by the recent determinations of Heycock and Neville. To check the calibration of the thermometers at higher temperatures, the melting point of palladium was used. In all cases observations were made from a temperature of 100° C. to temperature of 1200° C., and a number of the curves are extended to 1779° C. by a direct

[1] A paper "On the Use of Alloys in Art Metal-work." (*Journal* of the Society of Arts, June 13, 1890.)

[2] A similar solution for heightening the colour of gilded metals is described by Benvenuto Cellini in his "Trattato dell' Oroficeria in Fiorenza, 1568."

measurement of the emissivity of platinum and palladium at their melting points.

The platinum wire, which served at the same time as radiator and thermometer, was 0·112 cm. in diameter. It was placed in the axis of a vertical glass cylinder, which formed the enclosure.

The effect produced by a change in the size, shape, material, and temperature of the enclosure and in the position and diameter of the wire are also studied.

The temperature is expressed in degrees Centigrade, and the emissivity in C.G.S. units.

Part ii. consists of a bolometric study of the radiation emitted by platinum at temperatures ranging from 500° C. to the melting point of the metal. It is shown that for theoretical reasons the true rate of change of the total radiation with temperature lies between the values obtained by measuring the heat lost by the radiating body and those deduced from the readings of any form of bolometer or thermopile.

By comparing the observations of Dr. J. T. Bottomley and Schleiermacher, based on the first method, with those of F. Paschen and of the author, made by the second method, a criterion is obtained by which to test any formula intended to express the law of thermal radiation.

The formulæ of Dulong and Petit, of Stefan, and of Rosetti fail when tested in this manner; whilst Weber's formula, from 400° to 800° C., gives results in close agreement with the true rate of change of total radiation with regard to temperature.

The second part of the paper also contains a description of some points of interest in the design of the bolometer which was used during this work.

Part iii. refers to the variation of the intrinsic brilliancy of platinum surface with temperature.

The results may be expressed by the following formula:—

$$(t - 400) = 889 \cdot 6 \sqrt[6\cdot 9]{b},$$

where t is the temperature in degrees Centigrade, and b the intrinsic brilliancy in candle power per square centimetre. The constant 400 is taken as the temperature limit at which the visible radiation falls to zero.

Chemical Society, June 16.—Prof. Dewar, President, in the chair.—The following papers were read:—Preparation of a standard acid solution by direct absorption of hydrogen chloride, by G. T. Moody. The author prepares an accurately standardised solution of hydrogen chloride by determining the increase in weight consequent on absorbing the pure gas in water.—Researches on the terpenes. III. Halogen derivatives of fenchene and their reactions, by J. A. Gardner and G. B. Cockburn. An α- and a β-chlorofenchene hydrochloride are obtained by treating fenchene with phosphorus pentachloride; both readily yield a crystalline chlorofenchene $C_{10}H_{15}Cl$, which can be converted into a chlorofenchenephosphonic acid.—Researches on the terpenes. IV. On the oxidation of fenchone, by J. A. Gardner and G. B. Cockburn. Fenchone is very slowly oxidised by hot nitric acid with formation of isocamphoronic acid, dimethyltricarballylic acid, dimethylmalonic acid, isobutyric acid, acetic acid, and nitrofenchone.—Nitrocamphor and its derivatives. Part I. Isodynamic forms of nitrocamphor, by T. M. Lowry. Although solutions of nitrocamphor show multirotation the author has not been able to isolate the isodynamic forms of the constitutions

yet the corresponding forms of π α′-bromonitrocamphor seem to exist.—Cannabinol, by T. B. Wood, W. T. N. Spivey and T. H. Easterfield. Cannabinol is a mixture which yields a liquid and a crystalline acetyl-derivative, $C_{21}H_{26}O_2$.—An improved form of gas-analysis apparatus, by W. A. Bone.—Preliminary note on the action of light on acetylene, by W. A. Bone and J. Wilson. On exposing acetylene to sunlight a greasy brown deposit is formed which is still under examination.—Reversible zymohydrolysis, by A. C. Hill.—The solubility of isomeric substances, by J. Walker and J. K. Wood. The authors find that the rule that the order of solubility of isomerides is independent of the solvent is not strictly applicable.—Note on nitration and substitution in nitro-compounds, by A. Lapworth and C. Mills.—Hydroxydibromocamphorsulphonic acid. A correction, by A. Lapworth and F. S. Kipping.—Enantiomorphism, by F. S. Kipping and W. J. Pope.—Azobenzene derivatives of chrysin, euxanthone, gentisin and morin, by A. G. Perkin. Chrysin yields a disazo-derivative of the composition $C_{15}H_8O_4(N_2Ph)_2$; similar compounds have been prepared from other analogous colouring matters.—Constituents of the Indian dyestuff "waras," by A. G. Perkin. Waras, a purplish powder covering the seed pods of *Flemingia congesta*, contains flemingin, $C_{12}H_{12}O_3$, homoflemingin and two resins $C_{12}H_{12}O_3$ and $C_{13}H_{14}O_3$; it dyes silk a golden yellow shade.—Note on the oxidation of charcoal by nitric acid, by G. Dickson and T. H. Easterfield. By a process involving oxidation with fuming nitric acid and potassium chlorate, charcoal may be made to yield one-fourth of its weight of crystalline ammonium mellitate.

Zoological Society, June 21.—Dr. W. T. Blanford, F.R.S., Vice-President, in the chair.—Mr. J. Graham Kerr exhibited some specimens of *Lepidosiren* collected by him in the Gran Chaco of Paraguay during 1896–97. The adult males exhibited the characteristically varying appearances of the hind limb in the periods before, during, and after the breeding season. Mr. Kerr also exhibited specimens of the young of *Lepidosiren*, illustrating especially the external gills and sucker, the disappearance of these organs, and the change in the colour of the animal associated with the surrounding conditions of light or darkness. A small collection of Teleostean fishes collected in the same swamps in which *Lepidosiren* was found, and identified by Mr. Boulenger, was also exhibited.—The Secretary called the attention of the meeting to the arrival in the Society's Gardens of four living specimens of the Australian Lung-fish (*Ceratodus forsteri*), deposited by Mr. D. O'Connor, who gave an account of the mode in which he had obtained them and brought them to England.—Mr. G. A. Boulenger, F.R.S., exhibited specimens of the remarkable fish *Polypterus lapradii*, from the Lower Congo. They were provided with highly-developed external opercular gills, the presence of which, he remarked, was not dependent on age, as had been heretofore supposed, because they were retained for a long period, if not, in some cases, throughout life.—Mr. R. E. Holding made some remarks on some interesting animals he had observed during a recent visit to the Zoological Gardens at Belle Vue, Manchester.—Prof. Howes exhibited, on behalf of Mr. E. W. L. Holt, a specimen of a new British fish (*Argentina silus*), obtained eighty miles south-west of the Scilly Islands.—Mr. Abbott H. Thayer, of New York, explained his method of demonstrating, by actual experiments, the underlying principle of protective coloration in animals, and invited the members present, and their friends, to witness an exhibition of his demonstrations which (as arranged with the Secretary) would take place in the Society's Gardens next day.—Mr. G. A. Boulenger, F.R.S., read a memoir on the collection of fishes made by Mr. J. E. S. Moore in Lake Tanganyika during his expedition in 1895–96. Twenty-six new species were described, of which eight were made the types of new genera.—Mr. R. I. Pocock read a paper on the scorpions, spiders, and *Solifugæ* collected by Mr. C. S. Betton in East Africa between Mombasa and Uganda. Of the seven species of scorpions, six species of *Solifugæ*, and thirty species of spiders represented in the collection, five of the *Solifugæ* and twelve of the spiders were described as new, one species of the latter, viz. *Eucratoscelus longiceps*, being made the type of a new genus.—A communication was read from Mr. J. Stanley Gardiner containing an account of the fungoid corals collected by him in the Central Pacific. Twenty-one species were treated of, of which six were described as new. It was proposed to absorb the genus *Tichoseris* into *Pavonia*, and the genera *Maeandroseris*, *Coscinaraea*, and *Plesioceris* into the genus *Psammocora*.—On behalf of Dr. A. Dugès, Mr. G. A. Boulenger communicated the description of a new genus of Ophidia, proposed to be called *Geatractus*, for the reception of *Geophis tecpanecus*, recently characterised by M. Dugès.—Dr. G. H. Fowler presented three papers relating to the surface and midwater collections made by him on H.M.S. *Research* in the Faeroe Channel in 1896 and 1897. The first of these, by Mr. I. C. Thompson, dealt with the *Copepoda*; the second, by Mr. E. W. L. Holt, treated of the collection of fish-larvæ, and included an account of the larval ontogeny of *Scopelus glacialis*; and the third, by Dr. Fowler, contained a description of his new midwater net, and a discussion on the general features of the midwater fauna.

Geological Society, June 22.—W. Whitaker, F.R.S., President, in the chair.—Post-glacial beds exposed in the cutting of the new Bruges canal, by T. Mellard Reade. The following beds, enumerated in descending order, were found in this cutting: (5) Argile des polders supérieure; (4) *Cardium* (*edule*)-sand; (3) Argile des polders inférieure; (2) *Scrobicularia* (*plana*)-clay; (1) Peat with the remains of trees.—High-level marine drift at Colwyn Bay, by T. Mellard Reade. This paper describes a mound of sand capped by boulder clay, which occurs 1 mile south by west of Colwyn Bay Station. It measures about 90 yards on the longer axis, which runs north-east, 50 yards on the shorter axis, and is situated 560 feet above O.D. Among the pebbles and boulders in the drift, and scattered about in the sandpit, were granites from Eskdale and the south of Scotland, small flints, and local and Welsh rocks identified by Mr. Ruddy as derived largely from the head of the Conway valley. The base of the sand is not exposed, but the author has no doubt that it is geologically above the grey till with Welsh boulders.—Observations on the geology of Franz Josef Land, by Dr. Reginald Kœttlitz. This paper opens with a detailed description of the geography and geology of various portions of the archipelago. The basaltic rocks occur in tiers from 10 to 70 feet high, and range to a height of 1300 feet above sea-level. The associated and interbedded rocks consist of shale, sandstone, and basaltic tuff. The stratified rocks are not appreciably altered by the heat of the basalt, which is often vesicular both at the base and summit of the tiers. From this and other evidence the author concludes that many of the sheets are contemporaneous flows, and that as the fossil plants and ammonites are of Jurassic age, some of the lavas date back to Jurassic time. Dykes, sills, and necks are also described. The Jurassic rocks consist of shales and sandstones; they have yielded ammonites and belemnites, a portion of a specimen of *A. Lamberti* having been found embedded in "basaltic tuff." Pebbles of radiolarian chert have also been found embedded in these rocks, and a granite-block, mentioned by Payer as having been seen embedded in an iceberg, is believed to have come from the same source The raised beaches are very numerous, and occur at various heights, from just above sea-level to 287, 310, 340, and even 410 feet, drift-wood and bones of seals, walrus, and whales having been found on them. On Cape Mary Harmsworth twelve beaches are seen in a series one above another. The entire skeleton of a seal was found on the summit-plateau of Cape Neale, together with waterworn stones, at a height of 700 feet above sea-level. The highest waterworn pebbles noted were found at 1111 feet on Cape Flora. In some cases floe-ice at sea-level becomes covered over and preserved by gravel heaped upon it by the sea; and some of the raised beaches seem to consist of a similar mixture of ice and gravel, as is proved by the formation of pitfalls in them where the ice melts. Ice-masses are also sometimes preserved under taluses, avalanches, and slips. The "ice-cap" is probably not so thick as is generally supposed, and it has little downward movement. It forms domes on the summits and plateaux, but it seems to be a mere mantle on the terraced slopes, as it is rigid and dimpled, and during warm seasons raised beaches and terraces are thawed-out under the ridges. Comparatively few evidences of glaciation were met with. Roches moutonnées and rounded hills are absent, and only in the two valleys separating Cape Flora from Cape Gertrude were the rocks planed, scratched, and polished. Some of the landscape-features, including the separation of the group into individual islands, are attributed to marine action following lines of fault. The paper concludes with observations on soundings, the temperature of glaciers, the size of icebergs, and the finding of reindeer-antlers by Mr. Leigh Smith and the members of the Jackson-Harmsworth Expedition.—Notes on rocks and fossils from Franz Josef Land brought home by Dr. Kœttlitz, of the Jackson-Harmsworth Expedition, in 1897, by E. T. Newton, F.R.S., and J. J. H. Teall, F.R.S. In this communication an analysis of the basalt is given, which compares closely with those of basalts from Iceland. The silicification of the rocks, presumably by geyser action, the presence of a black analcime, pebbles of radiolarian chert, and crystals of selenite, probably formed *in situ* in shale, are also described. Notes are given on some of the fossil plants, on the drift-wood, and on apparently new species of *Inoceramus* and *Belemnites*.—On the Corallian rocks of Upware, by C. B. Wedd. The opinion usually held that the "Coralline Oolite" of the northern quarry at Upware is of older date than the "Coral Rag" of the southern quarry, gains support from the work detailed in this paper, although the results of recent excavation show that a rock of different lithological character from that of the northern quarry probably underlies the rocks of the southern quarry. A list of the fossils found in the lowest beds of the southern quarry includes eleven species not yet found in the "Oolite" of the northern quarry; a second list comprises the fossils found just below the "Rag" in the "Oolite" of the southern quarry. Both these faunas are intermediate between those o the "Rag" of the southern and the "Oolite" of the northern quarry. From the results of excavation and other evidence, the author considers that the "Oolite" can hardly be less than 40 feet thick, and that this rock is geologically below the "Rag" of the southern quarry.

EDINBURGH.

Royal Society, June 20.—Sir William Turner in the chair.—In a paper on steam and brines, Mr. J. Y. Buchanan discussed the relation of the concentration and the rise of boiling point of various solutions of salts, and instituted a comparison between the effect of pressure and the effect of concentration in producing this rise.—Dr. W. Peddie read a paper on torsional oscillations of wires, experimental and theoretical. In previous papers a relation of the form $y^n(x + a) = b$, where n, a, b are constants in any one experiment, was found to connect y the range of oscillation with x the number of oscillations. In the present paper five experimental results were given. (*a*) When the wire is subjected to great fatigue, n and b are independent of the magnitude of the initial range of oscillation; also n becomes unity when the fatigue is great. (*b*) Both log nb and log b may be regarded as linear functions of n in each of the series of experiments made, though both cannot be strictly so simultaneously. (*c*) In all of the series the linear function is such that, when n is unity, b has an absolutely constant value. This indicates a quantity which depends only on the nature of the material of the wire. (*d*) The period of oscillation has no observable effect on the results. (*e*) The time of inward oscillation over a given range exceeds that of outward oscillation. In the theoretical part of the paper a simple molecular theory of the action was investigated and was found to be in accord with observed facts, such as—the result (*e*) given above; the deviation from Hooke's law; the lessening of this deviation (as observed by Wiedemann) when an oscillation is stopped just short of zero, and again increased positively; and the relation between torsion and set.—Drs. Milroy and Malcolm read a paper on the metabolism of the nucleins under physiological and pathological conditions. It was found that the effect of nucleins and nucleic acid was to increase the number of the leucocytes in the blood, and also the amount of phosphorus excreted in the urine. Part of this phosphorus must have been derived from the tissues. On the other hand, metaphosphoric acid had no effect either on the leucocytes or on the phosphorus-holding tissue. An examination of pathological conditions in which leucocytosis was present showed that in leucocythæmia (spleno-medullary) the phosphorus excretion was diminished both absolutely and relatively to the nitrogen, while in plumbism the conditions varied only slightly from the normal. Emphasis was laid on the great caution required to be observed in drawing conclusions from the amount of alloxuric bodies secreted in cases where increased breaking down of the white blood corpuscles is suspected.

PARIS.

Academy of Sciences, June 27.—M. Wolf in the chair.—General formulæ giving the values of D for which the equation $t^2 - Du^2 = -1$ is resolvable into entire numbers, by M. de Jonquières.—On the new Giacobini comet, by M. Perrotin.—Report on a memoir of M. Lecornu, entitled "On the equilibrium of an ellipsoidal envelope submitted to a uniform internal pressure."—Observations on the Coddington comet made at the Observatory of Algiers with the 188 mm. equatorial, by MM. Ch. Trépied and J. Renaux.—Elements of the Giacobini comet, by M. I. Lagarde.—Determination of a surface by its two fundamental quadratic forms, by M. L. Raffy.—On the principle of correspondence, by M. H. Burkhardt.—On the mixing of gases, by M. Van der Waals. Remarks on a note by M. Daniel Berthelot.—Reply to the preceding, by M. Daniel Berthelot. The justification for the assumption criticised by M. Van der Waals is to be found in the close agreement between the results theoretically deduced by its aid and those of experiment.—On gaseous mixtures, by M. A. Leduc. Remarks on a note by M. D. Berthelot.—On the specific heat of air at constant pressure, by M. A. Leduc. Remarks on an error overlooked by M. Regnault in his determination of this constant. The neglect to fully correct for the expansion in the calorimeter, causes a systematic error in the final result of 0·6 per cent., the value being raised from 0·2375 to 0·239.—On the radiation of incandescent mantles, by MM. H. Le Chatelier and O. Boudouard. In the opinion of the author, there is no need to construct a special hypothesis to explain the action of the Welsbach burner. The emissive power is not greater that one, but the proportion of blue, green, and yellow radiations far surpasses that of red; and consequently the proportion of the energy given out as luminous radiations is very great. The absolute value of the luminous energy thus given out is, however, less than that which would be emitted by a black body at the same temperature.—Action of hydrogen upon silver sulphide, and the reverse reaction, by M. H. Pelabon. If the two systems, hydrogen-silver sulphide, and silver-hydrogen sulphide, are heated to the same temperature, the final state is the same in each case provided that the temperature be about 350° C. The velocity of the reaction is much accelerated by rise of temperature. The same state is finally reached if the starting system be sulphur, silver, and hydrogen.—On the heat of formation of lithium carbide, by M. Guntz. The value 11·3 calories was found by dissolving in water pure lithium carbide, details being given of the precautions necessary for the preparation of the latter.—On the combination of certain organic substances with mercuric sulphate, by M. G. Denigès. The mercuric sulphate reagent gives insoluble compounds when heated for a short time with fatty ketones, ordinary acetone giving an almost quantitative yield.—On a general method of preparation of mixed carbonic ethers of the fatty and aromatic series, by MM. P. Cazeneuve and Albert Morel. The carbonates of the phenols are heated either with the sodium alcoholate, or better, with an alcoholic solution of certain organic bases, such as pyridine.—On the nitro-derivatives resulting from the action of nitric acid upon ouabaine, by M. Arnaud. A mono- and a di-nitro derivative were isolated.—On the acids of the essential oils of geranium, by MM. Flatau and Labbé. An isomeride of myristic acid was isolated from the Indian essence.—Action of cyanamide upon chloranil in presence of potash, by M. H. Imbert. The reaction is similar to that already described for bromanil.—Contribution to the search for manganese in minerals, vegetables, and animals, by M. P. Pichard. Manganese appears to be very widely distributed. A list is given of natural orders of plants in which manganese has been found.—On the development of *Acmæa Virginea*, by M. Louis Boutan.—On the lakes of Roche-de-Rame (Hautes-Alpes), du Lauzet (Basse-Alpes), Roquebrussane, and Tourves, by M. André Delebecque.—On a method of measuring the area of the heart by radiography, by MM. G. Variot and G. Chicotot.—Improvement in the tubes employed in radiography, by M. L. Bonetti. The bulb is furnished with a sealed-in platinum wire, which can be heated by an external current.

NEW SOUTH WALES.

Linnean Society, May 25.—Mr. Henry Deane, Vice-President, in the chair.—On a myxomycete new for New South Wales, by D. McAlpine.—A preliminary study of the *Membracidæ* described from Australia and Tasmania, by Dr. F. W. Goding. The author has in contemplation the preparation of a monograph on the homopterous family *Membracidæ*, the Australian and Tasmanian species of which have not received much attention.—Further notes on Australian shipworms, by C. Hedley. A fresh-water shipworm from Fiji, first brought under notice by Mr. T. Steel at the Society's meeting in August 1895 is described and illustrated, under the name *Calobates fluviatilis*. *C. saulii*, Wright, in which *Teredo fragilis*, Tate, is included, is also dealt with. This species has now been traced from Adelaide, through Bass Straits to Sydney, where a second species, *C. edax*, flourishes, now first recognised as destructive to wharves in Port Jackson.—Descriptions of new mollusca, chiefly from New Caledonia, by C. Hedley. A remarkable new *Placostylus* from Dr. Cox's collection, aberrant alike geographically and structurally, is described; with further considerations on the range of the genus, dwelt on in a previous communication. Several molluscan novelties obtained during a visit to New Caledonia are made known, including a new *Teinostoma*, a *Diplommatina*, and an *Ischnochiton*.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Adressbuch für die Deutsche Mechanik und Optik, Band i. (Berlin, *Der Mechaniker*).—Stanford's Compendium of Geography and Travel (new issue): North America. Vol. 2. The United States: H. Gannett (Stanford).—Food Supply: R. Bruce (Griffin). The Making of a Daisy: E. Hughes-Gibb (Griffin).—Logic, Deductive and Inductive: C. Read (Richards).—Iowa Geological Survey, Annual Report, 1896 (Des Moines).—The Alpine Guide. The Western Alps: John Ball, new edition, by W. A. B. Coolidge (Longmans).—The Doctrine of Energy: B. L. L. (Paul).—Practical Organic Chemistry: G. George (Clive).—Wealth and Progress of New South Wales, 1896–97: T. A. Cogblan (Sydney).—Notes on Volumetric Analysis: A. Thornton and M. Pearson (Longmans).—A Short Course in Inorganic Qualitative Analysis: Dr. J. S. C. Wells (Chapman).—A Laboratory Guide in Qualitative Chemical Analysis: Prof. H. L. Wells (Chapman).—A Course of Practical Chemistry: W. G. Valentin, 9th edition, edited and revised by Prof. W. R. Hodgkinson (Churchill).—Hydrographical Surveying: Rear-Admiral Sir W. J. L. Wharton, 2nd edition (Murray).—Régularisation du Mouvement dans les Machines: L. Lecornu (Paris, Gauthier-Villars).—Müller-Pouillet's Lehrbuch der Physik und Meteorologie, Neunte Auflage, Zweiter Band, Zweite Abthg.: Drs. Pfaundler and Lummer (Braunschweig, Vieweg).—A First Year's Course of Practical Physics: J. F. Tristram (Rivingtons).—Facts about Bookworms: Rev. J. F. X. O'Conor (Suckling).

PAMPHLETS.—Additions to the Fungi on the Vine in Australia: D. McAlpine and G. H. Robinson (Melbourne)—Copenhagen (Danish Tourist Society, Copenhagen).—Publications of the Smithsonian Institution available for distribution, April 1898 (Washington).—Das Fernobjektiv im Porträt, Architektur und Landschaftsfache: H. Schmidt (Berlin, Schmidt).—Der Gummidruck: J. Gaedicke (Berlin, Schmidt).—Introduzione allo Studio dei Silicati: Prof. E. Ricci (Milano, Hoepli).—Tours in North of Ireland (Belfast, Baird).

CONTENTS.

THURSDAY, JULY 14, 1898.

EVOLUTION OF THE MORAL INSTINCT.

The Origin and Growth of the Moral Instinct. By Alexander Sutherland, M.A. Two vols. Pp. xiii + 461, and vi + 336. (London: Longmans, Green, and Co., 1898.)

MR. SUTHERLAND'S work is thoroughly Darwinian, being based on a huge mass of observations which he has selected without apparent bias, marshalled well, and handled judiciously. Few books written since Darwin's time on the evolution of the human mind, are so thorough and comprehensive and well deserving of study. Its chief merit lies in the solid treatment by which the writer confirms and extends the masterly sketch drawn by Darwin in the fourth and fifth chapters of his "Descent of Man," but it is also extremely original in many particulars; and though somewhat diffuse here and there, is interesting throughout. Mr. Sutherland resides in Australia, where it must have been more difficult to obtain that ready access to books and authorities which European students enjoy, and to obtain skilled help in his experiments; he is therefore entitled to a proportionate increase of praise and to much excuse where he is open to criticism.

The main argument and the general results of his inquiry may be stated in a few words, but the fulness of their significance will be imperfectly realised without carefully reading the whole of his book. They are, that a progression in complexity of organisation and faculty is closely associated with the duration of growth, including both the embryonic stage and that of immaturity. Next, that the duration of growth is closely correlated with parental care. It is shown that in the earlier stages of evolution of a species, the parental care is small, but as higher stages of evolution are reached, the amount of parental care successively increases until it grows into parental sympathy, and he argues that it is directly or indirectly from parental sympathy that all morality proceeds. The first of these three steps might rank as a corollary to Von Baer's law, namely that the successive stages in the history of each race are hurried through during the embryonic life of each individual in it. Consequently as the number of stages increases, the length of time required for individual development tends to increase also, though not in the same proportion because the rate of passing through them may and does to some extent become more rapid. The author shows by a large array of evidence that the above presumption is true, and that this essential basis of his further argument may be accepted without hesitation.

Leaving insects aside as creatures of an entirely different mental constitution to our own, and as evolved along different lines from vertebrates, he begins by tracing in detail the first appearances of the parental instinct in various species of fish. He finds—

"Of species that exhibit no sort of parental care, the average of forty-nine gives 1,040,000 eggs to a female each year; while among those which make nests or any apology for nests the number is only about 10,000. Among those which have any protective tricks, such as carrying the eggs in pouches, or attached to the body, or in the mouth, the average number is under 1000; while among those whose care takes the form of a uterine or quasi-uterine gestation which brings the young into the world alive, an average of fifty-six eggs is quite sufficient.

"It must hence be very evident how much better are a few that are tended than a great crowd left without care. And the first link in the chain of reasoning of this book is that in the struggle for existence an immense premium is placed upon parental care, and that not until this has been developed can the higher nervous types become possible."

There is another well-known way, as he points out, by which the life of the young is rendered more secure, namely by assuming mimetic characters and thereby escaping the observation of enemies. But successful mimicry leads to nothing further, and therefore does not enter into the plan of the present work.

He next examines into the case of amphibians and concludes that—

"Among all the non-parental species for which I have obtained information the number exceeds 800 eggs, yet the average of nine species that show parental care is only twenty-seven. Among the viviparous species the number of offspring declines to ten or less in the year."

Up to this point he considers that the story of evolution contains no indication whatever of the existence of real affection, but the true parental sympathy, which is destined to play a most important part in the survival of the nobler species, arises during the next stage.

Birds and mammals are understood to be developed from different points in the scale of reptile life, and the character of the protection they respectively give to their young differs accordingly. Some reptiles incubate their eggs, and birds carry on this process of incubation; other reptiles bring forth their young alive, and mammals follow that method. As their respective types advance in the scale of intelligence and affection, he shows that both birds and mammals present a lengthening period of parental protection, but the mammalian method reaches far ahead of that of the birds. It leads to the monkey, to the savage and to civilised man; the other seems to reach its acme in the bower bird.

In discussing birds, he divides them into three classes of progressive intelligence. The lowest contains the ostrich, emu, &c., which annually lay on the average twelve or thirteen eggs; the medium class includes partridges, petrels, coots, plovers and pigeons, these lay, on the general average, seven or eight eggs; the highest class includes birds of prey, parrots, woodpeckers, sparrows and finches, these lay, on a general average, four or five eggs a year. All birds of the higher grade

"hatch out young ones of abject helplessness, and the continuance of each species is absolutely dependent upon that parental love which is poured out in floods of unmeasured self-sacrifice. Among these birds the gracious charm of family life is first made fully known, and it is no mere chance that, concomitant therewith, comes that delight in throbbing melody which proclaims the fullest tide of joyous life. In all these genera, with their multitudinous species, male and female unite in their care for the tender brood, and show, as a rule, a steady attachment each for the other. Sometimes the male and female brood on the eggs alternately; while one is sitting the other is not far off; but this occurs only in twenty-eight per cent. of the genera, and these are on the whole of somewhat inferior type. In sixty-five per cent. the female alone undertakes the brooding, but the male is, throughout, her faithful attendant, feeding her assiduously, driving away intruders, and cheering her with the joy of his tumultuous song. In accordance with the teachings of economics, we must regard this division of employment as a sign of progress." . . .

"That family life, which T. H. Green, in his 'Prolegomena to Ethics,' so justly regards as the ultimate basis of moral ideals (p. 257) . . . is faintly seen in a few fish; it is not wholly absent among reptiles, but it is for the first time distinctly observable among the lower birds, increasing ever as the type advances, till we find the nest-life of one of these higher birds to be marked by many graces of an indubitably moral character. The conjugal tenderness of the mated pair, and their unwearied self-sacrifice in ministering to the wants of their offspring, are ethically beautiful. Where these appear in an equal degree in the human couple, we reckon them as a solid fundamental element of goodness. Much else is required of man and woman, but it is no slight praise to say 'he was a kind husband and a devoted father,' or that 'she was a tender wife and a mother of unwearied love and self-sacrifice.'

"The family life, which we see so beautifully developed in these birds, is like the seed, enclosing within itself the full potentiality of all the ethic good to be developed in yet later stages, wherein a growing intelligence makes the young always more and more dependent upon family and social union."

Similarly in mammalian species, the number of offspring decreases with each successive stage of increasing intelligence and parental sympathy. It not only does so in the four orders of monotremes, marsupials, deciduate and non-deciduate placentalia, taken as wholes, but also when they are severally analysed in much detail. It is impossible to go further into this subject within the space at our disposal.

The portion of the book thus far noticed, is but a small part in bulk of the whole, but it will be of superior interest to those who are disposed to argue in a lazy offhand way, that after parental instinct had attained the level reached in the lower savages, its further evolution would be merely a matter of time and of favourable conditions. This was, however, by no means the feeling of the author, for he has taken very great pains and given much anthropological research to trace its actual steps. It is only possible here to give extracts from his summary.

"The process of moral development, as I see it, has been a slow dawning of parental sympathy, whence arises a simple and natural morality which is strengthened by the growth of the sense of duty and other accessory developments of sympathy. Out of the morality thus engendered springs whatever is moral in law, though, fundamentally, law is not moral but retaliatory."

One of the most interesting parts in the later portion of the book relates to the evolution of the sense of chastity. In the course of that discussion he treats lucidly and with great fairness many vexed questions concerning marriage in early times. He is in full concurrence with and gives important contributions to the present reaction against the excessive but clever dogmatisms of McLennan about the universality of marriage by capture, endogamy and exogamy, and the rest. But it is impossible to cope in a short article with the wide range of careful inquiry contained in this really remarkable book. Yet extensive as it is, some additional chapters have been written and afterwards omitted, as the author informs us. Others, too, might have been inserted; for instance, it would be very interesting to trace and describe the origin and purport of superstitious fears in human nature and their bearing on moral instinct.

F. G.

THE ANIMALS OF ESSEX.

The Mammals, Reptiles, and Fishes of Essex. By H. Laver. Essex Field Club Special Memoirs, Vol. iii. Small 8vo. Pp. viii + 138, illustrated. (Chelmsford: Durrant, 1898.)

In respect of physical conditions Essex is one of the most favourably situated of the eastern counties of England for the possession of a large local fauna, its inland districts presenting variety of station, while it has a large sea-board, forming an estuary into which discharge several more or less important rivers. Indeed, were it not for the pollution of the Thames, the fish-fauna of the county would be even larger than is at present the case, and would reckon among its constituents the lordly salmon itself. Among other special advantages from a naturalist's point of view the county includes Epping Forest, which under its present excellent administration forms a sanctuary for wild creatures of many kinds. And in addition to its natural advantages, Essex is fortunate in possessing a Field Club which includes on its working roll many naturalists of high capacity. It is to a member of this club that we owe the present contribution to a knowledge of the fauna of the county.

So far as numerical completeness is concerned, the author seems to have done his work thoroughly; if he errs at all, it is in mentioning certain species which have admittedly been introduced into the county. The scientific importance of local faunistic works is not, however, to be reckoned by the number of kinds of stray cetaceans and other wanderers they record; but by pointing out the reason why particular species are restricted to particular districts, and in what respects the local representatives of each species recorded differ from their kindred in other districts. In both these respects the work before us fails to come up to modern requirements; since it completely ignores these portions of the subject, and merely gives general notes of little or no value on the animals mentioned. The work may be, and probably is, of considerable interest to the residents of Essex, but can lay no claim to a position of any scientific importance. It may, however, be useful as a foundation on which to build a more important superstructure, when the naturalist arises who will treat the Essex fauna from a broader standpoint.

It is somewhat unfortunate that the work appeared too soon after Mr. Thomas's revision list of the nomenclature of British mammals to admit of the author following the new light. In some cases, such as the retention of *Arvicola* for the voles, and of *Lepus timidus* for the common hare, the author is obviously behind the times. It may be uncongenial, but the sooner amateur naturalists take to follow the lead of their professional brethren in nomenclatural questions (always reserving the "*Scomber scomber*" principle) the better it will be for all parties. The change is bound to come, and it may as well be accepted gracefully. In making a family "*Arvicolidæ*," the author departs from all authority; and the adding of the name of its founder to each family and order of fishes is an unnecessary redundancy.

The volume is illustrated with several photogravures, all of which are excellent from an artistic point of view, while several afford interesting glimpses of local scenery. If it be regarded merely as a stepping-stone towards fuller treatment, the work may be welcomed as indicating the recognition of the importance of treatises on our local British faunas.

R. L.

THE AMERICAN EXCAVATIONS IN MESOPOTAMIA.

Nippur; or, Explorations and Adventures on the Euphrates. By J. P. Peters. Vol. i. pp. xvi + 375; vol. ii. pp. x + 420. (London: Putnam's Sons, 1897–98.)

THOSE who take an interest in Mesopotamian excavations, and in the building up of the history of the ancient empires which flourished in the land "between the two rivers" by means of almost undecipherable cuneiform documents, will welcome the appearance of Dr. Peters' volumes. We must, however, warn the reader that he is not to expect a thrilling narrative like that which the late Sir Henry Layard gave us in his "Nineveh and Babylon," and "Nineveh and its Remains," both of which works were published nearly forty-five years ago, and he is not to look out for vivid tales of the uncovering of the palaces of mighty kings in the presence of hundreds of wondering and enthusiastic natives, nor for anything of the kind. No Mesopotamian traveller can ever hope to attract the attention of the reading public as thoroughly as did Sir Henry Layard, for there is, unfortunately, no second Nineveh to "discover"; though, by the way, its site was not only never lost, but was thoroughly well known. Moreover, the reader must not expect from Dr. Peters a scientific work like Dr. Oppert's "Expédition Scientifique en Mésopotamie," the first part of which appeared in 1859, for the work which he undertook to do in Babylonia and Assyria was not on all-fours with that which the eminent French man of science was called upon to perform. Sir Henry Layard's want of knowledge of Assyrian was made up for by the possession of considerable skill in writing an easily read and popular account of his travels and works; in the early days of the science of Assyriology when he wrote, he was able to put forward theories which in subsequent years scholars like Sir Henry Rawlinson and Dr. Oppert were unable even to mention. Dr. Peters starts, of course, with much better equipment than any one of the three Mesopotamian explorers whose names we have mentioned, for he has all their experience to help him, and an enormous mass of archæological facts, which have been heaped up by several workers, at his free disposal. Notwithstanding these advantages, his work is not a scientific exposition of the results obtained from the excavations by the expedition of which he was the director, nor is it a very readable popular story, interesting by reason of the personal details which it contains. His two volumes are well printed and very fairly illustrated, and they have maps, an index, appendices, &c. Dr. Peters must have given much time and attention to the work before us, and those who are able to wade through some hundreds of heavily-written pages will, of course, thank him for it. It is not our intention to discuss "Nippur" in detail, for many of the results obtained from the excavations carried on at the city of this name by Dr. Peters, and by his distinguished successor Mr. Haynes, have already been made known by Prof. Hilprecht; our object is only to call attention to the excellent work which the Americans have done by establishing a Consulate at Baghdad, and by systematically working through a site.

Just as England owes its unrivalled collections of Babylonian and Assyrian antiquities in the first instance to the private initiative of the British Ambassador at Constantinople about the year 1845, so the fine collections of inscribed tablets and other antiquities which America now possesses are due to the private enterprise of some of the principal citizens of Philadephia. The American expedition was inaugurated by Mr. E. W. Clark, a leading banker of that city, and the scheme was adopted with great vigour and good-will by Dr. W. Pepper; other public-spirited men joined them, and their efforts have been crowned with such success that up to the present time nearly fifteen thousand pounds sterling have been expended by America on archæological researches in Mesopotamia. The chief site of the work of the Americans was at Nippur or Niffer, a city which was situated about fifty miles to the south-east of Babylon, and was the centre of a great and flourishing civilisation some seven thousand years ago. Some of the early explorers had ascertained that the mounds which marked the site of the old city contained remains of buildings, inscribed tablets, &c., but the work of digging them out seriously did not begin until Dr. Peters and Mr. Haynes arrived on the scene. Dr. Peters toiled for several weeks at Niffer in 1891 and 1892, and succeeded in clearing out part of the great Temple of Bel, and in finding a large number of inscribed tablets; the two volumes before us deal practically with the results of his labours. In 1893 Mr. Haynes took over the work, and was so fortunate as to light upon a "find" of thousands of tablets, seals, and other important documents; he was also enabled to lay bare the ruins of the greater part of the ancient city and its temple in such a way that we are now able to understand the plan upon which an ancient pre-Babylonian city was arranged and built. Many tablets and other precious objects had, according to the terms of the agreement between the Ottoman Museum authorities and the Americans, to be sent to Constantinople; but we are glad to learn from Prof. Hilprecht's publications that a substantial number have been allowed to cross the Atlantic as a reward for the money and labour expended by the Americans at Niffer. It is to be hoped that copies of all such documents may be made available for scholars as soon as possible, and that other cuneiform experts in America will follow the example which Prof. Hilprecht has set them. Meanwhile it is to be hoped that a successor to Mr. Haynes and Dr. Peters has been found, and that a good work so well begun may be continued.

OUR BOOK SHELF.

A Manual on General Pathology for Students and Practitioners. By W. S. Lazarus Barlow, B.A., B.C., M.D., M.R.C.P. Pp. xi + 795. (London: J. and A. Churchill, 1898.)

THE book before us is a treatise on general pathology, from which morbid anatomy is practically excluded. To the readers of Cohnheim this subject is familiar; the author has done well to take such a book as a model, and to, so to speak, bring it up to date.

The relation between morbid anatomy and disease has never been doubted. The study of a dead, dilated, hypertrophied and valvularly diseased heart has always been held to be of immense value to the student of medicine. It must be admitted, however, that it bears the same relation to disease as a scratched rock does to the action of a glacier. Both are the more or less permanent records of a process. However valuable such records may be, it must be admitted that the demonstration of the behaviour of a heart under conditions more or less exactly imitating disease is also of great value. It is to be regretted that while teaching in morbid anatomy is all-sufficient, instruction in experimental pathology is most often conspicuous by its absence. A careful perusal, however, of Dr. Barlow's work will in no small measure make up for this deficiency, and the student of medicine who wants to do something more than get qualified in a minimum time, will find it very helpful. Although the book is ostensibly written for practitioners, the reviewer is afraid that its contents will only appeal to a relatively small circle of medical practitioners, at any rate at present.

It would be impossible in a short notice to even enumerate the subjects treated by Dr. Barlow. The chapter on osmosis will perhaps appeal most to the general physiological reader; in it is to be found a description of the author's own work in this field of research, and also a fair account of the work of those who hold different views with regard to the function of the epithelium cells involved. The pathology of the circulation is well handled, but contains little of special interest. Under inflammation, chemiotaxis and its relation to phagocytosis are discussed. The author devotes a chapter to the "Pathology of Heat Regulation," at the conclusion of which fever, and tissue change in fever is fully considered. Under shock and collapse, which are viewed in the light of the recent experiments of Roy and Cobbet, transfusion is treated in an original manner. Chapter xii. forms an interesting monograph on the pathology of nutrition, which is dealt with exhaustively. Chapters on morbid secretion and excretion, and the pathology of respiration follow, and the book concludes with a miscellaneous appendix, in which, *inter alia*, ptomaine poisoning is briefly considered.

The book is eminently readable, and although the range of subjects covered by it is very wide, is not wanting in thoroughness. Its value is enhanced by the carefully compiled bibliography which concludes each chapter. It is somewhat to be regretted that it should appear so soon after almost similar subjects have been treated either in Allbutt's "System of Medicine" or in Prof. Schäfer's "New Text-book of Physiology," but this is obviously no fault of the author's. F. W. T.

A Text-Book of Entomology, including the Anatomy, Embryology and Metamorphoses of Insects, for use in Agricultural and Technical Schools and Colleges. By Prof. Alpheus S. Packard. Pp. xvii + 729. (London: Macmillan and Co., Ltd. New York: The Macmillan Co., 1898.)

DR. PACKARD has undertaken in this text-book to review and epitomise the vast literature relating to the structure of insects. For such a task special qualifications are necessary; among the rest, unflinching industry, a sound judgment, and a first-hand, practical knowledge of the subject. These qualifications our author exhibits on every page. He has worked long and hard as an investigator; he has a candid mind; and he has spared no pains either upon the collection or the elucidation of his materials. The critic who tries to be wholly impartial may feel compelled to point out a certain slowness to draw general conclusions, which is particularly evident in the concluding section on the causes of metamorphism. This reserve is natural, perhaps laudable, in the writer of an encyclopædic work. Dr. Packard's book will be of the greatest service to students of insect-anatomy, and almost indispensable to future writers on the subject. It is a great store of well-sifted and carefully arranged information, which will guide the naturalist to many a special research which he might easily have passed by in ignorance of its very existence. We must not leave the impression that Dr. Packard has done nothing but condense into a text-book the work of other men. He has made out for himself many interesting and valuable facts, and in no part of this treatise does he find himself altogether remote from his own published researches. The book before us is handsomely printed, profusely illustrated, and furnished with copious bibliographical lists. Together with the very dissimilar treatise by Dr. Sharp in the "Cambridge Natural History," it puts the student of scientific entomology into a far better position than he occupied a year or two ago. Dr. Packard's book, like Dr. Sharp's, should find a place in every library which includes comparative anatomy, and both should be the constant companions of all who occupy themselves with the structure and life-histories of insects. L. C. M.

The Mathematical Theory of the Top. Lectures delivered on the occasion of the Sesquicentennial Celebration of Princeton University. By Felix Klein, Professor of Mathematics in the University of Göttingen. Pp. 74. (New York: C. Scribner's Sons, 1897.)

THE four lectures constituting this little book are worthy of the great occasion which called forth their delivery. Prof. Klein uses the particular dynamical problem of the top as an illustration of the advantages that may be gained by utilising the modern theory of functions in applied mathematics. Instead of being content with analytical processes, he strives to the utmost to give a geometrical form to his formulas, and to make the solution intuitive. He passes beyond the parameters of Euler and Rodrigues to apply to dynamics a system of coordinates which Riemann introduced forty years ago in the discussion of certain geometrical problems. Using also Riemann's method of conformal representation, he gives an insight into the inner nature of elliptic functions, and shows that his new parameters are what he calls "multiplicative elliptic functions"—they miss being doubly periodic by being affected by an exponential factor when t (the time) is increased by a period. By means of these parameters the author attains to a clearer, neater and more complete solution of the problem of the motion of a body about a fixed point than had hitherto been reached, and justly claims that he has resolved the problem into its simplest elements. He also deals with Jacobi's famous theorem, that the motion of the top may be represented by the relative motion of two Poinsot motions (or rotations of a body about its centre of gravity which is fixed).

In generalising to the full the problem under discussion the author deals with the case when the time, t, by being supposed complex, becomes capable of two degrees of variation. In order to get a geometrical representation, he is led to consider the motion of a rigid body in hyperbolic non-Euclidean space.

The last lecture deals with a top whose point of support is no longer supposed fixed, but movable in a horizontal plane. The hyper-elliptic integrals of this more general problem are interpreted in a similar way to the elliptic integrals of the previous discussion. From the nature of the case, in these lectures, an outline sketch of a large subject is all that can be given, but the lines are traced by the hand of a master; and for filling in the details we must look to the author's treatise, "Ueber die Theorie des Kreisels," which is now in course of publication by Teubner.

William Stokes, his Life and Work (1804–1878). By Sir William Stokes. *Masters of Medicine.* Pp. 256; plate i. (London: T. Fisher Unwin, 1898.)

THE memoir before us is an interestingly written account of a man whom all physicians respect. Stokes was a master of medicine, and the inclusion of his biography in this series shows the wisdom of the editor. The name and work of Stokes are perhaps not as well-known to the modern student of medicine as they ought to be; this is probably due to the fact that not sufficient time has passed for us to appreciate his work, or rather for us to estimate its great value. He worked and taught at the time when exact methods of physical diagnosis were beginning to be applied by the clinician. Pathological chemistry and bacteriology were practically non-existent, and clinical thermometry was in its infancy. The work of Laennec on the stethoscope had attracted the attention of medical Europe, and opened up the enormous field of the correlation between physical signs and symptoms. It is in this particular field that the work of Stokes was done, and his treatise on the diagnosis and treatment of diseases of the chest still remains a classic. With the exception of Laennec's work, which it considerably amplified, this book must be regarded as one of the most noteworthy upon this subject which had until then been written.

To turn from his professional to his private life, the letters which are given us in this biography show us Stokes as a cultured Irish gentleman, forming the centre of a wide circle of friends. The biography is carefully written, and will appeal to all those who are interested in that epoch of the history of medicine to which its subject belongs. F. W. T.

Practical Organic Chemistry. By George George, F.C.S. Pp. 94. (London: W. B. Clive.)

THERE is no date on the title-page of this book, but the preface bears the date May 1898. No scientific book should, however, be published without the year of publication being printed upon the title-page.

The book is intended "for the elementary and advanced examinations of the Science and Art Department." It contains a few experiments on the detection of common elements in organic compounds, on melting and boiling points, organic acids, alcohols, sugars, &c., notes on the methods of examination of mixtures containing organic compounds, and on the preparation of some reagents used in organic analysis. The volume will thus make the student acquainted with the reactions of, and the tests for, common organic bodies.

Food Supply: a Practical Handbook for the use of Colonists and all intending to become Farmers Abroad or at Home. By Robert Bruce. With an Appendix on Preserved and Concentrated Foods, by C. Ainsworth Mitchell, B.A. Pp. xvi + 159. (London: Charles Griffin and Co., Ltd., 1898.)

THIS is the second volume of the "New-Land" Series, edited by Prof. G. A. J. Cole. It is a concise and soundly practical manual of farming in which the fundamental principles of successful agriculture, and of the selection and management of live-stock, are described. It is only paying a compliment to the author to state that the book contains the kind of information published by the Department of Agriculture of the United States, and in such official publications as the *Agricultural Gazette* of New South Wales and the *Agricultural Journal* of the Cape. As we are at present without a central office for supplying information to British farmers, it is the more necessary that the means of education in the science and practice of agriculture afforded by such books as the one under notice, should be widely known. The volume deals with the fundamental principles of most branches of farming, and will prove of service in any part of the world. The forty-nine half-tone reproductions of photographs of representative animals, illustrating the chief breeds of live-stock, will be of particular interest to farmers.

Royal Gardens, Kew. Bulletin of Miscellaneous Information, 1897. Pp. 437 + 68. (London: H.M. Stationery Office, 1897.)

THE well-known *Kew Bulletins* afford the best of evidence of the valuable work done at the Royal Gardens in advising upon possible developments of the natural resources of our Colonies and dependencies. Each *Bulletin* contains a number of plain statements of attempts made to introduce new and commercially profitable plants in suitable districts, of improved methods of cultivation, and of work that men trained at Kew are doing in the various parts of the world to which they have gone from the Royal Gardens. The *Bulletins* issued in 1897 are collected in the present volume, and together they make a worthy contribution to economic botany. Among the contents is a long list of publications issued from Kew during the years 1841–95. This record of accomplished work is an eloquent testimony of the important part which the Gardens take in botanical research, and in developing the resources of the Empire. Several papers on botanical exploration and enterprise are included, and sixty-three pages are devoted to the report of the Royal Commission appointed to inquire into the condition and prospects of the West India Colonies.

LETTERS TO THE EDITOR

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Spectrum of Metargon.

WE have delayed in replying to Prof. Schuster's letter in your issue of June 30 in order that we might make further experiments on the subject. We have had the kind assistance of Prof. Schuster, who demonstrated to us the close similarity between the group of green lines in the metargon spectrum and the spectrum of the blowpipe flame. We subsequently satisfied ourselves regarding the similarity of the metargon spectrum and the "Swan" spectrum, shown by carbon monoxide in a vacuum tube. At first sight, Prof. Schuster seems justified in attributing that spectrum to the presence of carbon or of one of its compounds. Yet we think that careful consideration of the following facts will necessitate a suspension of judgment:—

(1) The sample of metargon was mixed with twice its volume of oxygen, and sparked for two hours in presence of caustic soda. This sample, introduced into a vacuum tube after removal of oxygen, still showed the same spectrum.

(2) A little oxygen was introduced into the gas, and the mixture was then admitted to a vacuum tube. Oxygen lines became visible, but no bands of the so-called "carbonic oxide" spectrum. On removing the oxygen by means of phosphorus, the original spectrum appeared with its customary brilliancy.

Thinking it possible that the ordinary spark may not have had a sufficiently high temperature to decompose an imaginary stable carbon compound, a jar and spark-gap were introduced, and sparks passed through a mixture of metargon with twice its volume of oxygen, standing over caustic soda, for six hours. No contraction occurred, and the spectrum of the gas was unaltered, after removing oxygen.

(3) An artificially made mixture of carbon monoxide and argon —about equal volumes of each—was mixed with oxygen. It was sparked and exploded. It was then further sparked over soda for a quarter of an hour. On introducing the gas into a vacuum tube, after removal of oxygen, no carbon lines or bands were seen, but only the spectrum of pure argon.

The bands in the green of metargon are exceedingly brilliant, and the spectrum is by no means of the character of a subsidiary one. It does not appear to be possible to enfeeble them relatively to the rest of the spectrum.

We have found it possible, in hundreds of cases where it was necessary, to remove traces of carbon compounds from gases evolved in heating minerals—chiefly helium—to remove the carbon bands by "running" the tube, *i.e.* by increasing the intensity of the current until the aluminium pole melted. The green and red bands, under these circumstances, slowly disappear, and the spectrum of helium or of argon, as the case may be, shines out "clean-cut," and shows as bright lines on a black background. This process is impossible with metargon; no change is produced even after long "running."

We must again call attention to the facts that this gas shows the ratio of specific heats 1·66; that it possesses sensibly the same density as argon; and that it is a solid at the temperature of liquid air, boiling under atmospheric pressure.

Although, therefore, we are the first to admit that the spectrum of this gas requires further investigation, yet, from what we have observed, we provisionally adhere to our original view that it possesses the characteristics of a definite chemical individual.

We would take this opportunity of correcting a misprint in the *Comptes rendus*, cxxvi. p. 1762, where the wave-length 5849·6 is attributed to metargon, instead of to neon.

Liquid Hydrogen.

Prof. Dewar's letter in your last issue is such a pronounced personal attack on me, that I feel I ought to deal with the remarks to my prejudice which it contains, though I will try to avoid imitating its tone.

(1) He refers to the statements on which I base my claim to the invention of the self-intensive method as matter which "has already been refuted." I should be glad to know when and by whom. They are clearly numbered 1, 2, 3, 4, in my last letter, and form the substance of my first. At the Society of Chemical Industry Mr. Lennox, though he was present and heard the statements repeated, with every opportunity of contradicting them, did not do so. Prof. Dewar, far from refuting statements 1 and 3, did not even deny them; and his attack on the second (respecting the novelty of the invention) resulted in strengthening it, since it showed that he was reduced to building up an anticipation by taking material from several different sources, having been unable to find any account of the combination before my proposal in November 1894. The fourth statement had not then been made, as hydrogen had not been liquefied. Where then has the refutation taken place? In both his letters to you Prof. Dewar keeps all four statements at a very respectful distance.

(2) Prof. Dewar uses the words "accusations which he was compelled to withdraw when he met me face to face," and "when brought to book at the Society of Chemical Industry." It is quite untrue that I withdrew anything at all. On the contrary, I said that "I had nothing to withdraw," and that my assertions were "a simple and direct statement of historical facts," repeating more frequently than is shown in the printed report that the facts were exactly as I had stated them. As to what took place between Prof. Dewar and his assistant it is obvious that, not having been present, I could have no knowledge; and I can only publish what I know of my own knowledge, or can prove by conclusive evidence. Deductions from the facts must be made by every one for himself, and I reminded Prof. Dewar that as I had published no such deductions I could not withdraw them.

(3) I was not, at the time of my communications to Mr. Lennox, "convinced of the general dishonesty of Royal Institution methods," as Prof. Dewar suggests. I regarded the Royal Institution as one of the temples of science, and Mr. Lennox as its chief acolyte, who might, perhaps, when my offering had been examined and found worthy of acceptance, introduce me to the favourable notice of higher authorities.

(4) What I am "to be understood as saying in the letters you have published," is so clearly set forth in my four numbered statements in your issue of June 23, that Prof. Dewar's doubts on the point cannot be so puzzling as his question implies.

(5) Prof. Dewar's acquaintance with patent-law cases involving a host of partisan expert witnesses and costly counsel is too extensive and familiar to leave him in any doubt as to the reason why a man without means does not begin a prosecution for infringement. I could, however, warn the infringers; and this I did. The protest having been made, I am still free to prosecute when circumstances render it possible and advisable to do so, and the present prospects of low-temperature work make it by no means unlikely that action may yet be taken.

(6) Prof. Dewar's admission, referring to Dr. Linde's method, which he had just heard described, "that the practicability of such a mode of working had never struck him," was made in the opening sentences of his remarks, without any limiting qualifications, but with express inclusion of both "the mechanical ingenuity and knowledge of thermodynamics" involved; so that its only fair interpretation is with reference to the description that had just been given of Dr. Linde's combination, which is, except in details, the same as mine. The force of the admission is not lessened by quoting a subsequent passage which refers to one part of the combination. Dr. Linde and I had invented a combination which made it possible to liquefy air without using any other refrigerant than water. Prof. Dewar admitted that he had never thought out the whole combination. Whatever therefore he and others had done with some parts of it, when the combination came out he ought to have recognised its novelty, instead of endeavouring to piece it together out of old patents and experiments.

(7) Neither M. Solvay nor Prof. Onnes claims to have invented a combination by which continuous free expansion from a nozzle is able, without using other refrigerants, to liquefy air: so that Prof. Dewar misleads his less instructed readers by putting those gentlemen forward as my rivals on the ground that they claim to have used parts of the combination.

My communications to Prof. Dewar's assistant were, however, of earlier date than any publication of Dr. Linde's process. This is the fact of which, with its corollaries, I had hoped to obtain a frank admission from Prof. Dewar, and I would have much preferred that the discussion in your columns had been confined to the points raised in my first letter. Prof. Dewar, however, instead of frankly admitting my claims, as other prominent scientific men have done, or discussing the statements on which they are based, has seen fit to give his attention almost entirely to the more personal elements in the controversy. In two letters he has called my action "dubious" and "not straightforward," and has said that either I am "a singularly dull person" or am consciously imposing "upon the credulity of the world," that I contradicted myself "when brought to book," and that I "was compelled to withdraw accusations" which in fact I explained that I had never made, while refusing to withdraw anything at all. Under these circumstances I think that few of your readers will blame me for asserting the justice of my claims, though I regret that so much of your valuable space should have been occupied by matters of this nature. W. Hampson.

July 1.

The Distribution of Prepotency.

No numerical estimate appears to have been made of the frequency with which different grades of prepotency are distributed. Breeders are familiar with the fact that certain animals are peculiarly apt to impress their personal characters upon offspring, but how frequently and to what extent this tendency occurs has never, I believe, been investigated. The following attempt is therefore of interest, though not free from objection in minor details. In *Wallace's Year Books* of the American Trotting Horses, lists are given (1) of the sires of offspring, any one of which has succeeded in trotting one mile in 2 minutes and 30 seconds or less, or who has "paced" (= ambled) the same distance in 2 minutes and 25 seconds or less; (2) of the dams of at least two such offspring, or else of one such offspring and one such grandchild. A selection was made from lists (1) and (2) of sires and dams who were themselves foaled before 1870 and who therefore were, or would have been, at least 25 years old at the date of the last *Year Book* in my possession, which is for 1896. This is practically a sufficient allowance, giving say 5 years to the foals in which to make their record, and 20 years as the limit of the breeding age of either parent. My selection from list (1) contained 716 sires, and that from list (2) contained 494 dams. Reducing to percentages, the distinguished offspring (standard performers) to 100 sires and to 100 dams from these lists respectively, are tabulated below, disregarding decimals. Thus out of each

Distribution of the Parents of Standard Performers.

	Number of standard performers produced by a single parent, sire or dam.											Total parents.
	1	2	3	4	5	6 to 10	11 to 20	21 to 30	31 to 40	41 to 50	51 and above	
Sires ...	46	17	10	7	3	9	4	1	1	1	1	100
Dams ...	50	35	10	3	1	1	—	—	—	—	—	100

100 selected sires, we see that 46 produce only one standard performer, 17 produce two, 10 produce three, 7 produce four, and 5 produce three. Thus far the distribution of prepotency is not particularly abnormal, and we might have guessed that there would be about 3 cases more, none of which would contain more than from seven to eight standard performers, but the facts are surprisingly otherwise. Although the frequency of the successively larger families decreases with fair regularity, the rate of their diminution is far too slow to be compatible with the normal law of frequency. Instead of the expected 3 cases, each containing six, seven or eight standard performers, we find 17 cases of far higher contents. Thus in the list of 716 sires, the number of distinguished offspring are,—60 to *Blue Bull*, 71 to *Strathmore*, 83 to *George Wilkes*, 92 to *Happy Medium* and 154 to *Electioneer*. Making full allowance for the tendency of breeders to send the best mares to the best horses, the prepotency of the sires just named is enormous, that of *Electioneer* superlatively so. The same results are indicated by the produce of the dams, though the figures are less striking owing to the relative fewness of their offspring. A sire produces some 30 foals annually, a dam only one, while the period of production is presumably longer for the sire than for the dam. Consequently out of the list of 494 dams, the three mares *Emeline* (*sic*), *Minnehaha* and *Green Mountain Maid*, who produced respectively 7, 8 and 9 standard performers, seem as phenomenal as the five horses mentioned above. Again, prepotency is as we should have expected, heritable in a marked degree; thus all of the above five sires except *Blue Bull* are sons of "*Hambletonian* 10," and one of the three mares, *Green Mountain Maid*, was dam of *Electioneer*.

My conclusion is that high prepotency does not arise through normal variation, but must rank as a highly heritable sport, or aberrant variation; in other words its causes must partly be of a different order, or else of a highly different intensity, to those concerned in producing the normal variations of the race. In a sport, the position of maximum stability seems to be slightly changed. I have frequently insisted that these sports or "aberrances" (if I may coin the word) are probably notable factors in the evolution of races. Certainly the successive improvements of breeds of domestic animals generally, as in those of horses in particular, usually make fresh starts from decided sports or aberrances, and are by no means always developed slowly through the accumulation of minute and favourable variations during a long succession of generations.

FRANCIS GALTON.

Zoology as a Higher Study.

THE following, necessarily condensed, comments on Prof. Ray Lankester's criticisms may be permitted.

(1) Prof. Lankester's views on the citation of authorities in text-books have been published before. To the best of my belief "authoritative public opinion," if it had expression, would favour the side of common sense in this matter. A text-book, adapted to the needs of the elementary student, in which the "historical method of exposition" should be followed, and each discoverer awarded his due meed of recognition, is an impossibility, within reasonable limits of size and cost. Our reasons for omitting all references to authorities really were those given in the preface, which I invite Prof. Lankester to re-peruse, not those which he ungenerously ascribes to us.

(2) Where the names of the original authors of figures have not been quoted, and the proximate source from which the block was borrowed or the figure copied has alone been given, the name of the original author is, in most instances, a matter of no consequence whatever. In a very few cases the omission is regrettable.

(3) The main responsibility for the "most astonishing" of the errors which Prof. Ray Lankester has noticed in the text-book, viz. the statement that ossification occurs in the skeleton of Elasmobranchs, rests with me, and not with the two sons of W. Kitchen Parker. The most astonishing thing to the initiated onlooker will doubtless be Prof. Lankester's evident confidence that this is an error.

(4) The "error" with regard to the nephrostome of Lumbricus is Prof. Lankester's. If he will read over that part of the "Text-book" as it would be read by a student, taking the description of *Nereis* as the foundation, he will understand what I mean. "Corresponding segment" is not "same segment."

(5) The criticism of the statement regarding cœlome and hæmocœle in Peripatus would have lost all its apparent cogency had Prof. Lankester quoted only three lines more (see "Text-book," vol. i. p. 561).

WILLIAM A. HASWELL.

The Nature and Habits of Pliny's Solpuga.

I READ with much interest Mr. Pocock's article on "Solpuga" (NATURE, vol. lvii. p. 618). It may be worthy of note that a species of Galeodes is met not infrequently in Southern California, and is one of the few Arthropodous animals that is bold enough to attack and devour the honey-bee. It enters the hive and seizes the bee, worker as well as drone, and soon makes away with it. Were these Arachnoids as abundant as the Robber-flies (Asilidæ), they would be nearly as serious enemies of the bee-keepers of Southern California as are those insects. They are not, however, sufficiently numerous to do any serious mischief, and so are not feared or dreaded.

The Weather of this Summer.

IN your notice of Symons's *Met. Mag.* this week, I seem to be credited with (discredited by?) the announcement that this summer will probably be wet. May I point out that it is one thing to announce this, and another to say that in the five years ending with the next sunspot minimum year (say 1901, or thereabouts), there will probably be more wet summers than dry? Further, the two rules cited in the notice are based on data extending from 1816, not merely from 1841.

ALEX. B. MACDOWALL.

THE NATURAL HISTORY MUSEUM.

THE following memorial has been addressed to the Trustees of the British Museum:—

Sir, My Lords, and Gentlemen,—We, the undersigned, being persons interested in the science of Natural History, venture to address to you the following observations suggested by the retirement of Sir W. H. Flower from the post of Director of the Natural History Museum (British Museum).

It is, in our opinion, of great importance to the welfare of Natural History that the principal official in charge of the national collections relating to this subject should not be subordinate in authority to any other officer of the Museum. The Natural History Collections are in a part of London remote from the National Library and the other departments of the British Museum; the supervision of these collections and the direction of the large staff entrusted with the care of them are sufficient to tax the whole energies of any one entrusted with those duties. For the purpose of facilitating this task and avoiding possible friction, it seems to us necessary that the Directors should meet the Trustees and represent them before Her Majesty's Treasury as the responsible head of a department, and not as a subordinate.

A position such as we have described was held, to the great satisfaction of the scientific world, by Sir William Flower, who succeeded Sir Richard Owen; to abolish it now would involve a great change of policy. We believe that the existing system has given satisfaction to the staff of the Museum and to the public. Under it the collections have been so administered as to serve the needs of national education and of scientific research in a very efficient manner.

It may be pointed out that the interests presided over by the principal Librarian are totally different from those under the charge of the Director of the Natural History Museum, and that the same man cannot be expected to understand or to represent adequately the needs of two departments so complex and so distinct from one another. The progress which has been made in the Natural History Museum under its present organisation, especially in regard to its development as an instrument of public instruction and enjoyment, would have been difficult under the old system, in which the Head of the Natural History Collections had not a position of independence and freedom. In this connection it is important to remember that the support given to the institution by Parliament must be largely dependent upon public sympathy and approval. Further, it must not be forgotten that while the Natural History Museum has been developed as a place of public interest it has increased its reputation as an institution of first-rate scientific importance in Europe, both by the magnitude and organisation of its collections, and by the researches carried on by the staff within its walls.

At a meeting of the Standing Committee of the Trustees of the British Museum, held on the 9th inst., the following letter was directed to be sent to Sir William Flower. It is signed by the Chairman of the meeting, Lord Dillon.

"*British Museum, July* 9, 1898.

"DEAR SIR WILLIAM FLOWER,—With profound regret the Trustees accept the resignation of the Directorship of the Natural History Museum which, owing to failure of health, you have been unhappily compelled to submit to them. They had hoped that the remaining term of years which you might have spent in their service would have enabled you to perfect the arrangement of the collections so admirably planned and so systematically developed by you during your fourteen years of office, and they cannot but regard your retirement at this moment as a real misfortune to the Museum.

"They wish to record their high appreciation of your services.

"The rare combination of wide scientific knowledge with marked administrative ability and a sympathetic appreciation of the requirements of the uninstructed public has carried you through a most difficult task. Under your hands the Natural History collections of the British Museum have fallen into the lines of an orderly and instructive arrangement which no one, whether man of science or ordinary visitor, can examine without admiration.

"To you, as a worthy successor of Sir Richard Owen, will attach the honour of having organised a Museum of Natural History which now occupies a pre-eminent position among all the Museums of the civilised world.

"For these devoted services the Trustees thank you. In your retirement you carry with you their lasting gratitude and their sincere good wishes.

"Believe me, Dear Sir William Flower,
"Yours very truly,
(Signed) "DILLON."

ANIMAL INTELLIGENCE: AN EXPERIMENTAL STUDY.[1]

MANY are the writers on animal intelligence, but few have made comparative psychology a subject of scientific investigation by the methods of careful observation and of experiment under conditions allowing of some control. Right welcome, therefore, is Mr. Thorndike's experimental study, of which a brief preliminary notice appeared in NATURE a few weeks ago (vol. lvii. p. 372).

This careful research goes far to confirm the conclusion, to which the present writer has been led, that the method of animal intelligence is one of undiscriminating trial and error, of profiting by chance experiences, and one which depends on the establishment of direct associations—a conclusion which is in close accord with that reached by Prof. Wundt. Mr. Thorndike is, however, somewhat severe in his criticisms of previous writers in the same field, complains that they have made no observations of their own, and says that most of the books do not give us a psychology, but rather a eulogy of animals. "They have all been about animal intelligence, never about animal stupidity." One of the previous writers has, however, said: "And then, as Mr. P. G. Hamerton well remarks, we have to take into account the immensity of the ignorance of animals." Ignorance and stupidity are, of course, by no means synonymous. But it is the former rather than the latter that is so abundantly exemplified in animal life.

In many of his experiments Mr. Thorndike's method was as follows. Very hungry kittens were shut up in box-cages, 20 inches long by 15 broad and 12 high, and food was placed outside within the animals' sight. To get out the kitten had either to pull down wire loops placed in different positions in different cages, or turn a broad button, or press an ordinary thumb-latch, or push down a small platform, or simply pull a string stretched across the roof. These devices (each in its separate cage) were so arranged that on the fitting push or pull the door opened; and fish was the reward of success. In other cages two or three distinct actions on the part of the kitten were required before the door opened. In yet other experiments the kitten was released and fed directly she either licked herself or scratched herself. The object of the investigation was to watch and record the establishment of associations; and the results are plotted in curves, giving the time-intervals between imprisonment and escape in successive experiments.

The curves are far from smooth, as is indeed to be expected where the internal factors are necessarily somewhat inconstant, and where the difficulties to be overcome by the subjects are different in different cases; but they bear out the contention that the method of animal intelligence is to profit by chance experience, and is dependent on the gradual establishment of direct associations. I have endeavoured to extract from some of Mr. Thorndike's carefully plotted data a mean curve for the method of trial and error, and though it does not come out very well, it does serve to indicate that *gradual* sweep towards rapid and assured success, which would theoretically result on this method. In contradistinction to this the curve of rational procedure is quite different. I plotted some curves of this type a few months ago, after reading Dr. Lindley's dissertation on "A Study of Puzzles" (*Amer. Journ. of Psych.*, vol. viii. No. 4). They were for ordinary wire-puzzles, and show a *sudden* leap from failure to success when the trick of the puzzle was discovered and *understood*, and after that some slight improvement in rapidity of success as the manipulative details were mastered.

[1] "Animal Intelligence: an Experimental Study of the Associative Processes in Animals." By Edward L. Thorndike, A.M. (Monograph Supplement to the *Psychological Review*, June 1898.)

Passing reference may here be made to Dr. Lindley's interesting study above mentioned. He finds by observation that the method of the young child is largely that of the animal. Trial and error, chance success, and direct association are predominant. In older children, who are beginning to generalise the results of their experience, rational procedure based on a considered scheme or plan, makes itself more and more felt. Further observation on similar lines will serve to link such results as Mr. Thorndike's with the human psychology of the text-books.

To return to Mr. Thorndike's research. The conditions of his experiments were perhaps not the most conducive to the discovery of rationality in animals if it exist. The sturdy and unconvinceable advocate of reasoning (properly so-called) in animals may say that to place a starving kitten in the cramped confinement of one of Mr. Thorndike's box-cages, would be more likely to make a cat swear than to lead it to act rationally. And he may further urge that where the string passes out of sight and the bolt is hidden from view, the opportunities of understanding the situation are excluded. All the kitten could think would be: here's something loose and unnecessary to the normal constitution of a box; I'll try that on chance. But although I do not deem Mr. Thorndike's method so conclusive for the anti-rationalist view as observation under more natural, and, I may add, more sympathetic conditions, yet the form of his curves affords no particle of evidence for reasoned behaviour.

We may pass over his experiments on dogs and chicks with the barest mention. They serve to support the same conclusions with some differences of detail.

When we come to his psychological explanation of the nature of the associations involved, I find much to agree with but somewhat to dissent from. Where he argues that animals form no free ideas, I am heartily with him. I have myself contended that they are incapable of analysing a situation. And if in interpreting the facts of observation one's language may seem to imply that the sight of an object and its taste are analysed out and then associated, this is due to the inevitable analytic form which the use of words entails. Animals, in my opinion, do not analyse in this way, and do not form "free" ideas. The utmost that we can allow is that certain elements in a complex situation may, under given circumstances, predominate in consciousness over others; and this, not through any process of abstraction, but from the interplay of the nature of the animal and the circumstances of the case.

But when Mr. Thorndike says that "the groundwork of animal association is not the association of ideas, but the association of idea with impulse," I for one, as at present advised, am not prepared to follow him. "Impulse," he defines as "the consciousness accompanying a muscular innervation apart from that feeling of the act which comes from seeing oneself move, from feeling one's body in a different position, &c." Now in the first place this involves the assumption that physiological innervation is accompanied by a specific form of consciousness here termed "impulse." The question is still *sub judice*. But there is, at any rate, much to be said in favour of the view that consciousness is directly stirred only by *afferent* nerve-currents, and that the innervation process is itself unconscious, though its effects are communicated to consciousness by an afferent back-stroke from the motor organs as they move. This alternative view should, I think, have been mentioned, at all events in criticising one who provisionally holds it. On this view the efferent impulse (apart from its effects) cannot be psychologically associated with anything, since it is physiological and unconscious. In the second place, to suppose that one who holds the impulse as such to be purely organic, holds also that "an animal whenever it thinks of an act can supply an 'impulse' to do the act," savours, to say the least of it, of improbability. In any case I do not recognise it as my own view. I hold as strongly as Mr. Thorndike that the efferent impulse (as an organic link) is a *sine quâ non* in every case of association in animal psychology, and that no animal can supply it "at will."

A very interesting series of experiments were made with a view to extracting an answer to the question, Do animals imitate? The question is not so easy to answer as it looks. No one with adequate experience can doubt that young birds and mammals perform actions which, from the observer's point of view, are imitative. The sight of an animal performing some simple action is the stimulus which prompts to the performance of a similar action. This I have termed "instinctive imitation." And this Mr. Thorndike would not deny to animals, though he would, I take it, deny (and not without psychological justification) its right to be spoken of as imitation, properly so-called. On this basis are founded the numerous cases of imitation by suggestion where the sight of an action performed is the stimulus to the performance of a similar action. A more complex case is that of the bird which, hearing certain sounds, is not only stimulated to make sounds itself (like a laughing jackass to which one whistles), but gradually to make its own sounds resemble those which afford the stimuli (like the parrot which "draws a cork"). Here it seems that the resemblance itself gives satisfaction—in any case the factor of experiential selection is introduced. In these cases imitation by suggestion is supplemented by a tendency to more exactly reproduce the sound which affords the stimulus—a tendency which seems to be based upon the innate satisfaction which accompanies the act of reproduction. Thus far, in my opinion, animals can certainly go; but even this, it may be urged, is only pseudo-imitation. True imitation is seen only where a being of set purpose copies a given model, not only reproducing, but intending to reproduce. And it is the presence of true imitation of this type which Mr. Thorndike's experiments were designed to test. They afford, however, no evidence of it. Cats were allowed to see others do the trick of the box-cage. But they themselves, when placed in the cage, took the usual time to effect their escape. Their exit was no quicker from seeing others get out by the performance of certain clawings or pushings. The experiments do not carry complete conviction to my mind, though I regard the conclusion to which they lead as probably correct.

Mr. Thorndike thinks it likely that the primates stand at a higher level in this respect than dogs or cats. "If it is true," he says, "that the primates do imitate acts of such novelty and complexity that only this out-and-out kind of imitation can explain the fact, we have located one great advance in mental development. Till the primates we get practically nothing but instincts and individual acquirement through impulsive trial and error. Among the primates we get also acquisition by imitation, one form of the increase of mental equipment by tradition." My own observations on imitation in monkeys are too few and inconclusive to justify more than a very guarded expression of opinion. I lean to the view, however, that there is, even in them, little evidence of true imitation of the higher psychological type; and that the observed facts may be accounted for by a great extension of "instinctive imitation" suggestion, and behaviour directly founded thereon. I hope Mr. Thorndike will put the matter to the test of well-devised experiment.

Several interesting problems connected with the psychological interpretation of animal behaviour are briefly discussed, but can only be mentioned here. Mr. Thorndike accepts the conclusion that in animals "memory" is simply what has been termed "reinstating," and involves no true localisation in time or space. "The animal's self is not a being looking 'before and after.'" "Memory in animals, if one still chooses to use the word, is permanence of associations, not the presence of an idea of an experience attributed to the past." This is precisely the conclusion to which the present writer has been led. On the question whether animals are aware of the pleasure or pain that others are feeling, he says that the conduct of animals "would seem to show that they do not. For it has given us good reason to suppose that they do not possess *any* stock of isolated ideas, much less any abstracted, inferred or transferred ideas. These ideas of others' feelings imply a power to transfer states felt in oneself to another, and realise them as there." As thus stated I think his conclusion is correct, though he quotes me in an opposite sense. In my later discussion ("Introduction to Comparative Psychology," p. 320) I expressly exclude any such ejective transference.

In conclusion, some apology is perhaps demanded for reference to my own observations and conclusions in the same field of study. But it is well to preserve historical continuity in a topic, and it so happens that Mr. Thorndike's work has carried further and extended some of my own; and that his leading conclusions are in the main confirmatory of those which I have reached. In the general trend of our opinions we are perhaps more essentially in accord than, in some cases, he seems to suppose. Even our illustrations are sometimes closely similar; both utilising, for example, the consciousness of a man when he is playing tennis as illustrating the probable subjective condition of the conscious but not yet self-conscious animal. And this substantial agreement is not a mere personal matter. Were it such there would be no justification for drawing attention to it. It shows that the method of observation and experiment, on different but parallel lines, has led two independent investigators to results which are on the whole harmonious; and it affords some ground for the hope that comparative psychology has passed from the anecdotal stage to the higher plane of verifiable observation, and that it is rising to the dignity of a science. In any case Mr. Thorndike's research is one of no little value, and will, I trust, be supplemented by further investigations.

C. Lloyd Morgan.

THE FLORA AND FAUNA OF BRITISH INDIA.

NO portion of the earth's surface surpasses the British Empire in India in the wealth and importance of its vegetable and animal life. Not only is there no other equally large tropical area that has received the same amount of exploration from naturalists, but the territories and dependencies of British India comprise regions with a marvellous variety of climates, from tropical islands like the Andamans and hot plains like the Carnatic, to the snows of the Himalayas and the frigid plateaus of Tibet; whilst the rainfall varies from the "record" 600 inches or more on the Khasi hills to the meagre supply that occasionally damps the arid sands of the Sind desert, where, frequently, for years in succession, rain is unknown. The remarkable antiquity of the Indian peninsula, the greater part of which appears to have been land from the earliest geological times, adds greatly to the scientific importance of the fauna and flora.

Under these circumstances it is not surprising that the variety of plants and animals occurring in India should be very great. There is no other large tropical region with which comparison is possible, because, as already mentioned, there is none of which the natural productions are as well known. Europe (3,800,000 square miles) has more than twice the area of India (1,750,000 square miles), but it has a far poorer flora and fauna, only about 9500 flowering plants being known to occur against 14,500 Indian species; whilst British India and its dependencies contain more than twice as many species of mammals, nearly three times as many birds, considerably over four times as many batrachia, and about eight times as many reptiles as the whole of Europe. The moths known to be found in Europe are 3040 in number, those of India 5600; and in this case there is no doubt that the Indian list is far from complete.

The interest attaching to the botany and zoology of India makes the circumstance noteworthy that two important works published by order of the Government of India, and at its cost, have been completed within the last six months. These works are the "Flora of British India" and the vertebrate section of the "Fauna of British India." In neither case is the work exhaustive, but each deals with the most important group of plants or animals respectively, the "Flora" containing descriptions of all flowering plants, and the "Fauna" accounts of all vertebrate animals. It is scarcely necessary to say that flowering plants form a much larger proportion of the whole flora, than vertebrate animals do of the entire fauna; but some progress has already been made with an addition to the "Fauna" as originally planned, and with the description of the huge mass of Indian Invertebrata. Except that the plants of the Malay peninsula are included in the "Flora," whilst the animals are omitted from the "Fauna," the British India of the two works is the same, and includes all India proper with the Himalayas, Ceylon, Assam, and Burma.

The "Flora of British India" is a work to which Sir J. D. Hooker has devoted many years of his life, and it is chiefly written by him, portions having been contributed by other botanists, amongst whom are Mr. Thiselton-Dyer, Mr. C. B. Clarke, Dr. Maxwell T. Masters, Mr. J. G. Baker, and the late Dr. T. Thomson and Dr. T. Anderson. The undertaking may be said to have commenced originally by the publication of the first (and only) volume of Hooker and Thomson's "Flora Indica" in 1855; but the present work, which is on a smaller plan, has been brought out in parts, of which the first appeared in 1872, and the last, containing the index, in November 1897. The whole consists of seven thick octavo volumes, comprising altogether over 5000 closely printed pages, and containing descriptions of 14,520 species.

The "Fauna of British India" is on a different plan, and the completed portion, containing the Vertebrata, consists of eight octavo volumes and of over 4100 pages. Of the eight volumes, one contains the Mammals (402 species), four the Birds (1626), one the Reptilia (534) and Batrachia (130), and two the Fishes (1418). The whole is edited by Mr. W. T. Blanford, who is also the author of the volume of Mammals and of two volumes of Birds, the remaining two volumes of the latter being the work of Mr. E. W. Oates; whilst Mr. G. A. Boulenger has contributed the part containing the Reptilia and Batrachia, and the late Dr. F. Day wrote the account of the Fishes. The first part appeared in 1888, and the last volume of Birds has just been issued from the press.

As already mentioned the "Fauna," as originally projected, was intended to contain an account of the Vertebrata alone, and this is now complete. But some years ago the Government of India authorised an extension of the work, on the same plan and under the same editor, to certain Invertebrate groups, with the result that up to the present time four volumes on Moths, by Sir G. F. Hampson, have been published, with descriptions of 5618 species; and one volume on Bees and Wasps, by Colonel C. T. Bingham, containing descriptions of 995 species. Thus at present the series of the Fauna comprises thirteen volumes. No intimation has been given of any additional parts being in preparation. It may be hoped, however, that further additions will be made, and that, so far as is practicable, both the Flora and Fauna may be completely described. A thorough knowledge of the productions of India is as important for economic reasons as for scientific inquiry.

A. KERNER VON MARILAUN.

WE regret to announce that Dr. Anton Kerner von Marilaun, Professor of Botany in the University of Vienna, died suddenly on June 21 in that city from apoplexy. He was born at Mautern, Lower Austria, on November 13, 1831. He acquired at a very early age a considerable knowledge of the flora of his native province, and had already a good reputation as a botanist when still a student of medicine in the University of Vienna. After having taken his degree as Dr. Med. et Chir., he practised for a short time in one of the Vienna hospitals; but finding the medical career not to his taste, he accepted a professorship in the Josef's Polytechnicum at Ofen, Hungary. In 1861 he was called to the chair of Botany in the University of Innsbruck, which he occupied till 1878, when he succeeded Eduard Fenzl as Professor of Botany and Director of the Botanic Garden and Museum at Vienna, in which position he remained up to his death. In 1875 he was elected a member of the Imperial Academy of Science of Vienna; he received the order of the Eiserne Krone in the following year, in recognition of his achievements as a teacher and man of science, and was knighted in 1877, when he added the title "von Marilaun" to his name. When Eichler, the eminent morphologist, died, the University of Berlin invited him to the vacated chair; but Kerner, who had always been a staunch Austrian, declined.

Kerner's principal claims as one of the most prominent botanists Austria has produced, rest chiefly on his researches in phyto-geography and biology—this term to be understood in the narrower sense, in which it is so often used in Germany. Trained from early youth to observation in the field, thoroughly familiar with the Central European flora, gifted with a keen eye for the salient features of vegetation and, at the same time, with an analytic mind ready to break up the general aspect in which a given vegetation presents itself into its elements, he was eminently fitted to develop that particular branch of phyto-geography which deals with the association of plants in so-called plant-formations. This doctrine had just then assumed a definite shape through Grisebach's investigations, although it may well be traced back to Alexander Humboldt. In his book, "Das Pflanzenleben der Donauländer" (1863), Kerner applied with great success the new method to the vegetation of the Eastern Alps and a large part of Hungary, which he had explored in numerous excursions. In a contribution to "Die Oesterreichisch-Ungarische Monarchie im Wort und Bild," which was published under the auspices of the late Crown Prince Rudolf, he worked out in a general way the distribution of the various floras within the monarchy, their principal subdivisions and their history, and he added soon afterwards an excellent map, under the title "Florenkarte von Oesterreich-Ungarn." If he was early a master of descriptive phyto-geography, he was by no means indifferent to the historical side of the science, as his paper, "Beiträge zur Geschichte der Pflanzenwanderungen" (1867), in which he sided with Forbes and against Grisebach and his creation theory, an interesting essay, "Studien über die Flora der Diluvial-Zeit in den östlichen Alpen" (1888), and several more show. Of his biological researches the most remarkable are those dealing with the relations of flowers and insects.

His splendidly illustrated book, "Schutzmittel der Blüthen gegen unberufene Gäste" (1876), was translated into English ("Flowers and their unbidden Guests"), and, no doubt, gave a powerful impetus to the development of one of the most fascinating chapters in biology. In fact, I believe, nothing appealed more to his constitution of mind than investigations of this kind; for he was endowed with a wonderful amount of imagination which, in that inexhaustible field, found ample opportunity for asserting itself—now divining the explanation of some puzzle, now losing itself in fanciful flights. Among his other papers of this category, I may mention, as more widely known, "Können aus Bastarden Arten werden?" and "Parthenogenesis einer angiospermen Pflanze" (1876). The latter referred to *Antennaria alpina*, and the correctness of the construction he put on the facts observed has been doubted for a long time; but a paper by Dr. Juel, of Upsala, published just a week previous to Kerner's death, must have given him great satisfaction if it reached him, as the author confirmed fully the disputed points by independent observation and careful microscopical investigation. Among his papers concerning systematic botany may be mentioned one under the title, "Abhängigkeit der Pflanzengestalt von Klima und Boden" (1868), which contains a valuable and highly philosophical essay on the section Tubocytisus of Cytisus; further, his "Monographia Pulmonariarum" (1878), and a very great number of critical notes, which are scattered through his "Vegetations-Verhältnisse des mittleren und östlichen Ungarns und angrenzenden Siebenbürgens" which, began in 1867, run through thirteen volumes of the *Oesterreichische Botanische Zeitschrift*, however, without having been completed. Numerous similar notes are also contained in the "Schedae ad Floram Exsiccatam Austro-Hungaricam," a beautifully prepared collection of Austrian and Hungarian plants, the issue of which proceeded to Century xxii. In his investigations into subjects of systematic botany, Kerner hardly ever ventured beyond the boundaries of his special domain, *i.e.* Austria-Hungary and the adjoining districts. This, perhaps, was partly the cause of his strong tendency towards "Jordanism," or the excessive subdivision into species, of his occasional one-sidedness, such as is often found in strictly local botanists, and of the almost complete absence of any attempt at dealing with groups of a higher order and from a broad standpoint. The only time he tried a problem of this category, namely in the chapter on the "Stämme des Pflanzenreiches," or the phyla of the vegetable kingdom, in his "Pflanzenleben," he was rather unfortunate, and he wisely omitted it in the second edition.

His great work, "Pflanzenleben," well known to the English public from the translation by Prof. F. W. Oliver ("The Natural History of Plants") was in many respects the crowning result of his life-long labours. When he undertook to write the book, which was to be one of a series of popular treatises on natural history, published by the Bibliographische Institut of Leipzig, his plan was to incorporate all his own experiences and observations, many of which were only laid down in rough notes, to assimilate those of other authors, and to produce a standard work which would treat homogeneously all the various phases of plant-life. It was a tremendous task, and must have heavily taxed his constitution, which was not over-strong, although he was scarcely yet past the prime of life when he commenced it. The work is known for its lucid, nearly always fascinating and often classic style, its beautiful illustrations, few of which are not original, its fulness of suggestive matter, its occasional quaint mixture of truth and fiction—of course, unconscious fiction—and its independent conception, and little need be said about it in this place. It is the very embodiment of the genius of its author, and it reflects equally well his strong and his weak points. Measured by it, Kerner might appropriately be called the poet-botanist.

Kerner was an excellent lecturer, who raised the subject of his lecture high above the ordinary level by enlivening the purely morphological and otherwise dry details by constant references to the relations which exist between form and function, and also by his bold and highly artistic draughtsmanship. He was a man of refined culture, but naturally nervous; he came not rarely into collision with others, from the effects of which he, no doubt, ultimately suffered most. Many of his smaller papers are so scattered or buried in all but inaccessible periodicals, and even daily papers, that a careful selection and reissue of those amongst them which are really valuable is very desirable.

OTTO STAPF.

NOTES.

The Cambridge Anthropological Expedition to Torres Straits arrived at Thursday Island on April 22. The Hon. John Douglas, C.M.G., the Government Resident, did all in his power personally and officially to advance the aims of the expedition, as did also the other Government officials and many others. The Hon. C. T. J. Byrnes, Chief Secretary, sent a cordial telegram of welcome and offers of assistance on behalf of the Government. After a week's delay a start was made for Murray Island, and owing to unfavourable weather it took another week to traverse the hundred and twenty miles between the two islands. The Murray Islanders gave Dr. Haddon a very cordial reception; they appear to understand the main objects of the expedition, and many of them are assisting in various ways. A deserted mission-house is occupied as a dwelling, and it has been converted into a temporary anthropological and psychological laboratory, photographic studio, surgery and dispensary. All the members of the expedition are in good health, and work has commenced in earnest.

The French Société d'Encouragement has awarded the grand prize of 12,000 francs to M. Moissan for his numerous researches in chemistry; the prize of 2000 francs for the experimental study of the properties of metals and alloys to M. C. E. Guillaume; the prize of 1000 francs for an investigation of albuminoids to M. Fleurent; a prize of 2000 francs to M. Cord for his work on the agriculture and geology of the soils in the department of Lozère; an *encouragement* of 500 francs to M. Capredon for his work on metallurgical chemistry; of 500 francs to M. A. Bigot for his work on enamels; of 1000 francs to M. Pagès for his work on the agriculture of the Cantal Department; and 500 francs to M. Mazel for his work on the agriculture of the Vivarais district.

The Committee appointed in 1895 to examine and report upon the various monographs submitted in competition for the Loubat prizes to be awarded in 1898 have issued their report to President Low, of Columbia University. The monographs that were formally submitted for examination were the productions of eight different authors; of these the committee consider as being the most meritorious, and as most fully complying with the conditions prescribed for the competition, the treatise on "Stone Implements of the Potomac Chesapeake Tide-water Provinces," by Mr. William Henry Holmes, Curator of the Department of Anthropology in the National Museum at Washington, and to this author therefore the committee recommend the awarding of the first prize, value 1000 dollars. In the opinion of the committee the second prize, value 400 dollars, should be given to Dr. Franz Boas, of the Metropolitan Museum of Natural History of New York City, for his monograph entitled "The Social Organisation and Secret Societies of the Kwakiutl Indians." Special mention is also made in the report to a work by Mr. Alfred P. Maudslay, of London, dealing with the archæology of Central America. This work was not submitted for competition, and is not yet in a complete state, but its great merit is such as to be considered worthy of special mention by the committee.

Science states that the New York City Board of Estimates and Apportionment has authorised the reissue of 375,000 dollars in bonds for the construction of buildings for the botanical garden in Bronx Park. Work on the museum building is being carried forward, the contract calling for its completion early next year.

PROF. VON RÖNTGEN has been awarded the Elliot-Cresson medal of the Franklin Institute of Philadelphia.

SIR GEORGE STOKES, Bart., F.R.S., will deliver his presidential address before the Victoria Institute at the annual meeting on Monday, July 18.

As we go to press the annual meeting of the Society of Chemical Industry is being held at Nottingham, under the presidency of Dr. F. Clowes. During the meeting the Society's medal will be presented to Dr. W. H. Perkin, F.R.S.

THE French Botanical Association has elected M. G. Rouy of Asnières as its president for the year. The annual meeting will be held from August 3 to 12, and will be devoted to an exploration of the environs of Gap, Brianson, and du Lauteret.

SIR JOSEPH FAYRER, Bart., K.C.S.I., F.R.S., &c., has been elected a governor of Wellington College.

THE U.S. Commission of Fish and Fisheries has made arrangements for a biological survey of Lake Erie. The work will be under the direction of Prof. Jacob Reighard of the University of Michigan, with whom will be associated Dr. H. B. Ward, of the University of Nebraska, Dr. H. S. Jennings, of the Montana College of Agriculture and Mechanical Arts, Dr. J. Shaw, of Ann Arbor, Mr. A. J. Pieters, of the U.S. Department of Agriculture, and a number of other assistants. Experimental work will be a prominent feature of the survey, and among other problems to be considered are the rate of growth of fishes; the food of young fishes reared from the egg, and the changes in their regimen during growth; the source of food of aquatic rooted plants; the life-histories of food fishes reared in aquaria or ponds, and of certain aquatic insects and other invertebrates; the rate of increase of the plankton as a whole, and of its individual constituents. There will also be systematic studies of the habits, migrations, distribution and food of the fishes and other organisms of the lake. At the beginning of the work Prof. Reighard and Dr. Ward will devote a considerable amount of time to plankton problems, especially the perfection of methods and apparatus; Dr. Snow will carry on experimental work on the algæ; Dr. Jennings will undertake experimental researches on the protozoa, and Mr. Pieters will pursue studies of the aquatic flora. The summer headquarters of the survey will be at the Government hatching station at Put-in-Bay, South Bass Island, Ohio. Lake Erie affords an excellent field for work of this character, on account of its varied fauna, diversified physical features, extensive fishing interests, and the recent serious depletion of the supply of certain valuable food fishes. The investigations, it is stated, may ultimately be extended to some of the other Great Lakes.

THE fourth International Congress of Agriculture will be held at Lausanne from September 12 to 17 next, under the patronage of the Swiss Department of Agriculture. The work of the Congress will be divided into the following sections:—Rural economy, agricultural education, forestry, dairying, stock breeding, agricultural industries, viticulture, protection of birds, insect and other pests. Those who desire to join the Congress as members (subscription 20 francs) are requested to send in their names to M. S. Bieler, Director of the Agricultural Institute, Champ de l'Air, Lausanne, before the 15th instant. Copies of the preliminary programme may be obtained in this country on application to Sir Ernest Clarke, Secretary of the Royal Agricultural Society, at 13 Hanover Square, W.

AS has already been announced, the autumn meeting of the Iron and Steel Institute will be held in Stockholm on Friday and Saturday, August 26 and 27. An interesting and varied programme has been prepared by the local committee, and seven papers have been promised, two being by Swedish metallurgists. Mr. Richard Ackerman, Director-General of the Swedish Board of Trade, an honorary member of the Institute, and a Bessemer gold medallist, will read a paper on the development of the Swedish iron industry, whilst Prof. G. Nordenström, of the School of Mines, Stockholm, will submit a communication on the most prominent and characteristic features of Swedish iron ore mining. Mr. C. P. Sandberg will discuss the danger of using rails of too hard a nature, whilst Prof. W. C. Roberts-Austen, C.B., F.R.S., will describe the action of explosives on the tubes of steel guns. The chemical side of metallurgy will be represented by three papers. The first will be by Mr. J. E. Stead, on brittleness in steel produced by annealing; the second by Prof. J. O. Arnold, of University College, Sheffield, on the micro-chemistry of cementation; whilst the subject of the third paper will be the influence of metalloids on cast iron, by Mr. Guy R. Johnson, of Tennessee, U.S.A. An excursion of twenty days' duration will follow the meeting.

AN exhibition of the manufacturing and mineral wealth of the various States and Colonies of South Africa is to be opened at Grahamstown on December 15. It will be divided into five groups or sections dealing respectively with raw materials, manufactures, mining and machinery, natural history and science, and fine arts. The exhibition will remain open until January 21.

IT will be remembered that a few weeks ago Dr. T. E. Thorpe, F.R.S., and Dr. Oliver, of Newcastle-upon-Tyne, were appointed by the Home Secretary to inquire, as experts, into the causes and prevention of lead-poisoning in the Potteries. These two gentlemen have now been invited by the same authority to undertake a similar inquiry into the dangers incidental to lucifer match-making, and have been commissioned to visit some of the factories on the continent.

THE *Electrician* states that the International Submarine Telegraph Memorial Fund has now been closed, and the following amounts have been applied to the objects named: University College, Gower Street, London, to endow the Pender Electrical Laboratory, 5000*l.*; Glasgow and West of Scotland Technical College, to continue annual John Pender Gold Medal, 210*l.*; Glasgow University, to provide annual bursary for student of Glasgow and West of Scotland Technical College who proceeds to Glasgow University, 1650*l.*; marble bust of Sir John Pender, by Mr. E. Onslow Ford, R.A., to be placed temporarily in the Board-room of the Eastern Telegraph Company, and for replica, which has been placed in the reading-room of University College, Gower Street, London, and pedestals for same, 461*l.*

AN electrically-worked underground tubular post for letters and parcels has been designed by Dr. Alfred Brunn and Mr. Viktor Takács, of Budapest, and submitted by them to the Hungarian postal authorities. It has been decided to lay down a trial line from the eastern to the western stations of Budapest, and, if a year's working proves successful, the postal authorities will take over the line, and a scheme for connecting twenty-three offices on both sides of the Danube will be carried out.

THE doctors of Portugal are evidently very much in earnest about the medical and sanitary well-being of their country, as is shown by the number of resolutions carried by them at the close of the recently held National Congress of Medicine at Lisbon on various subjects which, in their opinion, are of pressing public importance. One resolution called on the Government to give effect to the vote of the Chamber of Deputies, that vaccination should be made compulsory in Portugal. Another series of resolutions had reference to the repression of tuberculosis. The Congress urged that permanent committees should be appointed for the purpose of diffusing a knowledge of the means of prophylaxis against that scourge. It further recommended that all tuberculous patients admitted to general hospitals should be placed in special wards. It was also decided to appoint a committee to study the question of the establishment of sanatoria for the treatment of tuberculosis in Portugal. With regard to leprosy, the Congress called upon the Government to organise a system of careful study of the disease, and regular teaching of the means of dealing with it; to take a census of the population; to establish agricultural colonies of lepers, in connection with each of which there should be places where all the means of combating the disease should be taught; to place legal hindrances in the way of marriages between lepers and the descendants of lepers; and to educate the poor to correct notions as to the hereditary and contagiousness of the disease.

THE *Times* of Saturday last contained a report of an address delivered on Thursday before the German Society for Public Hygiene by Prof. Koch on the subject of the plague, in which he dealt especially with his discovery of a plague centre in the Hinterland of German East Africa, whither the disease had been introduced from Uganda. After referring to the plague centres of Hu-nan, Tibet, and the west coast of Arabia, in the vicinity of Mecca, the lecturer went on to lay claim to a fourth centre in Equatorial Africa. It had been found that a devastating disease prevailed at Kissiba, in the extreme north-west corner of German East Africa, close to the Victoria Nyanza. Suspecting that it was the plague, Prof. Koch proceeded from India to East Africa in order to make investigations. With the help of Dr. Zupitza, who made a special expedition to Kissiba, he had been enabled to identify the disease as the bubonic plague. In the case of five persons who had died from the disease anatomical preparations were obtained, and the blood and lymphatic glands of plague-stricken patients were bacteriologically examined. All the ordinary features of the bubonic plague were present. Nine out of ten of those who were infected died. The disease was communicated to rats and to monkeys. It was found that an outbreak of the plague among rats frequently preceded a human epidemic, and, in fact, the rat plague might always be regarded as a warning. A further observation had been made, which was of importance. The inhabitants of Kissiba lived almost entirely on bananas. The banana groves were so thick that they admitted neither light nor air, and were perfect breeding places of the bacillus. It would be most interesting if physiologists could investigate the processes of nourishment and metabolic change which attended an almost exclusive diet of bananas. It had been discovered, however, that Kissiba was not an original plague centre, but that the disease had been introduced from Uganda, as the reports of missionaries who resided there showed. It had existed for a long time in Uganda, but it had recently moved in the direction of Budu. Its introduction to Kissiba had been traced to a native who had visited a friend in Uganda. He returned home and died of the plague, and of a large number of natives who attended his funeral many were infected and perished. It was a favourable circumstance that for the present Kissiba lay somewhat out of the ordinary caravan route.

DR. CAMPBELL MCCLURE, of Glasgow, describes in the *Deutsche Medicinische Wochenschrift* a bacillus which he discovered while making examinations of milk in the laboratory of Dr. Piorkowski in Berlin. In the agar plate cultures it formed brown granular colonies, which also grew well in glycerine agar at 37° C., presenting a white appearance, confluent in the middle and punctate at the margins, and becoming yellow and slimy in three or four days. Milk treated with the bacillus and kept at 37° C. for 48 hours was coagulated and had a strongly acid reaction and an acetous smell. The appearance of a bouillon culture kept for 24 hours at 37° C. was constant and typical, the fluid being slightly turpid with a considerable flocculent deposit on the bottom and sides of the tube. The bacillus could be stained with the ordinary aniline colours, but not with Gram's solution. Cover-glass preparations stained with methylene blue showed a great similarity to the diphtheria bacillus and the pseudo-diphtheria bacillus of Löffler and von Hofmann respectively.

THE current number of the *Lancet* has a note interesting to the vast army of cyclists. After a "spin" along a more or less dusty road the cyclist sometimes experiences a dry and subsequently sore and inflamed throat. Headache and depression often follow, and the symptoms generally simulate poisoning of some kind. When the bacteriology of road dust is considered, these effects are hardly to be wondered at. Hundreds of millions of bacteria, according to the nature of the locality, are found in a gramme weight of dust, and the species isolated have included well-known pathogenic organisms. Indeed, there can be no reason for doubting the infective power of dust when it is known that amongst the microbes encountered in it are the microbes of pus, malignant œdema, tetanus, tubercle, and septicæmia. The mischief to riders as well as to pedestrians would probably be largely averted if, as nature intended, the respirations were rigidly confined to the nasal passages, and the mouth kept comfortably though firmly shut. As investigators have shown, the microbes in the air seldom pass beyond the extreme end of the nasal passage, and consequently never to the larynx or bronchial surfaces. A useful precaution, therefore, in addition to exclusively breathing through the nostrils, would be to douche the nasal cavity, after a dusty run or walk, with a weak and slightly warm solution of some harmless antiseptic.

THE Berlin correspondent of the *British Medical Journal* calls attention to the prevalence of trachoma in the eastern provinces of Prussia, where it often assumes an epidemic character, especially among children in the lower schools. The authorities are at last fully alive to the gravity of the matter, and have determined to spare neither pains nor expense in order to stamp out the disease effectually. Thus the city of Königsberg has for the last six months employed ten ophthalmic surgeons especially for the purpose, and the report of their work just published is most satisfactory and hopeful, showing as it does by figures the results already accomplished. In October 1897, of 17,553 school children examined, 5568 were found to be suffering from trachoma; of these, 1763—10 per cent. of those examined—were serious cases. These latter were treated, some in the hospital, some in their own homes, and some in special trachoma classes. By the middle of February the number of cases had gone down to 1218, of which 345 were serious in character. At the date to which the report extends—that is, the end of April—there were only 826 cases, with 223 serious ones. The number of special oculists has therefore been reduced to six.

THE Photographic Convention of the United Kingdom was held at Glasgow last week, and we are glad to find, from the report of its proceedings in the *British Journal of Photography*, that so much attention was paid to the scientific side of photography. The President (Mr. John Stuart), in the course of his very interesting opening address, said concerning photography: "It has made the astronomer more than ever master of the heavens. By its aid he has mapped out the starry firmament, and been apprised of the existence of stars the most powerful telescopes had failed to show. In the investigations into the composition of the sun and its corona photography has been an invaluable agent. In the registration of storms in the body of the sun it plays a very important part. In the registration also of the barometric and thermometric variations it is in daily use. . . . Its utility in microscopic work has been abundantly proved of late; bacterial science has made rapid strides by its assistance, and every day seems to produce a more startling discovery than the day before. . . . In the medical profession photography promises to become one of the most beneficent agents science has as yet placed at the service of the healing art. The X-rays, or radiography, are now an indispensable adjunct in every well-equipped medical school. A flourishing society has been started to specialise in this hopeful field, and already developments are daily taking place almost beyond our conception." During the meeting a large number of slides illustrative of solar, lunar, and stellar photography, radiography, and slides in colours by various methods were shown, and everything done tended to bring home to those present the almost universal application of photography to art and science.

WE are glad to learn from *Nature Notes* that the Guildford Natural History and Microscopical Society have practically achieved the object of their memorial to the War Office on the making of Wolmer Forest a sanctuary for the preservation of birds, the War Office having adopted the opinion previously expressed by the Commissioner of Woods and Forests, to which reference has already been made in these columns. The forest came under the management of the Aldershot Game Preserving Association in 1895, since which time all birds have been strictly protected; no birds, except game birds, have been allowed to be shot, and hawks, owls, and other birds have been carefully preserved as far as possible. The heronry has gradually increased from one nest a few years ago to about twenty nests now, and nearly fifty young herons flew from the nest in 1897; foxes are also strictly preserved. The Secretary of the Association states, however, that to make the preservation a success a large area round the outskirts of the forest should be included in the scheme for protection, as at present the destruction of birds and animals is still carried out on private land round the forest.

THE Kew Gardens authorities have many problems submitted to them to solve in the course of a year. Many they succeed in unravelling, but occasionally they are baffled. The June number of the *Bulletin* places on record one of the most curious of the tasks brought before the authorities, and one that they have had but little success with. The specimens referred to in the following letter, which was received from Mr. Kenneth Scott, of Cairo, were carefully examined by Dr. D. H. Scott, of the Jodrell Laboratory, who could only conjecture that they were fragments of the paleæ of some grass. "For some time now malingering Egyptian soldiers have been sent in to the Kasr-el-Aini hospital under my care, suffering from extreme œdema and intense inflammatory injection of the conjunctiva of one or both eyes; the *cornea unaffected*. No discharge from the eye. The condition is entirely unlike that which they also produce by putting in the juice of Euphorbia, slaked lime, seed of 'melocheeya' (*? Corchorus olitcrius*) and other things. I obtained the specimens sent you by covering the eye with a thick collodion dressing so as to completely seal it up. The man at the end of five days had evidently feared the inflammation might subside, and therefore raised the dressing and renewed the baneful application, part of which I found on the face of the dressing lying against the eye. I have been entirely unsuccessful in obtaining here any information on the matter, nor have I been able to obtain further quantities of the leaf. The patient either began to fear the consequences of the affair, or his stock of the drug became exhausted, as he in no way interfered with the next collodion dressing which was applied, the eye being quite cured, and the dressing intact after a period of five days."

MR. J. BURTT DAVY has recently presented to the Kew Museum the ingredients of a Chinese prescription purchased by him at China Town, San Francisco, particulars of which, as far as their identification can be made out, may be of interest. The ingredients include fruit-heads of an *Eriocaulon*, apparently *E. cantoniense*. This plant has a reputation in China for various diseases, such as ophthalmia, especially in children, as a styptic in nose-bleeding, and in affections of the kidney. Spiny hooks from the stems of the Gambier plant (*Uncaria gambier*, Roxb.), which have astringent properties, and are mostly used in infantile complaints. Some very thin transverse sections of the stem of *Akebia quinata*, a climbing berberiadaceous plant, also occur in small quantities, as well as the bark of *Eucommia ulmoides* known as the "Tu Chung." Tonic and invigorating properties are ascribed to the latter, and its cost is therefore considerable. Among other ingredients which have not been identified, are crushed flower-heads of a composite plant, and slices of a slender, twig-like stem, probably a willow.

THE *Times* of July 11 states that the sum appropriated by Congress for the service of the United States Department of Agriculture for the fiscal year ending June 30, 1899, shows an increase of 326,300 dollars over that for the fiscal year just ended, the principal additions being for the Weather Bureau and the Bureau of Animal Industry. Under the Weather Bureau provision is made for the establishment of sixteen new stations, and the erection of a small building on the Government reservation at Sault Saint Marie (popularly known as "the Soo").

Engineering has the following interesting note on the most ancient steam engine in existence:—"The oldest engine in the world is in the possession of the Birmingham Canal Navigations, this engine having been constructed by Boulton and Watt in the year 1777. The order is entered in the firm's books in that year as a single-acting beam engine, with chains at each end of a wood beam, and having the steam cylinder 32 inches in diameter with a stroke of 8 feet, and erected at the canal company's pumping station at Rolfe Street, Smethwick. During the present year (1898) this remarkable old engine, which has been regularly at work from the time of its erection to the current year, a period of, say, 120 years, was removed to the canal company's station at Ocker Hill, Tipton, there to be re-erected and preserved as a relic of what can be done by good management when dealing with machinery of undoubted quality. It is worthy of note that the Birmingham Canal Navigations favoured Boulton and Watt in 1777 with the order for this engine, and in 1898, or 120 years afterwards, the company have entrusted the same firm, James Watt and Co., Soho, Smethwick, with the manufacture of two of their modern triple-expansion vertical engines, to be erected at the Walsall pumping station, having 240 horse-power and a pumping capacity of 12,713,600 gallons per day.

ACCORDING to the *Pharmaceutical Journal*, a fresh use for seaweed is claimed to have been discovered by a Norwegian engineer, who exhibited an invention at the Stockholm Exhibition for producing paper-glue, dressing-gum, and soap from seaweed. The first establishment for this branch of manufacture was, according to his statement, to be erected in the district of Stavanger, but, up to the present, nothing appears to have been done in this direction.

THE total number of chemical works registered in all parts of Germany, according to the latest trustworthy statistics, is 6144, the total number of persons employed by them being 125,440. Amongst the industries of the Hamburg Consular district which have attained to the greatest importance are those for manufacturing various chemical products, such as nitrates, sulphuric and nitric acid, sulphates, boracic acid, artificial manures, pharmaceutical products, dyeing and tanning extracts, essences, and more particularly different kinds of explosives. The factories in that district now employ altogether some 4000 workmen as compared with about 1300 ten years ago, a fact demonstrating once more the rapid strides made throughout Germany by most branches of chemical industry during recent years.

BOG iron ore is worked in the province of Quebec, Canada, and arrangements are being made (says the *Engineer*) to extract manganese from bog ore deposits in the province of New Brunswick. The ore is a soft, wet stuff, containing 50 per cent. of water, and is covered by a thin coating of vegetable earth. The depth of ore varies from 5 feet to 30 feet. When dried the residuum is a fine black powder, too fine to be treated in the blast-furnace, and this has therefore to be made into briquettes, as is done with the fine dust from blast-furnaces and the finely-divided iron produced from low-grade ores by the Edison electrical process. The cementing material used is kept secret. An analysis of the dried ore at 212° F. is given as follows: metallic manganese, 48·240 per cent.; metallic iron, 5·700 per cent.; sulphur, 0·096 per cent.; phosphorus, trace; silica, 1·88 per cent.

THE office of the Bureau of Mines at Toronto has issued a notice to the effect that the first discovery of corundum in Ontario was made late in the year 1896, and exploration work carried on under direction of the Government in 1897 shows that the corundum-bearing lands have an aggregate area of about 50,000 acres. The mineral rights over nearly the whole of this tract are held by the Crown, and they have been withdrawn from sale and lease pending a report on the occurrence of the mineral and the methods of treating it, undertaken by the professors of the Kingston School of Mining. Meantime the attention of prospectors, miners, and capitalists is invited to the district, and, with a view to its development and the establishment of industries in the province for treating and utilising the corundum ore, proposals will be received by the Dominion Commissioner of Crown Lands until the first day of September next.

PROF. KIENITZ-GERLOFF criticises, in the *Biologisches Centralblatt*, Prof. Plateau's attack on the hypothesis that the bright colour of flowers is the principal agent in attracting insects for the purpose of cross-pollination. He maintains that the facts support the conclusions of Darwin, Müller, and Lubbock much more than those of Plateau, the general results of whose observations he sums up as follows: "The new is not true, and the true is not new."

THE U.S. Weather Bureau has published a *Bulletin* (No. 22) on the climate of Cuba, with a note on the weather of Manila. The work has been somewhat hastily compiled by Dr. Phillips, in charge of the section of climatology at the Bureau, and is very useful as showing what information exists, and by giving references as to where it is to be found. There appears to be very little precise meteorological data obtainable for Cuba, excepting for Habana. Observations were begun there by the late Prof. A. Poey, about 1850, and since 1859 have been regularly continued at Belen College. During the ten years 1888–1897 the highest yearly mean temperature was 77°·2, and the lowest 76°·1. The warmest month is July, with an average temperature of 82°·4, and the coldest month is January, with an average of 70°·3. The highest temperature recorded was 100°·6, and the lowest 49°·6. The greatest rainfall occurs in October and June; the yearly average for thirty years was 51·73 inches, but the amount varies considerably in different years. The greatest annual fall was 71·40 inches, and the smallest 40·59 inches. Thunderstorms are of almost daily occurrence in the West Indies, but little damage results from them. Meteorological observations have been made for many years at Manila Observatory. From tables compiled by Prof. Hazen it appears that the average annual temperature is 80°. The hottest month is May, with an average of 84°, and December and January are the coolest months, each with an average of 77°. The highest temperature recorded was 100°, and the lowest 74°. The mean annual rainfall is 75·43 inches, of which more than 80 per cent. falls between June and October. Departures from the average are in some instances remarkable, the extremes varying from 121 to 35·6 inches, while the fall of 61 inches in one September, and only 2 inches in another September is still more remarkable.

PROF. KLEIN, of Göttingen, contributes to the *Nachrichten der K. Gesellschaft der Wissenschaften in Göttingen* a statement of the arrangements that have been made to complete the publication of Gauss's works, consequent on the death of Prof. Ernst Schering, who up till lately has undertaken the work. The remaining unpublished papers on Astronomy are to be edited by Prof. Brendel; those dealing with Theory of Numbers and analysis are taken over by Prof. Fricke, of Brunswick; for Gauss's geometrical investigations Prof. Stäckel, of Kiel, has been secured; Profs. Börsch and Krüger, of the Geodetic Central Institute in Potsdam, have promised their assistance for papers on geodesy; and Prof. Wiechert, recently appointed Director of the Gauss Magnetic Observatory, is to deal with Gauss's papers on mathematical physics. It is proposed to issue three further volumes and a supplementary index-volume; vol. vii. will be devoted exclusively to astronomy; vol. viii. will consist of matter supplementary to previous volumes, especially theory of numbers, analysis, geometry and geodesy; and vol. ix. will be reserved for biographical matter.

A DETAILED report on the growth of sugar-beet, and the manufacture of sugar in the United Kingdom, is contributed by Sir J. B. Lawes and Sir Henry Gilbert to the *Journal* of the Royal Agricultural Society. Reviewing the whole of the facts that are adduced in the paper, both as to the climate and other conditions essential for the production of sugar-beet in sufficient quantity, and of sufficient quality, the authors are disposed to think that, so far as the production of the roots is concerned, it could only be a success over comparatively limited areas, and not throughout the agricultural districts of Great Britain generally. As to the profits of the sugar factories, if established, the cost of roots of good quality would probably be so high as to make it doubtful whether, with the present price of sugar in the market, adequate profits from the manufacture could be expected. In conclusion the authors think that if the sugar-beet industry is to be established with any prospect of success, great caution should be exercised in the choice of the locality or localities, and that the undertakings should, in the first instance, be limited in number and confined to the most suitable localities.

THE latest issue of the *Izvestia* of the Russian Geographical Society (1897, iv.) contains a valuable paper, by Prof. Mushketoff, on the glaciers of Russia in 1896. The plan of the Russian Geographical Society is to obtain every year, if possible, accurate measurements of the state of a number of glaciers, especially in the Caucasus, so as to know with accuracy whether they increase in bulk, or decrease, and to which extent. For eight glaciers the measurements extend already for the past eight to ten years, and they show that these glaciers have been steadily decreasing, their lower ends having retreated at an average speed of from 9 to 38 metres every year. Taking the northern and the southern slope of the Caucasus separately, the average speeds of retreat are 22 metres a year for the former, and 25 metres for the latter. Several new glaciers were discovered in 1896 by the botanists Bush and Schukin. In Turkestan, the expedition of Lipskiy and Barschevskiy discovered in the Hissar Range a great number of large glaciers, formerly unsuspected, the biggest ones lying at the headwaters of the Yagnob River. Their lower ends descend to altitudes of from 10,500 to 11,000 feet, and their *névés* lie at altitudes of 13,000 feet and more. They are all much smaller now than they have been formerly, as may be seen from the moraines and débris with which they are surrounded. Photographs of the Zerafshan glacier, which were procured in 1896 by Maslovskiy, show that it has considerably decreased since 1881. In Siberia, a number of formerly insufficiently-known glaciers was described by Prof. Sapozhnikoff; the main ones, much greater than the well-known Berel, belong to the system of the Byelukha mountain—the Katuñ glacier consisting of two branches, 3½ and 4¾ miles long. The Altai glaciers reach by their lower ends the 6600-feet level. Three big ones were discovered at the headings of the Bukhtarma, and one in the Kimas Range of the South Altai. All are much smaller now than they were formerly.

THE Fauna of the Neocomian Belemnite Beds of Baluchistan is described (in the "Palæontologia Indica") by Dr. Fritz Noetling. Two plates suffice to illustrate the species, which include only *Gryphæa Oldhami* (n.sp.), and four well-known Neocomian Belemnites. A further contribution to the Palæontology of Baluchistan, by Dr. Noetling, is entitled "Fauna of the Upper Cretaceous (Maëstrichtien) Beds of the Mari Hills." As remarked by the author, the species described are of special interest, inasmuch as they shed quite a new light on the geographical distribution of the Upper Cretaceous fauna. Seventy-seven fossil forms have been obtained at present from the strata, and of these sixty-six have been described specifically—of the others only the genus could be determined. Twenty-three plates are devoted to their illustration. No less than twenty-four of the species have been identified with forms previously described, and these naturally are the more interesting. They include *Hemipneustes* (two sp.), *Ostrea acutirostris*, *Gryphea vesicularis*, *Pecten* (*Vola*) *quadricostata*, *Corbula harpa*, *Nautilus sublævigatus*, &c. The author concludes that the strata ("Hemipneustes beds") are of Upper Senonian age, and most probably represent the "Étage Maestrichtien." The fauna bears hardly any resemblance to that of similar age in southern India or northern Africa; it belongs rather to the European province of the Upper Cretaceous sea. This sea was most probably divided by a comparatively narrow land-barrier from the sea in which lived the Upper Cretaceous fauna of southern India, a view first expressed by Dr. W. T. Blanford.

THE Cephalopoda of the Lower Trias of the Himalayas are described by Dr. Carl Diener in a recent memoir of the Geological Survey of India ("Palæontologia Indica"). The fossils figured, in twenty-three plates, as in the above-mentioned monograph, are mostly Ammonites, together with a few species of Nautilus, and one Orthoceras. Among the forms described are *Prosphingites nala*, *Hedenstroemia Mojsisovici*, *Nannites hindostanus*, *Xenaspis* (*Vishnuites*) *Pralambha*, *Ophiceras Sakuntala*, *Koninckites Yudishthira*, *Kingites Varaha*, and *Lecanites sisupala*. The work bears evidence of great care, minute study, and research; but it seems a pity that generic or sub-generic names coined on a more uniform system should not be adopted, even for the sake of the palæontologist who confines his attention to the Order of "Ammonea," to which all the before-mentioned forms belong. Dr. Diener also describes the Permian fossils of the *Productus*-shales of Kumaon and Gurhwal. These shales are intimately connected with the lowest Triassic deposits in the Niti area of the Himalayas, and they rest on an eroded surface of Upper Carboniferous rocks; nevertheless, they contain species of *Productus* of late Carboniferous or Permian type. The fossils are figured in five plates, and they include the well-known European form *Athyris Royssii*.

THE Gasteropoda of the Trias of Halstatt form the subject of a well-illustrated and important monograph by Dr. E. Koken (*Abhandl. der K.K. geol. reichanstalt*, Band xvii., Wien). Twenty-three plates are devoted to the illustration of the fossils, and they include species of *Pleurotomaria*, *Murchisonia*, *Trochus*, *Natica*, *Chemnitzia*, and other genera; and multitudes of sub-genera (as most geologists would prefer to regard them), but the names of these, which are legion, can only be appreciated by the specialist.

RECENT researches on metallic lithium have shown that this metal cannot be distilled in either hydrogen or nitrogen gases, vigorous combination occurring in both cases. The metals of the alkaline earths would appear to behave similarly; so that if it should be necessary to heat these substances in an indifferent gas, argon or helium must be employed. In the current number of the *Comptes rendus*, M. Moissan shows that if pure calcium be heated in hydrogen, the metal takes fire and burns energetically, forming the hydride CaH_2, a transparent crystalline substance which is stable at a high temperature. It behaves as a strong reducing agent, and is violently decomposed by cold water, giving off one-seventh of its weight of pure hydrogen gas. It differs from the corresponding lithium hydride in that nitrogen is without action upon it at a red heat.

THE Cambridge University Press announce a series of monographs upon material obtained by Dr. Arthur Willey, Balfour Student of the University of Cambridge, from New Britain, the Loyalty Islands, and other islands of the South Pacific during the years 1895-97. The work, which will be illustrated, will embody the zoological results of the expedition, and will, it is expected, be completed in five or six parts. The first part (to be published in August) will contain the following contributions: (1) On the anatomy and development of *Peripatus novæ-brittanniæ*, by Dr. Arthur Willey; (2) on a little-known sea-snake from the South Pacific, by G. A. Boulenger; (3) account of the Phasmidæ with notes on the eggs, by D. Sharp; (4) *Metaprotella sandalensis*, n. sp., by Dr. Paul Mayer; (5) report on the Millipedes and Centipedes, by R. I. Pocock; (6) report on the Arachnida, by R. I. Pocock.

THE series of "Museum Hand-books" issued by the Manchester Museum has been added to by a paper on "The Nomenclature of the Seams of the Lancashire Lower Coal Measures," which was read before the Manchester Geological Society in January last by Mr. Herbert Bolton. Many students will doubtless be glad to have the paper in its present handy form.

FROM time to time we have noticed papers, chiefly of local interest, dealing with the Hereford earthquake of December 17, 1896. We understand that Dr. Davison's detailed report will shortly be published by Messrs. Cornish Bros., Birmingham, provided that a sufficient number of subscriptions be obtained to defray the cost of printing.

WE have received from Messrs. H. W. Cox, Ltd., their price list of induction coils and apparatus for producing X-rays. In it is to be found full particulars as to the prices and capabilities of the specialities of this firm.

THE current number of the *Journal* of the Society of Arts contains the first of the series of Cantor lectures, by Prof. Noel Hartley, F.R.S., on "The Thermo-Chemistry of the Bessemer Process."

THE additions to the Zoological Society's Gardens during the past week include two Vervet Monkeys (*Cercopithecus lalandii*) from Natal, presented by Mr. W. Champion; a Great Wallaroo (*Macropus robustus*) from South Australia, presented by Miss W. Jackson; two —— Hedgehogs (*Erinaceus*, sp. inc.) from North Africa, presented by Sir Harry Johnston, K.C.B.; a European Pond Tortoise (*Emys orbicularia*), European, presented by Mr. A. H. Cocks; an Algerian Tortoise (*Testudo ibera*) from Algeria, presented by Mr. G. H. Gude; a Sulphurous Snake (*Phrynonax sulphureus*), a Deadly Snake (*Lachesis atrox*), a Centipede from Trinidad, presented by Mr. R. R. Mole; a Lataste's Viper (*Vipera latasti*) from Algeria, presented by Mr. Carl Hagenbeck; two Yellowish Finches (*Sycalis luteola*) from Brazil, presented by Mr. F. L'hoest; an Arabian Baboon (*Cynocephalus hamadryas*) from North Africa, a Grey Parrot (*Psittacus erithacus*) from West Africa, a Swainson's Lorikeet (*Trichoglossus novæ-hollandiæ*), two Pennant's Parrakeets (*Platycercus elegans*) from Australia, a Thick-necked Tree Boa (*Epicrates cenchris*), a Corais Snake (*Coluber corais*) from Trinidad, deposited; a Giraffe (*Giraffa camelopardalis*, ♂) from Senegal, eight Lateral White-eyes (*Zosterops lateralis*) from New Zealand, two Indian Tantalus (*Pseudotantalus leucocephalus*) from India, two Spotted Pigeons (*Columba maculosa*), a Burmeister's Cariama (*Chunga burmeisteri*) from Argentina, four Wandering Tree Ducks (*Dendrocygna arcuata*) from the East Indies, purchased; a Puma (*Felis concolor*), two Barbary Wild Sheep (*Ovis tragelaphus*), a Burrhel Wild Sheep (*Ovis burrhel*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

COMETARY NEWS.—In the *Astronomische Nachrichten* (Nos. 3501 and 3504) we find the ephemeris for both of Perrine's comets, namely March 19 and June 14. The former, which is situated in the northern part of Auriga and is visible for the greater part of the night, is gradually receding from the earth and becoming faint. Its ephemeris for the present week is:—

12*h*. *Paris M.T.*

1898.	R.A. h. m. s.	Decl. ° ′ ″	Br.
July 16	5 28 46	+53 48 47	
17	30 46	44 17	0·08
18	32 44	39 48	
19	34 40	35 21	
20	36 33	30 55	
21	5 38 25	+53 26 32	0·08

Perrine's comet, discovered on June 14, is, however, rapidly increasing in brightness and is getting near the sun, rendering observation somewhat difficult towards the end of this month. Its ephemeris for the week, as calculated by Dr. Berberich, is—

12*h*. *Berlin M.T.*

1898.	R.A. (app.) h. m. s.	Decl. (app.) ° ′	Br.
July 14	6 8 45	+44 38·7	2·98
15	13 7	43 52·7	
16	17 25	43 5·6	
17	21 40	42 17·3	3·36
18	25 52	41 27·8	
19	30 0	40 37·1	
20	34 5	39 45·4	
21	6 38 7	+38 52·3	3·96

Wolf's comet, which is situated in Taurus, is gradually increasing in brightness and moving eastwards. This body will approach Mars very closely on July 19, their positions differing in R.A. and Declination by only 1·9m. and 0′·0 respectively, as computed by Herr Thræn. Its ephemeris is as follows:—

1898.	R.A. h. m. s.	Decl. ° ′	Br.
July 14	3 38 1	19 51·8	2·2
15	40 56	48·5	
16	43 50	44·8	
17	46 44	40·9	2·2
18	49 37	36·6	
19	52 31	32·1	
20	55 23	27·5	
21	3 58 15	+19 22·7	2·3

Comet Giacobini, though moving rapidly northwards as regards declination, is becoming now a faint object, being one-half the brightness it was at the time of its discovery.

STARS HAVING PECULIAR SPECTRA.—In a recent *Harvard College Circular* (No. 32) Prof. Pickering publishes a list of stars the spectra of which are described as peculiar. Most of these have great southern declinations, so we give below a short list of the few that can be observed in these latitudes. The stars were all discovered by Mrs. Fleming in her regular examination of the Draper Memorial photographs.

Designation. °	R.A. 1900. h. m.	Dec. 1900. ° ′	Magn.	Description.
−12 1500	6 23·7	−12 59	7·7	Type I. Hβ bright.
+ 5 1267	6 25 2	+ 5 57	7·1	" " "
− 8 1467	6 28·1	− 8 48	8·5	Peculiar. Variable with small range.
+ 6 1309	6 32·0	+ 6 14	6·5	Type I. Hβ bright.
" "	7 13·9	−13 3	"	Type V. Gal. long. 195° 30′, lat. + 1° 11′.
−11 1941	7 22·4	−11 31	8·9	Peculiar. Variable.
− 4 3199	11 59·6	− 5 13	8·7	Type II. Variable.
− 8 5858	22 16·5	− 8 7	8·5	Type III. Hyd. lines bright? Variable.

Two other stars with great southerly declinations, A.G.C. 14145 and 14686, show spectra with bright and dark hydrogen lines. In the former Hβ and Hγ are variable. On June 2, 1893, they were bright and superposed on a broad dark band. On April 17, 1895, and March 17, 1896, these lines, like the other hydrogen lines, were dark. In the latter star the hydrogen lines were also variable. On May 20, 1892, Hβ, Hγ and Hδ were dark. On April 3, 1895, Hβ was bright, and on April 21, 1895, Hβ and Hγ were bright. Hζ and Hη were dark with the edge of greater wave-length apparently bright.

A careful study of the spectra of some of the bright southern stars has enabled Miss Cannon to increase the number of stars containing the additional hydrogen lines first seen in ζ Puppis. Thus in A.G.C. 17572, 3925, 4027, 4202 and 4544 are present and dark. In A.G.C. 8631 and 22763 the lines 4027, 4202 and 4544, and the bands 4633 and 4688 are present and bright. In the stars A.G.C. 10863, 22748 and 22843, the hydrogen lines 3925, 4027, 4202 and 4544 are present and dark, and the bands 4633 and 4688 are bright. In the last two mentioned stars, and also in A.G.C. 9311, 26 Canis Majoris, the band 4633 is described as being double.

THE CONSTANT OF ABERRATION AND STELLAR MAGNITUDES.—In determining the constant of aberration by stars of different magnitudes, using the well-known method of Talcott, Prof. Doberck finds (*Astr. Nachr.*, 3504) that the values decrease as the magnitudes decrease. Thus, using stars averaging 4·4 in magnitude, the value of the constant he obtained was 20″·639 ± 0″·075, with stars averaging 5·4 it was 20″·430 ± 0″·063, and with those of 6·4 magnitude the value was 20″·385 ± 0″·066. Prof. Doberck suggests that perhaps this fact may explain differences in the values obtained at different observatories, such differences being always in excess of their probable errors.

THE ECLIPSED AND UN-ECLIPSED SUN.—In the *Bulletin de la Société Astronomique de France* (for July), M. Deslandres gives an account of the methods he adopts in photographing the entire chromosphere of the sun. As this beautiful method has been previously published, we need only draw attention to the very fine phototypes which illustrate the magnificent results that he has so successfully obtained. *Knowledge* for the same month contains two reproductions from Prof. Campbell's negatives of the solar corona obtained in India this year.

Although these do not give us the details as seen by the unaided eye, or as photographed on a small scale, they serve to show the structure of the lower corona. It is difficult, however, for reproductions such as these to do justice to the original negatives, as much of the fine detail is lost in the process. Prof. Campbell, it will be remembered, was stationed at Jeur, and his chief instrument was a large photographic telescope of 5 inches aperture and 40 feet focal length, the instrument being fixed, and the photographic plate made to follow the sun.

THE PLANKTON OF LAKE MENDOTA.

THE natural history of small lakes has long offered a most promising field for research in an important department of biology, viz. the inter-relations of species of plants and animals in the struggle for existence, and the dependence of both upon the physical factors of their environment. As compared with the majority of land and sea areas, a small lake constitutes a relatively perfect "unit of environment," the different elements of which can be determined with an accuracy impossible in most other cases. It is on this account, we suppose, that the detailed study of lake plankton has rapidly gained so many votaries since the lines of quantitative investigation were laid down by Dr. Zacharias and his pupils. In America, especially, the investigation of lacustrine plankton has been taken up with zeal by a considerable army of workers, the vast network of lakes in the basin of the St. Lawrence and the upper reaches of the Mississippi providing unrivalled opportunities for the most diversified inquiries. The latest[1] contribution upon this subject is at least as interesting as its predecessors, and we propose here to give a short account of Prof. Birge's principal results.

Lake Mendota is a sheet of water 6 miles in length by 4 in width, of moderately uniform depth, varying from about 18 to 24 metres, and without any large affluent. During the winter the lake is usually frozen over for three or four months. In the present memoir Prof. Birge gives an account of the Crustacea of the plankton of this lake. He deals firstly with the seasonal and annual changes in the frequency of the Crustacean constituents of the fauna, and secondly with the horizontal and vertical distribution of the total Crustacean population and of the individual species. In each case he discusses the nature and influence of the various factors which operate in the production of the observed changes. Serial observations and collections were made during a period of two and a half years.

Neglecting isolated individuals, the Crustacean fauna of Lake Mendota consists of eight well-represented species, which may be grouped as (*a*) perennial and (*b*) periodic. The perennial group includes three species of Copepoda (*Diaptomus Oregonensis*, *Cyclops brevispinosus* and *C. Leuckartii*), and two species of Cladocera (*Daphnia hyalina* and *Chydorus sphæricus*). The periodic group consists entirely of Cladocera (viz. *Daphnia pulex*, *D. retrocurva*, and *Diaphanosoma brachyurum*).

Prof. Birge shows by an elaborate series of curves and figures that the Crustacean population undergoes a cycle of seasonal changes which is regularly repeated in successive years—three periods of increase alternating with three periods of decrease in the course of each year. The maxima occur in spring (May), midsummer (July), and autumn (September and October); the minima in winter (December to April), early summer (June or early July), and late summer (late July or August).

The spring maximum is by far the greatest, and is due mainly to the rapid and preponderating increase of *Cyclops brevispinosus*. The summer depression is due to a subsequent rapid decline in the numbers of this species. Renewed reproductive activity on the part of other perennial species leads to the midsummer maximum, which is succeeded by a slow decline, reaching a point of greatest depression towards the end of August. During this period of decline most of the periodic species are introduced, but their numbers do not, as a rule, compensate for the falling off in the number of the permanent species. In this respect Lake Mendota appears to be peculiar, for it often happens in other lakes that the periodic forms are the dominant members of the summer population. The September rise is caused chiefly by the multiplication of *Daphnia* of all species and of *Cyclops*. The rapidity of the subsequent decline to the winter minimum is dependent on a number of different conditions, such as the abundance of the periodic forms present, the rate of fall of temperature, storms, &c. It varies therefore in successive years. But while the absolute number of Crustacea present, and the rapidity of the seasonal changes themselves, vary considerably in successive years, it is undoubtedly an interesting fact, clearly established by Prof. Birge's researches, that the general character of the vicissitudes of the floating population of the lake is remarkably constant from year to year.

The principal factors which determine the numbers of Crustacea in different years are, according to Prof. Birge, (1) food supply, both quantity and quality, (2) temperature, and (3) competition. It would appear that of these factors, the temperature of the water exerts a greater control over the number of Crustacea than does the food, since the number of Crustacea falls off in autumn while food is still abundant. The influence of temperature is felt through its effects upon the reproductive powers of the Crustacea, increased warmth favouring rapid multiplication.

So far as the food supply of the Crustacea is concerned, Prof. Birge assures us that the actual quantity of microscopic plant-life in Lake Mendota is almost always in excess of the demands of the Crustacea. A scarcity of food is brought about by changes in the quality rather than in the quantity of the algæ present, since some forms are more available than others as food for particular species or stages of Copepods or Cladocera. For example, young Crustacea are quite unable to eat *Ceratium* on account of its large size and its hard shell; consequently the regular predominance of *Ceratium* in the late summer is one of the principal causes which brings about the annual decline in the number of Crustacea at this season of the year. The Cladoceran *Chydorus* remains scarce while diatoms or *Ceratium* are the predominant algæ, but abounds when the place of these algæ is taken by Schizophyceæ or *Anabæna*. In seasons when the inedible filaments of *Lyngbya* predominate, there is a marked reduction in the numbers of all Crustacea present, except *Diaptomus*, which manages to maintain its numbers by combining great locomotive powers with effective means of catching food.

Equally interesting is Prof. Birge's account of the vertical distribution of Crustacea in the lake at different seasons. In winter, corresponding with the homothermous condition of the water, the Crustacea are uniformly distributed; but in summer the formation of the "thermocline" (or boundary between the upper stratum of warm, and the lower stratum of cold water) leads to a distinct stratification of the lake into layers inhabited by different types. The layers undergo changes in thickness as the thermocline descends, and these changes affect the distribution of the Crustacea to a marked degree. Moreover the layer of cold water below the thermocline becomes largely exhausted of oxygen by the decomposition of dead plants and animals which sink into this stagnant zone; and it is on this account, rather than on account of the difference in temperature, that the layer below the thermocline becomes largely destitute of Crustacean life. Insect larvæ, however, such as *Corethra*, may nevertheless be found in considerable number below the thermocline, obviously because they can carry a stock of air in their breathing tubes.

Space will not admit of further references, but we have perhaps extracted enough from this excellent memoir to justify our opening remark that the careful study of lake plankton is well worth the expenditure of time and labour such as the author of the memoir before us has clearly devoted to it. W. G.

[1] "Plankton Studies on Lake Mendota. II. The Crustacea of the Plankton, July 1894–December 1896." By E. A. Birge, Ph.D., Sc.D., Professor of Zoology, University of Wisconsin. (*Trans. Wisconsin Acad. Sci.*, xi., 1897, pp. 274 to 448.)

DESTRUCTION OF THE FRENCH OBSERVATORY IN MADAGASCAR.

AN interesting account of the destruction of the French Observatory in Madagascar is contributed by M. E. Colin to a recent number of *Cosmos*.

In October 1895, after the rupture between the Governments of France and Madagascar, the colonists and missionaries of the former country were requested to leave Antanánarivo. The observatory of Ambohidempona, belonging to the French Catholic Mission, was entrusted to the care of the Prime Minister by the priest Mgr. Cazet, together with all the instruments. The two natives, who acted as computers, were instructed to continue the series of observations commenced in 1889. Matters went well and quietly for a time; but after about nine months had elapsed a rumour was circulated by an Indian, a British subject, to the effeot that the French before leaving had hidden a lot of war materials in the cellars of the observatory. After a thorough inspection an electric battery was found in the cellars. However, the absence of instruments of destruction did not allay the suspicions, especially as the story was told at the time the French soldiers were approaching Antanánarivo.

In August, the Madagascan Government sent M. Ramarosaona to make a complete search over the observatory. He found in the north tower six cases with the following inscription on them: "Produits chimiques et photographiques, Brewer Frères, Paris," and at once concluded that this was the ammunition, deciding that the two copper-mounted telescopes were the cannons, and he announced his discovery to the Prime Minister with much pride. The Prime Minister, however, knew that the instruments were really telescopes and not cannons, and expressed the wish to look through one. On seeing how clearly distant objects could be observed, he at once concluded that the instruments were used for watching the manœuvres of the French soldiers. All suspicious instruments and boxes were then taken to the palace; inspectors were frequently sent to the observatory to try and find the hidden war material, but to no effect.

Finally, in September an order was issued from the Queen that the inhabitants of the neighbouring villages were to take the instruments and furniture of the observatory to the college at Ambohipo, and to destroy the observatory, in order that the French, who were advancing on the town, should not find a single shelter. With all possible speed the two men in charge dismounted as many instruments as possible, and packed them ready for transport. The inhabitants, however, were already in the buildings breaking down windows and doors, so that many instruments were broken, and others disappeared. The meteorological observations were continued up to the last moment, and much credit is due to the two assistants, who were indefatigable in their efforts to save as much as possible.

Soon after the destruction of the observatory, of which only a few feet of the walls were left, the French arrived, and an engagement followed between them and the Madagascans; and the position of the latter became so bad that they had to escape to Antanánarivo, leaving behind them their cannons and ammunition, which were afterwards used by the French to bombard the palace.

The next day an inspection was made of the instruments at the college, but most of them were found to have been damaged in transport; so much so, that it was either a case of sending them to France to be mended, or of replacing them by new ones. Most of the other instruments that were taken were returned, and in some cases money was sent to compensate for damages.

The observatory had been at work for a little over six years, and during that time very important observations in meteorology, astronomy, magnetics and geodesy had been made. A subscription is now open for a new observatory and for the College of France at Antanánarivo, and in all probability the new observatory will be dedicated to the memory of the soldiers killed in Madagascar.

TIDES IN THE GULF AND RIVER ST. LAWRENCE.

WE have received a copy of a paper[1] read before the Royal Society of Canada, giving a general description of the results of the tidal observations which are being carried out in the St. Lawrence under the direction of the Canadian Government. In NATURE of April 22, 1897, an account was given as to the origin of this survey and the manner in which the operations were being conducted by Mr. Bell Dawson, the officer in charge of the work, under the direction of the Marine Department of the Dominion. One of the principal objects of the survey is to obtain, by means of self-recording tide-gauges, data for computing trustworthy tide-tables for the use of the navigation.

Tide-tables for two of the stations—Halifax and Quebec—have been issued for the last two years, and for St. John for the present year. Owing to the great variation of the rise and time of the tides at different parts of the Gulf, the pamphlet affords an extremely interesting study of tidal conditions. The regularity with which the tide proceeds to Quebec after it has once entered the mouth of the river is in great contrast with its character while in the Gulf.

The variation in the period of time which the tidal undulation occupies in crossing the open Gulf is twice as great as the variation in the period between Anticosti and Quebec, where the distance is double. The main set of the tide is along the deep-water channel of 100 fathoms, which continues up the river to the mouth of the Saguenay, 130 miles below Quebec. Along the 240 miles from St. Paul Island in Cabot Strait to Anticosti the tide is propagated at the rate of 43 miles an hour; whereas over the 450 miles from Anticosti to Quebec the rate is 82¼ miles an hour. The variation in the range of the tide at different parts of the Gulf and river is even more varied. At some of the stations and in the Atlantic the range is from 4 to 5 feet. At Magdalen Island, in the middle of the Gulf, and also in parts of Northumberland Strait, the rise is almost imperceptible; while at Quebec and St. John the range is 26 and 32 feet. The wind is also found to have a material effect on the range and time of the tides, which are delayed or advanced from 1½ to 2 hours in some parts of the Gulf, according to its direction and force. The pamphlet is accompanied by a map of the Gulf and several tidal diagrams.

THE DUKE OF DEVONSHIRE ON UNIVERSITY EXTENSION.

A CONFERENCE on University Extension was held in Cambridge last week, and on Thursday, the second day of the proceedings, the Duke of Devonshire presided, and delivered an address, portions of which, taken from the *Times* report, we reproduce:—

LOCAL EXTENSION COLLEGES.

The most important outcome of University extension during the last few years has been the light which it has thrown on the possibility of coordinating, where the circumstances are favourable, various forms of adult education. A few weeks ago his Royal Highness the Prince of Wales opened the new buildings of the University Extension College at Reading, and the presence of a large and distinguished body of representatives of the University of Oxford showed the deep interest taken by the sister University in this new institution, which is the direct result of the University extension movement aided and supported by municipal contributions, local generosity, and the subsidies of the neighbouring County Councils. Special local circumstances and the encouragement given by the Board of Agriculture have given a particular character to the organisation of the Reading College; but the essential fact in its rapid and striking growth has been the part played by the representatives of the University in organising and stimulating local effort and in educing out of various elements a new type of educational institution which associates municipal and local activity with University traditions and prestige. The successful growth of the Exeter University Extension College, which stands in a close relation to the University of Cambridge, and largely owes its increasing educational importance to that connection, is another proof the value of the services which the Universities are rendering to this branch of national education. The differences in the organisation of the Reading and Exeter Colleges show how wisely the methods of University extension work have been allowed to adapt themselves to the various conditions of distinct localities. The operations of the University syndicates have been happily marked by a judicious sense of the need for elasticity and freedom in educational organisation, coupled with an earnest care for high aims and for a high standing of teaching. A good beginning has also been made, in close connection with the University of Cambridge, at Colchester, where the new University Extension College will, it may be hoped, render excellent educational service to the municipality and surrounding neighbourhood.

A VINDICATION OF THE EXTENSION MOVEMENT.

Apart from providing guidance and stimulus in studies for those who would otherwise be deprived of them, the University Extension colleges and courses have proved of great advantage to many who desire to keep up their intellectual interests and to refresh their knowledge. Teachers in the various grades of schools, public and private, are among those who have had reason to be grateful for the efforts made by the Universities to extend these educational opportunities. And stimulus given to the teachers reacts most beneficially upon the schools and pupils under their care. In educational as in all work it is necessary to have patience in awaiting results. The best results of an improved system of primary or secondary education are not those which are the first to show themselves. And in course of time it is probable that the number of persons desiring to avail themselves of opportunities for continuing their education within easy reach of their own homes and in the leisure hours of life will steadily increase. In the circumstances of our own country, where momentous issues of Imperial policy constantly turn upon the popular vote, it is of high importance that we should encourage by all the means in our power the growth of educational organisations which are providing dispassionate instruction in the duties of modern citizenship and diffusing that kind of knowledge which is necessary to the formation of a discriminating judgment. We do not believe that it is possible to indoctrinate busy people with a systematic knowledge of a dozen or fifteen subjects, to understand any one of which would require a preparatory knowledge of many years. But it is possible to aid intelligent students in every rank of life to gain the elements, the gist, of liberal culture, and to obtain that insight into the vast complexity of human affairs which is the salutary safeguard of intellectual modesty and the best protection against hurried and partial judgments. It is in training and providing the teachers for this great and difficult work of adult popular education that the Universities are rendering one of their highest services to the country. By equipping and sending out these intellectual missionaries, men of high purpose and of high culture, they are really guiding a national movement. Let us not imagine that great educational enterprises realise themselves mechanically—that the merely fortuitous combinations of County Councils or other public authorities will suffice to secure all that is wanted in the training of citizens for citizenship. Material aid of this kind is indispensable. It is a mark of local interest, it secures the further development of that local interest. But by itself it is insufficient. What is really indispensable is leadership. The man, or group of men, must be forthcoming who, in each centre of population, will take the lead and guide the various forces which are at our disposal into wisely-chosen channels of systematic effort. And it is one of the highest duties of the Universities to train and to send forth such men, to give them moral support in their difficult labours, and to attach to their enterprise the weight of academic prestige.

SOME CONDITIONS AFFECTING GEYSER ERUPTION.[1]

The Influence of Hydrostatic Pressure.

BOTH field observation and experiment have contributed to our present knowledge of the physical causes of geyser eruption. The natural history of geyser regions has been summarised by Weed (*School of Mines Quarterly*, New York, 1890, vol. xi. No. 4, p. 289), and the experimental work by Andreæ (*Neues Jahrbuch für Min. Geol. und Pal.*, 1893, Bd. ii. p. 1). Weed concludes that geysers occur only in acid volcanic rocks, and along natural drainage lines where meteoric waters accumulate for discharge. The source of heat is conceived to be escaping hot vapours from slowly cooling lavas, the only known geysers occurring in regions of recent volcanic activity. New geysers originate by the opening of new waterways along fissure planes in the rock, and such new orifices of overflow are continually forming to compensate the diminution in activity of older vents. The cause of the intermittent spouting which distinguishes the typical geyser was originally stated by Bunsen (Tyndall: "Heat as a Mode of Motion"; Appleton, 1888, p. 168); the boiling-point of water rises with increased pressure, hence decreases from the lower end of a water-filled tube upward. If water of a lower stratum, nearly, but not quite, at the boiling point, be lifted by the entrance of steam from below to a level of less pressure and lower boiling point, "the heat which it possesses is in excess of that necessary to make it boil. This excess of heat is instantly applied to the generation of steam: the column is lifted higher, and the water below is further relieved. More steam is generated, and from the middle downwards the mass suddenly bursts into ebullition. The water above, mixed with steam-clouds, is projected into the atmosphere. . . ." (Tyndall, *l.c.*, pp. 169–170).

The accuracy of Bunsen's theory was early confirmed by experiment; and the only mechanism necessary to produce geyser eruption is a tube filled with water, open above and heated below. Many further experiments have been made, however, with a view to explaining the variations observed in the period and interval of geyser eruptions, the relative amount of steam and water, and the effect of artificial stmulants in hastening eruption. Andreæ's experiments were directed toward the imitation of Peale's ("U.S. Geological Survey of the Territories, 1884," vol. xii. part 2) types, a classification based on the form of the basins and the relation of the periods of steam and water in the eruption. It is noteworthy that in most of these experiments, the apparatus recommended has an open basin above, which retains the water thrown out and permits it to *flow back* into the geyser tube.

In Peale's classification no mention is made of the nature of the geyser-spring during the interval of quiescence; in some cases there is continuous overflow or discharge, in others there is no overflow except during eruption. As it may be shown that this fact of the presence or absence of hydrostatic pressure at the geyser vent has an important bearing on the conditions of eruption, the writer would suggest a classification based on this very simple distinction; it is a singular fact that in the published descriptions of geysers this point has been frequently overlooked. If geyser waters represent meteoric drainage, they are affected by the laws of hydrostatic equilibrium. In such case a tube continuously overflowing is in a distinctly different class from one which throws off its waters to join the superficial drainage to the sea only during the period of its occasional or intermittent discharge. The first case is represented by such a geyser spring as "Excelsior," in the Yellowstone Park, a violently boiling cauldron in the hill slope, continually discharging vast volumes of water into the pond below, which in turn drains into the Firehole River; the Great Geyser of Iceland, and the Rotomahana Geyser (destroyed by the Tarawera eruption in 1886) of New Zealand are other types of the continually overflowing class. "Old Faithful" is the type of the second class; its waters may be seen in violent ebullition a few feet below the orifice of the vent, but overflow takes place only during eruption.

Any apparatus designed to imitate accurately either of these must be provided with a supply reservoir having subterranean connection with the geyser tube, by which water may siphon in to replace that discharged. Obviously this replacement takes place in nature: if the water, as asserted, is meteoric, and governed by the same laws that determine the loci of springs, the natural method of such replacement is by the action of gravity. In the case of Excelsior, this subterranean compensation is continuous; the effective head of water at the orifice of exit is fairly constant: in the case of Old Faithful the water-column is in equilibrium, and replacement occurs only after each eruption, when this equilibruim has been disturbed by the ejection of the column.

Experimental Demonstration.

A simple device to illustrate this process was described by G. Wiedemann (*Wiedemann's Annalen*, xv., 1882, p. 173) and mentioned by Andreæ (*l.c.*, p. 4). Wiedemann made no geological comparisons, the apparatus having been constructed for class-room illustration in physics; and most of the geological experimenters have used back-flow apparatus, without supply reservoirs. The essential parts of Wiedemann's apparatus are a water-column heated below, and a supply-tube entering this column and connecting it with a reservoir of cooler, superficial waters. When the excess of steam generated has thrown out the main column, cooler water filters in through the supply-tube, and fills the geyser tube to the level of the reservoir. For effective and regularly repeated geyser eruptions, the reservoir level must be maintained a little below the height of the mouth of the geyser tube.

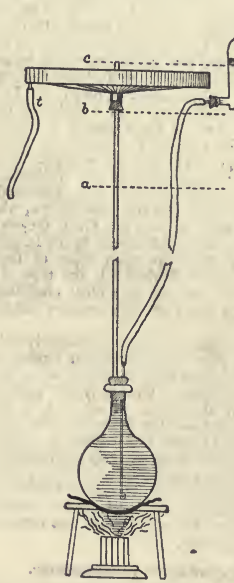
The accompanying figure illustrates Wiedemann's apparatus, as it has been used by the writer. The dimensions are as follows: capacity of each flask, one quart; length of main geyser tube 4 feet, diameter (outside) 5/16 inches; diameter of basin 2 feet; the bottom flares funnel-wise from the centre slightly, and is provided with a ¼-inch outlet tube *t*. The lower flask rests on a sheet of wire-netting over the flame of a

[1] By T. A. Jaggar, jun. (Abridged from the *American Journal of Science*, May.)

four- or six-tube Bunsen burner, and the basin and reservoir bottle are supported above on a wooden frame. The basin is of zinc, and may be raised or lowered so that the mouth of the geyser tube is flush with the bottom of the basin or raised above it as shown. The supply tube is recurved slightly at the bottom of the flask, so that the cold jets which siphon in from the reservoir will not be directed against the glass wall of the flask and break it. The reservoir bottle is connected by rubber tubing with the supply tube, so that the bottle may be freely raised or lowered to various levels indicated by the dotted lines *a*, *b* and *c*.

Experiment 1.—"*Old Faithful*" *Type.*

When heat is applied below, the reservoir level being at *a*, fter about 14 minutes an eruption takes place, characterised by violent ebullition in the flask below, ejection of the water-column to a height of about 4 feet and of a mixture of steam and water for a few seconds longer; then the water-level in the reservoir is seen to fall suddenly, a stream is seen to be flowing into the lower flask from the curved tip of the supply-tube, the cooling of the base of the column is accompanied by ondensation of steam and downward suction, the water rises



to level *a* again and a period of repose fellows. It should be noted that if the level of the cooler water in the reservoir is at *a*, the expanded warmer water in the geyser tube is somewhat above *a*. The process described is repeated at regular intervals of about 1½ minutes, the duration of each eruption being about 20 seconds. If the water in the reservoir be not renewed, it gradually becomes warmer and the intervals are of shorter duration. In this case, or with the reservoir level somewhat higher, as at *b*, and the geyser mouth raised above the basin, as shown in the figure, we have in miniature the conditions of "Old Faithful."

Experiment 2.—"*Excelsior*" *Type.*

The conditions are altered if we raise the reservoir level to the point shown in the figure, namely, just above the height of the geyser mouth (*c*). In such case there is continuous overflow of the hot water, and if the outlet tube *t* be left open, this will continually flow off; this over-flow must be constantly compensated at the supply tube by cooler water from the reservoir, so that the water in the flask never reaches the boiling point. If the water-level of the reservoir be maintained constant, this circulation will continue indefinitely, and in such case there will be a dome-shaped mass of hot water continually boiling up and overflowing at the geyser's mouth, as in the case of the Excelsior Geyser. Now at this stage, if the water-level in the reservoir be allowed to sink under the drain upon it, it may fall to a level six inches below *c*, without interrupting the continuous overflow; in other words, it may fall back to the *b* level, and yet the geyser will continue to act as a boiling spring, without entering into an eruptive phase. The cause of this is to be found in the differential expansion of the water noted above, and a convectional upflow which acts as a driving-power even against a reversed head, after overflow has once been established.[1] The overflow tube *t* may at this stage be led into the reservoir at the *b* level; this establishes a permanent circulation, the only loss being by evaporation. With the diminution in pressure if the level of the reservoir sinks, there is a tendency towards diminished inflow of cooler water at the supply-tube; this implies rise in temperature of the water at the base of the geyser-column, which tends to augment both volumetric expansion and convectional velocity. Hence there is here a critical point where the hydrothermal and hydrostatic forces are in very delicate equilibrium; if the reservoir is lowered an inch, the overflow decreases, ebullition takes place below, and an eruption of extraordinary violence takes place. The same effect is at once produced by placing the glass stopper in the reservoir bottle, and so checking the atmospheric pressure. When the mouth of the geyser-tube is flush with the bottom of the basin, an eruption may be induced by stopping the overflow tube *t* and permitting the water-level to rise in the basin, thus augmenting the pressure on the geyser-column. Eruptions once started will continue intermittently, if the hydrostatic conditions are maintained constant; if, however, the water-level of the reservoir again rises to a point where continuous overflow is possible at the geyser's mouth, the eruptions will cease and a hot-spring phase will follow.

Field Application of the Results of Experiment.

The two simple experiments described, when compared with the facts of nature, account for the most essential variations observed in the phenomena of geyser eruption. Both are methods of draining the reservoir—the one continuous, the other spasmodic. In the same way the geyser-springs drain off the superficial waters that accumulate from the abundant rainfall of the Yellowstone Plateau. The "Excelsior" cauldron is stated by Hague ("Geol. History of the Yellowstone National Park, *Transactions* Am. Inst. of Min. Eng., vol. xvi., 1888) to discharge constantly into the Firehole River 4400 gallons of boiling water per minute, "and there is no evidence that this amount has varied within the last two or three years (1887)." Weed (*l.c.*) has estimated, on the moderate assumption that one-third of the eruption-column of Old Faithful is water, that 3000 barrels are thrown off at each eruption. Here we have examples of continuous and spasmodic drainage methods, both sending their waters eventually to the Madison River, and re-supplied from a local source.

The geyser basins are topographic hollows, which supply vents for the meteoric waters accumulated in fissures of the decomposed rhyolite. These waters are heated by vapours escaping from the only partially cooled deeper lavas, and are escaping in the form of springs and geysers. In the springs the overflow is occasioned by hydrostatic pressure; in the geysers it is permitted by occasional violent discharge. The transition from one phase to the other may readily be induced, as shown in Experiment 2, by very slight changes in the hydrostatic pressure, *i.e.* variations in the mean level of ground-water (Grundwasserspiegel), or in the local head for any specific case. The head of water may be modified at either the source (supply reservoir) or the orifice of exit; head is diminished by lowering the reservoir through formation of new outlets or through decreased supply, or by building up a cone around the geyser tube. Conversely the head of water may be increased by excessive supply (rainfall) at the reservoir, by clogging of outlets, or by the water finding a new vent at a lower level.

Soaping Geysers.

It has long been known that by artificially confining the steam in small-mouthed geysers of high surface temperature, eruption may be brought about prematurely. In Iceland the Strokr is

[1] Such convection currents gain no momentum without overflow, hence at the *a* level convection played no essential part in the phenomena observed.

thus stimulated by dumping into the neck of the funnel large pieces of turf. In the Yellowstone district, it has been found that a small amount of soap or lye added to the geyser water will frequently hasten eruption. This is explained by Hague ("Soaping Geysers," *Trans. Amer. Inst. Min. Eng.*, vol. xvii., 1889, p. 546) as due to the increased viscosity of the liquid. "Viscosity must tend to the retention of steam within the basin and . . . explosive liberation must follow . . . Viscosity in these hot springs must also tend to the formation of bubbles and foam when the steam rises to the surface, and this in turn aids to bring about the explosive action, followed by a relief of pressure, and thus to hasten the final and more powerful display." Graham (*American Journal of Science*, January 1893, p. 54), as a result of experiments with an artificial geyser, agrees that viscosity has much to do with the confinement of steam, but questions the influence of bubbles and foam.

Experiment 3.—*The Effect of Soap.*

The apparatus was arranged to give regular eruptions as in Experiment 1, with the geyser-tube flush with the bottom of the basin and the water maintained about an inch deep in the basin without overflow. A small quantity of fine shavings of Ivory soap was thrown into the basin: these gradually dissolved and the milky solution was, after several eruptions, sucked into the flask below. The occasional steam-bubbles, which, in pure water, rise rapidly through the geyser-tube and escape at the surface during the intervals between eruptions, were less numerous, very small, and slower in their upward movement through the soapy solution; after five or six eruptions it became evident that the intervals were somewhat shorter (averaging 1 min. 20–30 seconds, instead of 1 min. 30–40 seconds), and the periods very noticeably longer (40–45 seconds, instead of 20 seconds). The ebullition in the flask was more violent than in the case of pure water, and columns of fine bubbles accumulated in the geyser-tube, only to be ejected with a violent sputter and give place to a new accumulation. It was evident that these accumulated myriads of tiny steam bubbles, confined within the tube and adhering to the walls of the tube, formed a cushion opposing considerable resistance to pressure from below.

After the diffusion of the soapy solution had become general, the reservoir (and consequently the geyser-column) was lowered to the level *a*; the intervals were at once shortened to an average of about one minute, in consequence of the rapid accumulation at the surface of the column and *within the tube* of the cushion of steam bubbles. So resistant is this cushion, that as it grows by the addition of new bubbles rising from below, the water column is actually depressed, down to the neck of the flask; here a point is reached where the frictional resistance of the froth cushion and the hydrostatic pressure are balanced. A further accumulation of steam forces up the column of foam, release of pressure permits the water to burst into violent ebullition, and an eruption takes place. From this it would appear that in those geysers where the tube is small, the growth of a cushion of steam soap-bubbles may play a very important part in accelerating the development of eruptive conditions.

Summary.

(1) Geysers and boiling springs are subject to the laws of hydrostatic pressure, in common with other springs.

(2) In a geyser-spring, overflow once established may be maintained by convection even against a reversed head; this leads to a critical point in the spring's mode of discharge.

(3) In this condition, with a constant source of heat, very slight changes in the local head are sufficient to induce a change in the nature of a geyser-spring's mode of action. Such change in the head may be caused by variation in rainfall, by building up a sinter cone by forcing new outlets at lower levels, or by clogging of old conduits.

(4) Geyser basins afford drainage channels for meteoric waters. The drainage takes place by either continuous overflow (hot springs) or spasmodic eruption (geysers). Both types, as well as transitional forms, are represented in the Yellowstone Park.

(5) In general, those geysers which are irregular in their eruptions have continuously overflowing vents; and the most regular geysers have confined waters, which overflow only during eruption. This is explained by the fact that the overflowing vents are under hydrostatic pressure, cooler water from lateral ducts is continually replacing that which flows off, and the ebullition necessary to produce eruption is thus prevented; eruption can only take place in the seasons of minimal inflow of cooler water, when the heat is in excess. Where the water is confined, on the other hand, and the supply of heat constant, cooler water rushes in only after each eruption, and a definite interval is required to bring it to the boiling point at the base of the column. Overflowing and confined springs should be distinguished in any description or classification of geysers.

(6) For the artificial stimulus of geyser eruption, an important effect of the bubble-forming alkalies, in small tubes, is the initial depression of the water-column by the growth of a confined cushion of minute steam bubbles. The release of pressure induced by the final ejection of the froth column causes eruption.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. MERRILL E. GATES has resigned the presidency of Amherst College.

THE following appointments are announced:—Dr. Charles Harrington to be assistant professor of hygiene, and Dr. Franz Pfaff to be instructor in pharmacology and physiological chemistry in Harvard University; Mr. R. A. Emerson to be assistant professor of horticulture at the University of Nebraska.

Science announces the following gifts for educational and scientific purposes:—50,000 dollars, from a source kept secret, to Amherst College, for an academic hall in honour of President Seelye; 20,000 dollars from Mr. H. L. Higginson, treasurer of the J. W. and Belinda Randall Charities Corporation of Monson, Mass., for the erection of a building, or as a permanent fund in connection with the University of Virginia. *Science* also states that two conditional gifts of 50,000 dollars, offered by Dr. D. K. Pearsons, have been secured by the colleges collecting the additional sums required. The endowment of Beloit College is thus increased by 200,000 dollars, and that of Mt. Holyoke College by 150,000 dollars.

THE *Calcutta Gazette* reports that representatives of La Martinière and Doveton Colleges have been appointed to consider the advisability or otherwise of the amalgamation of the two institutions. It appears that for many years these two colleges carried on with efficiency, and at a standard which compared favourably with corresponding schools in England, a large portion of the work of secondary education in Calcutta; but in recent years both La Martinière and Doveton, from causes over which they have had little control, have fallen behind in the race for up-to-date education. Owing to the keen competition of newly-opened hill schools, and the consequent loss of scholars and fees, also owing to heavy reduction in interest on the capital invested in Government securities, these colleges have not been able to keep pace with the requirements of modern education; while, on the other hand, they have been handicapped by heavy expenditure on the up-keep of extensive buildings and the payment of large sums in municipal rates and taxes. To remedy this state of affairs, which every year becomes more serious and pressing, the amalgamation of the two institutions has been suggested, in the hope that the result would be a considerable decrease in expenditure and a consequent gain in discipline and efficiency. It is fully recognised that there are difficulties in the way of the realisation of this scheme, but the Lieutenant-Governor sees no reason to believe them insurmountable. The aims and objects of the two institutions are almost identical, and it is hoped that petty differences of detail may not be allowed to stand in the way of arriving at a common understanding as to some broad scheme of amalgamation on lines which, by uniting the resources of the two colleges, will enable them to provide that standard of European education which it was the intention of their founders to give, but which under existing conditions it is practically impossible that either college alone can supply from its unaided resources.

SCIENTIFIC SERIALS.
