HISTOLOGICAL methods have become so perfected during recent years that we are apt to forget that there was an age of discovery when microtomes, special dyes, celloidin and paraffin were unknown. In the days of Max Schultze, of Schwann and Virchow, tissues were cut free-hand with an ordinary razor; for the purpose of embedding, pieces of carrot and liver were used, and stains were not dreamt of. Solutions of salt, acetic and mineral acids and iodine were the only reagents employed, and gradually carmine came in use. Yet that age turned out its heroes in such men as von Bäer, Remak, Schwann, Max Schultze, Johannes Muller and Virchow, who with tools and media which we are unable to use now, observed appearances and processes which have remained the corner-stones of normal and morbid histology. We are apt to forget their deeds as being antiquated. Gradually stains were introduced, and these led to fresh discoveries. Dr. Klein's work on histology, begun in Stricker's laboratory, is a permanent testimony of what a practised hand can do without our modern microtomes, embedding methods, and multitude of stains. Hæmatoxyline and carmine were the only dyes used. Since then various kinds of microtomes, simple and complicated, have been designed, and every laboratory possesses apparatus for cutting in paraffin, celloidin or ice, and instead of two simple stains, almost numberless reagents are a necessity for the modern worker.

On reading Dr. Morley Fletcher's edition of von Kahlden's book on "Methods of Pathological Histology," we cannot help being struck with the great strides made in histological *technique*. While fully acknowledging the brilliant work of our predecessors, and even regretting that the simpler methods of examination of unstained tissues have practically been forgotten, we feel that every histologist, however modest, should make himself acquainted with the *ars technica* of microtomy. With simple methods it is possible only to study simple processes, and these often with difficulty. The minute structure of the nervous tissues in health or disease, the pathological changes of the blood or of infective lesions, can only be approached, if the necessary staining methods have been fully mastered. Stains are chemical reagents, and their action must be properly appreciated. There exists in our midst a large number of "histologists" who have accustomed themselves to one stain, and whatever comes into their hands is treated in the same manner, and they even acknowledge their inability of recognising tissues or lesions stained in any other way. Carmine specimens often trouble those who have become the slaves of hæmatoxyline. We cannot sympathise with them; their methods are at fault, and they have not appreciated the value and *raison d'être* of staining. Many great and important discoveries have been made by morbid histologists such as Weigert, Ehrlich, and others, by methods which at first sight appear to be empirical, but are based on sound chemical principles, discoveries which have proved as useful to the physiologist and anatomist as to the pathologist. It is von Kahlden's merit to have collected the most important histological methods, previously scattered and hidden away in archives and journals, and thus to have made them more accessible; and we are indebted to Dr. Morley Fletcher for having given us a readable English translation of a work which rightly enjoys great popularity abroad.

The few critical remarks which we shall make apply chiefly to the German original. The methods of embedding in paraffin and celloidin, and of preparing sections by means of freezing, are well described, and if to some the hints given appear incomplete, it should be remembered that as the work is meant to be a guide for the pathologist, some knowledge of histological methods may reasonably be assumed to exist. The Cambridge rocking microtome was deserving of more than a short reference, at least in an English edition, for with us paraffin is much more *en vogue* for delicate work than celloidin. A few notes might have been added stating for what tissues and stains each embedding method should be used, for the inexperienced have generally difficulties in deciding how to proceed with tissues supplied to them for examination. For the staining of bacteria in tissues, for instance, the paraffin method is the only satisfactory one. The "metal lifter" is a piece of rough apparatus we object to, and recommend a strip of cigarette paper as being the most delicate carrier for transferring sections from water or clearing medium to the slide. Under "double staining" no allusion is made to acid fuchsine, a most selective and beautiful stain. We have little to add to the section on bacterial staining, but venture to offer an important suggestion. When examining for bacteria in albuminous or gelatinous media, it is advisable to remove the ground substance by means of acetic acid. From personal experience we do not agree that Gabbet's method is the best for the detection of tubercle bacilli in sputum. Ziehl's and Van Ketel's methods are far more certain. In the latter the bacteria are previously treated with carbolic acid, which destroys them, so that there is no danger of disseminating infective matter, while at the same time the staining power of the micro-organisms is greatly increased. Carbolic acid should be added to all microbic material, so as to avoid all possible risk of infection. Moreover, treated in this manner any material may be kept indefinitely for histological examination.

The chapter on blood examination is excellent, and must prove extremely useful also to the physician. The systematic study of the blood at the bedside is still too much neglected in this country, though in cases of anæmia it is of the utmost importance, and without a complete knowledge of the same, a certain diagnosis is often impossible. For this reason we should have liked to see a fuller account of the methods of examining blood for the *plasmodium malariæ*, for we feel certain that the inexperienced would not succeed with the meagre instructions given on page 109. The foot-note on page 115 is not clear, if correct. For purposes of simple diagnosis cover-glass preparations of blood should be stained "with a solution of alcohol-soluble eosine (·5 gramme in 100 cc. of 50 per cent. alcohol)," and not "with a 50 per cent. alcoholic solution of eosine," which would overstain everything. The summary of the methods used for the histological examination of the nervous system is perhaps the best part of the book.

So far our remarks apply to the work of von Kahlden. Dr. Morley Fletcher as translator and editor has done his share creditably. The editorial notes on the whole will be found useful, and in future editions we would suggest to raise them from their position at the foot of the page, and incorporate them with the text, at the same time adding others, so as to render the book entirely in keeping with English histological teaching. The idea of a book for the pathologist is so good that it should stimulate the editor to perfect it, all the more as there is no other work in the English language which serves the same purpose. Dr. Sims Woodhead's well-known manual will always remain a favourite book with the ordinary student, but as a compendium of descriptive morbid histology rather than a laboratory guide.

A. A. KANTHACK.

NATAL ASTROLOGY.

A Treatise of Natal Astrology. By G. Wilde and J. Dodson. To which is appended "The Soul and the Stars." By A. G. Trench. (Halifax, Yorks: The Occult Book Company, 1892.)

THREE authors have therefore combined to produce this work; and to accept a brief, either on behalf of, or in opposition to, a work exhibiting so much erudition, is to undertake a heavy responsibility. The peculiarity of your astrologer is that he is so heartily in earnest. He, with a faith that no disaster can overturn or contradiction disturb, believes his results are as certain and as unquestionable as the astronomy on which he relies for his calculations and configurations. He, worthy man, asks to be taken seriously, and society as a rule declines to accept his deductions and explanations otherwise than as literary curiosities. But his day of triumph and reward may be approaching, for in the preface it is distinctly asserted that the production (and presumably the sale) of this kind of literature is on the increase. This is curious, if it be true. What have the promoters of primary education and the machinery of the School Board to say to the assertion that "the literature of astrology is to-day more perused than that of any other natural science"? The authors cannot be angry with anyone for saying that such an assertion is as true as that the positions of the planets and luminaries decide the health of a person (p. 86).

It is only honest to confess our inability to do justice to the aims and ambitions of those who read the future in the skies. We need an exponent on whom the mantle of the late Prof. De Morgan has fallen. Of men who have enjoyed a reputation for sound mathematical knowledge, he is the only one, that occurs to us at the present moment, who has found leisure or inducement to make a serious study of the peculiar tenets of the astrologer. And after an examination, which was no doubt thorough and exhaustive, it is believed that he decided that there was no ground for the conclusions drawn by the students of horoscopes, a decision to the truth of which many will subscribe, who have not the same means and the same knowledge to guide them. But we have been told, and let us hasten to add the fact for the satisfaction of the votaries to this "science," that he did not pronounce this sentence till after three months' study. If three months were necessary to convince a De Morgan of the uselessness of further prosecution of this occult inquiry, it need be no wonder that a much longer period, embracing possibly a whole life-time, is in some cases necessary before a less cultivated and less gifted man can escape from the ensnaring meshes of a fascinating delusion. The authors of this book have not yet issued from the realms of darkness and recognised the inquiry as a curious, it may be an absorbing, but certainly a misleading study. Nor are they likely to gain enlightenment, for their methods of inquiry and examination are imperfect and deceptive. Their process seems to consist in the examination of many cases, and the exhibition of those which favour, or seem to favour, the conclusions drawn from the horoscope. The story of Dryden's sons is served up for our edification, and a tale is told of a gentleman who married at the age of fifty and went to Italy, which it is thought by the authors ought to carry conviction to the unconverted. How many men in a year do marry at fifty and go to Italy for a honeymoon? But averages or coincidences are alike disregarded by the student of horoscopes. "The successes of a science," say they, "establish it, while the failures cannot disprove it. The practice of medicine is recognised because of its successes, and not rejected because of its failures." This is a very curious remark, and apparently an oversight by the authors. What success or what failure can there be for medical science when men's health and condition are regulated by the position of the stars and planets?

But apart from the question of the usefulness or the worth of astrology, about which the authors wax eloquent, and with whom of course it is absolutely useless to argue, they have produced a book not without interest. Astrology is a study which has occupied men's minds for many ages, much time and ingenuity have been devoted to it, and the student of science or of human nature might very well like to know what were the methods by which these men worked, what was the character or the measure of the success that supported them in their labours, and urged them on, in days when planetary ephemerides did not exist and astronomical calculation must have been difficult. Kepler is perfectly frank about his horoscopes—he worked them for his daily bread, and despised himself for doing it; but others certainly looked for success, undaunted by disappointment and failure. "Horoscopes," and "cusps," and "houses," and "malefics," and what not, constitute a jargon that many an one might like to have explained and to know something about, without pledging himself to the accuracy of the conclusions which the experts draw. In this book he will find the definitions and the grammar of the subject lucidly explained, and if he be at all familiar with the use of planetary tables and understand that much ridiculed but nevertheless valuable science "the use of the globes," he will be able to construct, or rather to erect, a horoscope with certainty, and perhaps edification. Naturally, I have experimented in my own case, but I cannot say that the result has thrown a great deal of light, either on my character, my circumstances, or my future condition, on all points of which I expected information. But I have learnt one caution, that it is not desirable to operate on anyone, in whom we may be interested, indiscriminately, because the result may not be flattering, but is apt to be even disagreeable. A cynic might suggest that since there are more failures than successes in the world, it is necessary to connect a preponderance of gloom and disappointment with planetary configuration. It seems especially that Uranus is responsible for much that could easily be dispensed with, and one cannot help congratulating those who lived before his presence and influence were discovered. But if this is our flippant view, the authors, on the other hand, regret that the older astrologers were without the guidance that a knowledge of the motions of Uranus and Neptune could have afforded, and recognise the possible existence of yet unknown planets, that not only shape our destinies but also disturb the accuracy of astrological prediction. There is, however, no hint that the theoretical determination of horoscopes compared with the observed facts of individual life will in time lead to the assignment of the position of a hypothetical planet, as the perturbations of Uranus revealed Neptune.

Not a small portion of the book is taken up with the description of the horoscopes of distinguished men. How far they support the contention of the authors, and can be quoted as successes in astrological inquiry, must be left to a closer student of them and of history than I can claim to be. Mr. Gladstone, it seems, was so indiscreet as to admit that he was born about breakfast time. That might seem a sufficiently vague indication in these days, but, nevertheless, his horoscope appears in this gallery; but whether his admirers or his opponents will best agree with the estimate of character drawn, is a matter of doubt. We are sure only a few will see that the fact that the tail of Capricorn, said to bring danger from beasts, conjoined with Mars, affords an explanation of the "historic attack upon Mr. Gladstone by a cow." The incident of the ginger-bread-nut is apparently still unexplained.

The book concludes with a reprint from the *University Magazine* of 1880, of Mr. Trent's paper on "The Soul and the Stars." We are told in the introduction that the original grew out of a controversy on the topic of reincarnation, forsooth, and further that it is commended to the reader's indulgence as an honest attempt to elucidate a subject which ninety-nine out of a hundred understand just sufficiently to misunderstand. Having no claims to be the hundredth man, we must leave this honest attempt with a simple reference for the benefit of those who are interested in the subject.

W. E. P.

NAVAL ENGINEERING.

Elementary Lessons in Steam Machinery and the Marine Steam Engine. By Staff-Engineer J. Langmaid, R.N., and Engineer H. Gaisford, R.N. (London: Macmillan and Co., 1893.)

THIS work consists of a series of elementary lessons in steam machinery, and a short description of the construction of a battle-ship, intended for the use of junior students, and especially for the naval cadets in H.M.S. *Britannia.* The syllabus of subjects is based on the plan adopted by the Science and Art Department.

The first lesson relates to exact measurements, by the use of standard rules and gauges; the meaning of strain, stress and strength, factor of safety, &c.; the second and third upon the metals used in machinery and ship construction; the fourth and fifth upon rivets and rivetted joints, and various kinds of screws; the sixth, seventh, and eighth upon shafting, shaft-bearings, and toothed gearing; the ninth upon friction; the tenth, eleventh, and twelfth upon stuffing-boxes, packing, pipe-joints, valves, cocks, and pumps; the thirteenth to the eighteenth upon boilers and boiler mountings; and the nineteenth to the twenty-fourth upon the principal component parts of the marine engine, the indicator and indicator diagrams, and screw propellers. The last one contains a short description of the construction of a battle-ship.

These lessons appear well adapted for imparting to junior students a simple course of instruction, as a preliminary to a thorough study of marine engineering, which is the object the authors had in view. They are illustrated by well-executed and instructive sectional drawings of boilers and marine engines, and with sketches of many of the principal details of boiler and engine work. These include a very useful sketch, for a young student, of a section of cylinder, with movable piston and slide valve. There are also two very clear views of the triple-expansion engines fitted to H.M.S. *Sappho* and *Scylla*, which are representative of a large number of engines in the Navy, these ships being two out of a class of twenty-nine that have been recently built under the Naval Defence Act of 1889.

The terms strain and stress might be dealt with more accurately than is done on pages 8 and 9. Strain is defined as change of form due to load, and stress as the force or forces producing the strain. Tensile strain is then described as "a *stress* that tends to stretch the body acted upon"; and we find the various kinds of stress described as follows: Tensile *strain*, compressive *stress*, torsional or twisting *force*, bending *force*, and shearing *force*. The want of exactness in the use of these terms might easily be corrected. We observe that the thicknesses of the shell-plates of large marine boilers are stated to be 1 in. to 1¼ ins. In the largest marine boilers, however, the shell-plating exceeds 1½ ins.

The description of the construction of a battle-ship is very brief and general, but it serves at least to call attention to a very useful "Text-book of Naval Architecture" by Mr. J. J. Welch, formerly instructor at the Royal Naval College. In speaking of the division of a battle-ship into water-tight compartments, it is stated that "the total number of water-tight compartments is considerably over one hundred; several of them might fill without affecting the safety of the ship, provided they were not so situated as to cause the ends to be submerged, or the ship to capsize." It is surely, however, the object of the naval constructor to obtain such a relation between water-tight subdivision and the stability of a ship, both transverse and longitudinal, as would prevent capsizing, or going down head or stern first, if a few small compartments were filled wherever these might be situated. With regard to bilge keels, also, it is stated that they are generally fitted for about two-thirds of the length of a ship. The usual length is, however, from one-third to one-half.

It might appear hypercritical to call attention to such points as the above when dealing with a work that is so well adapted for the elementary purposes which the authors designed it to serve; especially as these do not affect the principal lessons that deal with those mechanical details and elements of construction that junior students require to be instructed upon. We can recommend the book to the diligent attention of those for whom it has been prepared.

OUR BOOK SHELF.

The Yoruba-speaking Peoples of the Slave Coast of West Africa; their Religion, Manners, Customs, Laws, Language, &c. With an appendix containing a comparison of the Tshi, Ga, Ewe, and Yoruba Languages. By A. B. Ellis. (London: Chapman and Hall, 1894.)

THE late Colonel Ellis, whose death was almost simultaneous with the publication of this book, had devoted long and earnest attention to the study of the West African tribes, amongst which his military duties led him. This volume completes and brings into focus his life-work. Like the previous volumes on the Tshi- and the Ewe-speaking peoples, it is a contribution to anthropology of the very highest order, combining the enthusiasm of a student and the literary power of a cultured scholar with the simple and unobtrusive directness of the soldier. Colonel Ellis touches no controversy, and records, with no more commentary than is necessary to do justice to the narrative, the facts of his own observation. The book begins with an excellent geographical and historical summary of the Yoruba country and people, goes on to consider their deities, priests and superstitions, and the laws and customs which prevail, and concludes with the citation of 250 Yoruba proverbs, many of them worthy mates of those of Solomon, and a series of folk-lore tales, in which we see the origin of many of "Uncle Remus's" best stories.

As the Tshi tribes represented the lowest stage of primitive culture, the Yoruba represent the highest, having fairly emerged from animism into polytheism. The similarities in their mythology to that of the Greeks, and in their customs to those of the early Hebrews, are in many instances remarkably close. In municipal government they show considerable enlightenment, having a female functionary, the "Mistress of the Streets," to deal with all disputes between women, only those which she is unable to settle being passed on to the *Bale* or civil governor. They are observant of the phenomena of nature, calling Sirius the canoe star, as it is believed to be a guide to canoe-men. The Milky Way is called "the group of chickens," the clearer stars being the hens; while Venus, according to the position in which it appears, is known as the morning or evening star, or when near the moon as "the moon's dog." The Yoruba calendar is based on the lunar month, and it is interesting to note that while the Tshi- and Ga-speaking people divide this period into four weeks of seven days with some odd hours, the Yorubas count six weeks of five days minus a few hours. All the tribes commence the reckoning of the day with the evening, the first day of each month being reckoned from the appearance of the new moon. The first day of each group of five is held as a day of rest, and looked upon as generally unlucky; but the follower of each of the recognised gods must observe another day of rest also, on which those not worshipping the same deity are at liberty to work.

The appendix to the book is an elaborate philological treatise in the form of a comparison of the grammar and vocabularies of all those West African languages which Colonel Ellis had minutely studied.

A Handbook to the Study of Natural History, for the use of Beginners. By various authors. (London: George Philip and Son, 1894.)

STUDENTS of science are usually inspired with the desire to create in others an enthusiasm for the pursuit of natural knowledge. This fact probably explains why so many books of mediocre quality are foisted upon the public. Lady Isabel Margesson, who has edited the book under review, had the laudable ambition of "putting before the Beginner a clue to the many paths of the somewhat bewildering labyrinth called Natural Science." To carry out her idea, she procured persons to write short descriptions which could be used as finger-posts pointing the way to the acquisition of knowledge concerning all manner of living things, of minerals, &c., and, to the whole, Sir Mountstuart Grant Duff has contributed an introduction, in which he expatiates upon the book's inception and the qualifications of the authors of the various parts. Lady Isabel's plan may appear excellent in the abstract, but its realisation is not deserving of much praise. We venture to say that there is scarcely a section in the book exactly meeting the requirements of beginners. Scientific names are frequently given without any explanation, and the beginner is led into the maze of botanical nomenclature before he is told how to disguish the parts of plants. One or two of the authors have confined themselves to describing the spirit in which their branches of natural science should be wooed in order to be won; others give descriptive lists of books suitable for sequential reading; while a third section devote their space to methods of work. When fourteen writers assist in making a book, inequality may be confidently expected. Thus it is that Lady Isabel's idea has not crystallised into a very symmetrical form.

Surveying and Surveying Instruments. (The Specialists Series). By G. A. T. Middleton. (London: Whittaker and Co., 1894).

THE contents of this book have already appeared in a series of articles in the *Building News*, but there is no doubt that in book form they will be found more serviceable to readers in general. The articles in question deal in a practical way with the methods of procedure adopted in surveying, and with the descriptions of the different instruments employed. The first chapter treats of surveys with chains only; here the author gives some very sound advice, and concludes it with a description of a worked-out survey, showing also the method of entering measurements in the field-book. In case of obstructions such as rivers, sheets of water, bog land, &c., modifications in the chain line methods have to be adopted, and these are discussed in chapter ii.; the reader is also brought in contact with right-angle instruments, such as the now comparatively little used cross-staff, the optical square, and Weldon's right-angle prism. Next is described the uses of that very important instrument the level, and the different methods of "levelling" are each dealt with. The numerous worked-out "levellings" with figures, should bring the subject home to the reader. The numerous forms of levels require the author to devote chapter iv. to a discussion of their qualities and of their different means of adjustment. This latter point is of the greatest importance to the surveyor, for on this depends to a great extent the accuracy and rapidity with which observations may be made. The chief levels discussed are the so-called "dumpy" and "Y" types, but other hand-levels are referred to, such as Stanley's builder's level, Watson's clinometer level, and Stanley's Abney and Stanley's improved Abney level. Short reference is made to the barometer as a measurer of differences of level.

Chapter v. is devoted to the uses of angle-measuring instruments, such as are employed in the determination of either the main points upon an extensive survey or of inaccessible points. By means of extracts from the field-book and illustrative diagrams, the method of procedure is carefully explained, and many practical hints are in addition interpolated. The following two and last chapters contain detailed accounts of the theodolite, other angle-measuring instruments, and instruments for ascertaining distances; among the last-mentioned being Stanley's tacheometric theodolite, Steward's omni-telemeter, and the Labbez Telemeter.

As a handbook for those employed in the practical work of surveying, the volume should be of great use; its value is greatly enhanced by the very excellent drawings of the numerous instruments which are inserted in the text.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Photography of the Splash of a Drop.

Prof. Worthington tells me that in his lecture on the splash of a drop, at the Royal Institution, on May 18, he was not able, through want of time, to explain how the photographs were taken, and has suggested to me that a short account of them, which was our joint work, may be of interest.

In our first attempts we employed the spark used by Prof. Worthington many years ago for viewing and making drawings of the phenomenon (*see Proc. Roy. Soc.* No. 222, 1882). This spark was produced by breaking at the surface of mercury a current of high self-induction; but we found that when this was made powerful enough for photographic purposes, it became of too great duration (from 4 to 6 thousandths of a second), so that the drop had time to move appreciably while under illumination. We therefore had recourse to the Leyden jar spark as employed by Lord Rayleigh (Nature, vol. xliv. p. 249). This is so exceedingly convenient a method of producing a suitably timed spark *at any place* without the necessity of insulating the leading wires, that, for the sake of making it more generally known, I venture to repeat with a simplified diagram the description of the arrangement, though really identical with Lord Rayleigh's.

Prof. Worthington's timing sphere had been of ivory; it was only necessary to substitute a brass ball, and the original timing apparatus was suited to the new conditions. (Fig. 1.)

[1] A is a Wimshurst machine, whose + and − terminals are connected to the inner coats of two large Leyden jars, B and C, the capacity of each being roughly equivalent to that of a glass plate condenser, the area of each surface being 4380 square cm, and the thickness 2 mm. These inner coatings were also connected by insulated wires to two insulated knobs, D and E, between which the timing sphere, F, falls. The jars stand on the same imperfectly-conducting table, and from their outer coatings are led stout uninsulated wires through the partition wall of the dark room, where they terminate in a spark gap, H, between two stout magnesium wires. Here the spark is produced which illuminates the drop. K is a rough electrometer, consisting of a brass sphere, L, carried on a pivoted wire, on which slides a suitable counterpoise; L is connected with the inner coating of one jar, and is attracted towards the oppositely charged sphere, M, connected with the inner coating of the other jar. When the spheres D and E are sufficiently charged for the timing sphere to cause a discharge when it falls between them, L is lifted by the attraction of M and strikes a glass plate which separates them; this is the signal for letting off the drop and timing sphere F. The timing sphere F has been held on a ring carried by a horizontal wooden rod or lever about six inches long, and pivoted about a horizontal axis.

A smart upward fillip throws up the other end of this lever, and leaves the sphere in mid-air free to fall, and simultaneously breaks contact with crossed platinum wires beneath the lever, and breaks the current of the electromagnet, N, in the dark room, thus allowing an india-rubber catapult to toss up, in precisely the same way, one end of a similar lever, whose other end carries a smoked watch-glass, O, on which the drop has been lying without adhesion. Thus drop and sphere are liberated simultaneously,

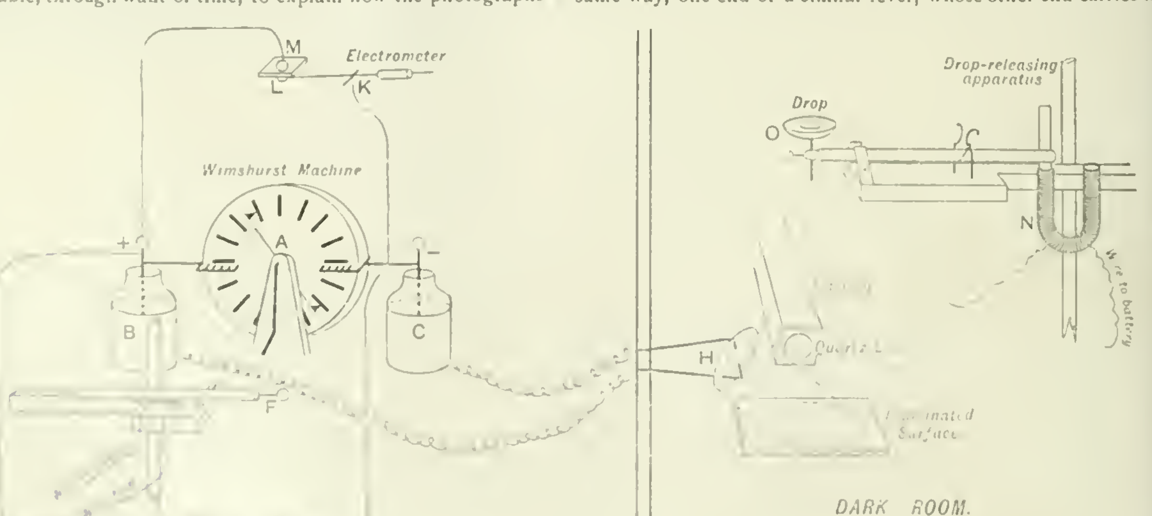

Fig. 1.—Apparatus for photographing a splash.

[1] The arrangement of jars was, I believe, first used by Dr. Lodge.

or if not so, with a very short and practically constant interval between them.

The discharge of the inner coatings of the jars by the timing sphere reaching the gap between them is accompanied by a simultaneous discharge of the outer coatings across the spark-gap in the dark room, and it is this that illuminates the splash, the stage of the splash that is illuminated depending on the height of fall of timing sphere, which can be adjusted at pleasure.

The duration of this discharge, if we may argue from Prof. Boys' experiments, probably did not exceed one-hundredth-thousandth of a second.

Great difficulty was at first experienced in getting enough illumination, and finally the spark-gap was placed in the focus of a small silvered watch-glass, which enclosed an angle of nearly 180°, and this was placed to illuminate the splash from one side, at an inclination of about 30° to the horizontal at a distance of 6 or 7 cm.; it is to this that most of the detail obtained was due.

FIG. 2.—Splash of mercury on xylonite.

The camera was inclined at an angle of about 30° to the horizontal, looking downwards, and was fitted with a single pebble spectacle lens to avoid the loss of the ultra-violet rays which occurs with glass; as the lens was far from achromatic, the proper adjustment of the distances of object and plate had to be found by preliminary experiments. The most rapid plates obtainable (not isochromatic) were used, and were developed for thirty or forty minutes with eikonogen, the developer being made as strong as possible in eikonogen. To avoid all chance of fogging, the operations were performed in the dark.

FIG. 3.—Splash of a drop of water into milk, early stage.

The mercury splashes with which we began turned out to be the most difficult to photograph, owing to the halation produced by the very bright reflection at some points, and the comparative darkness of the remainder (Fig. 2) We had to try various surfaces for the drop to fall on to find out how to obtain the best contrast; we finally adopted a piece of polished white xylonite.

Of many liquids tried, the easiest to photograph was milk, and with this there was plenty of detail (Fig. 3 and 4).

These photographs are, as far as we know, the first really detailed objective "views," as opposed to shadows, that have been taken with such a very short illumination.

Besides these we also took a number of shadow photographs, in much the same way as that in which Prof. Boys photographed a rifle bullet, by letting a drop of mercury fall on *the clean side* of the sensitive plate itself, and producing a spark between two magnesium knobs vertically above the splash. No difficulty was found in this case in getting enough exposure.

FIG. 4.—Splash of a drop of water into milk, late stage.

It will be observed that the method requires that different stages should be photographed from different splashes. We hope, however, to succeed in the more difficult task of photographing many stages of the same individual splash.

R. S. COLE.

On the Spreading of Oil upon Water.

IN a paper entitled "Die Lehre von der Wellenberuhigung," by M. M. Richter (see NATURE, vol. xlix. p. 488), the opinion is expressed that the tendency of oil to spread itself on water is only due to the free oleic acid contained in it, and that if it were possible to completely purify the oil from oleic acid, it would not spread at all.

This I found to be actually the case with olive oil, and though I agree by no means with the theoretical views of the author, I will mention the fact, for I may suppose it to be not yet generally known.

The Provence oil used in my experiment was shaken up twice with pure alcohol, and the rest of the latter being carefully removed, a drop of the oil was placed upon the freshly formed water-surface in a small dish by means of a brass wire previously cleaned by ignition. The oil did not really spread, but after a momentary centrifugal movement, during which several small drops were separated from it, it contracted itself in the middle of the surface, and a second drop deposited on the same vessel remained absolutely motionless.

Of course the surrounding water-surface proved to be in the anomalous state, the tension determined by the method of separating weights being =0·82 of the normal value. It has been diminished by the "solution-current" of the oil (as I have called the contaminating current, issuing from a body in contact with a clean water-surface), which may be observed if the surface be dusted over with sulphur or lycopodium before placing the oil upon it. The observation of the solution-current, preceding unpurified oil, is more difficult, because the oil itself covers rapidly the whole surface.

As soon as the relative tension 0·82 is attained, the slightest trace of a solution current ceases, whilst ordinary oil still shows solution-currents at much lower tensions. The surface-tension 0·82 is the lowest possible that can be produced on water by pure Provence oil; the surface then may be considered as saturated with oil.

This can be seen most clearly if the drop be deposited upon the adjustable trough filled with water, which was employed in my former experiments (NATURE, March 12, 1891, p. 437). The tension then remains constant on either expansion or contraction of the surface; on considerable contraction, however, one can perceive a slight precipitate of oil, which gives to the surface a turbid appearance.

Evidently the pure oil does not spread over a surface of the minimum tension attainable by its contact with water, because the sum of its surface-tension and the interfacial tension of oil and water, which we may call "tension of equilibrium," is greater than the minimum tension. Therefore upon a clean water surface the oil is repulsed by its own solution current.

On the other hand, a drop of common Provence oil placed upon the saturated surface spreads, while the surrounding surface diminishes its area and grows turbid. From this we see that the tension of equilibrium of the oil containing free sebacic acid is lower than its saturation tension, and this is also the reason why it is not prevented from spreading by its own solution-current.

I have repeated these experiments with various kinds of oil, and in each case found that by shaking up with alcohol the tension of equilibrium rose, and the tendency to spread was diminished.

In the case of ordinary olive oil there was but little difference between the purified and unpurified oil, although it was six times shaken up with fresh alcohol. With rape-seed oil and poppy oil I was more successful. Their tension of equilibrium was still somewhat inferior to the minimum tension, which was with rape-seed oil 0·85, and with poppy oil 0·82, but the spreading on a saturated surface was very slow, and upon a large clean surface the oils covered but a comparatively small area. The best success I had with almond oil, which behaved quite like Provence oil.

On the other hand, the tendency to spread, not only of pure oil, but also of benzol and petroleum, increased when oleic, palmitic, or stearic acid was dissolved in them.

Pure benzol can rest on water but in a rather thick layer. When the thickness is diminished to a certain degree, the layer breaks into drops, for which the following explanation seems to me most probable. The water-surface surrounding benzol, as in the case of oil, never is in the normal condition, the tension being diminished by the vapour streaming over the water. This vapour current ceases at the tension 0·88, which, as it appears, is somewhat lower than the equilibrium tension of benzol. Therefore a thin layer of benzol is broken by the vapour current.

When a floating fluid layer is not very thin, the tension of the surrounding anomalous water-surface, just balanced by it, is no longer equal to the sum of interfacial and surface tension. In the case of benzol it assumes a lower value than the minimum tension of the vapour-current, and therefore a sufficiently thick layer is allowed to spread coherently.

Benzol which is contaminated, for instance, by stearic acid or resin, behaves quite differently. The tension of equilibrium being lowered by those substances, it spreads so far as to show colours of thin plates.

Pure petroleum seems to be the only liquid which does not spread upon a normal surface. The vapour-current going out from petroleum ceases already at a relative contamination - 1, and therefore cannot produce a sensible decrease of tension. Nevertheless it may possibly prevent the floating drop from spreading. When sebacic acid is dissolved in petroleum, the latter shows a much greater tendency to spread.

In order to examine whether the effect of sebacic acids upon the tension of equilibrium be due to a decrease of the cohesion of the solvent, I have compared the surface-tensions of pure and contaminated benzol or petroleum, and those of the purified and unpurified oils. In no case have I found the surface-tension to be diminished by the sebacic acid, hence I came to the conclusion, that it is the interfacial tension which is altered.

Now let us consider the behaviour of common oil. It spreads in a coherent film to a certain thickness, which is different with various sorts of oil. Then small holes appear in the interior of the film, whilst the circumference of the latter is still increasing, and by the gradual increase in size of the holes the layer at last is broken and dissolved in small drops.

Why does the oil thus withdraw from the surface while its circumference is still increasing? The reason is, no doubt, that the oil spreads at the minimum tension of pure oil, but not at that of the free sebacic acid contained in it. The solution-current of the latter drives it back from the surface. Outside the oil film spreading upon a large water-surface the tension of the latter does not sink below the minimum tension of the pure oil; in the interior of the holes, however, a newly-formed surface would be instantaneously saturated with oil, and here the tension, therefore, can be further diminished by the sebacic acid.

The minimum tension of oleic acid, at which the latter also does not spread, is in relative measure 0·52, and that of palmitic acid about 0·55.

The depression of surface-tension which can be attained by unpurified oil is not so great, but much greater than that produced by pure oil, and depends upon the quantity of oil applied.

If the quantity be such as to cover the whole surface before breaking, the surface afterwards is not contaminated with oil at all, but only with sebacic acid; and the tension is still sinking slowly by the effect of the continued solution-currents of the single drops.

When less oil is employed, the free sebacic acid contained in it is often not sufficient to produce the lowest possible tension. Then one may observe that freshly added drops of oil still give solution-currents, whilst those of the older drops have already ceased.

When a water-surface, on which minute drops of oil which have not yet dissolved are present, is expanded, the tension rises to the minimum value for pure oil, and then remains constant till the whole oil is dissolved, where it begins to rise again in the same manner as the curve given in Nature, June 15, 1893, p. 152.

The value of surface-tension, at which the linear fall of the curve ceases, being identical with the minimum tension of pure oil, it is evident that the sudden change of direction at the relative contamination 1·3 means saturation of the water-surface with oil.

Agnes Pockels.

Prof. Ostwald on English Chemists.

"To see ourselves as others see us" is so difficult of attainment, that no mirror, however imperfect, should be passed by without a glance bestowed upon it. The image of us which Prof. Ostwald displayed to the electricians assembled in conclave at the second anniversary meeting of the German electricians on June 7, is the less pleasant by reason of the consciousness that the reflector is a good one. The opening words of the Professor's address were virtually as follows:—

"It is a positive fact that every year there are imported into Germany from England so many thousand centners of benzene, amounting to nearly the whole of the production of this material in the latter country. Now benzene is an intermediate product, destined to be converted into dye-stuffs, medicaments, and other commodities, so that we have the remarkable situation that the country of all the world, in which industry has flourished longest, relegates the most important and profitable part of one of her manufactures to a foreign country. The reason is of the plainest: England *cannot* undertake the conversion of its raw material into the finished product, and why? Because of the insufficient training of the English chemist. The would-be practical Englishman with the intention of entering a dye-factory, studies, not general chemistry, but the chemistry of dye-stuffs. The German studies chemistry, lock, stock and barrel, never wrecking what his calling is to be. Only when he has a really scientific foundation will he begin to build up his special knowledge. By and by there comes a change over the face of the industry in which these competing chemists are employed. The German—he is ready; without difficulty he adapts himself, and follows up the novel course. But the Englishman—he cannot imagine at what position he has arrived; he must begin, so to say, over again."

Thus spoke one of Germany's—nay, the world's—greatest thinkers. Let our manufacturers, who despise the college-bred youth, meditate thereupon.

Goldsmiths' Institute.

"Testacella Haliotidea."

Tate, in his "Molluscs of Great Britain," gives a list of counties in which this mollusc may be found. In this list Worcester is not included. Hence it may be of interest to note that specimens are not infrequently collected in asparagus-beds here, as also are those of the much rarer *T. scutulum*. A good specimen of the latter was recently given by me to Mason College, Birmingham.

Nematus grossulariæ.—Here the gooseberry plantations are often devastated by the larvæ of this saw-fly, in the extirpation of which pest the insectivorous value of the cuckoo to planters may be appreciated through the following incident. Recently the attention of a resident of Crowle, a village near Worcester, was directed to his gooseberry plantation, close by a window of his house. A cuckoo was in one of the grub-infested bushes, fluttering its wings, and so causing numbers of the pests to fall on the ground, whence they were quickly gathered by the bird.

Daily the bird visited the garden till the bushes were cleared, and so the crop was saved. In Crowle this year these birds are numerous. I have a garden in a place in North Wales where this year there are few of these birds. The grub stripped the bushes of leaves, and the fruit died.

Worcester, June 23. J. LLOYD-BOZWARD.

On the Diselectrification of Metals and other Bodies by Light.

REFERRING to a footnote on page 135 of NATURE, June 7, Messrs. Elster and Geitel have been good enough to call my attention to a great deal of work done by them in the same direction and published in recent numbers of Wiedemann's *Annalen*. The most important statement about it is that they had observed the photoelectric power of fluorescent minerals and the electrical activity of sunlight, and had worked for some time at the influence of these facts on atmospheric electrification; the idea that atmospheric electricity was thus caused (by the discharging action of sunlight) having been already mooted apparently by von Bezold and Arrhenius.

OLIVER J. LODGE.

Absence of Butterflies.

IT may be worth while to put on record what has happened this spring and summer, viz. the total absence of butterfly life. Beyond an occasional white butterfly, there are none to be seen. I have a large garden where there is usually abundance of them, but a coloured butterfly has not been seen this year yet.

Gravesend, July 2. DELTA.

THE SETTLEMENT OF THE EPPING FOREST QUESTION.[1]

BY a happy coincidence the *Essex Naturalist*, containing the full official report of the discussion on the management of Epping Forest, which took place under the auspices of the Essex Field Club on April 28,[2] and the Report of the experts appointed by the Corporation of London, have been published almost simultaneously, the former having been issued a fortnight or so before the latter. As the proceedings of the Conservators had been subjected to a running fire of the most vehement criticism ever since last autumn, the question of the management of the forest may be considered to have excited an amount of popular interest such as had never before been raised since the public dedication by the Queen in 1882. The reason for the popular outburst of indignation on the present occasion is to be found in the circumstance that the thinning operations had been carried on in a district which is well known to contain the finest example of a beech wood that the forest offers, viz. Monk Wood, and the amassed heaps of felled trunks, drawn to the roadside for removal, naturally attracted the attention of every passer-by, and gave rise to a not altogether unnatural feeling of uneasiness as to the fate of the forest's show woodland. A fair and unbiassed examination of Monk Wood, however, soon sufficed to dispel any fears of unnecessary destruction or permanent injury, and those whose judgment in such matters is worthy of the most serious attention, did not hesitate to express their belief that the operations had on the whole been carried out judiciously, and for the future benefit of the forest. This conclusion was arrived at in many cases against the preconceived notions of some of the visitors who attended the meeting on April 28, and some speakers in the discussion with great candour admitted that the result of the visitation and the explanations given on the spot had been to cause them to modify their views. This appears most distinctly from the speeches of such well-known friends of the forest as Sir Frederick Young, Prof. Boulger, and Mr. F. C. Gould, and it is only fair to add that many others who, without any special knowledge of forestal operations, attended the meeting, of which the proceedings are now reported, as lovers of the naturally picturesque, had their judgment materially aided by the opportunity given them for comparing portions of the forest which had been severely thinned in former years with other portions which had not yet been attacked. The arguments for and against the conservatorial doings are fully set forth in the *Essex Naturalist*, and will form an important chapter in the history of the forest management.

But the Essex Field Club has of course no official connection with the Epping Forest Committee, and although, as everybody knows, the chief executive verderer is Mr. Edward North Buxton, this gentleman gave his services as a conductor of the meeting because of his special knowledge on the one hand, and on the other as an officer of the Field Club. The decision at which the meeting arrived, as already reported in these columns, is in no sense an official utterance of the Club as a body corporate, but is simply to be regarded as an expression of individual opinions consequent upon a personal visitation and a discussion raised thereby. It seems desirable to make this statement in order to avoid future misunderstanding.

The Corporation of London, as the official Conservators of the forest, on April 12 appointed a special Committee of experts, in their own words, "to view the forest, and advise us forthwith as to the effect of the thinning, and our future policy with regard to the management of the forest." The names suggested were Viscount Powerscourt, Dr. Schlich (the Professor of Forestry at Cooper's Hill), Mr. James Anderson of Manchester, and Mr. William Robinson, the editor of the *Garden*. Sir Joseph Hooker was also asked to nominate two other members, and he suggested the names of Earl Ducie, Mr. A. B. Freeman-Mitford, M.P. (formerly Secretary to H.M. Commissioners of Works), and Mr. Angus D. Webster, formerly forester to the Duke of Bedford. Lords Ducie and Powerscourt were unable to join the Committee, but the five signatures attached to the Report may be considered as strongly representative of the art and science of forestry as the names of any committee of experts that has ever been or possibly could be brought together in this country.

Taking the Report as a whole, it will be seen that the Committee practically give their sanction to the policy which has been, and is being, pursued by the Conservators, and endorse the decision arrived at by the majority of those who took part in the meeting and discussion on April 28. Surely after this most weighty verdict there need be no further alarm as to the future of the forest. A detailed analysis of the Report would occupy too much space in these columns, but some of the most important recommendations may be considered. And first of all, with respect to the opening out of views and the making of clearings, there is no uncertainty about their statement:—

"As there is much beautiful landscape in and around the forest, the opening up of which would add much to its charms, we think that the best views should be carefully opened up by making judicious clearings. Such views would be in every way a gain. . . . . The rides and drives are beautiful features of the forest, and those made in recent years are well designed. They should receive constant attention, lest the encroachments of vegetation should mar their picturesque effect. In this connection we would call attention to the beauty of the glades which already exist. These should be increased in number, where it can be done without sacrificing the finer trees, or interfering with the massive groups of the forest."

[1] "*The Essex Naturalist*, being the Journal of the Essex Field Club," edited by William Cole, Hon. Sec. Nos. 1–5, vol. viii., published June 1894. "Epping Forest, Report of Experts as to Management, &c. Report, Epping Forest Committee," presented June 14, 1894.

[2] A brief report of the meeting appeared in NATURE, May 3, p. 12.

With respect to the thinning out of superfluous trees, the Commissioners touch upon a point of considerable importance:

"A vast proportion of the area of the forest is covered by pollard hornbeams. In parts they are an interesting feature; but the practice of pollarding having been discontinued, the trees are now so dense that neither light nor air can penetrate. We consider that, with a view to encouraging the growth of better trees and varying the monotony of the forest, the best course will be, not generally to thin the trees, but to make bold clearances among them. The finer pollard oaks throughout the forest should be carefully preserved."

The importance of this recommendation lies in the circumstance that such a large area of the forest is covered by pollard hornbeams, often most unsightly through overcrowding, while pollard oaks, and especially such as could fairly be called "fine," are comparatively scarce. There are very few naturally-grown hornbeams throughout the forest area, and it is to be noted with satisfaction that the policy adopted by the Conservators, and further enforced by this recommendation of the experts, will give an opportunity for developing the natural growth of a tree which is an almost unique feature of the forest. The writer is not acquainted with any woodland in this country where the hornbeam forms such a prominent feature.

The Committee lay stress upon the importance of preserving the "massive character of the forest," and this also is a point on which it appears necessary to make some observations. Where the trees admit of being "massed," as the beeches in Monk's Wood, or the oaks in Hawk Wood, this policy would naturally find favour. But discretion has been, and no doubt will be, shown in this direction. A large number of trees might advantageously be removed from such an area as Hawk Wood without destroying its massiveness; and yet, when the Conservators come to deal with this part of the forest, there will no doubt be another outcry. With respect to this area the Committee state:

"Hawk Wood is in the main an oak wood, and the trees are not such as would be improved by wholesale thinning. It would be, in our opinion, wise to take out no trees except such as are obviously dying, and a few scrubby stunted trees which are injuring the others. Where, here and there, a single specimen of more than usual beauty can be encouraged into noble growth, it should be protected from overcrowding."

This is precisely what the Conservators proposed to do with Hawk Wood before the present agitation, and a very good suggestion has been made that the chairman of the Committee of experts should be invited to go over this wood and mark the trees which he would recommend to be removed. The Conservators have already marked the trees which they proposed to remove. A comparison of the results would be a most practical lesson in forestry, and, so far as the writer is acquainted with Hawk Wood (which is very thoroughly), it may be safely affirmed that there would be no very serious division of opinion between the chairman and the verderers.

In connection with the question of encouraging the growth of underwood the Committee "do not think that in all parts sacrifices should be made for the purpose of encouraging it where the trees do not allow of its healthy growth, as under beeches." This observation no doubt applies more especially to Monk Wood, and so far may be claimed as a ratification of the work done there. The thinning cannot in this district be fairly considered to have led to any serious sacrifices of good trees, and a ramble through that woodland will convince the lover of the picturesque that the massiveness has not been interfered with. In view of the circumstance that the public attention was first drawn to the recent thinnings by the operations in this district, it is to be regretted that the experts have not expressed themselves more fully on this point. They express no disapproval of what has been done, but they consider that the thinnings will be sufficient "for many years to come," an observation which will no doubt be fully concurred in by the Conservators. There was never any intention expressed of thinning further in this woodland for the present.

The Committee recommend also that the trees in High Beech should not be interfered with, that the hollies in Walthamstow Wood should be allowed to develop by removing the dead or dying trees or the pollards which are interfering with them, and that the "healthy oaks, even where crowded, should be left standing. The beauty of tall oak stems, often lichen-covered, when growing in close woods, should be considered." In connection with this last remark it may be interesting to add that for some reason or another lichens refuse to flourish on the trees in Epping Forest—certainly in the lower forest, and the hoary trunks which are such delightful features of the Kentish and Surrey woods are unknown in the southern portions of the forest. In Theydon High Wood "moderate and periodic thinning" is recommended. In Lord's Bushes it is recommended that the young trees should be allowed to take the lead, and only the "finer and more picturesque pollards" preserved. All these recommendations are, it will be seen, substantially in accord with the line of action pursued by the Conservators.

The following suggestion with respect to drainage will give extreme satisfaction to naturalists:—

"We consider that there should be as little artificial drainage as possible, though in the case of rides or drives it is sometimes necessary. The natural drainage is in most places sufficient, and the streamlets should be allowed to make their own courses."

Another recommendation, which we endorse most heartily, is that "it may be necessary for a time to protect certain spaces against the inroads of cattle, horses, and deer."

The experts are opposed to artificial planting in general, and are in favour of letting nature do her own planting, excepting in cases where tree growth is insufficient, when they recommend that the seed of indigenous trees should be introduced. Four of the Commissioners are even opposed to having a nursery, but Dr. Schlich does not agree with this. In view of the fact that a large area of forest land was formerly under cultivation, and has only been thrown open in recent years, we are disposed to agree with Dr. Schlich. None of us will ever live to see these tracts restored to anything like a natural condition unless planting is resorted to.

Taking the Report in its entirety, it may be said that the question of the management of Epping Forest is now settled beyond cavil, and settled in a manner calculated to give strength to the hands of the Conservators and to reassure the public. The ridiculous exaggeration of seekers after cheap notoriety may in future be allowed to pass by unheeded. As Sir John Lubbock said in his late address to the Selborne Society:—"A great debt of gratitude was due to the conservators and verderers of the forest"; and again in the *Times* of June 11: —"We are greatly indebted to the Corporation of London, to Mr. Buxton and his colleagues, and . . . Epping Forest will be even more beautiful fifty years hence than it is now." The Report of the experts concludes with the very pregnant paragraph:—

"In conclusion, we may say that we are not prepared to endorse the strictures which have been passed upon the work carried out in Epping Forest. We are of opinion that much has been done judiciously and well. In some instances we should not, perhaps, unanimously approve of the whole of the action of the authorities. In others, we may consider that more might have been done. But of one thing we are certain, that whatever has been done has been animated by earnest desire to preserve the finest features of the forest, and through intimate knowledge of its necessities and peculiar conditions." R. MELDOLA.

NOTES.

THE meeting held on Saturday last at the Royal College of Physicians, and reported in the *Times*, was a very satisfactory one. It was attended by delegates from nearly all the institutions which it was proposed, in the report of the late Royal Commission on the Gresham University, should form constituent colleges of the reorganised University of London. Dr. Russell Reynolds, F.R.S., occupied the chair. Since Sir Albert Rollit gave notice in the House of Commons of a motion asking that some action be taken to carry into effect the report of the Royal Commission, there has been ample time for the various institutions involved in the scheme for a Teaching University to deliberate and deliver their opinions on the recommendations. Practically all the constituent schools and colleges have availed themselves of the opportunity, and have, in the main, expressed approval of the proposals. The time has arrived, therefore, at which to set the machinery in action which would lead the Government to appoint a Statutory Commission to frame a scheme on the lines of the report of the late Commission. The necessary motive power is contained in the following resolutions put before Saturday's meeting. It was moved by Prof. Erichsen, the president of University College, and seconded by the Rev. Mr. Whitehouse—"That this meeting of delegates from institutions mentioned in the report of the Royal Commission on the Gresham University desires to express generally its approval of the proposals contained in the report of the Royal Commission, and would urge on the Government that a Statutory Commission be appointed at an early date with power to frame statutes and ordinances in general conformity with the report of the Royal Commission." This resolution was put to the meeting and was carried, the only dissentients being the representatives of King's College. It was also agreed, on the motion of Dr. Norman Moore, "That a copy of this resolution be forwarded to the Lord Chancellor, the Lord President of the Privy Council, the Home Secretary, and the Vice-President of the Council, to be accompanied by a request that they will receive a deputation on the subject, the same to consist of the delegates to this meeting."

PAST and present students of the Mason College, Birmingham, presented Dr. Tilden with a silver bowl and a congratulatory address last week, on his removal to the chair of Chemistry at the Royal College of Science, and as a mark of appreciation of his long and honourable career in connection with the college. The proceedings were of a very enthusiastic character, and Dr. Tilden's students and colleagues vied with each other in expressing their esteem for him as a teacher and an investigator. In the course of his reply, Dr. Tilden remarked that fourteen years ago he went to Birmingham quite a stranger, at a time when there was no science college actually opened. His three colleagues—Profs. Hill, Poynting, and Bridge—were appointed with him as the first four professors of the college, when the building was quite empty. In the first session they had some eighty students between them, and those days were exceedingly happy. Those first professors had unusual privileges and responsibilities. They were naturally given a free hand. They had no traditions to live up to, no standard to go by except that which they themselves set up. They were entrusted with the great duty, the heavy responsibility, of creating their several departments and building up the life of the college, and setting up standards of teaching and conduct which would serve for their successors. Referring to his successor, Dr. Tilden said that, under Prof. Percy Frankland's care, he had no doubt that the work of the college would advance in the right direction.

OUR continental neighbours must often be amused at the forms in which we raise monuments. It will be remembered that a year ago a subscription list was opened for the purpose of erecting a memorial of some kind to Gilbert White. The appeal resulted in £250 being obtained. With this money a hydraulic ram has been fixed at the spring head near the village of Selborne, to force water into a reservoir erected eighty feet above the village. The water runs from the reservoir through pipes laid along the main streets, and tapped at convenient intervals. Selbornites are thus enabled to obtain a supply of water without journeying to the fountain at the spring head, as had previously to be done. This useful and unpretentious memorial is in keeping with Gilbert White's character; nevertheless, it seems to us that the committee having the funds at their disposal should also have taken into consideration the fact that he does not belong to Selborne alone, but to all lovers of nature.

WE learn from the *British Medical Journal* that three further remarkable instances of the success of Prof. Haffkine's system of anticholera inoculation are reported from Calcutta. In the first case, four out of the six members of a family were inoculated last March. The cholera appeared in the neighbourhood lately, and the disease attacked one of the two who had not been inoculated, while the inoculated remained free. In the second case, five members of a family consisting of eleven persons were inoculated in March. The cholera lately attacked one of the six who had not been inoculated. In the third case, six out of a family of nine were inoculated. When the cholera prevailed in the neighbourhood a few days later the disease attacked one of the three not inoculated. It is stated that the Corporation of Madras have passed a resolution inviting Prof. Haffkine to visit that city and introduce his system.

THE Council of the Royal Statistical Society announce that the subject of the essays for the Howard Medal, which will be awarded in 1895 with 20*l*. as heretofore, is as follows:—"Reformatories, and industrial schools of that class, in their relation to the antecedents, crimes, punishments, education after conviction, and training of juvenile offenders: together with the nature and extent of their influence on the diminution or increase of crime generally. These particulars have to be collected and analysed on a statistical basis, both as respects the institutions and agencies, public and private, at home and abroad, for the reclamation of juvenile offenders, and the best means of dealing with them on release. This does not include the industrial and training institutions certified by the Local Government Board under the 25 and 26 Vict. cap. 43." The essays should be sent in on or before June 30, 1895.

THE death is announced of Prof. F. Q. Rodriguez, Professor of Crystallography in the University of Madrid.

DR. JOSEPH COATS has been appointed Professor of Pathology in the University of Glasgow.

MR. L. O. HOWARD has been appointed entomologist to the U.S. Department of Agriculture, in succession to Prof. C. V. Riley.

MR. J. WOLFE BARRY, the engineer of the Tower Bridge, has had the honour of the Companionship of the Bath conferred upon him by the Queen.

PROF. W. ERB, of Heidelberg University, and F. Jolly, of Berlin, representing an influential committee, invite subscriptions for the erection of a monument to the late Dr. Charcot in the Salpêtrière.

The death is announced of Dr. Louis de Coulon, one of the founders of the Société des Sciences Naturelles de Neuchatel in 1832, and its president for more than half a century from 1836 to 1890, when he became "Président honoraire." Dr. de Coulon was born July 2, 1804, and died June 13, 1894.

A Medical Congress will be held at Calcutta at the end of next December, under the patronage of the Viceroy, and the presidency of Surgeon-Colonel Harvey. The objects of the Congress are "to bring together men from all parts of the Indian Empire, and to discuss medical subjects connected with Indian diseases, and to place on permanent record some of the work which is now lost to science for want of proper publication."

The seventy-seventh meeting of the Société Helvétique des Sciences Naturelles will take place at Schaffhausen, from July 30 to August 1 inclusive. The Swiss botanical and geological societies will also hold concurrent meetings. Papers intended to be read before the different sections should be in the hands of the Committee before July 15. The President for the year is Prof. J. Meister, and the Secretaries, Dr. J. Nüesch and H. Wanner-Schachenmann.

A number of papers were read at the meetings of the Museums Association, held in Dublin last week. Mr. F. W. Rudler described the arrangement of a mineral collection, and Mr. G. H. Carpenter read a paper on collections to illustrate the evolution and geographical distribution of animals. Among the subjects dealt with on the concluding day, June 29, were "Classified Cataloguing, as applied to Palæozoic Fossils," by Mr. W. E. Hoyle, and "The Functions of a Botanical Museum," by Prof. T. Johnson.

The Register for 1893–94 of the Johns Hopkins University of Baltimore has been received. One of the changes we note is that Prof. Newcomb terminated his active duties as Professor of Mathematics and Astronomy at the beginning of this year, the requirements of the Government service having obliged him to do so. The instruction in higher mathematics is now carried on by Profs. Craig and Franklin, and that in astronomy by Drs. Poor and Chessin. In all the departments of the University facilities are afforded for original research. In physics, Prof. Rowland expects all advanced students to devote most of their time to laboratory work and to undertake investigations designed to be of permanent value. Again, the chief instruction in every course of chemistry is that given in the laboratory. Prof. Remsen does not pander to those who merely take up chemistry in order to obtain a degree. "What is desired," he says, "is a certain maturity of mind with reference to the science of chemistry, and an ability to deal with chemical problems intelligently. This condition of mind is reached, if reached at all, by long-continued laboratory training accompanied by careful study of chemical journals and treatises. It may be said that the arrangements of the laboratory are made mainly with reference to those who wish to take up the study of chemistry in a broad way, and that those who want short courses in special branches of chemistry are not advised to come here. It is believed that whatever object the student may have in view, whether he intends to teach or to follow some branch of applied chemistry, the best preparation he can have is a thorough training in the pure science." We have seen few prospectuses in which the aims of study are more clearly defined. It is the same in all the other branches of scientific knowledge fostered at Baltimore; after students have become familiar with the methods of investigation through the study of typical and described material, they are encouraged to undertake original work. No wonder that the Johns Hopkins University is able to keep going journals of mathematics, chemistry, and biology, as well as numerous bulletins, circulars, and memoirs. The training given is just that calculated to produce results worthy of publication.

The temperature in the shade exceeded 80° in several parts of England and Wales during the three days ending Monday last, and reached 87° at Cambridge on Sunday. Thunderstorms occurred on Sunday night and following days in many parts of Great Britain, accompanied by very heavy rainfall in places. At Jersey 1·1 inch was measured on Monday morning, and 1·7 inch at Stornoway on Tuesday morning. These storms had the effect of cooling the air; the maximum shade temperature in the neighbourhood of London had fallen about 10° on Tuesday compared with that on the previous day.

The report of the German Meteorological Institute for the year 1893 contains some interesting details of the activity of that office, in addition to the routine work of dealing with observations from nearly 2,000 stations. During the year the important magnetic observatory of Potsdam became affiliated to the central office in Berlin; the very complete observations made there will be included with regular yearly publications. With the co-operation of the Alpine clubs an attempt has been made to reorganise a meteorological station on the Brocken, but hitherto it has not been successful. Fifteen scientific balloon ascents have been made during the year, in which the officials of the Institute have taken part. After the sixth ascent the balloon was exploded by lightning, but this only temporarily interfered with the work, as the Emperor granted funds to continue it. A complete account of the results obtained will be published in a special volume, when the work is discontinued. The introduction of Central European time into Germany has interfered materially with the meteorological work at the stations during the year.

At the meeting of the Vienna Academy of Sciences on June 14, Dr. J. Hann submitted an investigation on the daily period of wind velocity on the summit of the Sonnblick (3100 metres), based on a careful and laborious calculation and discussion of anemometrical observations for six years, and also on the range on mountain summits generally. The minimum of wind force takes place on the Sonnblick very early, about 8h. or 9h. a.m., and the maximum occurs about 8h. p.m. On the Santis (2500 metres), the minimum also takes place relatively early, between 10h. and 11h. a.m. But from the accepted theories of the cause of the daily period of wind force on mountain summits, it might be supposed that the minimum would occur in the afternoon. He therefore examined the records for several other stations, and found that in the summer, for altitudes ranging from 1400 to 4300 metres, the mean time of the minimum occurred at noon. He then investigated these facts to see how they fitted in with the assumed causes of the daily range, and as he could not reconcile them, he suggests that the possible explanation of the daily range on mountain peaks may be that the surface of the mountain being much more warmed than free air during the day affects the anemometers. It is assumed, however, that the chief effect is only active for a few hundred metres below the summit, in the morning, and that later it would be interrupted by the wind coming from the valley. If the minimum were due to the great ascending current, it would occur during the afternoon.

An apparatus for discovering internal flaws in iron and steel is described in *Industries and Iron*. It is electrical, and consists of a small pneumatic tapper worked by the hand, with which the sample of steel or iron is tapped all over. With the tapper is connected a telephone with a microphone interposed in the circuit. One operator is required to apply the tapper, and the other to listen through the telephone to the sounds produced. Both are in electrical communication, and in separate apartments, so that the direct sounds of the taps may not interrupt the listener, whose duty it is to detect flaws. In applying the system, one operator places the telephone to his ear, and while the sounds produced by the taps are normal he does nothing. Directly a false sound, which is distinguishable from the normal sound, is heard, he signals for the spot to be marked, and by this means is able, not only to detect a flaw, but to fix its locality.

THE current number of the Johns Hopkins University (U.S.A.) *Circular* contains a preliminary note, by Edwin F. Northrup, on a new method of obtaining the specific inductive capacity of solids under either slowly or rapidly changing fields. It is of great importance in connection with Maxwell's electromagnetic theory of light that, since the refractive index for most substances has only been measured for very short waves, the specific inductive capacity be measured under such circumstances that the field of force alternates with such rapidity as to produce waves comparable in length to the waves with which the refractive index is determined. The apparatus employed by the author consists of three heavy brass plates, fastened parallel to each other, and separated by about three inches. Each plate is held in position by four insulating strips of ebonite, through the ends of which pass four iron rods with a screw-thread cut upon their whole length. To the centre of each of the two outside plates, and perpendicular to the plate, is fastened a brass tube. A rod, half of which is of ebonite, moves in this tube and carries at its end a thin plane plate of glass, the surface of which is coated with metal foil. These small movable plates are as nearly as possible parallel to the large plates, and their position is given by a vernier attached to the ebonite rods. The two outside plates are connected by a metal rod which carries a metal ball. Another ball, nearly opposite the first, is fixed by a short metal pin to the middle plate so that the distance between the balls can be adjusted. In employing the apparatus to measure specific inductive capacity with rapidly varying fields, the following arrangement is used. The two outside plates and one terminal of a large induction coil being connected to earth, the other terminal of the coil is connected to the middle plate. When the coil works, sparks pass between the balls, and oscillations are set up. The lines of force, when air only is the dielectric, divide evenly between the plates, and in the region of the small plates the field may be considered as uniform; hence if these plates are at equal distances from the centre plate, they will always remain at the same potential. If, however, a plate of some other dielectric is placed between the centre plate and one of the movable plates, in order that the two small plates may remain at the same potential, they will have to be placed at unequal distances from the centre plate, and from their relative positions the specific inductive capacity can be deduced. In order to "weed" out the effects of the slow changes of potential due to the charge and discharge of the coil, the two small plates are connected to the primary of a small transformer, the secondary of which contains a spark-gap. In this way the effects due to the slow changes are eliminated, since the rate of variation of the induction in the transformer, due to these slow changes, is not sufficient to raise the potential in the secondary to the 300 volts or more required to break down the dielectric in the spark-gap.

STUDIES of the eastern Yucca Moth (*Pronuba yuccasella*) and its importance in Yucca pollination, have, from time to time, been recorded in reports of the Missouri Botanical Garden. In a recent report, Mr. J. C. Whitten describes observations which complete the knowledge of the life-history of this interesting insect. The observations refer to the time when the larva ceases feeding in the capsule, until it is encased in its underground cocoon, when, the following spring, it is to change to the pupa state. It was found that the larvæ made their escape from the capsules of *Yucca filamentosa*, and entered the soil during rainy weather, when the ground was softened, and consequently easily penetrable. They did this either during the daytime or at night, and not exclusively toward the end of the night, as Prof. Riley had predicted. The larvæ descended to the ground both by use of a thread and by crawling.

A CATALOGUE of works on entomology, being No. 26 of *Bibliotheca Entomologica*, has been issued by Herr Felix L. Dames, Berlin, Koch-Strasse 3.

WE have received from the Revenue and Agricultural Department of the Government of India a copy of the Returns of Agricultural Statistics of British India and the Native State of Mysore for 1892-93.

THE May number of the *Journal* of the Jersey Biological Station (*Jour. of Mar. Zool. and Micros.*, edited by James Hornell, vol. i. No. 3, 1894) contains several original contributions by the editor, in one of which is given an interesting account of the variability of the opercular filaments in *Serpula pectinata*. Elementary and picturesque descriptions are also given of the metamorphoses of the Crustacea *Squilla desmarestii* and *Scyllarus arctus*, and of the structure of anemones. The number is illustrated by several autographic plates and woodcuts, and contains a frontispiece giving a photographic view of the aquarium of the laboratory, which would seem, from the editorial report, to be making well-merited progress.

THE special articles, official reports, notes, communications, and reviews in part ii. of vol. v. of the *Journal* of the Roya Agricultural Society, issued on June 30, make up a number replete with information. The first two meetings of the Society—Oxford 1839 and Cambridge 1840—are described by Mr. Ernest Clarke. Profs. J. McFadyean and G. T. Brown write on the prevalence of anthrax in Great Britain, Mr. Joseph Darby on irrigation and the storage of water for agricultural purposes, and Dr. Fream on some minor rural industries. Among the official reports, we note one by Dr. J. A. Voelcker on aubury, club-root, or finger-and-toe, in turnips. Dr. J. M. H. Munro writes on sewage disposal and river pollution, and Lord Egerton of Tatton describes the Tewfikieh College of Agriculture, Egypt.

THE makers of a very neat little camera, Messrs. R. and J. Beck, have just send us a copy of the "Frena Handbook," in which the inventor says practically all there can be said with regard to the description, method of use, manipulation, &c., connected with this instrument. For the benefit of "some future philologist" who may at some time be in doubt as to the derivation of the word "Frena," an etymological note informs us that it is derived from "faro" and "crena," the former being the name of the well-known game of cards, and the latter meaning a notch; the instrument automatically discharging one film after another like a *faro-box*, and doing this by means of notches. In this camera notched films are used, being thin and stiff sheets of transparent cellulose film, and as many as forty can be carried in the holder at the same time. With regard to some of the technical data of the No. 2, quarter-plate, size, the lens is an "autograph" rapid rectilinear of focal length $5\frac{1}{2}$ inches, normal aperture F - 11, and covers a $3 \times 4\frac{1}{4}$ inch film; the dimensions of the case are $11\frac{1}{4} \times 5\frac{1}{2} \times 4\frac{1}{4}$ inches, and when filled with forty films the apparatus weighs four pounds. Among many of the advantages of this camera may be mentioned the arrangement by which the films may be tilted, thus providing a neat and easily worked form of swing-back. After the introduction, the author of this handbook gives a very brief and concise summary of the outline of operations necessary for the veriest beginner, printing them in red ink. This, however, s supplemented with fuller details by a series of extensive notes on the use of the "Frena," occupying nearly eight times as many pages as the "outlines" above mentioned. These notes contain some sound advice, of which the novice could not do better than take advantage, and they are written in a clear style. The illustrations and figures are exceedingly neat and clear, and the whole get-up of the book is all that can be desired.

Some new facts concerning the nature of the molecule of calomel are contributed to the current issue of the *Berichte* by Prof. Victor Meyer and Mr. Harris. The determinations of the vapour density of mercurous chloride made by Mitscherlich, Deville and Troost, and Rieth, in each case afforded numbers in close agreement with those demanded by the simple formula HgCl. Odling, however, disputed the possibility of the existence of molecules containing only one atom of each element, involving the assumption of univalency for mercury, and showed that when gold-leaf is immersed in the vapour it becomes amalgamated, indicating the presence of free mercury vapour. Erlenmeyer subsequently showed that this experiment was open to the objection that the amalgamation might be due to a chemical reaction between gold and calomel vapour, and pointed out that the presence of free mercury may be more conclusively shown by immersing a glass tube, cooled by containing a column of quicksilver, in the vapourised calomel, when an abundant condensation of mercury globules is observed. Debray afterwards immersed in the vapour of calomel a bent tube of silver, gilded outside and kept cool by the passage of a current of cold water, and found that both mercury and corrosive sublimate were condensed upon it, but that the greater portion of the sublimate consisted of unchanged calomel. Debray therefore concluded that dissociation into mercury and corrosive sublimate only occurred to an insignificant extent. Prof. Meyer and Mr. Harris now show that if a piece of gold-leaf is immersed for an instant only in the vapour of calomel it is invariably amalgamated, but if it is allowed to remain in the vapour for a few minutes it becomes pure gold again, the mercury being volatilised. They have further carried out a series of vapour density determinations by Prof. Meyer's well-known method, at the temperature of the vapours of boiling sulphur (448°) and phosphorus pentasulphide (518°). The numbers obtained are all in close proximity to that calculated for the molecular condition HgCl, agreeing in this respect with the older determinations above referred to, in which other methods were employed. The calomel was introduced into the apparatus in the form of a compressed pastille, thus obviating the necessity for a containing bulb or tube, and enabling almost instantaneous volatilisation to be achieved. A second series of experiments were then made with a mixture in the proper proportions of free mercury and corrosive sublimate, and the results were almost identical with those obtained from calomel. Of course this does not afford any conclusive evidence, but experiments are next described in which an attempt at identification of the substance or substances present in the vapour was made. It was shown that when the cylindrical bulb of the density apparatus was constructed of porous earthenware, a very large amount of mercury vapour diffused through it, and could be condensed upon an outer enveloping glass cylinder. Further, that when calomel is vapourised in a retort connected with a Sprengel pump, and in which the pressure has been reduced by the latter to about 30 mm., the upper portion of the apparatus becomes covered with a layer of mercury globules, and a proportionate quantity of mercuric chloride is formed. Chemical evidence is also adduced to prove the presence of mercuric chloride vapour in the gaseous product of heated calomel, for it is shown that pieces of caustic potash previously heated to the same temperature become instantly covered with orange-coloured mercuric oxide, just as when plunged into vapour of corrosive sublimate, proving the absence of any large quantities of mercurous chloride, which would have afforded a black deposit of mercurous oxide. Prof. Meyer and Mr. Harris therefore conclude that when calomel is vapourised it dissociates into mercury and corrosive sublimate, $Hg_2Cl_2 = Hg + HgCl_2$, and the necessity for the assumption of monadic valency for mercury is thus avoided.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*, ♂) from India, presented by Mrs. McHugh; three Barbary Turtle Doves (*Turtur risorius*) from North Africa, presented by the Misses E. and P. Mackenzie; a Common Cuckoo (*Cuculus canorus*), British, presented by Mr. W. Keen; two Horned Lizards (*Phrynosoma cornutum*) from Texas, presented by Miss Maitland, an Anomalous Snake (*Coronella anomala*) from South Africa, deposited; an Ostrich (*Struthio camelus*, ♀), from Africa, two Red-headed Merlins (*Hypotriorchis chicquera*) from India, purchased; an Æthiopian Wart Hog (*Phacochærus æthiopicus*, ♀), from South-East Africa, received in exchange; a Thar (*Capra jemlaica*, ♂), a Burrhel Wild Sheep (*Ovis burrhel*), a Great Kangaroo (*Macropus giganteus*, ♀), born in the Gardens.

Prof. W. R. Fisher requests us to make the following correction in his contribution to our last number:—On p. 193, line 8 from top, for "1·025" read "$1·025^{45}$."

OUR ASTRONOMICAL COLUMN.

The First Observation of Sun-spots.—A contribution to the history of the rival claims of the various alleged discoverers of sun-spots appears in the *Rendiconti dei Lincei*, from the pen of Prof. E. Millesovich. It is a criticism of Dr. Berthold's pamphlet on "Master Joann Fabricius and the Sun-spots," setting forth the claims of the son of the Frisian astrologer David Fabricius to the name of the true discoverer of the solar phenomenon in question. The other claimants are, of course, Galileo and the Jesuit Scheiner, known under the name of Apelles. The claims of Fabricius are based upon his book *De Maculis in Sole observatis, narratio*, &c., published at Wittenberg in 1611. He had been studying at Leyden University, whence he brought home Lippershey's newly-invented telescope to his father at Osteel. The latter was already well known among astronomers as the discoverer of the variability of Mira Ceti. The method of projecting the solar image on a screen is set forth in detail in the work referred to, as well as the correct conclusion that the sun rotates about an axis. Prof. Millesovich grants that the name of Fabricius was probably known to the Jesuits and suppressed as that of a heretic, but he comes to the conclusion that Galileo was actually the first discoverer, having observed the spots as early as the summer of 1610, whereas Fabricius saw them independently on March 9, 1611, and Scheiner about the same time, without, however, paying much attention to them before the publication of Fabricius's *Narratio*. He then observed them assiduously, and collected a large number of valuable records.

The Progress of Astronomical Photography.—Under this title, Mr. H. C. Russell, C.M.G., F.R.S., the Government Astronomer at Sydney, delivered an address, as President of Section A (Astronomy, Mathematics, and Physics), at the last meeting of the Australasian Association for the Advancement of Science. The address has now been issued, and it is the most complete statement that we have seen of the advance of astronomical photography from the time when Prof. J. W. Draper took daguerreotypes of the moon, in 1840, to June 1893. The references distributed through the address add to its usefulness. Reference is made to eighty-one sources of information in all, and of these, Nature claims the large proportion of thirty-two. Like many other enthusiastic workers in the realm of celestial photography, Mr. Russell believes that astronomical observations will eventually be automatically made by means of the sensitive plate of the photographer.

MR. TEBBUTT'S OBSERVATORY, NEW SOUTH WALES.—The report of Mr. Tebbutt's Observatory, Windsor, New South Wales, shows that there was no relaxation in the observations carried on during 1893. The work done is quite equal in importance and amount to that of previous years. In addition to constant meridian work, a number of occultations were observed. Interesting phenomena were noted at the disappearance of τ^1 Arietis on January 26, 1893, and Mr. Tebbutt thinks that the star should be examined with a powerful telescope, as it is probably a triple one. The conjunction of Saturn and Virginis in April was observed · also the occultation of Saturn and Titan on May 25. Brooks' Comet (1892 VI.) was followed from November 28, 1892, to June 19, 1893, and the Rordame-Quenisset Comet (1892 II.) from July 29 to August 13, 1893. A series of measures of the binary star α Centauri were also made. When it is remembered that all the astronomical, and nearly all the meteorological, observations are made by Mr. Tebbutt himself, as well as the greater portion of the astronomical reductions, it is impossible not to admire his devotion to astronomical work. The smallness of the number of southern astronomers makes his observations all the more important.

A NEW SPIRAL NEBULA.—At a recent meeting of the Royal Astronomical Society, Dr. Roberts exhibited a photograph of a new spiral nebula in Perseus (*Monthly Notices R.A.S.*, April 1894). The nebula is in R.A. 2h. 29m. 58s. Decl. + 38° 31′·4. It is 3m. 51s. *preceding*, and 5′·4 *south* of the nebula No. 1023 in the New General Catalogue. The accompanying cut, from one of Dr. Roberts' photographs, shows the latter nebula as a

lenticular body a little below the centre, while the new object appears as a faint patch almost directly above it near the top of the figure. The illustration will serve to indicate the position of the nebula, but the spiral character has been lost in the reproduction. Dr. Roberts thinks that the nebula is new to science, for it is not recorded in the New General Catalogue. With regard to its character he says:—"The convolutions of the spirals are very faint, but clearly visible on the negative, and involved in them are four 14-15 mag. stars, and six or seven stars, or star-like condensations, less bright than the 16th mag. The convolutions are symmetrical, and proceed from a very faint star-like nucleus."

TWENTY-FIVE YEARS OF CHEMISTRY IN RUSSIA.

IN November last, the Russian Chemical and Physical Society commemorated the twenty-fifth anniversary of its foundation, and the addresses delivered on this occasion are now published in a separate pamphlet, as an appendix to its journal. The activity of the Russian chemists having been chiefly centred round the Society, the addresses on the progress of physical chemistry, by N. N. Beketoff; of organic chemistry, by N. A. Mensbutkin; on researches in the aromatic series, by Th. Beilstein—all in connection with the Russian Chemical Society—may be taken as so many excellent reviews of the progress of these respective branches of chemistry in Russia. The first two addresses are especially full of interest, as there is not one of the great questions which have occupied the attention of chemists during the last five-and-twenty years to which Russian chemists have not contributed some work of importance. The researches in connection with the periodical law, by its discoverer himself, and later on by Bazaroff and Prof. Flavitzky; the work of Prof. Gustavson, on the double substitutions of anhydrides; the researches of Prof. Potylitzin, into the mutual substitutions of haloids, also in the absence of water and at a high temperature, which induced Berthelot to make new researches in order to verify his law; and the discovery, by the same chemist, of the dependency between the limit of substitution of chlorine by bromine and their atomic weights, are passed in review. Next come P. D. Khrushchoff's researches into the heat of solution of mixtures of salts, which gave a further confirmation of the Berthelot, Guldberg, and Waage's law; the well-known exhaustive researches of Prof. Menshutkin into the speeds of reactions; and those of Kajander (prior to those of Arrhenius), into the dependency of these speeds upon the electrical conductibility of the combining bodies; the thermochemical work of Lughinin and Werner, and other works of minor importance. And, finally, the Russian chemists have contributed many and varied researches into the dependencies of physical properties of bodies upon their chemical composition and structure; such, for instance, as Goldstein's, which have led to the discovery of a law expressing the rise of the boiling point of many hydrocarbons as a function of their molecular weights; while the important contributions of Mendeléef, Konovaloff, Alekséeff, and also Scherbacheff, to the theory of solutions, and Prof. Bunge's work in electrolysis, are well known to West European scientists.

The work done in Russia during the same period in organic chemistry is, perhaps, even still more important; but it can hardly be dealt with in a few lines, although, out of more than a thousand papers contributed in this department, Prof. Menshutkin only mentioned those "of which," he said, "the history of chemistry will retain some impression." Many works of importance have been grouped by the reviewer around Butleroff's researches into the tertiary alcohols—a whole school of explorers of the fat series having been created by the well-known Kazan professor; while another series of researches into the aromatic compounds was made under the impulse given to these researches by Zinin and Beilstein. These last are so extremely valuable that they rightly form the subject of another well-filled address, delivered by the present leader of this school, Prof. Beilstein. Th. R. Wreden, in Russia, was one of the first to recognise the importance of those organic compounds which stand between the fat and the aromatic series; and though his work, which went against the then current opinions in science, did not attract the attention it fully deserved, the ulterior researches of Beilstein, Kurbatoff, and Markovnikoff into the compounds entering into the composition of the Baku naphtha have shown that he was on the right track, and fully confirmed his suggestions. The existence of these intermediate forms, which have their rings composed of atoms of carbon only, is now a recognised fact, and their study has already led to many important discoveries, while it promises many more. A short review of the work done in Russia, in connection with stereo-chemistry, and with the relations between the physical properties of organic compounds and their chemical composition and structure, concludes this most interesting address. "Chemistry," Prof. Menshutkin says towards the end of it, "is rapidly approaching the time when it will be no more a descriptive science, but a mechanics of atoms, and the history of the Russian Chemical Society is intimately connected with that part of the history of science."

THE LANDSLIP AT GOHNA, GARHWAL.

SIR E. BUCK has sent to us, through Mr. E. D. Maclagan, Under-Secretary to the Government of India, an advance copy of a report, with maps and plates, by Mr. T. H. Holland, of the Indian Geological Survey, on the great landslip in the Kumaon Hills. The landslip has been more than once referred to in these columns, but Mr. Holland's report, from which the following extracts have been made, is the first detailed information that has reached us on the occurrence.

Mr. Holland made a journey to Gohna last February, that is, five months after the landslip, and when the lake, formed by the barrier fallen across the Birahi Ganga valley, had risen to within 290 feet of the top of the dam. His investigations lead him to believe that the lake will be full and will overflow the barrier about the middle of August. Means for recording, by instantaneous photographs, the effects of the water on the dam have been arranged by the Government of the North-Western Province.

Gohna in British Garhwal (lat. 30° 22′ 18″ N., and long. 79° 31′ 40′ E.) is a small village in the valley of the Birahi Ganga, a river running westward and joining, at a point 8 miles west of Gohna, the Alaknanda, one of the principal tributaries of the Ganges. The village is about 130 miles north of Naini Tal, and by the road which follows the valley of the Alaknanda, it is 160 miles from Hardwar.

The bed of the Birahi Ganga, sloping at about $2\frac{1}{2}$°, is at Gohna 4600 feet above sea-level, and is the bottom of a narrow gorge with steep, and sometimes precipitous, sides. The gentler slopes are grass-covered, and higher up clothed with evergreen oak, fir, and rhododendron. In the more open parts of the valley, a small amount of cultivation is carried on by the few inhabitants of the small groups of houses dignified by the name of villages. The river basin, which is twenty miles long and nine miles wide, is bounded on the north and east by a snow-clad ridge rising to 21,286 feet. A considerable portion of the water of the river is therefore derived from the melting snows, and it consequently receives its greatest supply during the warmer months. The area of the basin east of Gohna, and consequently the area draining into the lake which has been formed by the landslip, is about ninety square miles.

From the account of the villagers there seem to have been fields along the sloping portion of the gorge near Gohna on both sides of the river, whilst the hill they speak of as Maithána—the one which fell—rose almost vertically above the slope on the north side of the river. Two years ago there was a small slip between Maithana and Gohna village. On the 6th of last September (1893), and towards the close of the rainy season, two falls took place, damming back the river to form a lake. Falling continued for three days with deafening noise and clouds of dust which darkened the neighbourhood and fell for miles around, whitening the ground and tree-branches like snow. Further slips occurred at subsequent intervals after heavy rain; and at the time of Mr. Holland's visit, a day's rain or fall of snow was always succeeded by falls. Blocks of several tons would bound from ledge to ledge for more than 3000 feet over the broken hill face with a low rumbling noise and the production of clouds of dust. The hill which fell was a spur of over 11,109 feet high; but except on the edge of the precipice, where pieces could be pushed over with the foot, Mr. Holland found no cracks in the hill. The rocks exposed on the cliff-front are crumbled and faulted in a complicated manner and with varying dip; but on the west side of the slip the dip is towards the valley at a lower angle than that of the precipice, the average inclination of which is 54°. The mass of broken material which fell stretches for two miles along the river valley, and rests against the cliff of similar rocks on the opposite side a mile away. On the higher mounds, from which the mud has been washed away, large masses, sometimes weighing hundreds of tons, of crumpled dolomitic limestones are seen pitched in obliquely and shot out like a pack of cards. In the first fall, at any rate, the hill must have pitched forward and not have slipped down in the usual fashion of smaller slides. Blocks hurled a mile away against the opposite cliff have knocked down numbers of trees. The second main fall now stands as a heap of irregularly piled blocks weighing from about thirty tons down to ordinary hand specimens.

The surface of the dam exposed in early March was about 423 acres; but it was gradually being submerged on the eastern side by the rising lake. The lake in the beginning of March was $2\frac{1}{4}$ miles long, 1 mile wide at the widest part, and covered 370 acres. It was then rising at the rate of about six inches per day; but with the melting of the snows in the hot season, the rise must become more rapid. When full it will, unless a cutting is made, overflow at a point 5850 feet above sea-level; and the stream, rushing down an incline of 11°, will rapidly cut with increasing head a channel in the mud and loose stones, which cover that portion of the dam, until its speed is checked by the reduction of slope and the exposure of large blocks of dolomite which must occur below at no great depth. Mr. Holland found it impossible from mere inspection to estimate the thickness of the soft mud, but he thinks that if the rapid erosion becomes arrested before 100 feet has been cut, there will be preserved above a lake $3\frac{1}{4}$ miles long and $1\frac{1}{4}$ miles wide, the destruction of which by gradual erosion of the dam and silting up of the basin, though a matter of time geologically considered short, will be sufficiently slow for what historically may be called a permanent lake. The lake view from the dam is the crowning charm of scenery typically Himalayan and wild. The steep mountain slopes, partially clad with fir, evergreen oak, and gorgeously-flowered rhododendron, slope steeply down on either side to the blue-green waters of the lake, whilst to the east Tirsúl and two associated peaks, rising over 20,000 feet, with snow-clad slopes and glaciers, form the background of the picture (Fig. 1).

It is pointed out that at several places in the Himalayas, lakes have in the recent past been formed by landslips, filled, and afterwards cut through by their own streams. Mr. Oldham has described the very interesting case of Turag Tal near Gonain in Almora District, which was formed behind a barrier of slipped limestone 250 feet high. The level of the alluvium in the lake is now within 50 feet of top of the barrier, so the age of the lake is measured by the time required to deposit alluvium to a thickness of 200 feet. (*Rec. Geol. Surv. India*, vol. xvi. 1883, p. 164.)

Whilst the steep slopes of the mountains around the lake at Gohna add greatly to the beauty of the view, they are unfortunately a source of danger to the lake itself on account of their liability to follow the example of Maithána and slide down, displacing proportionately large bodies of water. At one spot, a little to the south-east of the dam and half-way to Durmi, where the dolomites dip in the direction of the steep slope towards the lake, the hill side may at any time slide into the lake. In 1869, higher up the same valley, a small lake, Gudyar Tal, having been formed in the same way by a landslip, became suddenly nearly filled with a second slip and displacement of a body of water, which flooded the valley of the Alaknanda and washed away part of Srinagar, 78 miles below. That this, sooner or later, will take place, seems to be certain; but when, it is impossible to say. The very size of the lake, however, will be a safeguard against high floods. Suppose, for instance, that the permanent lake had an area of 500 acres, and a slip of 12,500,000 cubic feet occurred—the maximum possibility near the south-east corner of the dam—the result would be that the water in the lake would rise about 7 inches. There are, however, one or two steep precipices on the north side of the lake, which Mr. Holland could not examine, and which he thinks might probably give larger slips.

Fears have frequently been expressed concerning the danger of the dam bursting under the hydrostatic pressure of the water accumulating in the lake above. The sections and map accompanying Mr. Holland's report should be sufficiently convincing to any engineer; but to remove any doubt concerning the security of the barrier, the strength of the dam is conveniently compared by a simple calculation with the actual hydrostatic pressure which it will have to resist before overflow occurs.

The point referred to as 5850 feet above sea-level is approximately in the centre of the dam, and lies in its weakest section. It is shown that this weak section would weigh about 401,922 tons. When the overflow is about to take place, the horizontal hydrostatic pressure against the section will be 13,950 tons.

The weight of the section is thus nearly twenty-nine times the horizontal pressure of the water. But even supposing this section to be free of friction from the sides, and only offers the resistance estimated by its own coefficient on a bed of the same material, it would require about four-fifths of its own weight to move it; that is to say, a pressure of 321,536 tons. But as the maximum horizontal pressure of the water will only be 13,950 tons, the weakest section of the dam is *at least* twenty-three times the necessary strength. This estimate would, of course, be still higher if the weight of the thousands of tons of dolomitic blocks which rise on either side the weak section and point of overflow were taken into consideration. Finally, the enormous pile of rubbish, weighing quite 800,000,000 tons and lying in a valley nearly one mile wide, would, if shifted, become jammed into a gorge only 500 feet wide.

Mr. Holland traces several causes, which were some time conspiring to the one end of bringing about the catastrophe that has been attended with such serious consequences at Gohna.

Among these the principal, or more correctly, the one which gave facilities for the action of all the others, is the dip of the strata towards the gorge. Over Gohna village, the dip of the dolomites in the south-east direction increases, until in Marthána itself the beds are inclined in the face of the cliff at an angle of about 45°–50°, and consequently large platey surfaces are exposed by the fall. As the dip of the rocks is greater than the angle of repose of dolomite or shale-slabs, sliding would naturally take place when necessary facilities are presented. So long as the slope of the surface does not exceed in angle the dip of the strata there is no danger of a slip; but when, as in this case, the foot of the slope is undermined by the action of a river and by springs, the average slope of the surface is increased, and there is a tendency for the beds lying between the line of slope and the line of dip to slide off.

It is pointed out that the influence of the dip of the strata in fashioning the surface slope is well illustrated in the Cheddar Valley. The river has cut a gorge approximately in the direction of the strike of the carboniferous limestone, which dips on both sides of the river at an angle of 15°-24° south. The south side of the gorge is an almost perpendicular cliff 400 feet high, whilst on the north side the slope is only slightly greater than the dip of the beds, which are constantly, though gradually, slipping down as the river is deepening its valley. Thus, whilst an almost perpendicular cliff is safe on the south side in which direction the rocks dip, there is a perpetual slipping on the north side, and no slope greater than the angle of repose of the loose blocks would be safe.

In the landslip at Gohna not only was the support removed by undermining at the foot of the slope, and loosening of the beds, but the beds were impelled outwards by a series of changes following as a natural consequence of the processes which destroyed the originally compact nature of the strata. These causes combined, taking advantage of the stratigraphical facilities, precipitated the mass of material which now dams back the Birahi Ganga. They are as follows:—

(1) *Those producing a loosening of the strata.*

(*a*) Dolomitisation.
(*b*) Solution by atmospheric waters.
(*c*) Reduction of coefficient of friction by water.

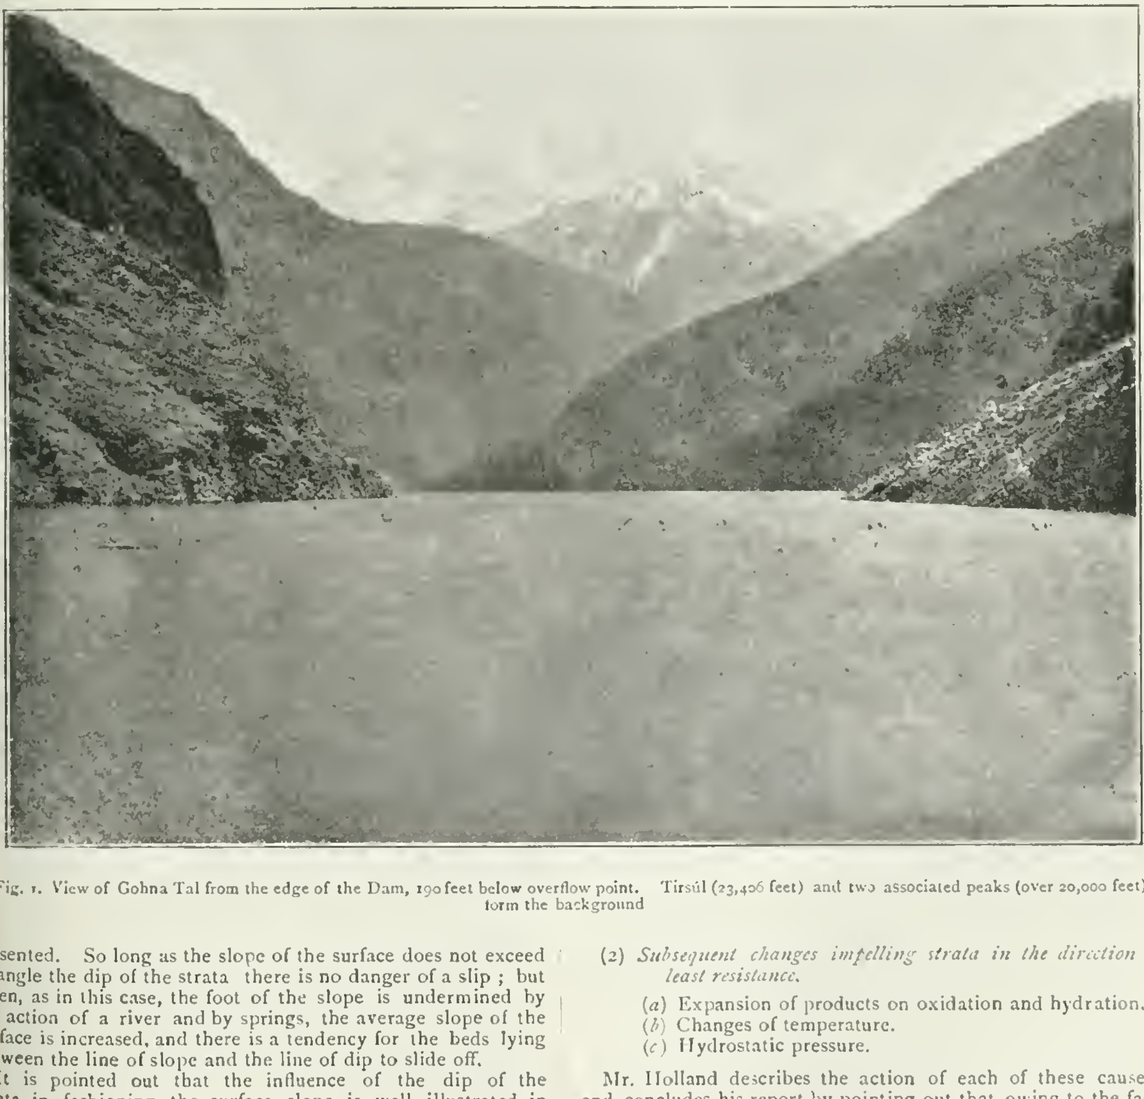

Fig. 1. View of Gohna Tal from the edge of the Dam, 190 feet below overflow point. Tirsúl (23,406 feet) and two associated peaks (over 20,000 feet) form the background

(2) *Subsequent changes impelling strata in the direction of least resistance.*

(*a*) Expansion of products on oxidation and hydration.
(*b*) Changes of temperature.
(*c*) Hydrostatic pressure.

Mr. Holland describes the action of each of these causes, and concludes his report by pointing out that owing to the fact that the folding of the Himalayan range has continued to times geologically recent, if not still in action, there has resulted a condition of strain frequently manifesting and relieving itself by earthquakes, and of steep slopes with rushing torrents, frequently resulting in landslips. When subsequently the inequalities of level have been sufficiently reduced by denudation, the slopes will be more stable, rivers less violent, and the scenery tamer—a condition of affairs exemplified by the more geologically old-fashioned peninsular portion of India. Water, the great agent of denudation, has, by its chemical and physical action, been the cause of the landslip at Gohna, but the effects of the potential energy accumulating in the lake have to be patiently awaited.

SCIENCE IN THE MAGAZINES.

In the *Fortnightly* Prof. Karl Pearson heads a forcible article on "Socialism and Natural Selection" with the following quotation from Darwin:—"What a foolish idea seems to prevail . . . on the connection between Socialism and Evolution through Natural Selection." His contribution is a diatribe against the views set forth by Mr. Kidd in "Social Evolution" and the reviewers who have hailed the work as scientific in its construction and conclusions. Dr. Louis Robinson points out the glaring moral inconsistency of the majority of anti-vivisectionists, who "while they claim to be actuated by the great principle that kindness to all living creatures should be a rule from which only the direst necessity can excuse us . . . are content to ignore the cruelties which are most wanton, most severe, and most frequently inflicted. Moreover, this strange callousness to the great mass of animal suffering is not deemed inconsistent with a frenzied onslaught on the practice of experimenting upon animals in the interest of medical science, although such experiments are deemed absolutely needful by nearly all those who know anything at all about the subject, and although the pain so caused is but as a drop in the ocean when compared with that inflicted in sport, or for monetary profit. . . . . Now what would all the good humanitarians say, if some man of science, pursuing knowledge rather than pleasure, were deliberately to smash the leg of an animal, and lacerate its flesh with some blunt instrument, and merely to save himself a little trouble, were to let it crawl about the laboratory, with a compound fracture and wounds unattended to, while he busied himself with something else? What, if he were to commence an operation on a pigeon by wrenching off a wing and gouging out an eye, and then were to stroll off to lunch, and a game of billiards, intending to come back and finish the business when he had leisure? What if he were to tear open the abdominal cavity of a rabbit, and, rather than spend a quarter of an hour in completing the operation he had begun, were callously to let it die in all the unspeakable agonies of peritonitis? What, again, would they say if, when the vicar dropped in to afternoon tea and asked about the result of the experiments, our investigator were to smile and rub his guilty hands as he replied that he had had a most enjoyable morning? And, lastly, what would they say about the vicar if on hearing this shameless avowal he joined in the abominable rejoicings of his host, and accepted a gift of the mangled carcases of the victims?"

The *Contemporary* contains a reply by Prof. Bonney to Dr. Wallace's arguments in favour of the excavation of lake basins by glaciers (*Fortnightly*, Nov. and Dec. 1893). Prof. Bonney winds up by saying: "Notwithstanding Dr. Wallace's ingenious advocacy of the erosive power of glaciers and ice-sheets, I maintain that these can excavate only under the most favourable conditions, and then but to a limited extent, and that they are proved by a close study of the Alpine peaks and valleys to have been incapable of hollowing out the great lakes of that chain."

Dr. Carl Lumholtz has been for the past three years making explorations in the almost unknown regions of the Sierra Madre in Mexico. The first of a series of papers on his discoveries appears in *Scribner's Magazine* under the title, "Among the Tarahumari." The paper is profusely illustrated from photographs taken by the author. The following extracts are of interest:—

"Cave-dwellers are found among the following tribes, counting from the north: The southern Pimas, the Tarahumaris, and the allied tribe of Huaregios, and the Tepehuanes. All these tribes inhabit the State of Chihuahua and are more or less mountaineers living almost entirely in the great Sierra Madre range. Of these people the Tarahumaris are most attached to caves, the Tepehuanes the least. All are linguistically related. In some of their customs and manners they also greatly resemble each other, while in others, as well as in character, they are strikingly different. Very little that may be called accurate was known of these tribes. The Tarahumaris, the most primitive of them and the least affected by Mexican civilisation, are the most interesting."

As to the relation of these people to the cliff-dwellers of the south-west, Dr. Lumholtz remarks: "Are the cave-dwellers related to the ancient cliff-dwellers of the south-western part of the United States and northern Mexico? Decidedly not. Their very aversion to living more than one family in a cave, and their lack of sociability, marks a strong contrast with the ancient cliff-dwellers who were by nature gregarious. The fact that people live in caves is in itself extremely interesting, but this alone does not prove any connection between them and the ancient cliff-dwellers. Although the Tarahumari is very intelligent, he is backward in the arts and industries. His pottery is exceedingly crude, as compared with the work found in the old cliff-dwellings, and its decoration is infantile as contrasted with the cliff-dwellers' work. The cliff-dwellers brought the art of decoration to a comparatively high state, as shown in the relics found in their dwellings. But the cave-dweller of to-day shows no suggestion of such skill. Moreover, he is utterly devoid of the architectural gift, which resulted in the remarkable rock structures of the early cliff-dwellers. These people, so far as concerns their cave-dwelling habits, cannot be ranked above troglodytes."

Prof. N. S. Shaler, of Harvard, continues his popular studies of domestic animals with a paper on "Beasts of Burden," showing the great part they have played in the civilisation of man. The article is richly illustrated.

A chatty article on British vipers is contributed to *Chambers's* by Dr. A. Stradling. This journal also contains "Wintering on Ben Nevis," by Mr. R. C. Mossman, being a description of meteorological phenomena observed during a winter's exile in the Ben Nevis Observatory. We also note a description of some of the methods adopted by the modern pharmaceutist to make the medicines he dispenses less objectionable than formerly; an article on diamonds, and others on recent developments of photography, "The Sleep of Plants," and "Nest-building Insects."

Sir Henry Roscoe writes on "The New Education" in the *Humanitarian*, and states in his article what is being done in the way of technical instruction. The same journal is the arena of a more or less heated discussion on vivisection. Lady Burton expatiates upon "The Position of Animals in the Scale of Nature," and Dr. E. Berdoe replies to Prof. Victor Horsley's criticisms which appeared in the June number. Lady Burton suggests that criminals sentenced to death should be given the option of being experimented upon or of dying a felon's death. The same idea has been put forward by another writer. In the *Sunday Magazine* we find a concluding article on "The Stuff we are made of," by Dr. J. M. Hobson.

Sir Robert Ball must have a rather poor opinion of the readers of *Cassell's Family Magazine*, or he would not offer them such "an old, old story" as that he tells in "A Talk about the Pleiades." A few remarks on the visibility of stars in the cluster are followed by some trite conclusions upon the gregarious character of the proper motions, a vague statement as to the spectra of the components, and a description of the photography of the group. All this is illustrated by two cuts from one of the author's books and a reproduction of the plate based upon the photograph taken by the Brothers Henry some years ago. Nothing but the author's reputation would have secured the insertion of such a commonplace contribution. An article of a better stamp is his sketch of the life of Sir William Herschel in *Good Words*, being the third of a series on "The Great Astronomers." This series is evidently intended to be published in book form when completed. Misconception will certainly result, however, from the description of the discovery of Uranus. From Sir Robert Ball's account, readers are led to believe that Herschel knew that the object that came within his ken in March 1782 was a planet, as soon as he had found that it was a disc capable of magnification. But it is well known that Herschel thought the object was a comet; in fact, he announced his discovery as cometary, and it was not until some months later that its planetary nature was established by considerations of the orbit it pursued. We would, therefore, suggest to the learned Lowndean professor that he would do well to modify the following statement—"Great then was the astonishment of the scientific world when the Bath organist announced his discovery that the five planets which had been known from all antiquity must now admit the company of a sixth."

The *Century* contains the third part of "Across Asia on a

Bicycle" by Messrs. T. G. Allen and W. L. Sachtleben, an article on "Coasting by Sorrento and Amalfi," and one on "The Higbroad from Salerno to Sorrento," all of them being well illustrated.

In addition to the magazines named in the foregoing, we have received *Longman's*, containing "Polar Bear Shooting on the East Coast of Greenland," by Dr. Nansen, and "Chamois Hunting above the Snow Line," by Mr. Hugh E. M. Stutfield.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following are the speeches delivered by the Public Orator, Dr. Sandys, Fellow and Tutor of St. John's, on June 27, in presenting Sir John Bennet Lawes, Bart., F.R.S., Sir Joseph Henry Gilbert, F.R.S., and Prof. Mendeléef, for the honorary degree of Doctor in Science:—

(1) Salutamus tandem par nobile collegarum qui de agrorum cultura, de pecudum alimentis variis, experimentis exquisitis una elaborandis annos quinquaginta, magnum profecto aetatis humanae spatium, dedicarunt. Tot annorum autem labores non modo chartae fideles in perpetuum custodient, sed etiam saxum ingens nomine utroque insculptum inter posteros testabitur. Ab ipso autem "monumentum aere perennius" erit exactum, experimentis tam utilibus, tam fructuosis, munificentia ipsius etiam in posterum continuatis. Auguramur, nec nos fallit augurium, in agri culturae annalibus talium virorum nomina fore immortalia.

Duco ad vos Baronettum insignem, Regiae societatis socium, virum doctoris titulo bis aliunde merito ornatum, IOANNEM BENNET LAWES.

(2) Quos tot annorum labores una coniunxerunt, eos in laudibus nostris hodie divellere vix possumus. Constat tamen labores illos viri huiusce scientiae admirabili et industriae indefessae plurimum debere. Constat eosdem eiusdem scriptis, eiusdem orationibus, non modo in patria nostra sed etiam peregre maximo cum fructu esse patefactos. Cum collega suo summa concordia coniunctus, Plinii verba iure optimo posset usurpare: "nobis erat nullum certamen, nulla contentio, cum uterque pari iugo non pro se, sed pro causa niteretur."

> "Felices ter et amplius
> quos irrupta tenet copula."

Duco ad vos Regiae societatis socium, virum ab ipsa Regina equitem propter merita nominatum, IOSEPHUM HENRICUM GILBERT.

(3) In scientia chemica investiganda diu inter peritos quaerebatur, quaenam ratio interesset inter atomorum pondera e quibus rerum elementa constarent et vires eas, sive chemicas sive physicas, quae elementis ipsis velut propriae inhaererent. Qua in ratione penitus perscrutanda atque ad certam quandam legem redigenda nemo plura perfecisse existimatur quam vir illustris qui Siberia in remota natus, et undecim abhinc annos a societate Regia Londinensi numismate aureo donatus, hodie nostra corona qualicumque decoratur. Magnum profecto est inter tot elementa rationem certis intervallis velut circuitu quodam recurrentem observasse, eque rerum notarum observatione etiam ignota providisse. Viri huiusce ingenio etiam elementa prius inaudita mentis divinatione singulari praedicta sunt posteaque in ipsa rerum natura reperta. Quae elementa, trium gentium insignium nominibus Gallium, Scandium, Germanium nuncupata, nomen ipsius illustrius reddiderunt et Russorum famam, quantum ad ipsum attinet, feliciter auxerunt. Ergo virum de scientia chemica tam diu tamque praeclare meritum, totque titulis aliunde ornatum, hodie etiam nostrorum

> "turba Quiritium
> certat tergeminis tollere honoribus."

Newtoni certe in Academia honos ei praesertim debetur, qui etiam in scientia chemica Newtoni in vestigiis tam fideliter insistit, ut alumni nostri "qui genus humanum ingenio superavit" imaginem intuens, Lucretii verba paululum mutata possit usurpare:—

> "te sequor, o Grantae magnum decus, inque tuis nunc
> ficta pedum pono pressis vestigia signis."

Duco ad vos scientiae chemicae professorem Petroburgensem, DEMETRIUM IVANOVITCH MENDELEEF.

SCIENTIFIC SERIALS.

American Journal of Science, June.—Notes from the Bermudas, by Alexander Agassiz. The story of their present condition is practically that of the Bahamas, with the exception that at the Bermudas we have an epitome, as it were, of the physical changes undergone by the Bahamas. The development of the true reef builders, of the massive corals, is insignificant. Subsidence has brought about the existing outlines of the islands, but there is no evidence to show that the original annular coral reef was formed during subsidence. That reef has disappeared, and nothing is left of it except the remnants of the æolian ledges extending to sixteen or seventeen fathoms outside the reef ledge flats, ledges which owe their existence to the material derived from it: the former æolian hills of the proto-bermudian land.—Discovery of Devonian rocks in California, by J. S. Diller and Charles Schuchert. During the field seasons of 1884 and 1893, the U.S. Geological Survey acquired six lots of Devonian fossils, comprising about thirty species, mostly corals. They demonstrate the undoubted presence of middle Devonian deposits in California, where rocks of this age have long been looked for by geologists, more particularly since the recent discovery of Silurian fossils.—New method of determining the relative affinities of certain acids, by M. Carey Lea. This method is based on the principle that the affinity of any acid is proportional to the amount of base which it can retain in the presence of a strong acid selected as a standard of comparison for all acids. When to free sulphuric acid a salt is added in sufficient quantity to cause the whole of the sulphuric acid to saturate itself with the salt base, it is possible by means of the herapathite test to determine the exact point of such saturation. From this we can deduce the exact nature of the resulting equilibrium. A series of equilibria thus obtained with different salts enables us to determine the comparative strength of the affinities of the acids of these salts. The fact that even small quantities of weak acids added to sulphates will set free a certain quantity of sulphuric acid, can be rendered visible to the eye by a well-marked chemical reaction.—A recent analysis of Pele's Hair and a stalagmite from the lava caves of Kilauea, by A. H. Phillips. The stalagmite is of the kind characteristic of the lava caverns of Kilauea, differing very slightly from Pele's Hair in constitution, but widely from ordinary stalagmites formed by undoubted solution. They are suggestive of fused drops, which falling one on the other are at the time sufficiently plastic to be quite firmly welded together and congealed in a slightly drooping position.

Bulletin of the New York Mathematical Society, vol. iii. No. 8, May 1894. (New York: Macmillan.)—"Utility of quaternions in physics" is an analysis by Prof. A. S. Hathaway of A. McAulay's essay, which is well known to our readers (see NATURE, December 28, 1893, amongst other references). The reviewer considers it to be "of undoubted scientific value, and the work of a man of genuine power and originality," and that it will go far towards accomplishing the author's purpose of arousing serious interest in quaternion analysis.—Prof. Eneström, in a note upon the history of the rules of convergence in the eighteenth century, calls attention to two other mathematicians, in addition to those named in a notice by Prof. Cajori, in vol. ii. pp. 1–10, viz. Maclaurin and Stirling: for the former he claims "a signal place in the history of these rules."—Prof. F. Franklin concisely abstracts Dr. Franz Meyer's "Bericht über den gegenwärtigen Stand der Invariantentheorie," a work which gives a remarkably full abstract of researches in the domain of algebraic forms and Invariants.—Cajori's "History of Mathematics" (pp. 190–197) is a work which Prof. D. E. Smith submits to a searching examination, the commencement of which is a severe condemnation of great part of the book, founded on a side by side comparision of Cajori's statements with those of previous writers on the subject, which he is alleged to have copied without giving due credit to the authors cited. He states the book to be weak in bibliography, and carelessly written. Its merits are that it tells the general story of the growth of mathematics in a popular way, is well printed and "altogether an attractive piece of book-making." Not having seen the work we cannot say if this witness is true, but he certainly adduces evidence which it will be hard to rebut.—"Gravitation and absolute units of force" is an abstract of a paper read before the New York Mathematical Society by Prof. W. Woolsey Johnson. Prof. Greenhill's views are noticed. The "notes" say that in a discussion on the paper, Mr. C. S. Peirce proposed that the term "Galileo" be applied to the unit of acceleration in the C.G.S. system. We also find in them an account of the proceedings at the centenary celebration of the birth of Lobachevsky by the Physico-Mathematical Society of the University of Kazan. Further we learn that Lambert's essay (cf. our notice of the *Bulletin* for December 1893) is to be incorporated in a volume entitled "Die Theorie du Parallellinien" (Teubner, of Leipzig), to be edited by Drs. P. Stoeckel and F. Engel. The prime factor will be the "first book of the marvellous work by Saccheri, 'Euclid vindicated from every fleck,'" in which (in 1733) the two hypotheses which, besides Euclid's, are possible are developed, and all the results obtained which have been ascribed to Legendre. There is a list of new publications in higher and applied mathematics.

Wiedemann's Annalen der Physik und Chemie, No. 7.—Further electro-optical experiments, by J. Elster and H. Geitel. The capacity of thin layers of sodium, potassium, and rubidium applied to the walls of vacuum tubes of promoting the passage of a current when illuminated differs for different colours. For long waves, rubidium is the most, and potassium the least sensitive. If the layers are illuminated by polarised light the current intensity is greatest when the plane of polarisation is perpendicular to the plane of incidence. Electric oscillations of small period can be transferred to rarefied gas by illumination in presence of an alkali metal.—A new phenomenon attending the passage of electricity through badly conducting liquids, by O. Lehmann. This is a description of the formation of halos round the electrodes in a solution of pigments in water thickened with gelatine, sugar, or glycerine. Considerable disturbance is produced where the different coloured halos meet, while the rest of the solution remains undisturbed.—Experiments with Tesla currents, by F. Himstedt. The author gives an account of methods by which Tesla's experiments can be repeated with ordinary laboratory apparatus. High potential and rapid oscillations were produced by a Lecher wire combination used for producing Hertz oscillations.—On the demonstration of Hertz's experiments, by P. Drude. The author avoids the necessity of a high tension accumulator, as used by Zehnder, by allowing the sparks of the resonator to discharge an electroscope charged by a dry pile. The point behind the concave mirror is put to earth; also one pole of the dry pile, the other pole being connected with the electroscope and the sphere behind the mirror. When sparks pass, the leaves of the electroscope collapse partly or totally. This may be shown to a large audience by projecting an image of the electroscope on to a screen.—The change of phase of light by reflexion at thin films, by W. Wernicke. Under the name of "optical phase analysis" the author describes a method of detecting exceedingly minute impurities on the surface of polished glass or glass covered with a thin layer of gelatine. The influence of the play of cohesive force upon free molecules as regards their optical properties is investigated for pigments and the metals, with especial reference to silver.

SOCIETIES AND ACADEMIES.

London.

Royal Society, February 8.—"Thermoelectric Properties of Salt Solutions." By George Frederick Emery, late Scholar of Trinity College, Cambridge.

In a circuit formed by a metallic wire and a solution an electromotive force is developed proportionately to the difference of temperature between the junctions. The solution to be examined is put in a U-tube with an electrode and thermometer in each limb, round one of which is a hot water-jacket. δ is $\equiv$ E.M.F. per 1° C., unit δ being 10^{-4} volt. Experiments were made with acetate, chloride and sulphate of zinc, and sulphate nitrate and acetate of copper. δ varied considerably with concentration. The value for pure water appears to be about 8·6, but cannot be measured directly; for some salts δ increases with concentration, for others it diminishes. In all cases examined the current would go from hot to cold through the solutions. With zinc salts amalgamated zinc electrodes were used; with the copper salts the electrode used was a fine wire projecting from the end of a drawn-out glass tube. Values of δ for mixed salts seemed to show that differences from the water value are qualitatively but not quantitatively additive. Thus δ, starting from about 8·6, tends for moderate concentrations to a nearly constant value for each salt. M. Bouty, with very strong solutions of zinc chloride, found that δ rapidly diminished, whence the entire curve for all concentrations between zinc chloride and pure water would have a point of inflexion. If, keeping the salt a fixed quantity, we use mixtures of two solvents, we get a complete curve for δ. Experiments on 1 per cent. of cadmium bromide gave good results with all solvents used; with mixtures of methyl alcohol and water with alcohol, it gave the following values:—

Methyl alcohol per cent.	δ
100·0	11·3
90·0	11·0
81·3	10·76
70·0	10·4 – 10·5
50·0	10·27
30·0	9·86
18·7	9·64
10·0	8·9
0	8·15

Water per cent.	δ
100·0	7·0
98·9	6·86
90·0	5·83
75·0	5·053
50·0	4·075
25·0	4·123
0	8·15

In the first we have an inflected curve never far from the mean, in the second a small admixture causes a large drop in δ. These two pairs of solvents represent two classes. The alcohols mix quietly without chemical action, while alcohol and water mix with evolution of heat, and change in bulk.

A few experiments, believed to be entirely novel, were made on the E.M.F. in a circuit composed of two kinds of liquid with junctions at different temperatures. Zinc sulphate 4 per cent. and weak zinc chloride gave $E/(t' - t) = 1·36 \times 10^{-4}$ V.

Zinc acetate and zinc sulphate gave $E/(t' - t) = 0·8 \times 10^{-4}$ V, $1·05 \times 10^{-4}$ V, $1·13 \times 10^{-4}$ V, mean value $= 1 \times 10^{-4}$ V.

Lastly, measurements of the Peltier effect at a metal-liquid junction were made with various apparatus with fairly consistent results.

For 15 per cent. copper sulphate and copper, different measurements gave the heat evolved per unit $\equiv$ H = 0·1992, 0·1927, 0·1956, 0·2078, 0·2091, 0·1952.

The last and best gives $H/T = 6·83 \times 10^{-4} = \delta$ for the solution. Cupric nitrate with $\delta = 6·14$ gave $H = 0·1764$, $H/T = 6·1$. Thus these thermoelectric effects are of a reversible nature.

May 10.—"The total eclipse of April 16-17, 1893. Report of results obtained with the slit spectroscopes." By Captain E. H. Hills, R.E.

This paper deals with the results obtained from the photographs of the spectrum of the eclipsed sun taken in Brazil and Africa at the total eclipse of April 1893. The instruments employed, of which there were four, were slit spectroscopes of the ordinary type, and were each arranged to take one photograph during totality. Of the four resulting photographs two were partially unsuccessful and were not measured. The two others each show a strong prominence spectrum, and on both sides of this a continuous coronal spectrum, in which latter are seen a number of very faint lines. The wave-lengths of these lines were determined by using the known lines in the prominence spectrum as reference points, and from these constructing an interpolation curve. The coronal lines, whose wave-lengths were thus fixed, were, in almost all cases, apparently identical with lines which had been observed at previous eclipses, instruments of a similar type having been employed at the eclipses of 1882, 1883, and 1886.

The prominence spectrum, as shown on the photographs, extends from w.l. 3667 to w.l. 5316. It is chiefly remarkable for the extended hydrogen series, there being eight lines beyond the one at w.l. 3699, the wave-lengths of which are given as 3692·5, 3687, 3682, 3678, 3675, 3672, 3669·5, 3667.

"Researches on Modern Explosives" (preliminary communication). By William Macnab and E. Ristori.

A series of experiments with explosive compounds has been undertaken by the authors for the purpose of studying chemical reactions at high temperatures and pressures, and of elucidating certain thermal constants relating chiefly to the specific heat of gases under such conditions. Nitroglycerin, nitrocellulose, and several combinations of these two bodies, which are used as smokeless powders, have been chiefly employed in these experiments. The results given in this communication relate principally to the amounts of heat evolved by explosion in a closed vessel, and the quantity and composition of the gases produced. The following table contains the results of some of the experiments:—

Table Indicating the Quantity of Heat, also the Volume and Analysis of the Gas developed per gram with Nitro-glycerin, Nitro-cellulose, and with several different Combinations of these two Explosives made at Ardeer Factory.

Composition of explosive.	Calories per gram.	Permanent gas.	Aqueous vapour.	Total volume of gas calculated at 0 and 760 mm.	Per cent composition of permanent gases.						Coefficient of potential energy.
					CO_2	CO	CH_4	O	H	N	
		c.c. per gram.	c.c. per gram.	c.c. per gram.							
A. Nitro-glycerin	1652	464	257	741	63·0	—	—	4·0	—	33·0	1224
B. Nitro-cellulose (nitrogen = 13·30 per cent.)	1061	673	203	876	22·3	45·5	0·5	—	14·9	16·9	929
C. { 50 per cent. nitro-cellulose (N = 12·24 per cent.) / 50 per cent. nitro-glycerin .... }	1349	568	249	817	36·5	32·5	0·2	—	8·4	22·4	1102
D. { 50 per cent. nitro-cellulose (N = 13·3 per cent.) / 50 per cent. nitro-glycerin .... }	1410	550	247	797	41·8	27·5	0 0	—	6·0	24·7	1124
E. { 80 per cent. nitro-cellulose (N = 12·24 per cent.) / 20 per cent. nitro-glycerin .... }	1062	675	226	901	21·7	45·4	0·1	—	15·7	17·1	957
F. { 80 per cent. nitro-cellulose (N = 13·30 per cent.) / 20 per cent. nitro-glycerin .... }	1159	637	227	864	26·6	40·8	0·1	—	12·0	20·5	1001
G. { 35 per cent. nitro-cellulose (N = 13·30 per cent.) / 5 per cent. vaseline .... / 60 ,, ,, nitro-glycerin }	1280	627	236	863	26·7	39·8	0·5	—	12·8	20·2	1105

Results are also given when several recognised smokeless powders were fired under various conditions.

The authors are continuing their investigations, and are especially endeavouring to measure the actual temperature of explosion, in which direction considerable success has been attained.

June 7.—"Contributions to the Life-History of the Foraminifera." By J. J. Lister, St. John's College, Cambridge.

In this paper it is shown from an examination of a large number of specimens of *Polystomella crispa* (*Linn*), that the individuals of this species fall into two sets, corresponding with the forms A and B (of Munier-Chalmas and Schlumberger), which have been shown to exist in species of *Nummulitidæ*, *Miliotidæ*, and other families of Foraminifera. The two forms may be distinguished as *megalospheric* and *microspheric*, being characterised by a marked difference in the size of the chamber occupying the centre of the shell.

Associated with this difference in structure there is a marked difference in the nuclei of the two forms.

Individuals of the microspheric form, whose central chamber is about 10 μ in diameter, have many small nuclei distributed through the inner chambers. Evidence is brought forward to show that in this form the nuclei multiply at first by simple division, and that ultimately they give off portions of their substance, which become distributed through the protoplasm in the form of irregular deeply staining strands. The ultimate fate of the microspheric form was not traced in *Polystomella*.

The megalospheric form, whose central chamber is generally about 70 μ in diameter, has, in the usual condition, a single large nucleus which grows in size with the growth of the protoplasm, and passes from chamber to chamber, moving towards the centre of the protoplasm contained in the series of chambers. There is evidence to show that in this form, also, the nucleus parts with portions of its substance. Ultimately the nucleus disappears, and in its place hosts of minute nuclei (1–2 μ in diameter) are found, which eventually become evenly distributed and divide by karyokinesis, the entire protoplasm being aggregated about the dividing nuclei in spherical masses. Resulting apparently from this division, flagellated swarm cells, having a diameter of 3–4 μ, are produced, which escape, leaving an empty shell.

In *Orbitolites complanata* (*Lamck.*), in which species the microspheric form attains the larger size, specimens of this form, with young in their peripheral annuli (brood chambers) were examined. It was found that the protoplasm was withdrawn from the central chambers, being represented by the megalospheric young massed in the brood chambers. The young contain a nucleus in their primordial chamber, which maintains this position during a large part of the period of growth of this form. While the production of megalospheric young by a microspheric parent, which was recorded by Brady, was thus confirmed, the production of megalospheric young by a megalospheric parent was also observed in three cases.

The relation of nuclear characters to the two forms was analogous to that found in *Polystomella*, and a similar relation was found in *Rotalia beccarii* (*Linn.*) and *Calcarina hispida*, Brady.

In conclusion, the question of the relationship of the two forms, under which the Foraminifera present themselves, is discussed, and reasons are urged for regarding them as distinct from their origin.

The hypothesis that they represent the two sexes is negatived by the case of *Orbitolites* in which both forms have been found producing the young of the megalospheric form, a condition incompatible with the view that either is male.

It is suggested that the two forms are members of a recurring cycle of generations, and on this view it must be supposed, from the condition presented by *Orbitolites*, that the megalospheric form may, at least in this genus, be repeated for one or more generations before the microspheric form recurs.

June 7.—"Niagara Falls as a Chronometer of Geological Time." By Prof. J. W. Spencer.

Various estimates of the age of Niagara Falls already have been published, the maximum being 55,000 years, the minimum 6000. The author, after describing the topography and geology of the district, calls attention to the fact that the Niagara river in pre-glacial times had no existence. The peculiar extension of the chasm at the Whirlpool and the buried valley at St. David's belong to a separate and shallower buried valley, through which the Niagara cañon has been cut. The drainage of the tableland in ancient times was across the direction of the Niagara river, and was strongly marked by bold limestone ridges, which have only been penetrated by the Falls in modern times. Even the Erie basin emptied by a route several miles west of the Niagara.

The basement of the present river channel is described, and the discharge estimated. Attention also is called to the fact that during a considerable portion of the life of the river, only the waters of the Erie basin, or 3/11 of the whole drainage of the great lakes, passed over the Falls.

From four surveys, extending over a period of forty-eight years, the mean modern rate of recession of the Falls is found to be 4·175 ft. a year. Its rate is variable with secular episodes of rapid medial recession, followed by its cessation along the axis, but with increased lateral retreat. This cycle appears to take about fifty years. This rate is, however, excessive, on account of the geological conditions favouring the rapid modern recession, but the rate taken for the mean recession under the conditions of the modern descent of the river with the present discharge is 3·75 ft. a year.

At one time a great proportion of the lake region was covered by a single sheet, or the Warren water. Upon its dismemberment—in part, at least, by the rise of the land—one large lake was formed occupying the basins of Huron, Michigan, and Superior; and another a portion of the Erie extending into the Ontario basin. The waters in these two basins were subsequently lowered, so that they fell to their rocky eastern rims; the three upper lakes discharged by way of Lake Nipissing and the Ottawa river, and the Niagara had its birth, draining only the Erie basin. Then the Niagara river descended 200 ft. In course of time the waters subsided 220 ft. more, but eventually they were raised again 80 ft. at the mouth of the Niagara, thus reducing the descent of the river from the head of the rapids above the falls to the foot of the last rapids in its course to the lake to 320 ft. During the lowest stage, Ontario lake receded twelve miles from the end of Niagara gorge, where the falls had been located at their nativity.

After a discussion of the laws of erosion, the author sketches as follows the history of the Niagara Gorge and Falls:—

First episode: Water falling 200 ft., in volume, 3/11 of modern discharge; gorge, 11,000 ft. long; duration, 17,200 years. Second episode: river descending 420 ft., in three cascades; first stage, only the discharge of the Erie waters; length of chasm, 3000 ft.; duration, 6000 years; second stage, drainage of all the upper lake; length of chasm, 7000 ft.; duration, 4000 years. Third episode: same volume and descent as in last, but the three falls united into one fall; length of chasm, 4000 ft.; duration, 800 years. Fourth episode: volume of water as at present, the level of lower lake as to-day; first stage, a local rapid making the descent of 365 ft.; work particularly hard; length of gorge, 5500 ft.; duration, about 1500 years; the second stage as at present; work easy; length of canon, 6000 ft.; descent of water, 320 ft.; rate of recession here taken as the full measured amount of 4175 ft. a year; duration, 1500 years. Thus the age of the Falls is computed to be 31,000 years, with another 1000 years as the age of the river before the nativity of the Falls. The turning of the Huron waters into the Niagara was about 8000 years ago. A difficult question was the amount of work done in each episode. This was in part determined by the position of the remaining terraces corresponding to different stages of the river, and by the changing effects of erosion.

These terraces in the lake region have been deformed by unequal terrestrial elevation, to which the changing conditions of the river are largely due. The deformation affecting the Niagara district, since the commencement of the river epoch, amounts to 2·5 ft. per mile; east of Lake Huron, 4 ft. per mile; and at the outlet of Lake Ontario, 5 ft. per mile; all in a north-eastward direction. Taking the amount of movement in each district as representing also the proportional measure of time, then calculations can be made upon several of the beaches, and in terms of the age of Niagara their antiquity can be inferred. In the application of these results it appears that the rate of terrestrial uplift in the Niagara district is about 1·25 ft. a century; 2 ft. east of Lake Huron, and 2·5 ft. at the outlet of Lake Ontario.

These sketches lead to the conclusion that the beginning of the lake age was about 64,000, or possibly 80,000 years ago; assuming that its waters were not held up by ice-dams. If that were so, the date would be much less remote. If the present rate of uplift continues, the Falls will be brought to an end, before they have reached Lake Erie, by the diversion of the waters of the upper lakes, by way of Chicago, to the Mississippi, which change might be expected 7000-8000 years hence.

June 14.—"Flame Spectra at High Temperatures. Part II. The Spectrum of Metallic Manganese, of Alloys of Manganese, and of Compounds containing that Element." By W. N. Hartley, F.R.S.

The spectrum of manganese has been the subject of much investigation; the spark spectrum was examined by Huggins, Thalén, and Lecoq de Boisbaudran; the arc spectrum was studied by Ångström, Thalén, Cornu, Lockyer, also Liveing and Dewar; the flame spectra obtained from compounds of manganese were investigated by Simmler, Von Lichtenfels, Lecoq de Boisbaudran, and Lockyer, while Marshall Watts has given us accurate measurements of the wave-lengths of lines and bands observed in the spark and oxyhydrogen flame-spectra of spiegel-eisen, manganese dioxide, and other compounds of this metal.

Photographs of the spectra of metallic manganese and of manganic oxide were taken and compared. They were also compared with the spectra of the alloys of manganese. The periods of exposure varied from a mere flash in the case of spiegel-eisen when being poured into a Bessemer converter, to 30 minutes and even as much as 80 minutes with manganic oxide.

The leading features of the spectra of manganese and manganese oxide are the same, but they differ in detail, as may be observed by comparing the wave-lengths of the lines and bands in their respective spectra.

A striking group of lines, the most persistent in the whole of these spectra, is situated in the violet. The following measurements were made:—

4036·5	4034·9	Ångström, also Cornu.
4032·0	4032·9, 4031·8	Ångström.
4029·5	4029·4	Ångström.

June 21.—"A Contribution to the Study of (i.) some of the Decussating Tracts of the Mid- and Interbrain, and (ii.) of the Pyramidal System in the Mesencephalon and Bulb." By Prof. Rubert Boyce.

Chemical Society, June 7.—Dr. Armstrong, President, in the chair.—The following papers were read:—The crystallography of the normal sulphates of potassium, rubidium, and cæsium, by A. E. Tutton. The author shows that the whole of the crystallographical properties of the strictly isomorphous rhombic normal sulphates of potassium, rubidium, and cæsium are functions of the atomic weight of the metal which they contain. —Observations on the nature of phosphorescence, by H. Jackson. The phenomena of fluorescence, of phosphorescence in air on exposure to light, and of phosphorescence of substances in a vacuum under the influence of the electric discharge, seem to be of the same order, and consist in a response on the part of the substances to the operation of radiant energy propagated after the manner of light in undulations of short length. —Note on the viscosity of solids, by J. Dewar. The author has investigated the viscosity of solid substances by forcing them through a narrow orifice by means of a hydraulic press; many substances, such as crystalline sodium sulphate, ammonium chloride, graphite, urea, &c., easily flow under a pressure of 30-40 tons pressure on the square inch. A number of substances, such as starch, sodium chloride, &c., could not be made to flow into wire under a pressure of 60 tons on the square inch.—Boiling points of homologous compounds; part ii., by J. Walker. The formula $T = aM$ which the author has previously used to represent the boiling points of members of homologous series is now applied to a number of other such series. —The action of methyl iodide on hydroxylamine, by W. R. Dunstan and E. Goulding. Attempts to prepare β-methylhydroxylamine hydriodide by the action of methyl iodide on hydroxylamine, as described by L. de Bruyn, were unsuccessful; the main product of the reaction is a trimethylhydroxylamine salt.—The reduction products of nitro-compounds, by W. R. Dunstan and T. S. Dymond. The action of various weak reducing agents on aliphatic nitro-compounds is being examined.—Notes on meta-azo-compounds, by R. Meldola and E. S. Hanes. The authors have prepared metanitrobenzene-azo-β-naphthol and several allied compounds.—Conversion of ortho- into para-, and of para- into ortho-quinone derivatives. III. The hydroximes of the lapachol group, by S. C. Hooker and E. Wilson. The action of mineral acids on the hydroximes of lapachol and hydroxyhydrolapachol yields the same hydroxime as is obtained by the interaction of hydroxylamine hydrochloride and β-lapachone; the authors are able to deduce from these facts the structural formulæ of the substances mentioned.—The behaviour of alloys in a voltaic circuit, by A. P. Laurie. If an alloy of several metals is merely a mixture in which no actual chemical combination exists between the constituents, then the E.M.F. generated by the alloy should change gradually as the composition of the alloy changes; the existence of chemical combination should be indicated by discontinuities in the curve connecting E.M.F. and composition. The author has already shown that compounds exist in the series of Cu : Sn, Cu : Zn and Au : Sn alloys, and is applying the method indicated above to other cases.

Zoological Society, June 19.—Dr. A Günther, F.R.S., Vice-President, in the chair.—Mr. Sclater exhibited the skin of a monkey of the genus *Cercopithecus*, and pointed out that it unquestionably belonged to the local form which he had spoken of in his recent paper on the *Cercopitheci* as *Cercopithecus diana ignitus*. Mr. Sclater also exhibited the typical specimen of *Cercopithecus grayi*, Fraser, formerly in the Knowslev collection, and stated that it was the same as *C. erxlebeni*, Pucheran.—Mr. H. Scherren exhibited a bottle in which an amphipodus crustacean (*Amphithoe littorina*) had built a nest and a series of runs of sand and pieces of weed.—Prof. Ray Lankester, F.R.S., read a paper on the external characters which distinguish the two Dipnoid fishes *Lepidosiren* and *Protopterus*, and pointed out that there could be no doubt that these two forms should be referred to distinct genera.—Dr. Fowler exhibited a specimen of antlers of the fallow deer, belonging to Mr. J. A. R. Wallace, of Loch Ryan, which showed the effect of the removal of one testis on the development of antlers; and made remarks on the effect of different degrees of castration upon antlers, as shown by specimens in the museum of the College of Surgeons. The continuity of variation displayed in the total length, and lengths of brow- and tray-tines, in abnormal antlers in the Natural History Museum was also commented upon.—Mr. P. Chalmers Mitchell gave an account of his observations on the perforated flexor muscles in certain birds recently dissected in the laboratory in the Society's Gardens.—A communication was read from Messrs. R. R. Mole and F. W. Urich containing biological notes upon some of the snakes of Trinidad, B.W.I. To these notes was added a preliminary list of the species of Ophidians recorded from that island.—A communication was read from M. E. Simon containing the second portion of a memoir on the spiders of the Island of St. Vincent, based on specimens obtained through the agency of the Committee for the exploration of the Natural History of the West Indies.—A communication was read from Mr. W. E. Collinge, containing the description of a new species of slug of the genus *Janella* from New Zealand, and giving a detailed account of its anatomy.—A communication was read from Mr. R. J. Lechmere Guppy, containing an account of some Foraminifera from the Microzoic deposits of Trinidad.—Mr. Arthur E. Shipley read notes on some nematode parasites obtained from animals formerly living in the Society's Gardens.—Messrs. F. E. Beddard, F.R.S., and P. Chalmers Mitchell gave an account of the anatomy of *Palamedea cornuta* as compared with that of its allies.—A communication was read from Dr. A. G. Butler, giving an account of a collection of Lepidopterous insects made by Dr. J. W. Gregory during his recent expedition to Mount Kenia. The specimens were referred to 215 species, of which ten were stated to be new to science.

Mineralogical Society, June 19.—Prof. N. S. Maskelyne, F.R.S., President, in the chair. The following papers were read:—A chemical study of some native arseniates and phosphates, by Prof. A. H. Church, F.R.S. This paper dealt with the composition of clinoclase, linoconite, berzeliite, tyrolite, and other minerals, especially as regards the water which they contain, and the amount which is lost on drying or on heating to various temperatures. The author finds calcium and carbon dioxide to be an essential constituent of tyrolite, but in berzeliite to be due in all probability to intermixed calcite.—The occurrence of mispickel in the stewartry of Kirkcudbright, by P. Dudgeon.—A goniometer for demonstrating the relation between the faces of a crystal and points representing them upon a sphere was exhibited by Miss M. Walter. In this instrument the crystal can be turned about two rectangular axes, and each face is adjusted in the usual way by telescope and collimator; a brass sphere turns rigidly with the crystal, and by an ingenious contrivance a small mark is stamped upon the sphere corresponding to each face. The angles between the faces are then ascertained by applying a graduated great circle to the sphere.—At the invitation of the President, Dr. J. E. Talmage, of Salt Lake City, gave an account of the occurrence of gigantic crystals of selenite in Wayne County, Utah, and also described a phosphate of aluminium, so-called turquoise, recently found in Utah.

Linnean Society, June 21.—Mr. C. B. Clarke, F.R.S., President, in the chair. Mr. G. Brebner exhibited and made remarks upon specimens of *Scaphospora speciosa*, Kjellm. describing with the aid of lantern-slides the structure and mode of fructification in this and other allied algæ.—Mr. J. R. Jackson exhibited the cone of a stone pine, *Pinus Pinea*, Linn., picked up by the Comte de Paris in the Coto del Rey, Seville, which had sprouted and continued to grow for a month afterwards. This peculiarity, which had been often noticed in the larch, was said to be of rare occurrence in the pine.—Mr. Thomas Christy exhibited and made remarks on a small-berried coffee-plant from Inhambane, East Africa, somewhat similar to a variety from Sierra Leone and other parts of the West Coast. It was said to be valued for its fine aromatic bitter taste, which made it useful for flavouring beans and other material ground up and sold as coffee.—Mr. A. B. Rendle gave an abstract of a paper upon a collection of plants from East Equatorial Africa, brought home by Dr. J. W. Gregory and Rev. W. Taylor, amongst which were several new species.—A paper by the President followed, on "Tabulation Areas," in which the views of Dr. A. R. Wallace and others on geographical distribution were discussed, and the best mode of tabulating results considered. The Society adjourned to November 1.

NEW SOUTH WALES.

Linnean Society, April 25.—The President, Prof. David, in the chair.—A contribution to a further knowledge of the cystic cestodes, by James P. Hill.—Notes on Australian Coleoptera, with descriptions of new species, part xv., by the Rev. T. Blackburn. One genus and twenty-nine species from various parts of Australia and Tasmania are described as new.—On an aboriginal implement believed to be undescribed, supposed to be a hoe, by R. Etheridge. The implement described was obtained from an aboriginal tribe living on the headwaters of the Endeavour River, N.Q., about 150 miles from the coast. It consists of the columellar portion of the body-whorl of the large melon shell ground to a cutting-edge and wedged into a hole in a stick fashioned by an iron tool. The implement is probably not of local manufacture, but was obtained by barter from one of the Torres Straits Islands.—On the life-history of Australian coleoptera, part ii., by W. W. Froggatt. An account of the life-histories of beetles bred during the season 1892-3, with a notice of their food-plants.—On some naked Australian marine mollusca, part i., by C. Hedley. Under this heading a description and drawings were presented of the external appearance of *Oscanius hilli*, n.sp., a huge sea slug from Sydney Harbour and Broken Bay, of a genus not known before from the South Seas.—Observations upon the anatomy and relations of the "dumb-bell-shaped bone" in *Ornithorhynchus*, with a new theory of its homology; and upon a hitherto undescribed character of the nasal septum in the genera *Ornithorhynchus* and *Echidna*, by Prof. J. T. Wilson. The full text of the paper, a preliminary note to which was communicated at last meeting (*vide* Abstract, March 28, 1894, p. vii.). Description of a new *Isopogon* of New South Wales, by Baron Ferd. von Mueller, K.C.M.G., F.R.S. A rare plant with always entire leaves, from the margin of the Grose Valley in the more elevated part of the Blue Mountains. With the aspect of the S.W. Australian *I. longifolius*, it is most nearly allied to *I. anemonifolius*, R.Br., which occasionally produces undivided leaves (Fragmenta, vi. 238).—Description of some new species of *Araneidæ* from New South Wales, No. iv., by W. J. Rainbow.—Two new Sydney spiders are described and figured—*Drassus perelegans* and *Cyrtarachne caliginosa*, g. et sp. n.—Australian plants illustrated, No. vii.—Genus *Notothixos*, by R. T. Baker. Two forms of *Notothixos* were recorded whose characters do not agree with those of the three species recognised by Oliver and Bentham (but united by Baron von Mueller): and the whole five are figured.—List of mollusca collected at Green Point, Watson's Bay, by A. U. Henn, with descriptions of new species, by John Brazier. The specimens on which this list is based (in number 1365, representing 154 species) were contained in a discarded bottle found in a rock pool accessible only at very low tides. A genus new to Australia and several new species were recorded.—On a new *Patella* said to have been found at the Kermadec Islands, by John Brazier.—On a new Australian *Croton* and on a supposed new species of *Acacia*, by J. H. Maiden and R. T. Baker.—Under the name of *C. affinis*, a species allied to *C. [illegible]*, from near Tinteobar, was described. It differs from the latter species in the number and length of the stamens, the marked occurrence of petals, the persistent calyx under the fruit, the shape of the capsule (broader than long), which is both furrowed and deeply lobed, and the thin texture of the leaves.

Amsterdam.

Royal Academy of Sciences, May 26.—Prof. van de Sande Bakhuyzen in the chair.—Some observations on oxygen, by J. H. van't Hoff.—The remarkable fact that gaseous oxygen sometimes exhibits more energetic chemical activity in the dilute than in the more concentrated condition, has been investigated in van't Hoff's laboratory by Dr. Ewan, the course of the slow oxidation of sulphur and of phosphorus being selected for study. With phosphorus and oxygen (saturated with aqueous vapour at 20°) it was observed that for pressures of oxygen greater than 700 mm. the velocity of oxidation is excessively small or nothing at all. Below 700 mm. it increases very rapidly. This limit corresponds to that found by Joubert, below which phosphorescence begins. After reaching its maximum velocity a very simple relation exists between the rate of oxidation and the pressure of the oxygen, provided that the change in the rate of evaporation of the phosphorus, which, according to Stefan, is produced by the change in pressure, is taken into account. The rate of oxidation is then directly proportional to the pressure of the oxygen. In absence of water the oxidation also begins suddenly, but at a lower pressure (about 200 mm.). Taking into account the change in the rate of evaporation, the velocity of oxidation then reaches a maximum at a pressure which is approximately the same as that which van't Hoff formerly found to be the most favourable for the explosive combustion of phosphine. After the maximum the relation between the velocity of the reaction and the pressure could not be made out with certainty, because in dry oxygen the coating of oxide which forms on the surface of the phosphorus disturbs the regular course of the reaction. With sulphur and dry oxygen, where the slow oxidation can be conveniently followed at 160°, this relation has, however, been obtained. It appears, again taking into account the change in the velocity of evaporation, that the velocity of the oxidation is proportional to the square root of the pressure. This would appear to point to the conclusion that in the absence of water, the active part of the oxygen is only that very small part of it which is broken up into atoms. This conclusion is perhaps supported in the case of phosphorus by the composition of one of the products of the oxidation in dry oxygen, viz. P_4O.—Mr. Bakhuis Roozeboom discussed the equilibrium of solutions and solid phases formed of the system: HCl, H_2O and Fe_2Cl_6. In a three-dimensional representation the solutions which may coexist with a hydrate of Fe_2Cl_6 form a vault, whose summit lies in the melting point of the hydrate; the isotherms are not unlike half a circle. With a compound of the three components, solutions may coexist, whose compositions are represented for each temperature by a closed curve, surrounding the point which indicates the composition of the solid compound. Two of these were discovered: $Fe_2Cl_6 . 2HCl . 8H_2O$ and $Fe_2Cl_6 . 2HCl, 12H_2O$; melting points:—3° and −6°. The different ways in which the vaults for all the existing solid phases may encounter are discussed.—By diagrams and models Dr. Schoute showed that the natural connection between the homogeneous divisions of space by means of cubes and of orthic tetrakaidekahedra (*see* Lord Kelvin's paper in NATURE, March 8 and 15, 1894) is given by the known theorem, that the plane, orthogonally bisecting a central diagonal of the cube, cuts it in a regular hexagon. Every cube of a given homogeneous division in cubes, we divide into eight equal minor cubes by means of three planes, parallel to the faces. In each of these eight minor cubes we draw the central diagonal ending in the centre O of the original cube, and we divide these into two equal parts by means of planes orthogonally bisecting the diagonals. In this manner every original cube is divided into sixteen equal parts. The eight parts that surround the centre O of the original cube form a tetrakaidekahedron. The remaining "intercellular" parts form equal tetrakaidekahedra, the centres of which are the vertices of the original cubes.—Mr. Kamerlingh Onnes communicated the results of further experiments made by Dr. Kuenen in the Leiden Laboratory, "on the abnormal phenomena near the critical point." Dr. Kuenen has explained the abnormalities observed by Zambiasi, de Heen, and others, by impurities of the matter used. He has now repeated with the utmost care the experiments, from which Galitzine drew the startling conclusion, that ether above the critical temperature has very different densities according to its having been before entirely fluid or partly vapour. The differences found by Dr. Kuenen in the duly corrected densities at some degrees above the critical temperature are only slight, and probably due to the admixture of not more than a two-hundredth of a milligram of a non-coercible gas. This gas, if not air, perhaps originates by the decomposition of some ether during the sealing of the tube before the blowpipe.

BOOKS AND PAMPHLETS RECEIVED.

Books.—Alembic Club Reprints, No. 6 (Clay, Edinburgh).—Nature's Method in the Evolution of Life, 1894 (Unwin).—Climbing in the British Isles: W. R. H. Smith (Longmans, 1894).—Tourist Guide to the Continent.: N.E., 1894 (30 Fleet Street).—Elektro-chemie Erste und Zweite Liefg: Dr. W. Ostwald (Leipzig, Veit).—A Selection of Photographs of Stars, Star Clusters and Nebulæ: Dr. J. Roberts (Universal Press).—The Country Month by Month, July, 1894: J. A. Owen and Prof. Boulger (Bliss).—Elementary Treatise on Natural Philosophy, 13th edition: Prof. J. D. Everett, 1894 (Blackie).—Repartition de la Pression Atmospherique sur l'Ocean Atlantique Septentrional d'Après les Observations de 1870 a 1889: par le Capitaine G. Rung, 1894.—Returns of the Agricultural Statistics of British India and Native State of Mysore, 1892-3 (Calcutta, 1894).—Malaysian Spiders, Parts 1, 2, and 3: T. and M. E. Workman (Belfast, 1894).

THE CATALOGUE OF SCIENTIFIC PAPERS.

Catalogue of Scientific Papers (1874–1883). Compiled by the Royal Society of London. Vol. X. (London: Clay and Sons, 1894.)

WE are glad to welcome this new volume of the Royal Society's great Catalogue. In February 1892 we noticed Vol. IX., which was the first of the three volumes that are to contain the titles of papers published in the decade 1874–83. The present volume, containing the second instalment of the material for those years, forms the tenth in the entire series of that monumental piece of bibliography for which the scientific world is indebted to the Royal Society. The section of the alphabet it includes extends from *Gis* to *Pet*, covers 1048 pages quarto, and contains considerably over 30,000 entries, giving references to the papers published in some 570 different serials. In a year or two we may hope to have the concluding portion in our hands, and our only regret is that the complete index could not have been issued within the ten years following the close of the period it covers. Such a bibliography is a work of enduring value, but it is undoubtedly most urgently needed and its services most readily appreciated in the years more immediately following the dates of the papers themselves. However, if ten or twelve years should appear an over-long interval, we must remember the magnitude of the task and the fact that the Royal Society have carried out the work single-handed. The six volumes of the first series of the Catalogue sufficed for something more than six decades (1800–1863), but for the next ten years (1864–73) two volumes were required, and now three are found necessary for 1874–83. Moreover, it is probable that the proportion of important serials which the Catalogue has *not* taken cognisance of, has gone on increasing. At any rate the Society, as we know, have now found it advisable to devote a supplementary volume (which we believe is in active preparation) to the contents of these hitherto neglected series. This want of comprehensiveness, which is, perhaps, the only blemish on this great work as it stands, is the more noticeable as the selection of serials for indexing shows traces of having been either arbitrary or dependent upon some fortuitous circumstance. Thus it may puzzle a medical writer, whose work has appeared in both, to find papers of his cited from the *New York Medical Journal*, but none from the *British Medical Journal*. But no doubt the Royal Society would be the last to claim perfection for their work, for which, as it stands, they are entitled to the highest praise. These volumes are handsomely printed, the contents are easy to consult and astonishingly free from inaccuracies of any kind. This last, their crowning excellence, is one that can be appreciated best by those who make the most use of the work. Our own experience is that for checking a series of references, to turn to the Royal Society's Catalogue is practically the same as hunting up the originals themselves, and of course vastly more expeditious. And the volumes now issuing are even more easy to consult than their predecessors; for instance, the volume numbers are now given in Arabic instead of Roman numerals—a much more legible fashion and much safer, especially in the case of high numbers. Again, the year of publication is printed in heavy type, so that this vitally important particular catches the eye at once. The abbreviations of the titles of the serials remain practically as before, and though no doubt much longer than specialists are in the habit of using in their own notes and publications, they possess the great advantage which is claimed for them—that they are "so clear as to speak for themselves." For the chemist *Ber.* may be quite sufficient, but would require interpreting to his fellow-workers in other departments of science, who would recognise at the first glance the meaning of the abbreviation adopted in the Catalogue—*Berlin Chem. Ges. Ber.* Perhaps, however, so familiar a series as the oft-quoted "Comptes Rendus" might safely admit of a shorter form than *Paris Acad. Sci. Compt. Rend.*

Altogether, anyone with any acquaintance with bibliography cannot be insensible to the enormous amount of tedious labour involved in the production of these volumes. Perhaps not more than half the entries are mere reproductions of a single title and reference, the title simply transferred as it stands from its original source to its place in the Catalogue. Many titles to make them at all intelligible have had to be amplified, in some cases they have been entirely supplied, the names of new species described are filled in, and so forth; while a large percentage of the entries contain two or three, or even more references, to reprints, translations, abstracts, &c., which with such a mass of material implies a task of alarming magnitude in their satisfactory collation. Then there is the perplexing work of distinguishing rightly among the numerous authors bearing the same name—thus we count more than fifty Müllers, and nearly as many Meyers. There is, too, the initial difficulty which besets the compiler in the case of serials of general or technical character, of deciding which "papers" are proper to be indexed, and which should be passed over. The result, as presented in these volumes, is no doubt not an exhaustive enumeration o all the contributions in the whole body of scientific serial literature, but it is a catalogue of all the best and the most worth studying. More than this no bibliography is ever likely to be.

But withal the Catalogue of Papers furnishes but the one half of what is required. It furnishes the key to the workers, and only through them to the work. The complementary volumes, which should supply a direct key to the work, and thence to the workers, are still a desideratum. Until this also is supplied, equally systematically and comprehensively, the bibliography of science at large will remain regrettably one-sided, in spite of the numerous special *Records*, *Fortschritte*, and *Jahresberichte*. The fact of course is that a great Subject-catalogue or index is a far more difficult undertaking than the Author-catalogue to which it would run parallel. We all know the object to be aimed at—to enable the worker in science to ascertain readily what work has already been done upon his particular subject—and we are all agreed as to the desirability of attaining it. It is in the practical execution of the work that the difficulties come in, and there they meet us in battalions. At the outset, the co-operation of working specialist and practical bibliographer is required; but viewing the subject from different standpoints, the specialist has his ideas and the bibliographer his, and we are fortunate if we escape the familiar difficulty—*quot homines, tot sententiæ*. As to the difficulties of execution, they are, of course, primarily, how the whole system of the sciences should be divided, how far the divisions should be carried, and how the material, the particular items to be entered, should be distributed among them. For it is clear that for so vast a material no mere alphabetical index would suffice. All the contributions to one particular subject must be brought under the eye in one group, not scattered up and down through a thousand pages, according to the mere accident of the words used by the authors in their titles. The mere alphabetical arrangement attracts by its simplicity; but in a work of this extent it would be misplaced, the entries would be lost, and the exhaustive search which would always be required would take longer than the time needed to make one's self acquainted with the scheme of classification adopted, which trouble would only need to be taken once for all. There are, moreover, important collateral advantages attaching to the preparation of practically distinct indexes for the different branches of science. Not to enlarge further on the difficulties of a Subject-catalogue such as terminology, translation, consultation of originals, &c.—we would only say there is no royal road through all these obstacles. The path through them must always be a thorny one. Neither is there any standard of perfection, nor would it be attainable if there were. The best that can be expected is a sensible workable compromise. This is attainable, and we have little doubt will ultimately be attained, and so a key furnished to the whole series of contributions to the growth of every twig and branch of the tree of scientific knowledge from one end of the nineteenth century to the other. Since the inception of their present undertaking, the Royal Society have not ceased to occupy themselves with the question of a parallel Subject-catalogue, nor is it any wonder if the result has so long continued to be only negative. But with each decade the matter becomes more urgent, and to deal with it increased efforts are demanded, and greater sacrifices become justifiable. We believe that the Society are now on the eve of starting actual work upon the undertaking, and so commencing another monumental contribution to the "Improvement of Natural Knowledge."

EPIGENESIS.

Gestaltung und Vererbung. Eine Entwickelungsmechanik der Organismen. By Dr. Wilhelm Haacke. Pp. 337, with illustrations. (Leipzig: T. O. Weigel Nachfolger, 1893.)

WHILE it is correct to say that, as a matter of history, epigenesis implies merely the observed fact that the fertilised egg-cell, from which the new organism of each generation arises, is, under the microscope, a nucleated mass of protoplasm not differing from other cells, it is not so certain that the simplicity of the historical conception is any help to the problem as it exists for us to-day. For in the growth of an idea as it passes from mind to mind, there is, at the best, but a formal continuity. Most often the meaning of the word has been so added to, and so taken from, that it becomes like the famous patched coat, which contained none of the original material. For the present, the question at issue is very different from the problem of those who used the word in earlier times. We know that we must not expect to see under the microscope the character of an elephant or of a mouse stamped upon the protoplasm of the fertilised egg-cell. We wish to know whether the observed facts of development and inheritance can be co-ordinated under the idea that the protoplasm of the fertilised egg-cell is as like the protoplasm of other cells as it seems; or, under the idea of preformation, that each structure of the adult has a structural representative in the egg. But many side issues arise, and identical sets of facts really devoid of bearing upon the main question are brought forward with equal triumph by advocates of either theory. Take an example, not one that, so far as this writer knows, has been employed, but which may serve as a type. The intestine of the higher animals is very much longer than the length of their bodies, and is disposed in coils and loops. Dr. Gadow has shown that this disposition in the case of birds falls into seven or eight well-marked types which are so constant as to have high corroborative value in classification. It may well be that these varieties of twisting and coiling depend upon physical conditions, upon the relations of the growing intestine to the growth and structure of the surrounding viscera and of the skeletal tissues. Here, the advocate of epigenesis would say, are characters that need no preformation in the egg, that are stamped in due course upon its simple protoplasm. But no preformationist need suppose that the invincible elements in the germ are to grow up by their own force out of all relation to surrounding conditions. The centrifugal activities of the egg, if they exist, are there to supply those differences for which there is no cause in the outer world. They supply the factor, the resultants between which and the forces of the outer world show differences under what seem to be identical conditions.

In Dr. Haacke's book a large number of instances are brought forward in which facts of the organic world seem to be explicable by physical conditions. These are all used as arguments against preformation, and specially against Weismann and, as is the fashion just now, against the generalisations of Darwin.

Thus, under the name *Epimorphism*, he groups together a number of facts that seem to show the existence of grades and lines of development apparently independent of utility. Such are, for instance, the increase of size in organs like horns or, indeed, of whole animals; increases which in the past history of the earth have apparently actually led to the destruction of the animals in question. Again, in most groups gradual alterations of form generally leading from regular symmetry to irregular form can be traced. Specific markings, colours and so forth, as Eimer before has showed, in many cases seem to follow in regular sequences independent of utility and adaptation. The degeneration of useless or of unused organs goes on independently of direct advantage to the animals. Geographical distribution, as Dr. Haacke showed in an interesting paper, published in 1885, reveals that for most groups of animals a distribution of forms exists, such that the higher are found nearer the centre of the great land masses that radiate from the North Pole; the lower towards the ends of continents and the islands reaching down into the watery waste of the southern hemisphere. This sequence of form he now explains by an interesting view. The natural selection of individuals does not depend upon their protective or adaptive qualities, but upon their good or bad constitutions. If an insect-eating bird gets upon the track of a set of caterpillars, it is unlikely to distinguish between the slight variations they may have in protective colouration. But in the struggle between race and race, the race better protected will, on the whole, attract the attention of enemies a less number of times. The selection between individuals is a selection between the generally strong and the generally weak, between those whose life-pulse beats high and those of low vitality; not between those with an organ or an adaptation a shade weaker or stronger. The appearance of the differences between races which tend to the adaptation of some and the non-adaptation of others are due to causes independent of selection. Thus it happens that in cases where there is a wide range there are more varied local conditions, more local races, and a greater material for that competition between races which is the cause of progress. And thus where continents spread widely evolution is more rapid than in the confined areas which stretch towards the South Pole. This view is complicated by the further view that the result of crossing is not a production of variation by the mingling of characters, but an equalisation of the divergent characters of individuals.

Those who are interested in controversy will find these and a number of most interesting views and collections of facts in Dr. Haacke's book. But they are so entangled with elaborate and chiefly mathematical arguments against the views of Weismann, that they form somewhat difficult reading for the uncontroversially disposed. Moreover, they are complicated by a highly elaborate theory of Dr. Haacke's own invention. He accepts the view of Verworn that the nucleus is an organ of metabolism for the cell, and sees in the plasma with the centrosome as its organic centre, the true bearer of heredity. The plasma is composed of ultimate elements called "gemmæ." These are rhombic prisms, the ultimate shape of which is as proper to protoplasm as are the shapes of inorganic crystals to their chemical compositions. These "gemmæ" are built up into "gemmaria" by association into variously shaped layers and rods. The shape of the "gemmaria" determines the shape of the whole organism, and a number of ingenious references of symmetry to hypothetical gemmarial structures are given. The "gemmaria" of a whole organism are identical, and by a system of attractions and repulsions remain in a condition of equilibrium. But outer forces acting upon any part of the organism disturb this system of equilibrium until the organism settles down into a new position of equilibrium. As the germ cells contain gemmaria like all the gemmaria of the body, outer changes cause a new condition of equilibrium in them, and this new condition naturally is the starting-point of the new organism. The differences between individuals are chiefly differences between the degrees of closeness in which the gemmæ of "gemmaria" are attached to each other. Those with weak attachment have weak constitutions, and in each generation are weeded out. In sexual union, the primary cause of which is the attraction between similar crystalline systems, the inequalities of attachment between the gemmæ are redressed.

It is perhaps unnecessary to add that Dr. Haacke considers that acquired characters are inherited, but that it is absurd to expect any proof of this inheritance, as, he says, the whole organic world is a proof of it, and because without it epigenesis would be impossible.

AGRICULTURAL ENTOMOLOGY.

Handbook of the Destructive Insects of Victoria. (Prepared by order of the Victorian Department of Agriculture.) By C. French, F.L.S., Government Entomologist. Part II. (Melbourne: 1893.)

TWENTY notorious insect pests are dealt with in this volume, each being illustrated by a coloured plate, which shows not only the metamorphoses of the insect, but the nature of the mischief of which it is the cause. The chapter on each insect is complete in itself, and there is no definite order of treatment of subjects; nor in a volume of this character was any such sequence called for. Arranging the insects systematically, however, it is found that the Homoptera are represented by the green peach aphis, the black peach aphis, the orange aphis, the grape louse, the cabbage aphis, the cottony-cushion scale, the oleander scale, the lemon scale, and the red scale of the orange; the Coleoptera by the plum curculio, the cherry green beetle, the apple root-borer, and the strawberry beetle; the Lepidoptera by the orange moth, the case-moth of the orange, the vine moth, the silver-striped vine moth, the potato moth, and the cabbage moth; and the Neuroptera by the so-called "white ant," *Termes australis*, Hagen. With three or four exceptions, therefore, most of the insects dealt with are pests of fruit trees, and not more than half a dozen of them have acquired notoriety in England.

As the main object of the work is to supply to growers information as to the means whereby they may protect their crops against the ravages of injurious insects, we naturally look for very full information under this head, and it must be admitted that the author has admirably acquitted himself in this respect. In addition to the concise details of methods of prevention and of remedy given under the head of each pest, there is a well-illustrated appendix, containing descriptions of the various kinds of apparatus which are coming more and more into use for insecticidal purposes. Several appreciative references are made to the ingenious English-made spraying machine known as the "Strawsonizer"; but the light knapsack modifications of this apparatus, termed the "Antipest" and "Notus" respectively, are of too recent introduction to find a place in the volume. The list of insecticide materials given in the first volume of the work is supplemented here by a further series. Moreover, as part i. contained a list of the insectivorous birds of Victoria, so part ii. contains a list of the fruit and grain eating birds of the colony. We are glad, also, to note the many references to insectivorous insects: for it is quite as important that a cultivator should know what insects to protect and encourage, as to recognise those which it is to his advantage to suppress. Several of the coloured plates afford illustrations of the insect foes of insect pests, and not merely of the familiar hymenopterous parasites, but of such friends to the cultivator as the species of Syrphus which devours the cabbage aphis, and of the Australian ladybird, a species of Novius, which orange-growers both in Australia and in California have found so effective an ally in keeping their groves free of the dreaded cottony-cushion scale, *Icerya Purchasi*, Maskell.

In noticing the first part of this work we appealed to the author to add to its international value by appending in every case the authority for the systematic name. We are glad that Mr. French has been able to adopt this suggestion. The agricultural entomologists of the United States are great offenders in this respect: indeed, they sometimes give no systematic names to the injurious insects which are made the subjects of their bulletins, whilst they not infrequently coin trivial names which are certainly not elegant, though they may be expressive. Hence it becomes difficult to know with any degree of certainty what is the precise species referred to; confusion consequently arises, and the bulletin has only a local value. In connection with the trivial names themselves, there is room for improvement. For instance, in the volume before us, descriptions are given of the "green peach aphis" and the "black peach aphis"; but as it is the aphis and not the peach to which the colour refers, the names "peach green aphis" and "peach black aphis" would be more descriptive. This is no mere quibble, for in the volume itself the principle is conceded in the name of the "cherry green beetle." In the year 1892, when *Plutella cruciferarum*, Zell.—an insect described in this volume as the cabbage moth—wrought tremendous destruction amongst the cruciferous crops of England and Scotland, the newspapers teemed with descriptions of the ravages of the "diamond-back turnip moth." This naturally led to inquiries, perhaps ludicrous, as to the nature of diamond-back turnips; but our Board of Agriculture set a good example by describing the pest in an official leaflet as the "turnip diamond-back moth," and thus reverting to the name by which John Curtis made the insect familiar half a century ago.

We welcome this second instalment of a valuable publication, and trust Mr. French may be encouraged to bring to a successful conclusion a work of the highest economic importance to agriculturists and horticulturists.

OUR BOOK SHELF.

Proceedings of the Edinburgh Mathematical Society. Vol. i. Session 1883. (London: Williams and Norgate, 1894.)

From time to time we have noted the annual volumes of this Society from vol. ii. to vol. xi., which appeared last year. The volume before us fills up a lacuna and now makes the series complete. In the early days of the Society the publication of *Proceedings* was not contemplated, and when an accession of members rendered publication possible, the cost of printing absorbed the major part of the funds, and each session's subscriptions have only sufficed for the current session's volume. Some few years since a special appeal was made and funds sufficient to warrant publication obtained. The result is the admirable piece of geometrical work before us. For, in fact, the volume is almost entirely one man's work. The first president was Dr. J. S. Mackay, whose edition of Euclid for the Messrs. Chambers in 1884 gave ample evidence that there was an elegant and specially learned geometer in our midst. The article on "Euclid" in the *Encyclop. Britannica* confirmed this discovery. It has been long known that Dr. Mackay had large stores of notes, and we are glad to find that he has found an outlet for much of this interesting matter. At the second meeting of the Society the president read a paper on the triangle and its six scribed circles. A portion of this paper was given in abstract in vol. ii., and was considerably enlarged in vol. xi., under the heading "History of the Nine-point Circle." In the long interval, with the permission of the Council, Dr. Mackay has amassed a collection of notes, divided into twenty sections, filling more than 1600 quarto pages of manuscript. A selection has been made which most nearly corresponds with what was actually communicated to the Society in 1883. The nine-point circle is accounted for above. The sections embraced in the present instalment treat of the centroid, the circumcentre, the incentre, the excentres, the orthocentre, Euler's line, relations among the radii, and area. They occupy pp. 6–128, and are accompanied by sixty-eight lithographed figures. Each property is traced back, as far as can be ascertained, to the first discoverer, the author having had the assistance of French, German, and Belgian mathematicians in addition to the aid of personal friends in Great Britain. The result is a rich repertory of almost, if not quite, all that is known on the special points indicated above.

We sincerely hope that Dr. Mackay may be recouped for the vast amount of work he has gone through, and the expense to which he has been put, by an appreciative and purchasing audience. This will encourage him to put his remaining notes into the hands of some publisher, or possibly he may adopt the present mode of publication.

The only other paper is a collection of notes on Plucker's first equation connecting the singularities of curves, by Dr. C. G. Knott. These are printed in the form in which they were handed over to the committee eleven years ago.

The Starry Skies. By Agnes Giberne. (London: Seeley and Co., 1894.)

This small book will be found a very useful addition to the series in which it is published. It is written in a clear and intelligible style, and should just suit those young readers who wish to obtain some of the more elementary ideas about the world on which we dwell, the moon, and the planetary and stellar systems in general. Great tact seems to have been shown throughout in the choice of suitable examples for giving the reader a good mental grip of distances, sizes, shapes, &c., of the heavenly bodies, without over-burdening his or her mind with too much detail. The clear print and the not too liberal use of dark type render the book very pleasant reading, while the questions and answers at the conclusion of each chapter will be serviceable. The illustrations throughout are very good indeed; the majority of them being excellent reproductions from the more or less important recent photographs. Among them we recognise Roberts' Andromeda nebula, the Pleiades, a fine Orion picture, cluster in Hercules, and several others nearly equal in quality. As a book for the young, we can heartily recommend these pages on the starry skies.

W. J. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

New Army Regulations.

IT appears, from the letter in the daily papers of yesterday, signed by the Headmaster of Eton, that the headmasters are beginning to cry out under the smart of the rod they have made for their own backs. When, five or six years ago, Latin was made a compulsory subject for the Army Entrance Examinations, I for one, as a schoolmaster, welcomed it in that capacity, from its value as a mental discipline, and as a remedy to some extent for a certain illiterateness and incapacity for accuracy of expression, which one met with too often in Army candidates. But it was soon found that the position assigned to it was taken advantage of by men of non-scientific education, as a pretext for driving science into the background, and making it contemptible in the eyes of boys and parents, by a considerable curtailment of the time previously given to it, and then, with Egyptian logic, wondering that the marks fell off.

I do not say that the headmasters were altogether to blame for this. The spirit of the cram-shop has invaded the public schools, and is utterly spoiling their intellectual life; and, when this spirit allies itself with other motives, the pressure may be too strong for the most noble-minded headmasters. But they, like other mortals, must reap as they sow, and accept the results of their policy. Their intellectual incapacity as a body to appreciate the value of scientific training *per se* is the fault, not so much of themselves, as of the traditions, which still hold the dominant place in this country, among those in whose hands their appointment rests. I sincerely hope that all will be done, that can be done, to minimise the mischief with regard to Latin, which is deprecated in the circular; but I do trust that, for the public weal, the military authorities, having "put their foot down," will remain firm in insisting upon *all candidates for the scientific branches of the Army being trained, not crammed, in Experimental Science.* This they will doubtless do with their hands strengthened by the strong Committee which has been dealing with the matter in its relation to Woolwich during the last two years.

When we recollect that back in the '70's and the earlier '80's, though Latin was a *voluntary subject*, classical scholarship continued to flourish in the public schools, it is difficult to read without a smile the alarmist predictions contained in Dr. Warre's letter, as to what is likely to ensue from what he calls "the degrading of Latin from Class I., and making it a voluntary subject." The headmasters have had their opportunity, and had they, in the spirit of their intellectual ancestors of the sixteenth century, shown more magnanimity towards the "New Learning" of the nineteenth century, this rude shock to their intellectual consciousness might have been unnecessary.

Looking at the matter now from the outside, one can perhaps see the true perspective of the whole better than one could while in the thick of the fray.

A. IRVING.

Hockerill Vicarage, Herts, July 6.

Erosion of the Muir Glacier, Alaska.

DR. WRIGHT, in his "Ice Age in North America," has calculated that the Muir Glacier erodes its bed annually to the depth of one-third of inch (p. 64), and Prof. Harry Fielding Reid, in his very interesting "Studies of the Muir Glacier" (*American National Geographical Magazine*, March 21, 1892, p. 51), arrives at the still more startling result of three-quarters of an inch per annum. As one who has paid some attention to rates of denudation by various eroding agencies, I felt some curiosity to know in what way these figures were arrived at. I find that these two calculations are substantially the same, the difference arising from Prof. Reid crediting the whole of the erosion to the glacier bed which occupies only half of the watershed of 700 square miles.

As this rate of erosion is nearly 244 times that of the glaciers of Norway descending from the Justedalsbræen, calculated from the observations of Prof. Amund Helland (*Q. J. G. S.*, 1877, vol. xxxiii. p. 158), and is altogether an abnormal and unprecedented rate of erosion of any agency we know of that acts over so large an area, I think most geologists will agree with me that before it can be accepted we must be satisfied that the data are reliable and beyond question.

Dr. Wright unfortunately gives no particulars of the method adopted of sampling the sub-glacial waters, or the number of specimens taken, or the times and circumstances under which they were taken, all of which form material elements in the calculation. He contents himself with the bare statement that —"The amount of sediment contained in each United States gallon (231 cubic inches) of water collected from the sub-glacial streams is, as determined by the analysis of the late Prof. H. C. Foote, of Cleveland, 708·48 grains.

This proportion of sediment is nearly eighty-five times the mean of that from the sub-glacial rivers of the Norwegian glaciers descending from the snow and ice field of Justedalsbræen, and nearly twenty times the mean of the sediment from seven of the sub-glacial rivers of Greenland (*Q. J. G. S.*, 1887, p. 158), as observed and recorded by Amund Helland.

It will be seen from these bare figures that this prodigious calculation requires some explanation. It is certainly a wonderful amount of "work" to credit a glacier with that only moves 2555 feet per annum at the surface in its central position, and of course at a considerably less average rate on its bed.

The American geologists have supplied us with so much and such accurate information on many points which could not be investigated in this country, that I trust those who are able will help to correct this little sum.

T. MELLARD READE.

Park Corner, Blundellsands, June 7.

IN response to the questions contained in the communication by Mr. Reade, I would say that the estimations, both of Prof. Reid and myself, concerning the erosion of the Muir Glacier are based upon a specimen of water collected by me from a large sub-glacial stream issuing from near the south-east corner of the glacier at a height of about 150 feet above tide-level. This stream is only one of many which issue from the ice-front; but it is practically the only one from which any calculations could be safely made. At two or three places where the front of the glacier is pushed out into tide water, powerful sub-glacial streams issue, boiling up at low tide with great force just in front of the ice, and discolouring the water of the inlet for miles beyond. The head of the inlet is a mile and a half wide, enlarging very soon to nearly twice that distance. The water in the middle is more than 100 fathoms deep.

The appearance and everything else indicated that the stream chosen for examination was truly representative. It was a rushing torrent from ten to fifteen yards wide, which could be waded with difficulty. The specimen was collected about the middle of August 1886, when the melting upon the surface of the glacier was proceeding at its maximum rapidity, so that the volume of water was probably much larger than the average through the year. Prof. Foote had a high reputation for accuracy, and kindly analysed the water for me, evaporating the entire amount and distilling it, so that after he had weighed the sediment the identical elements were reunited, and, as I write, it stands before me as characteristic a specimen of glacial milk as one can anywhere find.

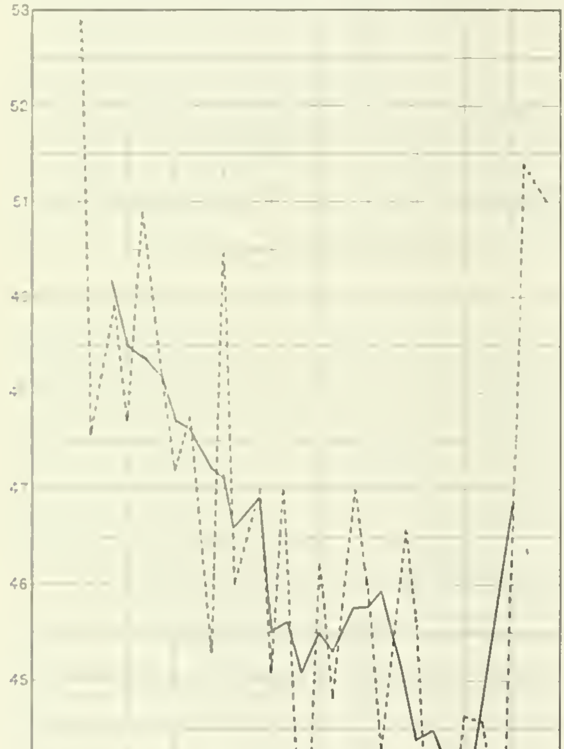
As stated in my "Ice Age in North America" (p. 64), the estimates of erosion are based upon the supposition that the total rainfall in the drainage basin of the Muir Glacier is the same as at Sitka, namely, 100 inches, and that a certain proportion of this passes off as icebergs and in evaporation, and that the balance which is carried away by subglacial streams is properly represented by this specimen. Of course if there is any serious error in either of these data it will affect the result. But I can scarcely believe that the error can be so great as to account for all the difference between our calculations and those made concerning the erosion of glaciers in Norway and Greenland; for the conditions are very different in the Muir Glacier from those either in Norway or in Greenland, as observed by Helland. The glaciers of Norway have a very slow movement as compared even with Prof. Reid's estimate of the movement of Muir Glacier; while in Greenland the continental proportions of the ice and the unknown conditions of the country upon which it rests quite preclude comparison; for it is evident that the best of the Muir glacier has a rapid gradient, while it is not certain that the best of many of the Greenland glaciers has any gradient at all. Judging from Helland's description of the appearance of the sea-water in the fiords of Greenland, I should think it was much less milky than that of the Muir inlet in Alaska.

I am thankful to have had my attention called to the subject by Mr. Reade just upon the eve of departure for a few weeks among the glaciers of Umenak Bay, in Greenland. I will give special attention to the subject, and report upon my return in the autumn. G. FREDERICK WRIGHT.

Oberlin, Ohio, June 23.

On a Recent Change in the Character of April.

THE months are all, of course, continually changing in temperature, rainfall, &c. And, as a rule, those changes are not long in one direction; the curve of variation has many zig-zags. Yet, by methods of averaging, one may sometimes detect a gradual process of change extending through a good many



years; we might compare it to the slope of an ocean-swell underlying the surface-ripples. The mean temperature of April at Greenwich is a noteworthy example of this.

Here are the values since 1865, and averaged in fives in a second column:

	M.T. April.	Av.		M.T. April.	Av.		M.T. April.	Av.
1865	52·9	—	1875	47·0	47·6	1885	47·6	46·1
66	48·6	—	76	48·0	47·9	86	46·6	45·4
67	49·9	50·2	77	46·1	46·5	87	44·2	45·5
68	48·7	49·5	78	48·0	46·6	88	43·5	45·1
69	50·9	49·4	79	44·5	46·1	89	45·7	44·6
70	49·2	49·2	80	47·2	46·5	90	45·6	45·2
71	48·2	48·7	81	45·8	46·3	91	44·2	46·8
72	48·8	48·6	82	48·0	46·7	92	46·9	47·8
73	46·3	48·2	83	47·0	46·7	93	51·4	—
74	50·5	48·1	84	45·3	46·9	94	51·0	—

Thus from a maximum of 50°·2 in 1867, the average went down, with some slight interruption at one point, to 44·6 in 1889 (*i.e.* 5·6 degrees), the extreme actual values being 52°·9 in 1865 and 43°·5 in 1888 (difference 9·4 degrees). Last year and the present yield values in marked contrast to those just before, and a pronounced rise appears in the average curve.

The data for Paris and Geneva give results very similar, so that the process is not merely local. Thus the smoothed values for Geneva descend from 10°·6 C. in 1864 to 7°·9 in 1889.

A general, though less continuous, decline in the mean temperature of the entire spring (March to May), at Greenwich, may also be noticed.

I do not know whether any cause can be assigned for prolonged changes like these in April: some of your readers may be able to throw light on the matter.

The accompanying diagram illustrates the change referred to.

A. B. M.

The Deposition of Ova by "Asterina Gibbosa."

I RECENTLY brought back from Jersey three specimens of *Asterina gibbosa*, all of which deposited ova in the small aquaria in which they were kept. As it appeared evident that the ova exuded from the oral surface, two specimens were selected for experiment.

The first was placed with the oral surface uppermost in a small glass well, with just sufficient water to cover it. When examined about half an hour later, ova had exuded from a genital pore on the oral surface, and had floated up to the top. Had the opening been on the aboral surface, they would have been retained beneath the starfish.

The second specimen was then placed in a glass dish with the aboral surface uppermost. Sufficient water was added to allow the animal to be moved easily with a pair of forceps, but not enough to enable the tube-feet to act. Consequently ova, if deposited, could not float away. In this position it was left for about an hour. When turned, so as to bring the oral surface uppermost, it was seen that ova had exuded. The starfish was killed with the eggs still adhering.

The sexes of starfish are generally said to be separate. But in this case only three specimens were brought: all deposited ova, and in one small aquarium there are now young Asterinas.

HENRY SCHERREN.

BIFILAR PENDULUM FOR MEASURING EARTH-TILTS.

INSTRUMENTS designed for measuring movements of the earth's crust belong to two classes. The first consists of seismographs which register the amplitude and period of the rapid vibrations of earthquake-shocks, and by their records enable the velocity and acceleration of an earth-particle at any instant to be determined. The second class includes nadiranes and various forms of pendulums (such as the bifilar pendulum here described) which are, or should be, unaffected by vibrations of short period, and which indicate only slow tilts or bendings of the ground, showing the change of inclination at any spot, the rate at which it is taking place, and, if periodic, the length of its period. No part of the earth, so far as we know, is free from such movements. Every day, and every year, the surface of the ground at any spot tilts forward and backward through a small angle, perhaps not exceeding a small fraction of a second. Sometimes regular pulsations are observed, each a very few seconds or minutes in duration, and lasting, it may be, for hours; at other times the tilting is irregular and occasionally abrupt; but invariably it is so slight, and takes place so slowly, that without the aid of refined instruments it could never be perceived.

The report of the Earth Tremor Committee (British Assoc. Report, 1893, pp. 291–303), presented at the last meeting of the British Association, contains an account of a new bifilar pendulum designed by Mr. Horace Darwin, and of some of the first experiments made with it at Birmingham. This preliminary trial brought to light one or two slight defects which Mr. Darwin has endeavoured to remedy in the latest form of the instrument, of which a description is given in the present article.[1] The objects of the improvements are (1) to lessen the disturbing effects of the changes of temperature which take place in the neighbourhood of the instrument, and (2) to enable the angular value of the scale-divisions to be determined with greater ease and accuracy.

The chief novelty, both in the old and new forms of the bifilar pendulum, is the introduction of the double-suspension mirror for the purpose of magnifying the movements of the pendulum. This method was used by the Messrs. Darwin, at the suggestion of Lord Kelvin, in 1881, but it was also employed ten years earlier by M. Delaunay at the Paris Observatory.[2] In the latter case, however, the pendulum had a suspending wire 30 metres in length, and was installed in a deep pit, in which the effects of changes of temperature were so great that the successful working of the instrument was impossible.

The Double Suspension Mirror.—A small mirror, M (Fig. 1), is held in a light frame, from the upper edge of which there project two hooks or eyelet-holes, H H'. The mirror hangs by these on a fine silver wire or a silk thread, W, the ends P and P' being attached to two supports very close to one another. In the figure

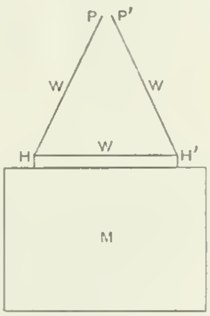


FIG. 1.

these are shown in the same horizontal line; but this is not essential. All that is necessary is that the horizontal distance between them should be small.

It is evident that the wire must always lie in a vertical plane passing through the centre of gravity of the mirror and its frame. If, then, while the point P' remains fixed, the point P be slightly displaced at right angles to the plane of the wire, it follows that the mirror must turn through the same angle as the line P P'. To take a numerical illustration, let P P' be one millimetre, and suppose the displacement of the point P to be one-thousandth of a millimetre, then the mirror will turn through an angle of 3' 26", a ray of light reflected by the mirror will turn through an angle of 6' 52", and consequently the image of the source of light upon a scale three metres distant will move through about six millimetres.

If the distance P P' be diminished, the angle through which the mirror turns for a given displacement of the point P is increased, and the arrangement becomes more sensitive. In the position of the supports shown in Fig. 1, the thickness of the wire imposes a limit to the sensitiveness that may be attained. But if one support is placed above the other, the horizontal distance between them may be made as small as desired. It will be seen that this arrangement is the same as that in Mr. Darwin's pendulum, and therefore, in physical investigations in which the double-suspension mirror is used, the vertical distance between the points of support should be small, otherwise the accuracy of the results may be affected by the occurrence of earth-tilts.

If the support P were rigidly connected with the end of the pointer of a delicate balance, the plane of the mirror being perpendicular to that of the beam, the delicacy of the balance will, as Dr. Poynting has shown, be greatly increased. This is, in fact, the method used by him in his recent determination of the density of the earth.[1] Or, if the support P were attached to the bob of a pendulum, the movements of the latter might be magnified many hundred times, and the most minute earth-tilts be rendered visible. Here we have in principle the apparatus employed by Messrs. G. H. and H. Darwin to investigate the lunar disturbance of gravity. Their inquiry, as is well-known, did not lead to the desired result, the movements due to the action of the moon being masked by the much larger ones produced by the continual tilting of the earth's surface.[2]

The Bifilar Pendulum.—The modified form of the bifilar pendulum was designed by Mr. Horace Darwin for

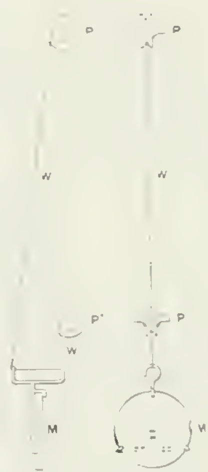

FIG. 2. FIG. 3.

the special purpose of observing and recording these earth-tilts and pulsations, the points in which it chiefly differs from that used in 1881 being that the mirror itself is the bob of the pendulum, and the whole instrument is much smaller. Fig. 4 is a sketch of the complete instrument, while Figs. 2 and 3 show the manner in which the mirror is suspended.

A circular mirror, M, about 20 mm. in diameter, hangs by two small hooks on a very fine silver wire, W.[3] The ends of this wire are fixed to two points, P P', in the instrument, one of them very nearly vertically over the other. The distance between these points is about 180 mm. If the instrument be tilted about a horizontal line in the plane of the wire, the point P will be displaced relatively to P' in the direction at right angles to that plane, and the mirror will in consequence turn round a vertical axis. At a short distance from the mirror is a lamp with a translucent disc in front, and the reflection of this disc in the mirror is observed by a fixed telescope. The stand supporting the lamp and disc is moved along a scale, and the position on the scale is read when the

[1] I am indebted to Mr. Darwin for notes about the changes made in his pendulum, as well as for the loan of the electros of Figs. 2-4. The pendulum was made by the Cambridge Scientific Instrument Company. One, of the improved form, has recently been placed in the Royal Observatory on Calton Hill, Edinburgh.

[2] British Assoc. Report, 1881, pp. 93-126; 1882, pp. 95-119.

[3] The plane of the mirror is arranged at right angles to the plane of the suspending wire, in order that heat effects may as far as possible be eliminated. (See British Assoc. Report, 1893, pp. 300-301.)

image of a wire in front of the disc coincides with the cross-wire of the telescope. The change of readings gives the tilt of the earth's surface about a line parallel to the plane of the wires supporting the mirror. Or, keeping the source of light fixed, a continuous record can be taken on a moving piece of photographic paper, and the value of the instrument will of course be greatly increased.

If the instrument be tilted about a horizontal line at right angles to the plane of the suspending wire, the only effect is to alter the horizontal distance between the points of support, P P, and therefore to change the sensitiveness. If the tilt be about any other horizontal line, it may be resolved into two components, one about a line parallel and the other about a line perpendicular, to the plane of the wire. The first of these deflects the mirror, the second alters the sensitiveness; but this change of sensitiveness is nearly always very small, and may as a rule be neglected, because the displacement of P is always very small compared with the horizontal distance between P and P. It will be obvious, however, from these remarks that the instrument is only capable of measuring tilts, or components of tilts, in one definite direction. For a complete knowledge of any given movement, it would be necessary to have a combination of two such instruments placed with the planes of their suspending wires at right angles to one another.

The body of the instrument consists of a copper tube fixed into a heavy gun-metal casting, containing a small chamber very little larger than the mirror, and covered in front by a glass window. Each end of the fine silver wire is attached to a small pulley, and the axles of the pulleys are gripped tightly so that the weight of the mirror is not sufficient to turn them. A strong copper frame carries the pulleys, and can be easily removed from the instrument, thus rendering possible the delicate operation of manipulating the silver wire. The bottom of the frame rests in a hollow cone inside the instrument just above the window; and the length of the silver wire is adjusted by turning the copper pulleys so that the mirror hangs in the small chamber facing the window. The top of the frame is pressed by a spring against the point of a micrometer screw, and can move only in a straight line in the direction of the screw, which is at right angles to the plane of the suspending wire.

A turn of the screw thus tilts the frame of the instrument about a line parallel to the plane of the wire. Knowing the dimensions of the frame and the pitch of the screw, the tilt caused by one turn, or given fraction of a turn, of the screw can be calculated, and the corresponding change of scale-reading determined. The screw is turned through a small angle by means of a lever (Fig. 4), and adjustable screw-stops are arranged at the bottom of the lever so as to allow it to move through only that amount which will make the frame tilt through an angle of two seconds. The lever is moved by a rocking-arm turned by means of two small bellows, into which air is forced by squeezing two india-rubber balls connected with them by long tubes.

The instrument stands on three screw-feet, which are turned by two tangent-screws fixed to long rods. The ends of these rods are shown in Fig. 4. The tangent-screws are arranged so that turning one will tilt the instrument about an axis parallel to the plane of the suspending wire, and will therefore move the spot of light sideways, so that, when it has nearly left the photographic paper, it is easily brought back to the required position without approaching the instrument. Turning the other screw tilts the instrument about an axis perpendicular to the plane of the suspending wire, and this alters the sensitiveness.

When the ends of the silver wire have been fixed to the pulleys, and the frame, to which the latter are attached, has been inserted in the instrument, the copper tube is completely filled with paraffin oil. If the frame is tilted, the mirror then comes to rest very slowly, and rapid

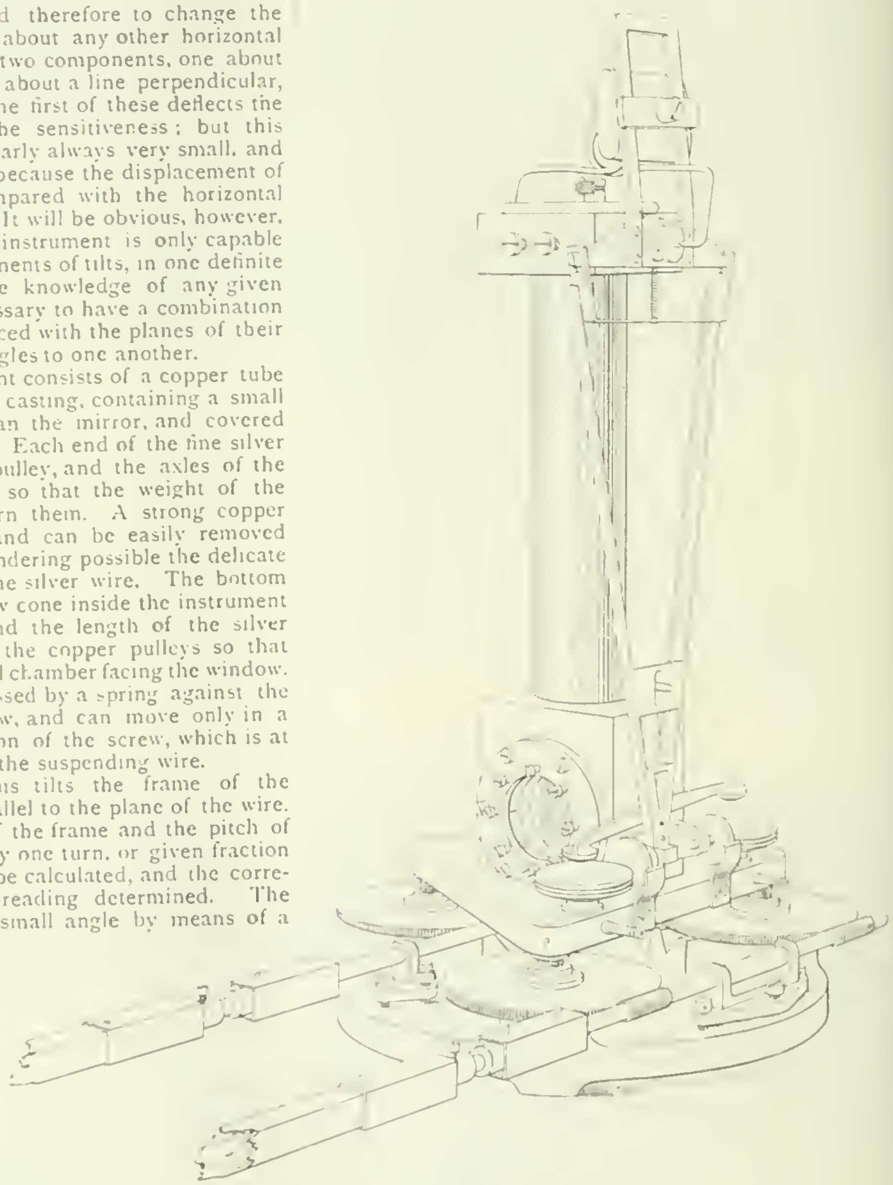

FIG. 4.

vibrations, like those caused by passing carts and trains, do not affect it. Thus the pendulum is designed, not so much for the study of earthquakes, as for the investigation of slow tilts and pulsations of the earth's crust, by whatever cause they may be produced.

Delicacy and Uses of the Bifilar Pendulum.—In the pendulum with which the preliminary experiments were made at Birmingham, the vertical distance between the points of support of the silver wire is one foot, while the horizontal distance between them is about $\frac{1}{250}$ of an inch. If the instrument be tilted through an angle of one second about a line parallel to the plane of the suspending wire the mirror turns through an angle of 49′, and the magnifying power of the instrument is therefore very nearly 3000. A scale is placed at a distance of ten feet, and 3·44 inches of this scale correspond to a tilt of one second. If the lamp be displaced by $\frac{1}{100}$ of an inch, the movement can be clearly perceived. It follows, therefore, that it is possible to observe with this pendulum a tilt of less than $\frac{1}{300}$ of a second, an angle less than that subtended by a line an inch long placed at a distance of a thousand miles.

It would seem, then, that the bifilar pendulum is admirably adapted for measuring the minute changes of level, which are perhaps the cause of some of the uneliminated errors in many astronomical and physical inquiries. Indeed, it may be hoped that the time is not far distant when a pendulum of this kind will be regarded as a part of the ordinary equipment of every great observatory. Again, the bendings of the earth's crust by changes of barometric pressure,[1] by the ebb and flow of the tides, &c., may be studied, as well as the long-period pulsations produced by violent earthquakes in almost any part of the world. It is not too much to expect, also, that in time we may be able to trace out and measure the slow secular movements of the earth's crust which, after the lapse of ages, become perceptible to the geologist; and that the vexed question of the origin of lake-basins may receive an answer that will remove this most debatable of subjects from the domain of controversy for ever.

C. DAVISON.

THE SPECTRUM OF OXYGEN IN HIGH TEMPERATURES.[2]

AT a previous meeting, I brought before the Academy a method, founded on the use of electricity, of bringing gases under pressure to a high temperature without heating sensibly the recipients which contain them.

Before rendering an account of the experiments already made on oxygen by means of this method, I shall mention first those which have preceded them, and in which temperatures not exceeding 300° have been realised by means of a line of gas jets playing directly on the tube containing the oxygen.

The arrangement was as follows:—A steel tube ten metres long, lined inside with red copper, and closed at its extremities by glass, according to our ordinary modes of closing, was placed in a trough containing a sand-bath. This trough was immediately warmed by a line of a hundred gas jets. The temperature of the tube was taken by means of thermometers metallically connected to the tube.

After having introduced the oxygen at the required pressure, and before the heating of the tube has begun, a good spectrum of a luminous light source is obtained, the beam being thrown along the tube in such a way that any change in the spectrum brought about by heating the gas is perceptible.

When the jets are lighted, the spectrum changes in proportion, as the temperature increases at the same time as the pressure. If the experiment is well conducted, the the pressure of the gas at the end, that is to say, when lights have been extinguished and the temperature has become what it was at first, returns to its original value. To obtain this result there must be no loss of gas during the experiment.

This loss of gas is caused principally by the lengthening of the pins that unite the pieces of steel which hold the glasses at the extremities of the tube. In order to prevent this lengthening, bands of brass have been placed between the heads of the pins and the disk, the length of which has been calculated to compensate by their expansion that of the pins. Thus the same degree of pressure is obtained at all temperatures.

The experiments have been made with varied pressures of oxygen. They show that from the ordinary temperature up to about 300° the bands and lines of the spectrum of absorption of oxygen do not undergo modification.

But quite a new feature is produced. A remarkable point is the very remarkable augmentation of transparency of the gaseous column with the increase of heat, a transparency revealed by a considerable augmentation of the brightness and the limits of the spectrum, above all on the side of the red. I shall have to return to the theoretical consequences of this important fact.

To ascend further in the scale of temperatures, it is necessary to make use of the platinum spiral tube rendered incandescent by the passage of the current.

I will not repeat the general arrangement of the experiment already described. The incandescence of the

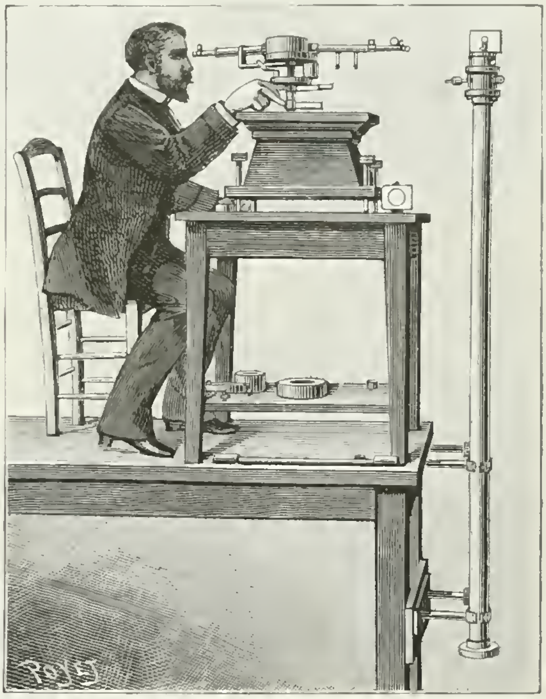

FIG. 1.—Experiments with a vertical tube and incandescent spiral.

spiral is more difficult to obtain if the pressure of the gas is greater.

The temperature to which the spiral is carried can be determined in different ways:—(1) The thermo-electric couple; (2) the observation of the increase of the pressure of the gas caused by the passage of the current; (3) and finally, the brightness and length of the spectrum given by the incandescent spiral, when it furnishes the light alone.

The experiment works thus:—

The tube being placed in a vertical position, the lamp, which must produce the beam to be analysed after its passage in the tube, is first regulated, and then the spectrum analysing apparatus is arranged. Pressure is then put on, and the constitution of the spectrum having been well observed, a current is made to pass, the power of which is proportional to the temperature which has to be obtained.

[1] Such observations would gather additional interest if made in the neighbourhood of a great line of fault.

[2] A communication made by Dr. Janssen to the Paris Academy of Sciences. Translated from *La Nature*.

The pressure increases immediately, and stops when equilibrium is established. The spectroscopic phenomena are always followed and compared at the beginning and when equilibrium is established.

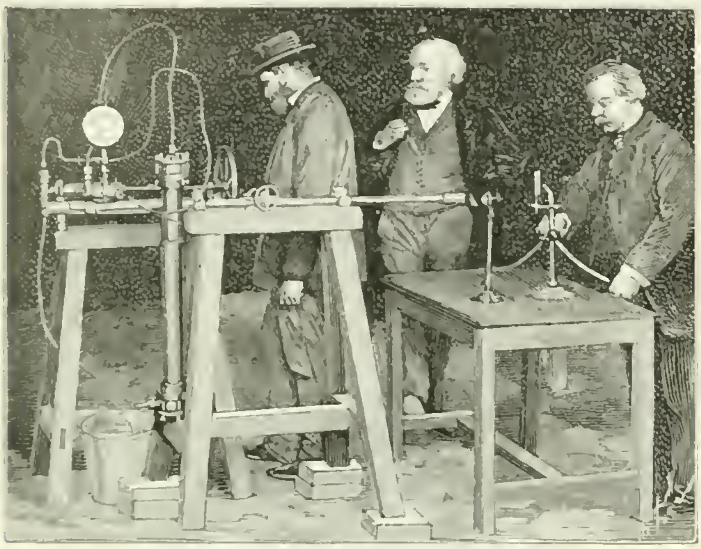

FIG. 2.—Apparatus for experiments at high pressure.

In the experiments made with the tube of two metres in length, and with gaseous pressures up to 100 atmosphere, perceptible modifications in the length of the spectrum observed have not been noted. The attained temperatures have been estimated between 800 and 900°, according to the spectrum given by the spiral.

To obtain higher temperatures it is necessary to increase the power of the electric generators, and that is what it is proposed to do; but it must be observed that the solar phenomenon point of view, it is the exterior and middle parts of the coronal atmosphere which interest us most. It is those which, if they contain oxygen, would, above all the others, produce steam, by reason of their lower temperatures. But temperatures of 800 and 900°, which have already been realised, correspond to the deep parts of the coronal atmosphere, and in these, as well as in those which are more exterior, and consequently colder, the absence of oxygen may be affirmed.

PHOTOGRAPH OF A LANDSCAPE IN LIVING AND DEAD BACTERIA.

A FILM of living bacteria in Agar was distributed over very thin (cover-slip) glass sterilised, this thin glass alone separated the film from the negative. After exposure over a mirror for two hours, and then forty-eight hours' incubation, the bacteria behind the transparent parts of the negative were killed; those behind the opaque parts developed normally; those partly protected were retarded, giving the half tones. The photograph was sharper when first made, several weeks before reproduction.

NOTES.

LORD KELVIN has been awarded the Grande Médaille of the Société d'Encouragement pour l'Industrie Nationale of Paris, for his scientific works. Among other awards we note the following: 3000 francs to M. Dulac for a means of diminishing smoke at industrial centres; 1000 francs to MM. Fuchs and de Launay for their work "Gîtes Minéraux"; and 500 francs to M. Chapel for his "Caoutchouc et la Gutta-Percha"; 2000 francs to Prof. Roberts-Austen for his work on alloys (see NATURE, June 7); 1500 francs to M. Pagnoul; and 500 francs to the Société d'Agriculture in the Meaux district, for investigations on the comparative physical nature and chemical constitution of the soils of certain regions.

AFTER a long illness the Right Hon. Sir Henry Layard passed away on July 5, at the age of seventy-seven. His excavations at Nineveh and Babylon, and his travels through various parts of Asia, have made his name eminent among archæological investigators and discoverers.

WE regret to record the death at Paris of M. Mallard, the Professor of Mineralogy in the Ecole Nationale Supérieure des Mines.

THE *Times* correspondent at Calcutta telegraphs that, since the beginning of the rainy season, the water in the Gohna Lake has been rising about two feet daily, and is now 160 feet from the top of the dam. As percolation has begun through the dam, and is increasing with the increased pressure, it is thought that the overflow will probably not occur before the middle of September.

A REUTER telegram from St. John's, dated July 7, states that the Peary Auxiliary Expedition has sailed on board the steamer *Falcon* for Inglefield Gulf, Greenland, to bring home Lieut. Peary's party. They will call at Carey Island, where the Swedish naturalists Bjorling and Kallstenius were wrecked in the schooner *Ripple* in 1892, and will also search at Cape Faraday and Clarence Head to ascertain the fate of the naturalists. The party will explore Jones's Sound and make a chart of the coast, returning to Bowdoin Bay for Lieut. Peary on September 1. The expedition is expected to return by September 20. Dr. Ohlin, the Swedish zoologist, and Messrs. Chamberlain and Libbey, represent the scientific side of the party, which is under the leadership of Mr. Bryant.

Dr. M. A. Veeder informs us that the Jackson-Harmsworth Polar Expedition, which starts from London to-day (see p. 255) for an extended sojourn in the Arctic regions, will co-operate in observation of the aurora upon the concerted plan which is in use by a large number of observers in various parts of the earth, and by the expeditions of Lieut. Peary and Dr. Nansen. This, together with what has already been done, insures the continuance and perfecting of these observations, which are having results that promise to be of great practical value both to astronomical and meteorological science, as well as to the study of physics in general.

At the last meeting of the Physical Society it was announced that in future the meetings of the Society will be held in the rooms of the Chemical Society, Burlington House. Since its foundation in 1874 the Society has met in the Physical Lecture Theatre of the Royal College of Science.

Violent earthquake disturbances were experienced in Constantinople on Tuesday afternoon. The first shock occurred shortly after noon, and is said to have lasted twenty seconds. Another wave was felt at four o'clock. In both cases the direction of motion appears to have been from east to west. About the same time, a severe earthquake was also felt at Smyrna and Scio, and in the Dardanelles.

Miss Ormerod, writing to the *Times* of Saturday last, mentions that bad attacks of the grass-destroying caterpillars of the antler moth are now occurring in some localities in Scotland. She says that in 1884 these caterpillars devastated an area of about ten miles in extent of the mountainous parts of Glamorganshire, and in 1885 spread over an area of about seven by five miles in Selkirkshire, N.B. The district infested at present is that in which the voles not long ago did so much damage, and Prof. Wallace reports that the caterpillars are doing even more mischief than the voles.

Thunderstorms again occurred in nearly all parts of Great Britain on the 6th inst., and were reported at places during several subsequent days; the disturbance appears to have been caused by a shallow barometric depression advancing northwards from the south-west of France. The thunderstorms were again preceded by abnormally high temperatures, especially over the eastern and southern parts of England, where the thermometer rose above 85°, while at Rochefort, in France, the maximum temperature in the shade rose to 99° on the 5th. Some very heavy falls of rain have also been reported, the total in two days amounting to about three inches in the south-west of Ireland, and quantities of considerably over an inch in twenty-four hours fell in Scotland and the south of England. The average rainfall since the beginning of the year has now been about reached, or exceeded, in all districts except the midland parts of England; in Scotland the average has been exceeded by about five inches.

At a Council meeting of the Pharmaceutical Society of Great Britain, last week, Mr. Martindale moved the following resolution:—"That after the first day of January, 1895, a practical knowledge of the metric system of weights and measures shall be required of all candidates for the Minor examination in the subjects of prescriptions and practical dispensing, and that the Board of Examiners be instructed to require from candidates a general knowledge of posology in terms of the metric as well as the British system of weights and measures as defined by the British Pharmacopœia, 1885; and in practical dispensing 'to weigh, measure, and compound medicines' by the metric as well as the British system of weights and measures." After some discussion the resolution was altered to the effect that the Board of Examiners should be requested to consider the advisability of acquiring a practical knowledge of the metric system of weights and measures for the Minor examination. In this form it was carried.

We regret to note that the recently issued report of the Council of the Marine Biological Association states that there is no immediate prospect of a satisfactory boat being obtained by the Association: the question is purely a financial one, and its solution is only to be found in the generosity of public companies or private individuals. The Council points out that it is impossible that a sea-going boat can be purchased out of income, so long as the revenue of the Association is so small. During the past year the work of collection has been largely carried out by means of hired vessels, a method both expensive and unsatisfactory. As to scientific investigations, we read that, during the past year, both Mr. Cunningham and Mr. Holt continued their inquiries into the various questions relating to the maturity of food-fish which were so prominent last year before the House of Commons Select Committee on Sea Fisheries, and upon which much information is still required. More important, perhaps, is the fact that Mr. Cunningham has finally settled by direct experiment the much-debated question of the identity of the egg of the pilchard. He has been able to rear the larvæ of plaice, hatched and fertilised in the aquarium at Plymouth, to the age of thirty-seven days; no flat-fish larvæ had previously been reared in confinement from the ovum to this age, and the result is of great economic value.

The German Fisheries Association offers prizes of 800, 1000, and 600 marks, respectively, for the best works on the following subjects:—(1) Simple, trustworthy, and generally applicable methods for the determination of the gases oxygen, carbonic acid, and nitrogen found in natural waters, or at least of the first two, special importance being attached to methods independent of the higher resources of the chemical laboratory. Competitors to send in before June 1, 1895. (2) Investigations concerning the pathological and anatomical effects upon fishes of the following bodies found in drain-waters:—Free acids, free bases, especially lime, ammonia, soda, and the soluble carbonates of potash and soda; free bleaching gases, such as chlorine and sulphurous acid. Further, the determination of the symptoms of suffocation from these causes. Partial and even negative answers are not excluded. Representatives of the Salmonidæ and Cyprinidæ families are recommended for investigation. Papers to be sent in before November 1, 1896. (3) The development and conditions of life of the water fungus *Leptomitus lacteus*, and its appearance and disappearance in polluted waters. Papers to be sent in before November 1, 1895. All papers for the competition are to be sent in registered envelopes to the General Secretary, Prof. Dr. Weigelt, Berlin, S.W., Zimmerstrasse 90, 91. They may be written in German, French, or English, and are to be provided with a motto and with the name and address of the author in a sealed envelope bearing the same motto. The object of the Association is to throw light on the pollution of natural waters by animal and industrial refuse. The withdrawal of the gases mentioned, which have an intimate relation to the amount of putrifying matter, is difficult to prove. The symptoms of death due to pollution by free acids and other poisons are not as yet very well known. Sugar and starch factories send drain-waters into the rivers, which offer ample sustenance to the white river algæ, especially *Leptomitus lacteus*. These may be regarded as having a purifying effect, but the decomposition of the dead floating masses gives rise to further pollution. An examination of the habits of this plant appears, therefore, highly desirable in the interests of the inland fisheries. The judges are Drs. Fleischer, König, Tiemann, Hermann, Nitsche, Virchow, Halwa, Kirchner, Magnus, and Weigelt.

AN investigation by Prof. W. J. Sollas, F.R.S., "On the Relation of the Granite to the Gabbro of Barnavave, Carlingford" (*Trans.* Royal Irish Academy, vol. xxx. part xii. 1894), has added facts of considerable importance to what was previously known about the mountain groups of Carlingford and Slieve Gullion, which rise from the centre of the Palæozoic tract of the counties of Lough and Armagh, and represent the remains of extinct volcanoes of the Tertiary period. From an examination of the district, and a study of rock-sections from it, the following statements are deduced:—(1) The gabbro of the Carlingford district is older than the granite which penetrates it. (2) The gabbro was already completely solid, traversed by contraction joints, and, probably, fractured by earth movements before the injection of granophyric material. (3) The granophyric material was in a state of great fluidity at the time of its intrusion. The granophyric dykes are in no case contemporary veins. The results of the investigation suggest to Prof. Sollas some reflections on the difficult question of the "differentiation of originally homogeneous igneous magmas." In his opinion, "much more attention must be given to the investigation of the details of the now prevalent differentiation hypothesis before it can be regarded as established on a firm basis." In fact, the importance of this paper as a contribution to physical geology is liable to be overlooked, owing to the topographical nature of its title; but it soon becomes apparent to the reader that the close intermingling of rocks of different composition which has taken place at Barnavave, is not likely to be an exceptional occurrence. The proofs of microscopic penetration of the gabbro by the granite, until a bulk-analysis of any specimen would be most misleading, are interesting to all geologists, and practically open a new field of observation. A severe blow is struck at the whole theory of "segregation veins," or "contemporary veins," which has perhaps been maintained too academically and without complete confirmation in natural exposures. It is worth noting that this memoir is issued separately by the Royal Irish Academy, like all published in their *Transactions*.

IN a paper published in the *Electrotechnische Zeitschrift*, in which he described a new form of gas voltameter, Prof. Kohlrausch expressed his surprise that the gas voltameter was so seldom used for measuring currents. The reason for this state of affairs is probably to be found in that the form of gas voltameter ordinarily in use is both inaccurate and troublesome to use. A new form of gas voltameter has recently been devised by Herr H. A. Naber, of Amsterdam, which embodies several improvements. The burette in which the gas evolved (either hydrogen or oxygen) is collected, can be turned about a vertical axis, so as to bring its lower end over the electrode, and thus start or stop the collection of gas at any given time without breaking the current passing through the voltameter. By means of an auxiliary vessel into which air can be driven, the level of the liquid inside and outside the burette can be made the same, so that there is no correction to be applied to the barometric pressure in order to find the pressure under which the gas is measured. The burette is fitted with a tap, so that the oxygen or hydrogen evolved can be passed into another vessel and collected. The whole of the apparatus is constructed of glass, except, of course, the electrodes, which are of platinum, and are so arranged that the two gases evolved can never possibly mix, and thus cause an explosion, if by any chance the platinum of the electrodes becomes exposed to this mixture of gases.

A NEW form of automatic steering compass has been invented by Lieut. Bersier, of the French Navy, and a very full description is published in *La Nature* for June 25. The difficulty with any form of automatic compass is that any arrangement by which the compass card makes or breaks a mechanical contact when the course deviates from a straight line will interfere with the free set of the needle. Lieut. Bersier, in his compass, uses a spark from a Ruhmkorff coil, which passes between a metal point on the edge of the compass-card and one of two semicircular metal plates fixed to and insulated from the sides of the compass bowl. These metal plates are connected to two small electromagnets, and when the electric current which forms the spark passes, it closes the circuit of a small motor which actuates the steering gear. If the spark passes to one plate the motor works in one direction, while if the spark passes to the other plate the motor works in the reverse direction; so that it is only when the point on the card is half-way between the two metal plates that the rudder is amidships. It is said that the new compass has been tried in the French Navy for several months past, and has given entire satisfaction, which, considering the very delicate and complicated nature of the mechanism employed, is very remarkable. The new form of compass can be made to automatically register the course steered, the spark being caused to pierce a band of paper which is moved by clockwork.

IN a short paper communicated to the Johns Hopkins University *Circular*, Mr. A. S. Mackenzie describes some experiments he has conducted to test the validity of the Newtonian law of attraction for crystalline and isotropic masses at small distances. In discussing the elastic solid theory of refraction in physical optics, it is often customary to introduce an optical density which may be different in different directions. In uniaxal crystals there are two such directions, and in the case of Iceland spar the square roots of the densities are as 1·486 to 1·658. Thus the question arises, does this property depend upon the distribution of the mass with reference to the optic axis? and if so, could a crystal attract a particle in a manner dependent upon the position of the particle with reference to the optic axes of the crystal, so that it would act as if it were of greater mass (and therefore density) in one direction than in another? It is to elucidate this point that the author has been conducting a series of experiments, using for this purpose a form of apparatus which, at any rate as far as the magnitude and suspension of the attracted masses are concerned, resembles that used by Prof. Boys. The apparatus, however, is designed for relative rather than absolute measurements. Although the greatest divergence between any two results only amounted to 1 part in 200, no difference in the attraction of a crystalline mass along, and at right angles to, the axis was discovered. A second set of experiments was undertaken in which the attracting masses were isotropic, but in which the distances between the attracting and attracted masses was varied, with a view of testing the law of the inverse square of the distance. The form of apparatus used seems particularly ill-suited to test this point, as the distances between the centres of the masses are very hard to measure. The author, however, says these distances could be measured to within $\frac{1}{10}$ mm., and he finds that while the deflections as calculated, assuming the correctness of the inverse square law for distances of about 7·4, 5·5 and 3·6 cm. between the centres of the large and small masses were as 1 : 2·05 : 5·25, while the observed deflections were as 1 : 2·04 : 5·24. So that the Newtonian law has been found to be true for the attractions of non-isotropic, and for istropic masses at distances apart as small as 3 or 4 cm.

IN the *Modern Medicine and Bacteriological Review* for May, attention is called to a subject which is attracting special interest just now amongst bacteriologists—the existence of sub-varieties of microbes of specific species. We have frequently referred in these notes, directly and indirectly, to the polymorphism exhibited by one and the same variety of micro-organism when submitted to different conditions of environment, &c., whilst Prof. Percy Frankland has repeatedly shown how the power of fermenting various solutions may not only be imparted to particular microbes by suitable training, but also removed from them. M. Péré has recently shown that there exist many sub-varieties of the bacillus *coli communis*, and Dr. Sanarelli has demonstrated the same in a series of investigations, conducted under Prof. Metchnikoff, for the typhoid bacillus, whilst the list of pseudo and other cholera vibrios is fast becoming unmanageable. The desirability of a due recognition of the fickleness of microbes to prescribed forms, &c., in the diagnosis of disease, where the bacteriological evidence is regarded of first importance, is obvious to all; whilst at the same time it is but one of the difficulties which a larger horizon has placed in the path of the bewildered bacteriologist. The other microbial notes are mainly on subjects already reviewed in these columns, whilst the medical articles are too technical to admit of reference here.

An interesting account of hereditary malformation of the hands and feet is contributed by Drs. W. Ramsay Smith and J. Stewart Norwell to the *British Medical Journal*. In the subjects examined, the malformations in the hands affected the middle and ring fingers. These fingers were webbed to the tips, and the bones were disposed in an extraordinary manner. For instance, on the left hand the tip of the middle finger looked as if it were twisted in front of the ring finger, while the nails, which in the right hand were in the same plane, formed in the left a well-marked angle with one another. Each foot of the subjects had six toes. The second and third toes were webbed almost to the first interphalangeal joints, and the first and sixth toes up to the nail, while the fourth toe was comparatively free. It is not so much the striking abnormalities that are interesting, however, as the persistency and consistency with which the malformation has affected several generations. Taking back the history of the case as far as they could investigate it, the authors found that twenty-one out of twenty-eight of the family were malformed. An important point in this record is that malformation of the hands was always associated with malformation of the feet. In no instance was there a malformation of the hands alone or of the feet alone; and the malformation, as far as could be ascertained, showed very little variation. Another point is that it seemed to go very much in the female line. It is also remarkable that the wife of one of the subjects had been married previously, and had borne three children by her first husband, nevertheless all the children of the second husband inherited the malformation possessed by him.

Messrs. Blackie and Son have published the third part of Prof. F. W. Oliver's translation of Prof. Kerner's "Natural History of Plants."

Messrs. Williams and Norgate have issued a list of new scientific works published in German, French, and other foreign languages. The list is No. 59 of their scientific series of foreign book circulars.

We have received an advance copy of the eleventh annual report presented to the Chemical Section of the American Association for the Advancement of Science, by the Committee on indexing chemical literature. The report consists of a descriptive list of bibliographies published during last year.

Some very interesting reminiscences of the late Rev. Leonard Blomefield, together with a portrait of him, are given by Mr. H. H. Winwood in the *Proceedings* of the Bath Natural History and Antiquarian Field Club (vol. iii. No. 1). Mr. Blomefield was the founder of the Club, in 1855, and took the warmest interest in its work up to the time of his death in September last.

Part ii. of volume lvii. of the *Journal* of the Royal Statistical Society has just been published. Mr. Charles Booth's paper, "Statistics of Pauperism in Old Age," and the discussion on it, as submitted at the meeting of the Society in March, is contained in this number. The paper forms the first part of a volume since published by Messrs. Macmillan. Two other papers are included in the *Journal*, viz. "Conditions and Prospects of Popular Education in India," by Mr. J. A. Baines, and "Modes of Census-Taking in the British Dominions," by Mr. R. H. Hooker.

We stated some time ago that the United States Hydrographic Office was collecting information with the view of publishing a monthly Pilot Chart of the North Pacific Ocean. The first chart, for the month of July, has now been issued, and contains, among other useful information, data showing the calms and prevailing winds, the currents, and mean isobars drawn for Greenwich noon, for that month. The chart is at present far from complete, because of the limited number of observations in unfrequented portions of the ocean; nevertheless it is a good beginning, and no doubt the appeal made to observers to co-operate in the work will eventually enable the hydrographer to fill in the details where they are now wanting.

Every student of physics knows Deschanel's "Natural Philosophy," by Prof. J. D. Everett, F.R.S. For many years this treatise, and that by Ganot, have been the standard works for classes in elementary physics, and the thirteenth edition, just published by Messrs. Blackie and Son, will enable this position to be maintained for some time to come. It is well known that the work is not merely a translation; in fact, Deschanel's "Traité de Physique" only forms a basis upon which Prof. Everett has constructed an invaluable text-book. So many are the additions to the new edition that three pages of the volume are taken up with the enumeration of them. The work has been entirely recast, much of the old matter has been rearranged, and new matter has been largely introduced. Part II. contains a new chapter on Thermodynamics, in which free use is made of the methods of the Differential Calculus. An explanation of entropy, Dewar's experiments, and Van der Waal's theory with respect to the departure of gases from Boyle's law, are among the many additions to this part. Two new chapters have been added to Part III. (Electricity and Magnetism), and much of the antiquated matter has been omitted. Very extensive changes have also been made in the optical portion of Part IV., and a new chapter has been introduced dealing with systems of co-axal lenses. These judicious revisions and expansions have resulted in the production of a work which bears the same relation to physics of to-day that the original treatise did to the state of physical knowledge at the time of publication. The work may, therefore, be expected to be just as successful in the future as it has been in the past.

The nature of the explosive decomposition of the ammonium and mercury salts of diazoimide, N_3H, forms the subject of a communication to the *Annales de Chimie et de Physique*, by MM. Berthelot and Vieille. The ammonium salt, N_3NH_4, was obtained in large, brilliant, transparent crystals by the method of Curtius, the action of ammonia upon diazohippuramide suspended in alcohol and recrystallisation from water. The crystals may be handled without much danger of explosion if due care is taken. They sublime at the ordinary temperature *in vacuo*. The pressure produced during their explosion has been determined in a small steel cylinder provided with piston and registering apparatus; a similar cylinder of copper was burst by the violence of the explosion. The pressure produced was found to be equal to that of one of the gunpowders recently tested by M. Berthelot, but the combustion appears to be a relatively slow one; the temperature of deflagration is about 1350–1400°. Hence the ammonium salt of diazoimide is a remarkable explosive on account both of the force developed during explosion and of its low temperature of deflagration. The products of the decomposition are ammonia, hydrogen and nitrogen. The ammonia was actually liquefied in the cylinder. The temperature is not sufficiently high to dissociate ammonia, so that there is first a decomposition into ammonia and diazoimide and then a subsequent decomposition of the latter into its elements. This probably accounts for the extreme force of the explosion, the energy which would otherwise have been absorbed in effecting the dissociation of the ammonia being available in the explosion. The mercurous salt of diazoimide, N_6Hg_2, was obtained by precipitating a dilute aqueous solution of the ammonium salt with mercurous nitrate. The precipitate requires very careful washing and drying, owing to its highly explosive character. Its explosive decomposition is extremely rapid, analogous to that of fulminate of mercury, and the temperature of deflagration high, about 2700°. The mercuric salt, N_6Hg, may be conveniently obtained from the mercurous salt by decomposing it with sulphuric acid, and treating the solution of diazoimide thus prepared with freshly precipitated yellow mercuric oxide. The greater portion of the salt separates as a white precipitate, but it is somewhat soluble in cold water, and very considerably soluble in hot water, from which long acicular crystals are deposited on cooling. It is the most dangerously explosive of the salts investigated, and the experiments have unfortunately had to be abandoned on account of serious accidents to M. Berthelot's assistants. It is much more sensitive and therefore more dangerous than fulminate of mercury, and explodes when least expected and in a most violent manner. It furnishes the same volume of gaseous products of decomposition as fulminate of mercury.

THE additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. Conrad W. Cooke; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mrs. Wheeler; a Cheetah (*Cynaelurus jubatus*) from Somali-land, presented by Mr. William Mure; four Hedgehogs (*Erinaceus europaeus*), British, presented by Mr. F. C. Smith; two Senegal Touracous (*Corythaix persa*) from West Africa, presented by Miss E. B. Redwar; a —— Falcon (*Falco*, sp. inc.) captured at sea, presented by Mr. Arthur L. Sclater; four —— Anolises (*Anolis*, sp. inc.) from North America, presented by the Southern Curio Company; a Crowned Lemur (*Lemur coronatus*) from Madagascar, three —— Opossums (*Didelphys*, sp. inc.) from South America, deposited; two Obsolete Tinamous (*Crypturus obsoletus*) from Brazil; a Smooth Snake (*Coronella laevis*) from Austria, purchased; three Indian Cobras (*Naia tripudians*) from India, received in exchange.

OUR ASTRONOMICAL COLUMN.

THE SPECTRUM OF THE ORION NEBULA.—Two papers on the spectrum of the nebula in Orion are contained in the current number of *Astronomy and Astro-Physics*, one by Prof. J. E. Keeler, and the other by Prof. W. W. Campbell. The former observer photographed the spectrum of the nebula many times during last winter. A comparison, of the photographic and visual observations of nebular lines, with dark lines in the spectra of the Orion stars, indicates that an intimate relation exists between the two. "Indeed," says Prof. Keeler, "taking into account the relative intensities of the lines, the spectrum of Rigel may almost be regarded as the nebular spectrum reversed." Spectroscopists will remember that Dr. Huggins obtained an anomalous spectrum of the Orion nebula in 1889, his photograph showing a large number of fine lines apparently connected with the spectra of the trapezium stars, while the hydrogen lines H_δ and H_ϵ were absent. Prof. Keeler has tried to obtain the same result by photographing the spectrum in the same way as Dr. Huggins, but without success. He shows that "contrary to the belief which has been held up to the present time, the trapezium stars have spectra marked by strong absorption bands; they have not the direct connection with the nebula that would be indicated by a bright-line spectrum, but are in fact on precisely the same footing (spectroscopically) as other stars in the constellation of Orion. While their relation to the nebula is more certain than ever, they can no longer be regarded as necessarily situated *in* the nebula, but within indefinite limits they may be placed anywhere in the line of sight." Finally, with regard to the appearances that have led to the belief that the nebular lines are bright in these stars, Prof. Keeler believes that they are of physiological and photographic origin, and do not actually exist. It is pointed out that these conclusions have an important bearing on theories of stellar development.

Prof. Campbell's paper, which is continued from the May number, deals with the spectrum of the Orion nebula and other well-known nebulæ. In it Prof. Campbell brings together all his spectroscopic observations of nebulæ. Like Prof. Keeler, he was unable to confirm Dr. Huggins' observation of the absence of certain hydrogen lines in the spectrum of the Orion nebula. His photographs also show that the spectra of the trapezium stars all conform to the Orion type, and contain numerous dark lines, but no bright lines. By tabulating the observations published up to the date of the paper, it is shown that of the twenty-five bright lines known to exist in the spectrum of the Orion nebula, at least nineteen are definitely matched by dark lines in the Orion stars, and at least fifteen by dark lines in the six faint stars situated in the dense parts of the nebula. Including his own observations, Prof. Campbell finds that thirty-six bright lines have been observed in the spectra of the seven nebulæ examined by him. He has tabulated all the lines that have had their positions determined either from photographs or by direct observation.

THE NEBULOUS CHARACTER OF NOVA AURIGÆ.—The question of the telescopic appearance of Nova Aurigæ is again brought up in *Astronomische Nachrichten*, No. 3238. Prof. E. E. Barnard, at the end of a communication on micrometrical observations of the object, made with the 36-inch telescope of the Lick Observatory, says that when he examined the star on August 19, 1892, it appeared to be densely nebulous, and that since then it has not appreciably changed. He has made a very careful examination of the star in order to test whether the nebulosity was due to instrumental defects or not, and the result of his investigation is the conclusion that—"When the Nova is in the best possible focus it is hazy and surrounded for 5″ or 6″ with a decided nebulosity. . . . How much of this nebulosity is due to the peculiarity of the spectrum of the Nova, I am not able to tell. But from my experience with nebulæ I would unhesitatingly say that the Nova is distinctly and unquestionably nebulous." This testimony, coming from such an experienced observer as Prof. Barnard, is very important. An inspection of the micrometrical observations made at the Lick Observatory, failed to show any marked periodic variation of the star's position, such as might be due to parallax. The object must therefore be at an enormous distance from us.

A series of observations of the relative position of Nova Aurigæ and a comparison star of magnitude 10·2, is also communicated to the same number of the *Astronomische Nachrichten* by F. Renz, of the Pulkowa Observatory. The observations extend from September 1892 to March 1894. The series shows no perceptible variation in the relative positions of the two stars. As regards the suspected nebulosity, Dr. Renz found that it disappeared on pulling out the eyepiece by about 3·6 mm., thus indicating that the nebular appearance was due to a want of definition produced by the different refrangibility of the light emitted by the Nova. He thinks that the object has never appeared so nebulous as it was in September 1892, and he suggests that this may be accounted for by the fact that the hydrogen line at λ 486 μμ (F) and that at λ 495 μμ have diminished in intensity.

THE APIS PERIOD OF THE ANCIENT EGYPTIANS.—The Apis Period of the ancient Egyptians formed the subject of a recent paper read before the Vienna Academy by Dr. E. Mahler. The author showed that this 25-year period could no be related to the duration of life of an Apis, since many different periods are recorded for that. But by reducing the dates of the enthronement of Apis as given by Brugsch and Lepsius in the Egyptian reckoning to the Julian chronology on the basis of the fixed Sirius year, the significant fact was discovered that such enthronement always took place on the day of the full moon. Since Apis is known to be the visible representation of Osiris, and the latter is identified with the full moon, it is reasonable to suppose that the Apis-period of $9125 = 25 \times 365$ days was purely astronomical, and that the name was derived from its connection with the full moon and Osiris.

OBSERVATIONS OF THE PLANET MARS.—A telegram transmitted by Prof. Pickering to Prof. Krueger, and printed in *Astr. Nach.* No. 3241, reads as follows:—"Holden telegraphs: Bright projection of Mars terminator like that previously observed at Lick Observatory and seen several mornings, best seen June 28 near Polar Cap, Ganges seen double."

THE JACKSON-HARMSWORTH POLAR EXPEDITION.

THE private Polar Expedition led by Mr. F. G. Jackson, and financed by Mr. A. C. Harmsworth, sails from the Thames to-day, July 12, on board the steam-whaler *Windward*, for Franz Josef Land, calling *en route* at Archangel.

Many of the equipments of the expedition were exhibited to a select party at an "at home" given by Mr. and Mrs. Harmsworth at the Grafton Galleries on Friday evening, and on Monday last a number of visitors were shown over the ship in the Shadwell Basin, when the special arrangements for the expedition were more fully explained.

The staff which has been finally selected by Mr. Jackson to accompany him on his projected land journey in the far north includes the following:—Mr. Albert Armitage, second in command, a young officer of the P. and O. Company's service, who is a practical navigator and trained in astronomical and magnetic observations; Dr. Kettlitz, medical officer; Captain Schlosshauer, a merchant skipper; Mr. Fisher, curator of the Nottingham Museum, as scientific collector; Mr. Burgess, who has had some previous Arctic experience, and will act as cook; Mr. Childs, who undertakes mineralogical work and photography; and Mr. Dunsford, who, like Mr. Jackson and Mr. Armitage, has a knowledge of surveying. Some friends of the explorers sail with the party, intending to return from Archangel.

Several previous expeditions have acquired some knowledge of the natural conditions of Franz Josef Land, and it is confidently expected that game, in the shape of bears, seals, and birds, will be abundant. Accordingly a complete outfit of sporting guns, rifles, harpoons, &c., is being taken. The expedition is, however, fully provisioned for four years with the most highly condensed and thoroughly preserved foods obtainable. Much reliance is placed on the fresh bear and seal meat, expected to be shot, for the prevention of scurvy, but Mr. Jackson also proposes to use port wine as a specific. The use of alcohol and tobacco, which has recently been entirely discarded in Arctic work, is one of the peculiar and probably not unpopular features of the present attempt on the Pole.

The arrangements for travelling include boats for crossing open water. One of aluminium, measuring 18 feet by 5 feet, weighs only 150 lbs., and can carry twenty people; it is made in three sections for convenience of transport on sledges, and each section will float by itself. A similar copper boat, weighing about 200 lbs., is also carried, and three light wooden Norwegian boats. A fast steam-launch, appropriately named the *Markham*, is expected to be of service if it is found possible to proceed from the base for some distance by sea, or up Austria Sound.

Eighteen sledges of exceptionally light and strong construction, each calculated to carry 1000 lbs. weight if necessary, are taken; these are to be drawn by Siberian dogs or ponies. There are three collapsible tents, and suits of Samoyed clothing for use in winter, the cumbrous-looking garb of these Siberian nomads being considered better adapted for rough work in bad weather than the tighter-fitting costume of the Eskimo pattern. The scientific instruments carried are perhaps the finest that have ever been taken into the far north, the extensive use of aluminium ensuring a lightness and strength never before attained in Arctic exploration.

After landing the exploring party in Franz Josef Land about the end of August, the *Windward* will return to England, if possible, and sail again next year with fresh supplies.

The whole cost of the expedition is estimated at £25,000.

ANNUAL REPORT OF THE PARIS OBSERVATORY.

ON the 3rd of March of this year, M. Tisserand presented his report to the Council of the Observatory regarding the state of the Observatory during the past year. In his preliminary remarks he refers briefly to the work in course of execution. Under the direction of Le Verrier, great attention was concentrated on the meridian service, which comprises observations of the sun, moon, planets, asteroids, and the revision of the catalogue of Lalande. Extra-meridian observations of comets and small planets have been made with the equatorial in the west tower, and M. Wolf has been occupied in astro-physic researches. An important work in hand is that of publishing a catalogue of the Observatory, based on all the values of the meridian observations made from 1837–1881, while special researches on the R.A. of fundamental stars have been undertaken, and on the declinations, after methods proposed by M. Lœwy. The equatorial service has been enlarged by the addition of another coudé, which instrument is devoted to the observation of planets, comets, systematic measures of double stars and nebulæ, and will be occupied in future with the study of the most interesting variable stars.

With regard to the work in hand, M. Tisserand says that there is enough "assuré pour plusiers années." In remarking on the great preponderance of meridian work, he refers to its considerable importance in astronomy, furnishing as it does the constants for calculating the positions of planets and stars. Photography, he says, gives the means of determining exactly the positions of small stars on a cliché with relation to a certain number—say a dozen—of reference stars; but the positions of these last-mentioned ought to be measured by meridian instruments.

The movement relative to the lengthening of the railroad has been making great headway, and already the means of protection suggested by the Council have been commenced, notably that of the *mur d'isolement* constructed near the tunnel.

Let us take a rapid survey of the work done with each of the separate instruments as reported by the head of each department.

Large Meridian Circle.—Besides general transits observed, it was attempted to correct the catalogue of polar distances of fundamental stars, in continuing zenith distance measures of stars with the adopted latitude. A series of sixty stars, six times observed, showed that the corrections agreed very satisfactorily among themselves, and harmonised well with those furnished by the normal catalogue of M. Auwers.

Simultaneous observations have also been made to correct the ephemerides of the *Connaissance des Temps* and the latitude, while active researches have been started for finding out the causes of the inequalities. With reference to the "flexion horizontale," the instrument has remained firm, the mean value given by the collimators being $-0''.68$, those for the three preceding years being $-0''.54$, $-0''.73$, and $-0''.66$.

Meridian Instrument, Gambey.—The work started in May 1890, of correcting catalogue R.A.'s of fundamental stars, has been continued, and the corrections found are "faibles et bien concordantes," as shown from the following few values:—

Stars.	1890. s.	1891. s.	1892. s.
θ Virginis	+0·03	+0·03	+0·02
25 Canes Venatici ...	−0·03	−0·12	−0·14
m Virginis	+0·07	+0·06	+0·03
T Virginis	+0·09	+0·06	+0·04
Arcturus	+0·07	+0·05	+0·04

Circle of Gambey.—Employed exclusively for researches on the variation of latitude; 127 nadir distances of polaris were measured, of which 101 were direct, and 26 by reflection.

Cercle Méridien du Jardin.—During the earlier months this instrument was used for the determination of polar distances of fundamental stars and for latitude, by methods of M. Lœwy. A minute determination of the inclination of the horizontal thread of the instrument was also made, and also the influence of personal equations in the cases of stars near the pole, M.

Kenan having installed in front of the eyepiece a prism which reversed the direction of apparent movement of the stars, either in right ascension or declination.

The "Supplément à l'Histoire Céleste de Lalande" is undergoing revision, and the positions of 2250 stars are required to be re-observed, each three times by meridian observations. Since April 1893, sixty series, comprising about 1000 stars of the catalogue, have been obtained.

The [illegible] of the meridian observations made during the year shows that the instruments were by no means idle, no less than 17,248 observations having been made. The *résumé* of the planets observed during the same period gives the total number as 556.

Équatoriaux Coudés.—The large equatorial has been receiving several alterations and additions, and it is hoped to maintain the position of a fixed or movable star on the same part of a photographic plate with an approximation of 0"·2 nearly. The small coudé has been the means of effecting the complete measurements of 186 double stars, besides some observations of minor planets, comets, occultations, &c.

The Equatorial in the West Tower.—This instrument is under the direction of M. Bigourdan, who, with M. Faye, were away observing the total eclipse of the sun at Sénégal. During their stay there, fifteen lunar culminations for longitude and four series of observations for latitude were made, besides meteorological observations and four independent determinations of the relative intensity of gravity. The solar observations, among other things, consisted in observing the four contacts, and searching round the limb of the sun for any small bodies that might be visible.

The observations made with the equatorial above referred to consisted of measurements of 280 double stars, besides those of comets, occultations, &c.

The equatorial in the east tower, under M. Callandreau's direction, has been devoted chiefly to observations of minor planets.

In the departments where photography is employed, MM. Henry have obtained, among other results, 169 clichés for the catalogue of the *Carte du Ciel*, twenty-nine large clichés of the moon, enlarged directly eighteen times, these latter marking "un progrès très sensible sur les résultats obtenus antérieurement."

The "Bureau des Mesures des Clichés du Catalogue," under Mdlle. Klumpke's supervision, is now supplied with two machines. The total number of stars measured in the twelve months amount to 27,750; of these 26,831 were measures of stars, 343 measures of double stars, and 32 planetary measures.

The meteorological observations and the hour service have been regularly continued, the latter without any failure during the entire year.

In the spectroscopic department, M. Deslandres has been continuing the researches on the sun and stars; but much time was devoted to the preparations for the observations of the total eclipse of the sun last year. The results obtained during the eclipse consisted of twenty-two photographs of the corona. Some of the negatives show luminous jets from the corona extending to a distance of two diameters. The ultra-violet spectrum of the corona has been traced up to the limit of the ordinary solar spectrum, and in addition fifteen lines have been observed in the new region. In the researches concerning the rotation of the corona, it has been found that one of the negatives shows the spectra of two points of the corona, situated at the extremity of an equatorial diameter and 10' from the solar limb, placed side by side. The bright H and K lines of calcium present a slight displacement corresponding to a difference of velocity of 5 to 7·5 kilometres. M. Deslandres admits that the solar corona is animated with a motion of rotation, the angular velocity of which corresponds with that of the sun.

Other spectroscopic work being continued is that of the study of the radial velocities of prominences and stars.

THE CHEMISTRY OF CLEANING.[1]

As a great city grows, and the agglomeration of struggling humanity increases, such questions as the disposal of sewage and other waste matter rise from comparative insignificance into problems of almost insurmountable difficulty; and whilst we are able to put the burden of cleansing our towns upon the urban authorities, the responsibility of keeping our homes and bodies in a condition of at least sanitary cleanliness devolves upon the individual, and a knowledge of the causes of dirt and the methods by which it can be removed, cannot be regarded as devoid of interest, or at any rate utility.

Before we can cleanse, we must have dirt to remove, and this prime factor of our subject naturally must claim our first attention.

Dirt has been variously defined: a great statesman has spoken of it as "matter out of place," poets have christened it the "bloom of ages," whilst more matter-of-fact individuals have been content to look upon it as something which causes an infinite amount of trouble in the household, and leads to the consumption of much soap and water. If, however, we divest our mind of prejudice, and approach the subject of dirt from a scientific point of view, we shall find a silver lining to the grimy cloud, and shall have to admit that a wondrous store of interest is to be found in the dust with which the housemaid wages perpetual war, and which when glued by nature to our skins, requires special methods for its removal.

Observation shows that in our town houses, only a very short interval of time is needed to cause a considerable deposit of dust upon any horizontal surface, whilst vertical surfaces and draperies, especially if their surface be rough, also accumulate a considerable quantity, although of a lighter and more finely divided kind. We also find that this dust is borne to its resting place by the air which penetrates from the outer atmosphere, and that its deposition is caused by the comparative condition of rest insured to it by the absence of wind or violent currents.

The presence of these air-borne particles of solid matter can be made visible in any town by allowing a beam of sunlight or a ray from an electric lantern to pass through the air of a darkened room. If the room be filled with air previously filtered by passing it through cotton wool, the beam of light is invisible until it strikes the opposite wall; but if the air be unfiltered, the path of the beam is mapped out by the suspended matter reflecting and dispersing portions of it, and so becoming visible to the eye as "the motes in the sunbeam."

The heavier the nature of the particles, the more quickly will they settle, with the result that the dust on horizontal surfaces, such as the tops of sideboard, piano, and mantel-board, may be expected to differ somewhat from the lighter form, which has continued to float until contact with vertical surfaces has brought it to rest.

These particles of dust are composed of matters of the most varied nature, and will be found, when collected, to consist partly of mineral and partly of organic substances, namely, siliceous and carbonaceous matters, hair, epidermis from the skin, pieces of vegetable fibre, pollen from various plants and grasses, the sporidiæ of fungi and bacteria.

The heavier portions of the dust are found to contain ground-up siliceous matter, pulverised by traffic in the road; small particles of salt carried inland by winds from the sea, together with sulphate of soda, with other impurities of a local character. If a sample of dust be collected and carefully ignited, the organic matter will be burnt away, and any ammonium salts volatilised, whilst the mineral portion will be unacted upon; and in this way it has been shown that more than one half of the suspended matters in the air are of organic origin, a large portion of this organic matter consisting of germs which are capable of setting up fermentation, disease, and decay.

It is only within the last few years that the importance of the work done by the solid particles of dust floating in the air has been recognised, and it is to Pasteur that we owe the knowledge that these germs set up the various processes of organic decay.

Pasteur collected the lightest portions of dust, which are left floating in the air after the heavier portions have settled down, by gently drawing air through a plug of soluble collodion cotton; and after he had collected sufficient dust in this way, he dissolved the cotton in a mixture of alcohol and ether, and examining the residual particles under the microscope, was able to show the presence of a large and variable number of organisms obtained from the atmosphere.

He also found that solutions of sugar mixed with beer yeast, and left exposed to the air, rapidly decomposed. If, however, the solution was kept in contact with air, that had been previously heated, it would remain unchanged for months, but de-

[1] A lecture delivered at the London Institution, by Prof. Vivian Lewes.

composition was started in a few hours if some of the germs collected from the air were added to it.

If a pot of ordinary paste, after being used, is placed on a shelf for a few days, the surface will be found coated with a fine crop of mould or mildew. On examining this mould under the microscope, it will be seen to somewhat resemble a bed of rushes; after a few more days, some of these rush-like filaments will have developed little pods, not unlike poppy-heads, and after the lapse of another week the pods will have split open, and myriads of seeds or germs will have poured forth into the air to carry on nature's cleansing work, for these germs possess the power of setting up the process of decay, by which the waste matter derived from vegetable sources is once again resolved into the water vapour and carbon dioxide used by nature as the foundation of all organic creations.

Decay and putrefaction are the great factors of change which nature utilises for removing the waste products of animal and vegetable life, and for once more bringing them into a condition in which living things can again assimilate, and use them for building up their tissues and carrying on their functions. Without decay, the dead animal and vegetable matter would remain choking the face of nature, and life would be impossible, because the food of life would be cut off; and it is the almost imperceptible germs floating in the air which start this marvellous natural action, germs so minute that it requires the strongest microscope to detect them, yet so potent that the whole balance of life hangs on their existence.

These facts show us that not only has dust a most marvellous history, but that in it nature has disguised her most important factor for cleaning the face of the earth from waste matter of both mineral and vegetable origin.

The surface soil when mixed with water gives the mud which dirties our boots, and forms clots on the train of our skirts; but this, as well as the dust which has settled in our living rooms, and merely clings mechanically to the surfaces upon which it has deposited, may be removed by such simple physical means as the duster and brush. When dust has found its way into a fabric such as a carpet, it requires considerable force to again dislodge it, and this is applied by means of the broom, but in vigorous sweeping we find that the largest proportion of the dust is driven up into the air, only to resettle once again on other surfaces, so that although we can make the nuisance "move on," we do not in this way remove it, and experience has taught our servants that wet tea-leaves scattered on the carpet before sweeping lessen this evil In some cases, instead of using this method, it has been argued that it must be the moisture which acts in preventing the raising of the dust, and the carpet has been sprinkled with water. This converts the dust into mud, which remains fixed in the fabric whilst the sweeping is going on, but as soon as the water has evaporated from it, again reasserts its right of rising as dust.

When, however, wet tea-leaves, damp sawdust, or even moistened sand is scattered over the surface to be swept, the dust when dislodged adheres to the moistened substance and is removed. In choosing moist bodies for this purpose, the only points to consider are that they must have no staining action on the carpet, must not be too wet, and must not be so finely grained as to sink into the fabric, nor so clinging as to resist easy removal by the broom.

It is manifest, however, that the mechanically held dirt which we have been considering, differs very considerably from the dirt on our skins, and on linen in contact with our bodies, which although derived from the same sources as the dust on the furniture, resists any ordinary mechanical process for its removal, and rinsing dirty hands or linen in cold water has but little cleaning effect, whilst if the hands are afterwards dried in the usual way, a transfer of a portion of dirt to the towel takes place.

If we carefully notice the portions of our skin and shirt which become most soiled, we at once observe that it is where the skin is exposed to air, whilst the linen, which is in contact with both air and skin, becomes dirty more quickly than when exposed to either alone.

The part played by the atmosphere is made clear by the facts which we have already been considering, but the action of the skin introduces a new and most important factor. For the healthy carrying on of the functions of life, nothing exceeds in importance the skin with which our body is covered. We may live for days without giving our stomach any work to do, the liver may cease action for several days before death ensues, but it is impossible to survive for the same length of time if the functions of the skin are entirely stopped.

The skin not only plays an important part in throwing off and getting rid of waste matter from the system, but it is also credited with being an important auxiliary to our lungs, and experiments have clearly shown that if the skin of animals be coated in such a way as to completely stop its action, a very few hours will bring about death. Indeed the experiment has been once accidentally tried on a human being, a child gilded all over to represent a statue having died in a few hours; all the symptoms pointing to suffocation as being the cause of death.

If we examine the structure of the skin, we find that it is built up of two distinct layers, an outer skin called the cuticle or epidermis, and an inner termed the cutis or dermis. A third layer intermediate between these two, used to be looked upon as a third skin, but more recently has been recognised as being only a transition form of the outer skin.

The cuticle or outer skin consists of several fine layers of scales which gradually assume a more rounded and granular form the deeper one gets into the cuticle. These rounded granules form the middle skin of the old observers, and as the outer portion of the cuticle roughens and scales off as scurf, these granules gradually flatten and form the new surface to the outer skin, and we differ therefore from other scaly reptiles by being continually in a condition of renewing our skin, whilst most reptiles and fish cast their scaly covering in on operation.

No nerves or blood-vessels find their way into this outer skin, as may be seen when it becomes detached from the inner skin in the formation of a blister, the outer portion of which is devoid of sensation.

The lower or true skin varies in thickness, being thicker in the palm of the hand and sole of the foot, where most resistance is needed.

When we look at the skin of the hand, we notice delicate grooves in it, which examined through a magnifying glass are seen to be pierced with small orifices, and if the hand be warm, minute shining drops of perspiration will be seen issuing from them.

The glands for the secretion of the perspiration are set in the lower side of the inner skin, and are in connection with the capillary network of blood-vessels, which cover the surface of the body. The gland or duct which conducts the perspiration to the surface of the skin is about a quarter of an inch in length, and is straight in the true skin, but becomes spiral whilst traversing the outer skin. Over 3500 of these small ducts have been found to exist in a single square inch of the skin, and it has been computed that the aggregate length of the sudoriferous ducts in the body of an ordinary-sized man is about twenty-eight miles.

These little glands and ducts perform the important function of throwing off the moisture produced during the combustion of waste tissue, by the blood-borne oxygen of the body, and secrete about 23 ounces of perspiration in the twenty-four hours, which under ordinary conditions evaporates, without our noticing it, into the air, but under conditions of considerable exertion or unusual heat, accumulates as beads of perspiration.

The throwing off of the perspiration and its evaporation on the skin, is a beautiful natural contrivance for regulating the temperature of the body, as the conversion of the perspiration into vapour renders latent an enormous amount of heat, which being principally derived from the body keeps it in a comparative state of coolness, even when subjected to high temperatures.

That this is so, is proved by the fact that a bath heated to 120° F. (=49° C.) is almost unbearable, because the evaporation from the surface of the skin is checked, whilst it is perfectly possible for a person with the skin fully exposed to go into an oven and remain there for some time at a temperature of 325° F. or 162°·8 C., at which temperature a beef-steak can be cooked, and it can be clearly noticed in a Turkish bath, that although there is a feeling of oppression at first, the temperature of the hot room can readily be borne as soon as perspiration begins to flow.

In the 23 ounces of liquid so secreted in the course of the twenty-four hours, there will be found rather more than an ounce of solid matter, which is left when the liquid portion of the perspiration evaporates, and tends to clog the pores of the skin, and it is the removal of this by the morning tub and rough towel, which is responsible for a considerable portion of the refreshing influence of the British bath.

Besides these sudoriferous glands, however, there is a second set, called the sebaceous glands, the ducts of which are spiral, and open generally into little pits, out of which the fine hairs which stud the skin grow, and these glands secrete an oily or waxy substance, which nourishes the hair, and also keeps the outer skin smooth and pliant. This waxy substance is developed in largest quantity inside the ear, where it serves to protect the more delicate portions of that organ, and next to the ear, these glands are found most abundantly on the face and other portions of the body which are exposed to external influences and friction.

It is the presence of this oily secretion which holds the dirt glued to the skin, and being also rubbed off on the inside of the wristbands and collars of our shirts, causes these portions of our linen to become the most soiled. We may look upon this form of dirt, therefore, as being glued on to the surface by oleaginous materials, which being insoluble in water resist any mere rinsing, and the most important function of our cleansing materials is to provide a solvent which shall be able to loosen the oil, and so allow of the removal of dirt from the skin.

The skin, however, is not the only source of oily matter, and in all fibres of animal origin more or less fat is to be found, which although not in sufficient quantity to play any very important part in the fixation of dirt, still adds its iota to the general result.

We notice, moreover, that the air of a big town has a far greater dirtying effect than country air, this being partly due to the fact that the number of solid particles per cubic foot of atmosphere are greatly reduced, but chiefly because country air does not contain certain products of incomplete combustion, which are to be found in all large towns.

In London we annually consume some six million tons of bituminous coals, and if we examine the smoke which escapes up our chimney during the imperfect combustion which the coals undergo in our fire-grates, we find that not only will that smoke contain small particles of unconsumed carbon in the form of blacks or soot, but also a considerable quantity of the vapour of condensible hydrocarbon oils, which depositing on the surface of the solid particles of floating dirt, gives them an enhanced power of clinging to any surface with which they come in contact.

If we have a heavy fall of snow in London, as the snow melts it leaves a black deposit, which is formed of the solid particles with which the snow has come in contact in its passage through the air, and a recent analysis of a deposit of this character, collected on the glass roof of an orchid house at Chelsea, gives a very good idea of the constituents of these solid impurities.

Carbon	39·00	per cent.
Hydrocarbons	12·30	,,
Organic bases	1·20	,,
Sulphuric acid	4·33	,,
Hydrochloric acid	1·33	,,
Ammonia	1·37	,,
Metallic iron and magnetic oxide .	2·63	,,
Other mineral matter, chiefly silica and ferric oxide	31·24	,,
Water	not determined.	

Hydrocarbon oils of this character are not as a rule affected by the solvents which we utilise for loosening the dirt which is held to our skin by animal grease; but there is no doubt that the dirtying influence of town air is greatly increased by their presence.

If we take any grease of vegetable or animal origin, we find that it can be dissolved in liquids containing free alkalies, this term being applied to the compounds formed by water with the soluble metallic oxides, which, when dissolved in water, give solutions having a soap-like taste, affecting the colour of vegetable extracts, such as that obtained by the red cabbage, and possessing the power of neutralising the acidulous properties of the compounds we call acids.

If we take two metals discovered by Sir Humphrey Davy in 1807, potassium and sodium, and expose them to dry pure air, they rapidly become converted into a white powder by absorbing oxygen from the atmosphere, and form compounds which we term respectively oxide of sodium and oxide of potassium. These oxides, when dissolved in water, enter into combination with a portion of it, producing sodic hydrate and potassic hydrate, two substances which have pre-eminently the properties which we term alkaline, and which exert a strong solvent action upon all forms of animal and vegetable grease.

These solutions exercise a wonderful power of cleansing upon the grease-bound particles of dirt which veil our skin, but so strong is their solvent power upon animal membrane, that not only do they dissolve fatty matter, but also the cuticle itself, so that they are manifestly unfitted for removing dirt from a tender skin, and we are forced to look further afield for a grease solvent.

If instead of dissolving our sodic and potassic oxide in water, we had left them exposed to ordinary air, we should have found that they gradually attracted from the atmosphere a gas called carbon dioxide, which exists in all air to the extent of 4 parts in 10,000, and that by combining with this gas they became converted into sodic and potassic carbonates, bodies which we call salts, and which, although not so violent in their action upon the skin, will retain to a certain extent their solvent action on fatty matters.

The carbonates of sodium and potassium are found in the ashes of many vegetable and animal substances, and in the earliest records which have been discovered, we find mention of the cleansing power of wood ashes, the ashes of certain marine plants, sea-weed, and "natron," which is an alkaline efflorescence from some kinds of soil; nor has the use of ashes for this purpose entirely died out at the present time.

It was only in 1884, that during some structural alterations in Rome, an old tomb was broken into, and the ashes which it contained removed by one of the workmen, who conveyed them home to his wife, as an offering towards the next washing-day, whilst a few days later the antiquarians were horrified to discover that they were the remains of the Emperor Galba, cremated some eighteen centuries before, which had been put to such practical use.

As early as A.D. 69, however, we find that the elder Pliny mentions another form of cleansing material made from tallow and ashes, the components most recommended being goat's suet and the ash of beechwood; whilst the ruins of Pompeii were found to contain a fairly perfect soap factory.

Although soap and Christianity date from the same period, it was only at the commencement of this century that the classical researches of Chevreul on the constitution of fats, gave the key to the reactions taking place during its formation, whilst even at the present time we probably only know a true explanation of part of the actions which lead to its cleansing effect upon the skin.

If we take sulphuric acid diluted with water, we find that it has certain well-marked characteristics, which leave no room for doubting its acidulous nature, and if we pour a few drops of it into the violet-coloured solution obtained by boiling sliced red cabbage in water, the violet solution at once becomes bright red. On repeating this experiment with the violet cabbage solution, and a few drops of sodic hydrate solution, we obtain a vivid green colour, and now on mixing the solution rendered red by the acid, and the second one turned green by the alkaline base, we once more obtain the original violet colour, and on examining the solution can find no trace of either acid or alkali, but can distinguish the presence of a compound called sodic sulphate, which can be obtained in the crystalline form by concentrating the solution, and such a compound formed by the union of an acid and a base, we are in the habit of calling a salt. During the combination of the sulphuric acid and sodic hydrate to form sodic sulphate, we also had water being formed, which, like the neutral salt, had no action upon our coloured solution. If we had carefully weighed our sulphuric acid and the sodic hydrate, we should have found that it is only in certain definite proportions that they unite to give a solution without effect on the vegetable colouring matter, and we might sum up our experiments on the combination of these two substances as follows:—

Acid.		Base.		A salt.		Water.
Sulphuric acid, 98 parts by weight.	+	Sodic hydrate, 80 parts by weight.	=	Sodic sulphate, 142 parts by weight.	+	36 parts by weight.

And if we take crystals of sodic sulphate, and dissolve them in water, we can decompose them once more into sulphuric acid and sodic hydrate by the aid of galvanic electricity.

My aim in this experiment has been to impress upon you that a salt is a compound formed by the union of an acid and a base, and one of Chevreul's greatest discoveries was that in tallow—the fat of oxen or sheep—you had a salt of organic origin, from which by decomposing the tallow with heated steam, you could obtain the sweet viscous liquid "glycerine," which played the part of base in the compound, and two acidulous compounds—one a lustrous white wax, called stearic acid, and the other an oil called oleic acid.

Now a salt can have its base replaced by another base. If I take two solutions, the one containing sulphate of copper, and the other chloride of iron, and add to each sodic hydrate, decomposition takes place in each case, sodic sulphate is left in solution, and the hydrates of copper and iron being insoluble in water, separate out as precipitates.

In the same way, if we add sodic hydrate to tallow, glycerine separates out, and two salts—sodic oleate and sodic stearate—are formed, a process which we call saponification, as the two sodium salts are "soaps."

It is not necessary to use tallow; any vegetable or animal fat or oil will give reactions of a similar character, and it may be broadly stated that soap is formed by the action of sodic or potassic hydrate upon fats or oils which contain fatty acids.

Organic salt.		Base.		Salt.		
Tallow	+	Sodic hydrate	=	Soap	+	Glycerine.

It is only potassic and sodic hydrates which can be used for ordinary soap-making, as the soaps formed by the combination of other metallic hydrates with the fatty acids are insoluble in water, and therefore useless for detergent purposes.

The soap formed by using sodic hydrate has the property of setting hard, and all the ordinary forms of washing-soap contain sodium as the base; the potash soaps are far softer, and do not set, the soft soap used for scrubbing and cleansing in many manufacturing processes, and also a few toilet creams and shaving pastes, being of this character.

It would occupy far too much time, and would, moreover, be outside the scope of this lecture, to go into the details of the manufacturing methods by which soap is made on the large scale, and if I give a rough idea of the general processes employed, it will be sufficient for the purpose.

Carbonate of soda is first converted into hydrate by dissolving it in water, and then boiling with quicklime. Quicklime consists of calcic oxide, and this, when put into the vat containing the sodic carbonate in solution, combines with water, forming calcic hydrate, which then reacts with the sodic carbonate, forming calcic carbonate or chalk, which being insoluble sinks as a mud to the bottom of the vessel, whilst sodic hydrate remains in solution.

$$\left.\begin{array}{l}\text{Calcic hydrate}\\ \text{Sodic carbonate}\end{array}\right\} = \left\{\begin{array}{l}\text{Sodic hydrate}\\ \text{Calcic carbonate.}\end{array}\right.$$

Of late years the soap-boilers have to a great extent bought the sodic hydrate direct from the manufacturer, and so have avoided this operation.

The solution of sodic hydrate, called caustic ley, is made in different strengths, and tallow is first boiled with a weak ley, and as the conversion into soap proceeds, so stronger leys are used until the whole of the fatty matter has been saponified.

If a strong ley had been used at first, the soap as it formed being insoluble in strong alkalies would have coated the surface of the fat and prevented its complete conversion.

If at the end of the saponification process, the alkaline solution is sufficiently strong, the soap will on standing separate as a fluid layer on the surface of the spent ley, which contains the glycerine set free during the saponification, but in any case separation can be rapidly brought about by adding salt to the liquid, when the soap being insoluble in salt water or brine, separates out and is removed and placed in moulds to harden.

The block of soap so cast is then cut first into slabs, and then again into bars.

A soap made in this way with tallow or lard as the fatty matter, would be "white curd," whilst if yellow bar is required, rosin is added to the mixture of ley and soap after most of the fat has saponified.

When rosin is boiled with alkaline solutions, a compound is formed by the direct union of the resinous acids with the alkali, which strongly resembles ordinary soap, so that the yellow soap is really a mixture of fatty and rosin soap, and when the ingredients are of great purity, the product goes by the name of "Primrose" soap. Bar soaps so made on a large scale are, as a rule, the stock from which the various forms of toilet soap are made by processes intended to render them more attractive for personal use, but generally the consumer gets far better value for his money, and far less injury to his skin, by using a good "white curd" or "Primrose" soap than by employing a high-priced toilet soap, whilst cheap toilet soaps, especially cheap transparent soaps, should be studiously avoided.

The demand made by consumers for cheap soaps, which in many cases are sold retail at prices considerably below the wholesale market price for a true soap, has given rise to the introduction of highly watered soaps, caused to set hard by the addition during manufacture of sodic sulphate, which enables the manufacturer to make a so-called soap often containing less than 20 per cent. of true soap.

Any person desiring to obtain the fullest particulars as to the manufacturing details of the soap trade, cannot do better than consult Dr. C. R. Alder Wright's admirable treatise upon the subject.

Having got our soap, the next point is to try and gain an idea of the way in which it acts as a detergent.

Supposing we are fortunate enough to have a sample of pure neutral soap, we find that on dissolving some of it in water, it undergoes a partial decomposition into alkali, and fatty acid, this action being called the hydrolysis of soap.

The small quantity of alkali so set free, attacks the fatty matter which glues the dirt to the skin, and by dissolving it loosens and enables the water to wash off the particles of dirt.

If this were the only action, however, soap would have no advantage over soda, a solution of which would equally well perform this part of the operation. As the soap decomposes and the alkali removes the grease and dirt, the fatty acid liberated simultaneously from the soap comes in contact with the newly-cleansed skin, and not only softens and smooths it, but also neutralises any trace of free alkali, and so prevents irritation and reddening of the cuticle.

These are probably the main actions by which soap cleanses, but other causes also play a subsidiary part. We know that a solution of soap causes a lather when agitated, this being due to the cohesive power given to the particles of which the liquid is built up by the presence of the soap, a phenomenon which also enables us to blow bubbles with the soap solution on account of the strength of the fine film of liquid, a property which is not found in water alone.

The power of cohesion which the soap solution possesses is in all probability an important factor in removing the particles of dirt from the skin at the moment that they are loosened by the action of the alkali. Prof. W. Stanley Jevons suggested yet a fourth way in which the soap solution might act; when finely divided clay is suspended in water, the microscope reveals the fact that the minute particles are in rapid movement, and hence settle but slowly in the liquid. This movement he christened pedetic action, and he observed that the addition of soap or silicate of soda—often used in soap—to the liquid, enormously increased this agitation of the particles, which would tend to aid the breaking away of the dirt particles the moment they were set free.

Many soaps, even among the varieties intended for the toilet, contain a considerable excess of free alkali, which being greater than the liberated fatty acids can neutralise, cause most painful irritation of the skin, as is testified to by the smarting which annoys the chin after the use of certain shaving soaps; and every lady knows that an alkaline soap, when used for washing the hair, renders it harsh and brittle, and destroys the gloss, but in both cases a rapid rinse with water, containing a few drops of vinegar, will neutralise the free alkali and prevent much of the mischief.

We have now dealt with our grease solvents and dirt looseners, but without the aid of water they would be useless; and experience teaches us that the source of the water used for cleansing, has a great deal to do with its efficiency whether used with or without soap.

As the new-born rain-drops fall from the breaking clouds, they are practically pure water, containing at most traces of gaseous impurities which the mist has dissolved from the upper strata of air whilst journeying in the form of cloud, and where the rain is collected in the open country, it gives us the purest form of natural water, healthful to drink, because it is highly aerated, and free from all impurity, organic and inorganic, and delightful to wash in because of its softness and the ease with which the soap gives a lather.

In towns, however, a very different state of things exists, as the rain in falling washes the air from a large proportion of the suspended organic matters inseparable from a crowded city, and also from the unburnt particles of carbon, which incomplete combustion allows to escape from our chimneys; and charged with these, it still collects more dirt of various kinds from the roofs of our houses, and finally finds its way into our water-butts as the semi-putrid sludge which often causes the true-bred cockney to wonder "if this so-called purest form of natural water is so foul, what on earth must the other forms of water be like?" If in the country the rain water is collected and stored in suitable reservoirs, then we have the most perfect water that can be obtained for washing and cleansing purposes.

In some kinds of water collected under what we might consider ideal circumstances, we find "a something" which acts as a check upon the cleansing action of the soap.

In Attica, close to Atheus, on the slopes of Mount Pentilicus, the Emperor Hadrian built some huge marble underground aqueducts to collect and lead the rain water down as a supply for Athens, the whole water-shed consisting of marble; this mountain being justly celebrated as the source from which the finest statuary marble is obtained. Here, falling through the clear southern air on to a collecting ground formed of the material which all ages have considered the most suitable for baths and reservoirs, one would expect the water to be like the pure rain water, absolutely free from dissolved solid impurities, and one of the best waters of its kind for washing purposes; yet not only does it waste a large amount of soap before a lather is obtained, but if we examine the channels through which it has for centuries flowed down to the valley, we find that it has formed a heavy deposit, which collecting unchecked through long ages, has all but choked up the once spacious passages. A piece of this deposit I have obtained through the kindness of a friend, and on analysis it proves to be:—

Calcic carbonate	96·81
Silica	0·49
Organic matter	1·40
Moisture	1·30
	100·00

It is, in fact, a natural incrustation deposited by the water, and a similar action is seen in the formation of stalactites in many caverns, through the roof of which water charged with certain calcareous compounds has slowly found its way.

In the passage of the rain through the air small quantities of carbon dioxide or carbonic acid gas are dissolved from the atmosphere, whilst in slowly percolating through the surface soil on which it has fallen the water is brought in contact in the pores of the soil with far larger volumes of this gas, which is being continually generated there by the decomposing vegetation and other organic matter in a state of decay. Under these circumstances the water becomes highly charged with the gas, and sinks on through the ground until it comes in contact with some impermeable strata through which it cannot penetrate, and here it collects until a sufficient head of water has been formed for it to force its way along the strata to the surface of the earth, where it now appears as a spring, and during this passage through the earth it has dissolved everything that will yield to its own solvent action or to the activity of the carbon dioxide, which dissolved in water forms the weak carbonic acid, a compound which will dissolve many substances insoluble in the water itself, such as calcic carbonate, occurring in the soil as marble, limestone, or chalk, and also the carbonates of iron and magnesium. If we examine a spring water, we shall find that its dissolved impurities can be divided into two classes: for instance, taking the Kent water supplied at Greenwich, and obtained from deep wells in the chalk, we find its saline constituents in grains per gallon are:—

Calcic carbonate	16·30
Calcic sulphate	5·37
Magnesic sulphate	0·93
Magnesic nitrate	1·20
Sodic chloride	2·64
Sodic nitrate	1·21
Silica, alumina, &c.	0·97

And of these the calcic sulphate, magnesium, and sodium salts are dissolved by the solvent action of the water in the same way that sugar would be, whilst the chief impurity, calcic carbonate, is scarcely at all soluble in the water itself, 16,000 parts of pure water only dissolving one part of the carbonate, but is readily soluble in the carbonic acid, in the water which converts it into soluble calcic bicarbonate.

In the household, waters are roughly classified as hard or soft waters, and the property of hardness manifests itself, as a rule, to the householder by its action upon soap, and also by the amount of "fur" which it causes in the kettle, these actions being due to calcic bicarbonate, calcic sulphate, and the magnesium salts present in it, all of which act upon soap and cause it to curd instead of forming a lather by converting the soluble sodic oleate and stearate into insoluble lime salts, whilst the bicarbonate by decomposing and depositing "chalk" causes the fur.

A more careful examination, however, reveals the fact that this property of hardness owes its origin to two different causes, for if we boil water until all the bicarbonate is broken up and the calcic carbonate deposited, the clear water left behind it is still hard, though to a far less extent, and will still decompose a certain proportion of soap. The hardness which can be got rid of by boiling is due to bicarbonate of lime, and sometimes also bicarbonate of magnesia, and is called "temporary hardness," whilst the hardness left after boiling the water is due to calcic sulphate and the soluble magnesium sulphate, chloride and nitrate, and is called "permanent hardness."

The relative hardness of waters is estimated by the amount of soap they will destroy, *i.e.* convert from the form of soluble sodic oleate and stearate into the condition of insoluble oleates and stearates of lime, and one grain of calcic carbonate or its equivalent in sulphate or salts of magnesia dissolved in a gallon of water, is said to equal 1° of hardness.

The sample of Kent water of which an analysis has been given, contains 23·6 grains of these salts, and would be said to have nearly 24 hardness, 7·5 of which would be permanent and 16·3 temporary.

When it is considered that 1° of hardness in water will waste 10 grains of soap per gallon of water used, we become aware of the economic importance of the kind of water employed in the household, a gallon of the Kent water, for instance, using up 236 grains or nearly half an ounce of soap before any becomes available to form a lather and exert a cleansing action upon the skin.

Glasgow used to have a hard water service, and when this was discontinued and the soft Loch Katrine water was supplied in its place, it made a difference of several thousands a year in the money expended in soap.

From these facts it is manifest that a soft water supply is an important factor in cheapening our cleansing processes, a pure rain water being the best attainable, whilst surface and river water are as a rule softer than spring water.

I have now discussed the chemistry of cleaning as fully as the time at my disposal will permit, and I hope the facts I have brought before you will have quickened your interest in soap, soda, and water, and will have helped to impress upon you that without proper processes of cleansing, the health of each unit, and therefore the prosperity of the masses, must suffer deterioration.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The following pass list for the degree of Doctor of Science of London University has been issued:—Experimental Physics: Mr. Edwin Henry Barton. Chemistry: Mr. Bevan Lean, Mr. Thomas Kirke Rose, Mr. Arthur Landauer Stern. Botany: Miss Margaret Jane Benson. Zoology: Mr. Arthur Willey.

Her Majesty's Commissioners for the Exhibition of 1851 have made the following appointments to science research scholarships for the year 1894, on the recommendation of the authorities of the respective Universities and Colleges. The scholarships are of the value of £150 a year, and are tenable for two years (subject to a satisfactory report at the end of the first year) in any University at home or abroad, or in some other institution approved of by the Commissioners. The scholars are to devote themselves exclusively to study and research in some branch of science, the extension of which is important to the industries of the country:—Scholar nominated by the University of Edinburgh, John Carruthers Beattie; by the University of Glasgow, James Robert Erskine-Murray; by the University of Aberdeen, William Brown Davidson; by University College, Bristol, Reginald Charles Clinker; by Yorkshire College, Leeds, Frankland Dent; by University College, Liverpool, Alfred James Ewart; by University College, London, David King Morris; by Owens College, Manchester, Julius Frith; by Durham College of Science, Newcastle-on-Tyne, Robert Beattie; by University College, Nottingham, William Beckit Burnie; by Queen's College, Galway, John Alexander M'Clelland; by the University of Toronto, Frank Boteler Kenrick; by Dalhousie University, Halifax, Nova Scotia, Frederick James Alexander M'Kittrick.

THE President and Council of the Royal Society have, upon the recommendation of the Joule Studentship Committee, elected Mr. J. D. Chorlton, of the Owens College, to the first Joule Studentship. This studentship was founded for the purpose of enabling students to carry on certain researches on lines laid down by Dr. Joule, more especially with the view of determining the constants of some of the instruments employed by him, which his representatives can place at the student's disposal.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 31.—"The Root of *Lyginodendron Oldhamium*, Will." By Dr. W. C. Williamson, F.R.S., and Dr. D. H. Scott.

During a re-investigation of the structure of *Lyginodendron*,[1] the results of which the authors hope to lay before the Royal Society on a future occasion, an important fact has come to light, which they place on record without delay.

A carboniferous fossil, with the structure perfectly preserved, has been described in previous memoirs, under the name of *Kaloxylon Hookeri*, Will.[2] The authors have now established the fact that *Kaloxylon* was not an independent plant, but was the root of *Lyginodendron Oldhamium*.

Specimens, presenting in every respect the typical *Kaloxylon* structure, have been found in actual continuity with the stem of *Lyginodendron*, arising from it as lateral appendages. Their structure and mode of origin prove that they were adventitious roots. These organs branched freely, and the authors have found roots and rootlets of all sizes, and at all stages of development.

This discovery enables a complete account to be given of the vegetative organs of *Lyginodendron*, as they are now fully acquainted with the structure, not only of the stem and foliage, but also of the adventitious roots.

June 14.—"On a Method for determining the Thermal Conductivity of Metals, with Applications to Copper, Silver, Gold, and Platinum." By James H. Gray.

The object of this investigation was to obtain a method for determining thermal conductivities of metals, which would not require either elaborate preparations or large quantities of the substances to be tested, and by means of which a test could be made in a few hours.

The essence of the method is to keep one end of a given length of the wire at a constant known temperature, and to measure the rise of temperature of the other end of the wire every minute. If proper precautions be taken to prevent loss by radiation from the sides, the data are obtained for calculating the thermal conductivity.

The wire to be tested is soldered at one end into the bottom of a copper box. The diameters found most convenient were from 2 to 4 mm., the lengths from 4 to 8 cm.

The box is filled with water and supported at its middle by being fitted into an asbestos-lined wooden screen, 24 × 24 cm. 3 mm. length of the other end of the wire is soldered into a solid copper ball, diameter 5·5 cm. In the ball a hole 3 cm. deep is made, so as to admit the bulb and part of the stem of a small and very sensitive thermometer. This thermometer is graduated from 5° C. to 20° C., and can easily be read to within one-fortieth of one degree. The bulb is surrounded by water.

[1] *Cf.* Williamson, "On the Organisation of the Fossil Plants of the Coal Measures," Part IV. *Phil. Trans.* 1873, p. 377; Part XVII. *Phil. Trans* 1890, B. p. 89.

[2] *Cf.* "On the Organisation of the Fossil Plants of the Coal Measures," Part VII *Phil. Trans.* 1876, Part 1, p. 1; Part XIII. *Phil. Trans.* 1887, B. p. 289.

All the probable errors are practically tested by using different lengths or diameters of the wire, and the results obtained in the present investigation indicate that the errors have been eliminated.

In order to make a complete test of a metal it is only necessary to take a wire of 5 or 6 cm. length and solder it firmly, the one end into the bottom of the heating box, the other into the calorimeter ball. The water in the heating box is kept boiling briskly, and readings are taken every half-minute from the thermometer in the ball. These readings are then put upon a curve as ordinates, with the time in minutes as abscissæ. From this curve the rise of temperature per unit time can then be accurately read off, and, the thermal capacity of the ball being already determined, the flow of heat per unit time is obtained.

At the beginning of the experiment the ball is cooled to about 6° or 7° C. below the temperature of the air, and the rise for equal temperatures above and below that of the air taken, the radiation being thus eliminated.

The metal which was chiefly used for the exhaustive tests of the method was copper wire, of diameter 0·21 cm., density 8·85, volume specific (electrical) resistance at about 13° C. 1834 in absolute units.

It must be noted that the found values are the means of the conductivities corresponding to the temperatures at the ends of the wire. When compared with the values obtained by other experimenters, the results of the latter must be taken for the mean of 97° C. and 10° C., that is, 53° C.

For this temperature Ångström gives 0·9208.

Several qualities of copper were tested, as well as pure gold, silver, and platinum, kindly lent for investigation by Messrs. Johnson, Matthey, and Co.

The values are given below:—

"Flame Spectra at High Temperatures. Part III. The Spectroscopic Phenomena and Thermo-Chemistry of the Bessemer Process." By Prof. W. N. Hartley, F.R.S.

The flame issuing from the mouth of a Bessemer converter was first investigated by Sir Henry Roscoe[1] in 1863; by Lielegg,[2] and by Marshall Watts in 1867;[3] by Tunner,[4] J. M. Silliman, Rowan,[5] Von Lichtenfels,[6] Spear Parker,[7] Kupelwieser,[8] Brunner,[9] and Wedding in 1868;[10] also by A. Greiner in 1874.[11]

Up to the present time the precise nature of the spectrum, the cause of its production, its sudden disappearance when decarburisation of the metal takes place, and the connection between the decarburisation of the metal and the extinction of the spectrum have not been satisfactorily explained. According to Roscoe, Lielegg, Kupelwieser, and Spear Parker, the spectrum is characterised by bands of carbon or of carbon monoxide, which disappear when all carbon is burnt out of the metal.

On the other hand, the investigations of Simmler,[12] Brunner, Von Lichtenfels, and Wedding, the spectrum is not due to

carbon (Roscoe) or to carbon monoxide (Lielegg and Kupelwieser), but to manganese and other elements in the pig-iron.

The very careful examination of these spectra by Watts and his comparison of them with that of the Bessemer flame led to the conclusion that it was not the spectrum of carbon in any form nor of manganese, but that of manganic oxide.

Owing to the courtesy of Mr. F. W. Webb, the engineer of the Locomotive Department of the London and North-Western Railway, and of Mr. E. P. Martin, the manager of the Dowlais Ironworks, observations have been made at Crewe and at Dowlais during the past year. Ninety spectra were photographed, about fifty of which were available for study.

Ninety-two lines were identified with lines in the solar spectrum, with lines in Kayser and Runge's map of the arc spectrum of iron, and in spectra from steel and ferric oxide heated in the oxyhydrogen flame.

The Constitution of the Bessemer Spectrum.

The spectrum is a complex one which exhibits differences in constitution during different periods of the "blow," and even during different intervals in the same period. As originally observed by Watts, the spectrum differs in different works, the difference being due to temperature and to the composition of the metal blown.

During the first period.	The lines of the alkali metals, sodium, potassium and lithium, are seen unreversed on a bright continuous spectrum caused by carbon monoxide. The C line of hydrogen and apparently the F line were seen reversed during a snowstorm.
During the second period. The "boil."	Bands of manganese are prominent, overlying the continuous spectrum of carbon monoxide. There are lines of carbon monoxide, manganese, and iron, also those of the alkali metals.
During the third period. The "fining stage."	The spectrum is the same as the foregoing, but the lines of iron are not so strong and not quite so well defined. Some of the short lines disappear. The lines of the alkali metals are visible.

The alkali metals do not show themselves in the Bessemer flame until a layer of slag has been formed, and the temperature has risen sufficiently high for these basic constituents to be vapourised. At the temperature of the "boil" or second period, both metallic manganese and iron are freely vapourised in a current of carbon monoxide, which, in a highly heated state, rushes out of the bath of molten metal. The evidence of this is the large number of bands of manganese and lines of iron in the spectrum.

When the metal blown contains but little manganese, the manganese spectrum in the flame does not arise from that substance being contained in the bath of metal, it must be vapourised from the slag. That this is so has been proved by photographs of the spectrum from samples of slag obtained from the Crewe works. This explains the fact observed by Brunner, namely, that when a converter is being heated with coke after it has been used, but not relined, the spectra of the Bessemer flame makes its appearance; manifestly it comes from the adhering slag.

The luminosity of the flame during the "boil" is due, not merely to the combustion of highly heated carbonic oxide, but also to the presence of the vapours of iron and manganese in the gas.

The disappearance of the manganese spectrum at the end of the "fining stage," or third period, is primarily due to a reduction in the quantity of heated carbon monoxide escaping from the converter, which arises from the diminished quantity of carbon in the metal. When the last traces of carbon are gone, so that air may escape through the metal, the blast instantly oxidises any manganese, either in the metal or in the atmosphere of the converter, and, furthermore, oxidises some of the iron. The temperature must then fall with great rapidity.

The entire spectroscopic phenomena of the "blow" are undoubtedly determined by the chemical composition of the molten iron, and of the gases and metallic vapours within the converter, the temperature of the metal and that of the issuing gases.

The Temperature of the Bessemer Flame.

The probable temperature of the Bessemer flame at the finish is that produced by the combustion in cold air of carbonic oxide heated to about 1580° C., that is to say, to the temperature which, according to Le Chatelier (*Comptes Rendus*, vol. cxiv. p. 670) is that of the bath of molten metal from which the gas has proceeded. The bath of metal acts simultaneously as a means of heating the blast, producing the gas, and as a furnace, on the regenerative principle, which heats the gas prior to its combustion. The heating effect is therefore cumulative. The temperature, as is well known, can easily rise too rapidly, and the metal has then to be cooled.

If we may judge by the lines and bands belonging to iron and manganese which have been measured in photographed spectra of the Bessemer flame, the temperature must nearly approach that of the oxyhydrogen flame, and may easily attain the melting point of platinum, namely, 1775° C. (Violle).

From thermo-chemical data the heat evolved during the "blow" has been calculated, but the specific heats of cast iron, slag, carbon monoxide, and nitrogen are unknown at temperatures between 1200° C. and 2000° C. If we allow for 50 per cent. of heat developed at high temperatures being lost by radiation or otherwise, then the estimated temperature of the metal in the converter is more than 1900° C.

Le Chatelier (*Comptes Rendus*, vol. cxiv. p. 670) found the steel in the ladle of a Robert converter to be at 1640° C. Reasons are adduced for believing that it was hotter than this at the highest temperature of the "blow."

The Technical Aspect of this Investigation.

The complete termination of the "fining stage" is clearly indicated, but there is no indication by the flame of the composition of the metal within the converter at any previous stage. As the progress of the "blow" is governed by the composition of the metal and its temperature in the converter, and as these cannot be controlled with perfect exactitude during each "blow," it follows that the practice of complete decarburisation [1] is the best course to pursue, the required amount of carbon and manganese being added subsequently in the forms of grey iron, spiegel, or ferro-manganese.

Mathematical Society, June 14.—Mr. A. B. Kempe, F.R.S., President, in the chair.—Abstracts of the following communications were read by the secretary (Mr. R. Tucker).—The solutions of $\sinh\left(\lambda\frac{d}{dx}\right)y = f(x)$, $\cosh\left(\lambda\frac{d}{dx}\right)y = f(x)$, λ a constant, by Mr. F. H. Jackson.—A theorem in inequalities, by Mr. A. R. Johnson. This was a theorem which in a natural way fills up the gap between the A.M. and the G.M. of a number of positive quantities.—Some properties of a circle, by Mr. R. Tucker.—Note on four special circles of inversion of a system of "generalised Brocard" circles of a plane triangle, by Mr. J. Griffiths.—On the order of the eliminant of two or more equations, by Dr. R. Lachlan. In analytical work it is often important to know what will be the order of the eliminant of two equations containing several variables when one of them is eliminated. This question can in general be answered even when it is not easy to perform the elimination. A discussion of the question is given in Serret's "Cours d'Algèbre Supérieure," and is said to be due to Minding. But a simpler method would seem to be arrived at by geometrical considerations. Thus, suppose that it is required to find the order of the eliminant in y when x is eliminated from any two equations,

$$f_1(x, y) = 0 \text{ and } f_2(x, y) = 0.$$

Let a third variable, z, be introduced, so that the equations may be written in the homogeneous forms,

$$\phi_1(x, y, z) = 0 \text{ and } \phi_2(x, y, z) = 0,$$

and let the degrees of these equations be m and n. When these equations are regarded as representing curves, the eliminant will represent the lines connecting the point $y = 0$, $z = 0$ to the points common to the two curves. Hence, the order of the eliminant will be at most mn, because the curves will intersect in that number of points. But a little consideration will show that it will not in general be necessary to take into account the points common to the two curves which lie on the lines $y = 0$, $z = 0$. Similarly, if it is required to eliminate x and y from three equations containing x, y, and z, let a fourth variable, w, be introduced, so as to make the equations homogeneous. Then

[1] The words "carburising" and "decarburising" are to be preferred to "carbonising" and "decarbonising" when applied to metals, because these expressions were those originally used in the older works on metallurgy, and they avoid confusion with the other signification of the word "carbonising."

the order of the eliminant will be the number of common points of the surfaces, less the number of common points which lie in the two planes $z = 0$, $w = 0$. In the paper several examples are considered. It will suffice to mention here the case which led to these investigations. Consider two equations of the form

$$\frac{a_1 x_1}{\alpha_1 + \theta} + \frac{a_2 x_2}{\alpha_2 + \theta} + \frac{a_3 x_3}{\alpha_3 + \theta} = 1.$$

These equations may be written in the homogeneous form

$$\frac{a_1 x_1 \phi}{\alpha_1 \psi + \theta} + \frac{a_2 x_2 \phi}{\alpha_2 \psi + \theta} + \frac{a_3 x_3 \phi}{\alpha_3 \psi + \theta} = 1,$$

and thus represent curves of the third order. But the curves have evidently three common points on the line $\phi = 0$; and a common node (with different tangents) at the point $\theta = 0$, $\psi = 0$. Hence the degree of the eliminant of the given equations is

$$9 - 3 - 4 = 2.$$

More generally, the eliminant of two equations of the form

$$u_n + u_{n-1} + \ldots + u_0 = 0,$$

$$v_m + v_{m-1} + \ldots + v_0 = 0,$$

where u_i and v_i are homogeneous expressions of the ith degree in

$$\frac{x_1}{\alpha_1 + \theta}, \frac{x_2}{\alpha_2 + \theta}, \ldots, \frac{x_r}{\alpha_r + \theta},$$

is shown to be of degree $(r - 1)mn$ in the variables $x_1, x_2, \ldots x_r$. —Solvable cases of the motion of a top or gyrostat, by Prof. A. G. Greenhill, F.R.S. When the sum of the parameters of the two elliptic integrals of the third kind, whose poles correspond to the highest and lowest position of the axis of the top, is an aliquot part of the associated elliptic function periods of the form $K + fK'i$, where f is a proper fraction, then Abel's theory of Pseudo-Elliptic Integrals can be utilised to construct an algebraical solution of the motion, provided that in the general case a secular term pt is associated with the azimuth ψ of the axis. Denoting by θ the angle between the axis of the top and its highest position, and supposing θ to oscillate between α and β, $\alpha > \theta > \beta$, then the dynamical equations to be satisfied are of the form

$$\tfrac{1}{2} A \left(\frac{d\theta}{dt}\right)^2 + \tfrac{1}{2} A \sin^2\theta \left(\frac{d\psi}{dt}\right)^2 = Wgh\,(d - \cos\theta),$$

$$A \sin^2\theta \frac{d\psi}{dt} + Cr\cos\theta = G;$$

equivalent to, with $n^2 = Wgh/A$,

$$\sin\theta \frac{d\theta}{dt} = n\sqrt{2}\sqrt{(\cosh\gamma - \cos\theta \,.\, \cos\beta - \cos\theta \,.\, \cos\theta - \cos\alpha)},$$

$$\sin^2\theta \frac{d\psi}{d\theta} = \frac{\dfrac{G - Cr\cos\theta}{\sqrt{(2AWgh)}}}{\sqrt{(\cosh\gamma - \cos\theta \,.\, \cos\beta - \cos\theta \,.\, \cos\theta - \cos\alpha)}};$$

and it is found that the constants in the problem can be expressed in terms of two arbitrary constants m and c.

In the simplest case, $f = \frac{1}{2}$, the motion of the axis, or of a fixed point on it, will be given by the equation

$$\sin^2\theta e^{2(\psi - pt)i} = (\cos\theta - D)\sqrt{(\cosh\gamma - \cos\theta \,.\, \cos\beta - \cos\theta)} + i(E\cos\theta - F)\sqrt{(\cos\theta - \cos\alpha)},$$

where

$$\cos\alpha = \frac{m^2 - 1 - c - c^2}{\sqrt{M}},$$

$$\cos\beta = \frac{m^2 - 1 - c + c^2}{\sqrt{M}},$$

$$\cosh\gamma = \frac{m^2 + 1 + 3c + c^2}{\sqrt{M}},$$

$$M = (m^2 - 1 + c + c^2)^2 + 8(m + 1)(c + c^2).$$

$$D = \frac{3m^2 + 4m + 1 - c - c^2}{\sqrt{M}}, \quad E = \frac{(2m + 1)\sqrt{2}}{\sqrt[4]{M}},$$

$$F = \frac{2m^3 + 3m^2 + 2(1 + c + c^2)m + 1 + 3c + 3c^2}{M^{\frac{3}{4}}},$$

$$\frac{p}{n} = \frac{2m + 1}{2\sqrt[4]{M}}, \quad \frac{G^2}{2AWgh} = \frac{2m^2}{\sqrt{M}}, \quad \frac{C^2r^2}{2AWgh}$$

$$= 2\frac{m^6 - 2(1 - a)m^4 + (1 - 6a + a^2)m^2 - 4(a - a^2)m + 4a^2}{M^{\frac{3}{2}}}$$

where $a = c + c^2$.

The modulus k of the associated elliptic functions is given by $k = c/(1 + c)$, so that the period of the axis between its highest and lowest position is $\frac{\sqrt[4]{M}}{(1 + c)\sqrt{2}}$ times the period when the body makes plane oscillations, swinging through an angle $4\sin^{-1}c/(1 + c)$.

By putting $m = -\frac{1}{2}$, the secular term pt is made to disappear, and the path of a point on the axis of the top is a closed curve with four branches; this curve has four cusps if $c = \frac{1}{2}$, and it has four loops if $c > \frac{1}{2}$.

The term Cr can be made to disappear by determining a in terms of m by the solution of a quadratic equation, and the motion is that of a spherical pendulum; but it is not possible now to make p vanish. In the next case of $f = \frac{1}{3}$ the motion of the axis is given by an equation of the form

$$\sin^3\theta e^{3(\psi - pt)i} = (\cos^2\theta - D\cos\theta + D')\sqrt{(\cosh\gamma - \cos\theta \,.\, \cos\theta - \cos\alpha)}. + i(E\cos^2\theta - F\cos\theta + F')\sqrt{(\cos\beta - \cos\theta)}$$

and

$$\cos\alpha = \frac{m^2 - 1 + 4c - 5c^2 + 0 + c^4}{\sqrt{M}},$$

$$\cos\beta = \frac{m^2 - 1 + 4c - 5c^2 + 4c^3 - c^4}{\sqrt{M}},$$

$$\cosh\gamma = \frac{m^2 + 1 + 0 - 5c^2 + 4c^3 - c^4}{\sqrt{M}},$$

$$M = (m^2 - 1 + 8c - 15c^2 + 8c^3 - c^4)^2 + 8(1 - c)^2(2c - c^2)(1 - 2c)(m + 1 - 3c + c^2),$$

$$k^2 = \frac{2c^3 - c^4}{(1 - c)^3(1 + c)}, \quad \frac{p}{n} = \frac{3m + (1 - 2c)(2 - c)}{3\sqrt[4]{M}}$$

$$E = \frac{3m + (1 - 2c)(2 - c)}{\sqrt[4]{M}}\sqrt{2} \ldots$$

D, D′, E, E′ being readily found by verification. In this case the secular term pt is destroyed by taking $m = -\frac{1}{3}(1 - 2c)(2 - c)$, and a point in the axis now describes a curve with six loops. The case of $f = \frac{2}{3}$ can similarly be made to give a curve with three loops, the general state of motion being given by an equation of the form

$$\sin^3\theta e^{3(\psi - pt)i} = (\cos^2\theta - D\cos\theta + D')\sqrt{(\cos\beta - \cos\theta \,.\, \cos\theta - \cos\alpha)} + i(E\cos^2\theta - F\cos\theta + F')\sqrt{(\cosh\gamma - \cos\theta)}.$$

A similar procedure will serve for

$$f = \frac{1}{4}, \frac{3}{4}, \frac{1, 2, 3, 4}{5}, \text{\&c.};$$

the results are of rapidly increasing complexity, but the constants D, E, ... are readily determined when p is known, E being the simple multiple $\mu\sqrt{2}$ of p/n, while

$$\frac{p}{n} = \frac{\mu m + \rho}{\mu\sqrt[4]{M}},$$

where

$$\tfrac{1}{2}\int \frac{\rho(Pu - Pv) + \mu P'v}{Pu - Pv}\,du$$

is the pseudo-elliptic integral corresponding to a parameter v, which is a μth part of a period. The Rev. F. J. Smith, F.R.S., of Oxford, has constructed an apparatus by which the preceding theory can be tested, and the agreement between the predicted and experimental results is very satisfactory.—Impromptu communications were made by Dr. J. Larmor, F.R.S. (on the wave surface), and Dr. M. J. M. Hill, F.R.S. (on Monge's solution of a differential equation).—At the special meeting, held on the same evening, for considering certain resolutions relating to the incorporation of the Society under the Companies Act 1867, authority was given to the Council to carry out the incorporation.

PARIS.

Academy of Sciences, July 2.—M. Lœwy in the chair.—Researches on phenylhydrazine. Action of oxygen and of water; formation of salts, by M. Berthelot. Oxygen reacts on a solution of phenylhydrazine hydrochloride, giving off a volume of nitrogen equal to that of the oxygen absorbed, and yielding an uncrystallisable oily compound answering to the reactions of diphenylhydrazine. Pure anhydrous phenylhydrazine heated at 100° with oxygen in sealed vessels yields about half as much again nitrogen. Phenylhydrazine forms a crystalline hydrate melting at 24° C. and having the composition $2C_6H_8N_2 . H_2O$. Thermal data are given for the formation of the hydrate and some of the salts of this base.—Impurities of commercial aluminium, by M. Henri Moissan.—Preparation of a crystallised aluminium carbide, by M. Henri Moissan. A carbide of aluminium forming fine yellow transparent crystals is described. It has the composition C_3Al_4, and slowly decomposes water at the ordinary temperature with the formation of methane.—On the place of production and the mechanism of the murmurings in tubes through which pass currents of air, by M. A. Chauveau. The murmurings are the effect of the transmission of sounds originated by vibrating fluid veins which form at the orifices or at the entrance of dilatations of the tubes. —The use of the potato for feeding cattle—production of meat, by M. Aimé Girard. The results of an extended investigation show that the potato is much superior to beetroot as a food-material for cattle and sheep, and can be used economically with remarkable results as a normal meat-producing forage.—A note by M. Drake del Castillo.—On the algebraical integration of differential linear equations, by M. Paul Painlevé.—On a class of polynomials decomposable into linear factors. An extract from a letter to M. Appell, by M. Moutard.—Experimental researches on the conditions of employment and forms of boats used for haulage, by M. J. B. de Mas.—On the elasticity of torsion of an oscillating wire, by MM. G. Berson and H. Bouasse.—On the calorific radiations comprised in the luminous part of the spectrum, by M. Aymonnet.—Reception of sounds, by M. Henri Gilbault.—On enharmonic gamuts, by M. A. de Berthe. —On an application of cathode rays to the study of variable magnetic fields, by M. Albert Hess. An apparatus is employed in which the cathode rays are generated in a Geissler tube and received on a photographic film. Being given that deviations of the rays are due to modifications of the state of tension of the ether under the influence of the magnetic field, the cathode rays form an index without inertia capable of registering the variations of intensity of a magnetic field with a speed only limited by the sensitiveness of the photographic film.—Determination of the form of periodic currents as a function of the time by means of the electrochemical inscription method, by M. P. Janet.—A transformer of monophase into triphase currents, by M. Désiré Korda.—Researches on the action of the acid molybdates of sodium and ammonium on the rotatory power of rhamnose, by M. D. Gernez. Small additions of molybdate determine a relatively great increase of the observed rotation. A maximum effect is produced by the addition of $\frac{6.75}{24}$ of the molecular weight. Greater quantities produce no further appreciable change. The maximum effect is produced by quantities of the molybdates equal to those found to give maximum effects in the cases of mannitol, sorbitol, and persitol.—On the change of sign of the rotatory power, by M. Albert Colson. The author concludes that, from the experimental evidence given, (1) there exist compounds having a rotatory power very variable with the temperature, even to the extent of changing sign, as in the case of isobutylamyl oxide; (2) in certain cases these great variations are caused by alterations in the state of chemical equilibrium.—On the line spectrum of sulphur and on its detection in metallic compounds, by M. A. de Gramont.—New researches on the bromo-boracites, by MM. G. Rousseau and H. Allaire. A description is given of the preparation and properties of compounds of magnesium, zinc, cadmium, manganese, cobalt, and nickel of the general type $6MO . 8B_2O_3 . MBr_2$.—Influence of pressure on the combination of hydrogen and selenium, by M. H. Pélabon. The dissociation theory indicates that the pressure should have no influence on the ratio of hydrogen to hydrogen selenide produced, as there is no alteration of volume in the reaction. The experimental numbers obtained sensibly agree with this conclusion, better as the temperature is higher. The augmentation of pressure increases very slightly the quantity of hydrogen selenide produced at a certain temperature, more as the temperature remains lower.—On a reaction of aldehydes. Differentiation of aldoses and ketoses. By MM. A. Villiers and M. Fayolle. Fuchsine decolourised by sulphurous acid may be used to discriminate between aldoses and ketoses, the former giving when present in sufficient quantity the aldehyde reaction, though less intensely than ordinary aldehyde.—On the substitution of alcoholic radicals combined with carbon or with nitrogen, by M. C. Matignon. A claim for originality as against MM. Stohmann and Langbein.—Remarks on the preceding note, by M. Berthelot.—On piceine, a glucoside from the leaves of *Pinus picea*, by M. Tanret. The glucoside has been resolved into glucose and piceol, $C_8H_8O_2$. The latter substance is described as a monotomic phenol.—On the presence of hydrogen and ethylene in the residual nitrogen from blood, by M. L. de Saint-Martin.—Action of sulphuric acid on camphene, by MM. G. Bouchardat and J. Lafont. The products are (1) the mixed ether of borneol and inactive camphene; (2) borneol sulphuric acid; and (3) polymerides of camphene.—On the bromo-derivatives of tetrachlorethylene, by M. A. Besson.—On some new organo-metallic combinations, by M. G. Perier. Anhydrous aluminium chloride forms, with ketones and similar bodies, compounds of the type $R_2 . Al_2Cl_6$. This article demonstrates the existence of similar compounds with amines, amides, and their substitution products.—On the formation of succinic acid and glycerine in alcoholic fermentation, by M. J. Effront. —The influence of chlorides on nitrification, by MM. J. Crochetelle and J. Dumont.—A new case of commensalism: association of *Aspidosiphon* with coral polyps and a bivalve mollusc, by M. E. L. Bouvier.—Transformation of the aortic arches in the frog, by M. S. Jourdain.—On the respiration of leaves, by M. L. Maquenne.—The mechanism of movements incited in *Berberis*, by M. Gustave Chauveaud.—The "brûlure" of vine-leaves produced by *Exobasidium vitis*, by MM. Prillieux and Delacroix.—On a new disease of wheat caused by Chytridineæ, by M. A. Prunet.—"Brunissure" in Algeria, by M. F. Debray.—On the earthquake of Locrides (Greece) in April 1894, by M. Socrate A. Papavasiliore.—Potatoes as food for milch-cows, by M. Ch. Cornevin.—The vegetation of vines treated by submersion, by M. A. Muntz.—On the determination of the agricultural value of several natural phosphates, by M. G. Paturel.—Currents and winds on the coast of the Landes of Gascony, by M. Hautreux.

ANCIENT ASTRONOMY.

Recherches sur l'histoire de l'Astronomie Ancienne. Par Paul Tannery. (Paris: Gauthier-Villars et Fils, 1893.)

THE author's previous work, "Pour l'Histoire de la Science hellène," in which early Greek scientific ideas are treated of from the time of Thales to that of Empedocles, and which first appeared in fragments in the pages of the *Revue Philosophique*, leads the reader to open the present with high expectations, which its perusal will assuredly not disappoint. It in no degree trenches upon the ground occupied by the former; but its main object is to furnish an analysis of the Almagest, more accurate and complete than those given by previous writers, and also to discuss the views of those who may fairly be called the precursors of Ptolemy, and especially of Hipparchus. On this latter point M. Tannery's researches have led him to conclusions somewhat different from those which have been generally entertained. The part played by Hipparchus in the progress of astronomy he considers to have been singularly exaggerated, and the ground to have been prepared rather by the earlier writers of the Alexandrian school, particularly by Apollonius of Perga, in the invention of geometrical and trigonometrical methods, and the first systematic combination of recent with earlier Chaldean observations. To illustrate clearly his meaning, he affirms that, without these previous works, Hipparchus would have been unable to accomplish the greater part of that which has made his name immortal; whereas without that of Hipparchus, Ptolemy would have been able in great measure to have composed his Almagest; it would have been undoubtedly much more imperfect and less accurate in many numerical details, but "l'ensemble ne présenterait pas un caractère très notablement différent."

The work begins with an etymological discussion (certainly conducted on historical principles) of the origin of the words (*i.e.* of their Greek equivalents) "astronomy" and "astrology." The former is the older of the two, and is found in Plato and in Aristophanes; the substitution of "astrology" was made by Aristotle. Hipparchus preferred the term mathematician to astronomer or astrologer; and following in his wake, Ptolemy called his great work (for which we usually use the Arabic designation "Almagest") the mathematical composition. It may be interesting to remember that though in modern times the expressions astronomy and astrology returned into use (at first with the same meaning, but the latter became degraded by exclusive application to absurd and superstitious attempts, in the manner of the Chaldeans and Egyptians, to predict future events by supposed planetary influences), yet Flamsteed's favourite way of designating himself was as M.R., for "mathematicus regius." M. Tannery thinks that the term ἀστρονόμος preceded that of ἀστρονομία, and that it strictly signified one who distributed the stars into groups, or, as we call them, constellations. With regard to the well-known passage in Homer, speaking of the Bear that alone has no part in the baths of the ocean, he takes the poet to include under that name all the stars within the circle of perpetual apparition. The knowledge of the distribution of the stars in the visible firmament was obviously of use in navigation; the extension of this astronomy to reasoning on their motions, for which the expression astrology was afterwards logically preferred by Aristotle, was, we are told by Xenophon, discouraged by Socrates; but the language of the historian rather points to the works of Eudoxus of Cnidus, which appeared subsequently to the time of Socrates.

M. Tannery takes occasion to allude to the famous story or legend of the number of the year in the Metonic Cycle taking its name from its being graven in golden letters on a public square in Athens; whereas Boeckh has proved that the cycle in question was not brought into use there until the reform of Calippus, a century after the time of Meton, and Aristophanes in more than one passage ridicules the disorders of the calendar in his own time.

In his second chapter, M. Tannery treats of the progress made in the science which acquired the name of astrology (but for which modern science prefers the more ancient term astronomy, to avoid confusion with what Kepler called its hair-brained sister, though we refuse to recognise any relationship, and it was felt to be too much trouble always to call the other judicial astrology) during what may be considered the Athenian period, for thither came Eudoxus, who founded the school of Cyzicus and introduced the use of the instrument called the ἀράχνη, identical in principle with the astrolabe, the invention of which was long falsely attributed to the Arabs; and there also Calippus conferred with Aristotle. But Alexandria was destined to take the place of Athens as the principal seat of Greek learning. It was, however, to the second period of its prosperity, under the Roman domination, that the astronomical glory of Alexandria culminated in the hands of Claudius Ptolemy, whose work may be said to comprise all that was known of astronomy until the era of Copernicus and Tycho, soon to be followed by that of Kepler and Galileo. Meanwhile one of the islands on the coast of Asia Minor, on which, according to the Greek proverb, the sun always shone, so that it may be presumed that the stars also frequently did at night, had been the scene of the scientific labours of Hipparchus, probably the best known amongst the ancient astronomers. Mr. Chambers calls him "the Newton of Greece," but it is evident that M. Tannery does not share that view at any rate. The illustrious Bithynian is usually considered, he says, "comme un génie absolument hors de pair"; but without desiring in any way to depreciate his very important contributions to science, he adds, "L'importance de son rôle est en tout cas assez grande pour que ce ne soit pas lui faire injure que d'essayer de le ramener à des proportions un peu plus humaines. Il a possédé, sans contredit, les qualités essentielles à un astronome; habile et patient observateur, calculateur émérite, il fut également doué de la sagacité qui conduit aux découvertes capitales et de la puissance de déduction qui permet d'enchainer les vérités nouvellement acquises dans un système solidement construit. Eut-il, au même degré, le génie de l'invention mathématique? C'est ce qui semble pouvoir être mis en doute."

The author proceeds to show that in many of the advances usually attributed to Hipparchus, especially those in which mathematical acumen was requisite, he had been preceded by others, though undoubtedly his store of observations was of great value to his successors, and in practical methods he made many and important inventions. "Trigonometry," we read in the article on Ptolemy in the Encyclopædia Britannica, "was created by Hipparchus for the use of astronomers." M. Tannery gives reasons for believing that his qualifications were not of a kind to enable him to make discoveries of this nature, whilst as for the systematic development of the hypothesis of epicycles and eccentrics to represent the celestial movements (which, since the time of Kepler, "n'est plus que l'objet d'un dédain qu'à vrai dire, elle ne mérite guère en elle-même"), the testimony of antiquity attributes this to the great geometer, Apollonius of Perga. Even in the systematic utilisation by Hipparchus of the ancient Chaldean observations of eclipses, he had probably to a great extent been anticipated by Conon of Samos, best known as the friend of Archimedes, and for his ingenious flattery of the Egyptian queen by raising her hair to the heavens as the constellation Coma Berenices. Seneca, it is true, speaks of Conon's use of Egyptian observations; but this was in all probability an error for Chaldean, brought about by the astronomer's residence in Egypt. It would seem, in fact, that Hipparchus should rather be compared to Flamsteed than Newton amongst the moderns. M. Tannery goes on to dwell upon the mathematical importance of the work of Apollonius, who was probably the same as the astronomer of that name who also lived under Ptolemy Philopator, and was called Epsilon on account of his researches on the theory of the moon; the old ordinary form of that letter resembling a crescent.

Geminus and Cleomedes (whose native places are unknown), Theon of Smyrna, the elder Pliny, are passed in review; but the principal part of the work before us respects, as before said, the great composition of Ptolemy, of which a very complete and interesting account is given. The ancient astronomer who, unknown to Copernicus (as it appears only from a work of Archimedes inaccessible to him), had anticipated him in the theory of the earth's motion, was Aristarchus of Samos. But, however worthy of admiration this may be, "on ne doit nullement exagérer le tort que subit la science astronomique par le fait qu Hipparque et Ptolémée ont maintenu le système géocentrique. Au point de vue mécanique et physique, la conception héliocentrique réalisait un immense progrès; au point de vue géometrique, que la science des anciens n'a pas dé passé pour les astres, cette conception ne présentait aucun avantage réel." The position and work of Copernicus is so often little understood, that it may be well here to quote further M. Tannery's language:—

"Le véritable titre de gloire de Copernic est peut-être moins d'avoir réprouvé le système d'Aristarque que d'avoir en même temps, mais à la suite d'un travail considérable et tout-à-fait indépendant de ce système, simplifié extrêmement les hypothèses relatives aux épicycles et excentriques, tout en conservant les mêmes principes géométriques que les anciens pour l'explication des mouvements des planetes."

The space at our disposal renders it quite impossible to do more than offer some indications of the contents of a work of which we may well say with Osiander of that of Copernicus, "eme, lege, fruere." But we may be permitted to express our concurrence with its closing remark:—"En tout cas, on ne pourra se refuser à admettre cette vérité que *la science ne se développe que lorsqu'elle est cultivée pour elle-même;* voilà sans doute la plus solide conclusion que l'on puisse tirer de son histoire."

There are several interesting appendixes, particularly those on the trigonometry of the ancients, on the great year of Josephus, on the conjectural opinions of the ancients concerning the distances of the planets from the earth, and one (by M. Carra de Vaux) on the celestial spheres of the Persian astronomer Nasir-Eddin Attûsi (born at Tûs in Khorasan, A.D. 1200), with a translation of part of his work. But there is not, what there certainly should be, a general index to the whole. W. T. L.

SCOTTISH LAND-NAMES.

Scottish Land-names. By Sir Herbert Maxwell, Bart., M.P. (Edinburgh and London: W. Blackwood and Sons, 1894.)

THIS book is practically a collection of a course of lectures called the "Rhind Lectures in Archæology," published "just as they were delivered." Sir Herbert Maxwell has done well to print them, by way of furnishing material for future workers, amongst which we may hope that he may himself make one.

The book furnishes a large number of notes and suggestions; and good work might be done by some philological scholar, who would go over the suggested etymologies, and verify them one by one. It is tolerably certain that some of them will not stand any very rigid test; whilst others will, no doubt, be found to be quite correct.

The author clearly recognises the great principle upon which all such investigations must be conducted. We must in every case try to find out the earliest written form in some charter or deed; and it will then often be found that such early form wholly contradicts the suggestion which the modern name presents.

"From a charter of the same king (William the Lion) it is evident that Granton, near Edinburgh, is not, as it appears, Grant's-town, like Grantown-on-Spey; for it is written *grendun*, the Anglo-Saxon *grene dun*—green hill." Similarly, we may remark, we find in England such names as Grendon and Grindon.

After laying down this all-important principle, it is not a little surprising to find, at the end of the work, an index of place-names, with etymologies, in which not a hint is given of the authority upon which each explanation rests. Thus "the Braid Hills" is explained from the Gaelic *braghad* (braad), the breast; and, of course, if there is documentary evidence for it, there is no more to be said. But if not, it is by no means clear why *braid* may not be the ordinary Lowland-Scotch word for "broad." In every such case, we have a right to expect that the evidence should in some way be given; precisely as, in Bardsley's book on Surnames, the whole value of the work really resides in the copious lists of references which are given at the end of it.

We have noted a considerable number of other points on which we desire further information. The remarks on the pronunciation (which is rightly said to be of great importance) are frequently bewildering. It may be well to point out two typical instances, for the bettering of the book in a future issue.

"Broad-ford in Skye retains the full sound of the Norse *breidr fjördr*, broad firth" (p. 84). This is precisely the thing which it does not do. *Broad* is not Norse, but Southern English; and *ford* suggests the word *ford* rather than *firth*.

"*Völlr*, a field, generally becomes *wall* in composition, as Dingwall in Ross-shire" (p. 89). Here "becomes" really means "is represented by"; for, as a fact, the form *wall* shows a far older stem, in which the *w* has not yet become *v*, and the *a* has not yet been treated with the *u*-umlaut. In other words, it would be far more correct to say, conversely, that the old stem *wall* has become *völlr* in the nominative case of the modern Icelandic word.

One thing, at any rate, must go. And that is, the extraordinary definition of *umlaut* on p. 39. "The law of *umlaut*, as the German philologers call it, whereby the vowel-sound in one syllable is altered by the vowel-sound in a syllable following (all fairly well so far, but mark the sequel), as *husband* and *nostril* stand for *house-band* and *nose-thrill*." Certainly, no German philologer ever said anything of the kind. The *u* in husband and the *o* in *nostril* are not examples of *umlaut* at all, for they do not depend in the least upon the vowels *a* or *i* in the second syllable. They simply exhibit examples of vowel-shortening before a collection of consonants, which is a different thing altogether. This is indeed a sentence to induce doubt in the author's methods.

Nevertheless, the book has its place and use. The collection of examples is a thing to be thankful for; and we heartily commend the author for attempting it. But, oh! that he had produced his authorities in every possible case, and had told us where the guesses come in!

OUR BOOK SHELF.

Systematic Survey of the Organic Colouring Matters. By Drs. G. Schultz and P. Julius. Translated and edited, with extensive additions, by Arthur G. Green. (London: Macmillan and Co., 1894.)

THE German edition of this standard work of reference has already been reviewed in these columns (vol. xlvi. p. 313). The translator and editor has done good service in rendering the work more available to English technologists by adding a preliminary section on the raw materials used in the industry, as well as by giving prominence in the tables to English patents. In these particulars the present edition differs from the German, and its value from the English point of view is thereby greatly enhanced. The work is also brought up to date, as all the later discoveries are tabulated. The total number of colouring matters now recorded is 454, as against 392 in the last German edition (1891). Even while Mr. Green was preparing the translation new products were being introduced, and no less than twenty-two new compounds have had to be added in an appendix. Another valuable addition to the English edition is the synoptical table for the qualitative analysis of artificial colouring matters, which was published by the translator last year in the *Journal* of the Society of Chemical Industry, and which is reprinted at the end of the volume.

One reflection which occurs in looking through the tables is the very unfair action of our patent laws upon English manufacturers. Most of the new discoveries are patented by German, French, or Swiss firms in this country, but the patentees do not make the products here—their patents simply blockade the industry in Britain, without giving our manufacturers any benefit. On the other hand, it is well known how stringent is the attitude, especially of the German Patent Office, in granting patents to foreign inventors. But this is a side issue, suggested only by the large number of references to English patents in the tables before us. Of these tables and of the work as a whole we have only to say that it will be welcomed by manufacturers and students as the latest and most complete synopsis of the organic colouring matters that has hitherto been drawn up.

R. M.

A Handbook to the Marsupialia and Monotremata. By Richard Lydekker, B.A., F.G.S. (London: W. H. Allen and Co., 1894.)

MR. LYDEKKER'S capacity for book-making seems to be unlimited. Zoological science is indebted to him for the diffusion of accurate knowledge on the fowl of the air, and "every living thing that creepeth upon the earth" and moves in the sea, from the days when the icthyosaurus disported itself in the Jurassic ocean to the present enlightened age. He is not, however, a brilliant writer, and all his works possess a sameness of diction, the dead level of which becomes oppressive after a time. The volume under review is a "popular monograph," in which the Marsupials and Monotremes are taken in order and have their characters, distribution, and habits detailed in a more or less attractive manner. These interesting mammals are dealt with one after another, and their characteristics are described in a way that strongly reminds us of the verbal expositions of the guide of a menagerie. The thirty-eight excellently coloured plates, with which the book is embellished, help to render the analogy more realistic. This monotony, however, is probably unavoidable in a work having the scope of Mr. Lydekker's handbook, and, in fairness to him, we must say that he has struck a good compromise between zoological treatises bristling with technical details, and works designed for the profoundly ignorant. It is almost unnecessary to say that the book is thoroughly up-to-date as regards recently discovered species, one of the most interesting of these being the remarkable Marsupial Mole described by Dr. Stirling a few years ago. With the exception of the matter relating to a few species, the book is founded upon Mr. Oldfield Thomas's "Catalogue of the Marsupialia and Monotremata in the Collection of the British Museum" (1888), with the addition of some notes on fossil species of these Orders. Mr. Lydekker has made an admirable and handy abridgment of this "indispensable compendium," and his work, though stodgy in places, will well serve the purpose of a popular book of reference on Australian mammals.

Climbing in the British Isles—England. By W. P. Haskett Smith, M.A. Pp. 162. (London: Longmans, Green, and Co., 1894.)

MOUNTAINEERING is a passion. Men who have climbed, rarely, if ever, get rid of the unrestful instinct to scale unconquered peaks and wriggle through unexplored "chimneys." This love of climbing has been growing in England for some years past, and Mr. Haskett Smith's book will certainly assist in extending it still more. The book is the first of a series describing the climbs available in the British Isles, two complementary volumes, dealing respectively with Wales and Scotland, being in preparation. It is not, of course, suggested that hill-climbing in these islands is the same as mountaineering in the

Alps, but it is rightly held that the man who goes through a course of training among the crags of Cumberland qualifies himself to tackle the giants of the Alps or Caucasus. Beginning with the tors on Dartmoor, the would-be Alpinist can pass by easy stages to such climbs as those of Deep Gill, Mickledoor and Napes Needle, and then complete his course of instruction on the Alps. For convenience of reference, all the headings are arranged in alphabetical order. It is easy, therefore, to turn up information about hills or rocks which afford climbs, and to find the meaning of technical terms and expressions. It would have been an advantage, however, if Mr. Smith had given a list of climbs in the order of difficulty, for beginners would then know exactly where to commence their mountaineering education. The book is illustrated with twenty-three sketches by Mr. Ellis Carr, and five plans. It will doubtless increase the number of climbers, and the many admonitions it contains ought to keep down the mortality from what someone has called the "greasy pole" exercise.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Trituberculy and Polybuny.

IT is a matter of regret to me that so clear-headed a naturalist as Dr. Forsyth Major should have misunderstood what I thought to be clear intelligible language.

In his letter (NATURE, May 31) Dr. Forsyth Major declares that, in my paper on the Stonesfield mammalia, I stated that he has expressed views in his paper on Squirrels (*P. Z. S.* 1893) the very reverse of those recorded by him in that paper. All that I have said about Dr. Major, whose paper I read after writing mine, is "Dr. Forsyth Major does not favour this view," viz. that all the various forms of lower molars of Ditrematous mammals can be derived from the tubercular-sectorial type. I shall be glad if Dr. Forsyth Major will either state that he *does* favour this view, or withdraw his charge of misrepresentation.

Again, I think, Dr. Major has misunderstood my words when he proceeds to declare that I have made "some obviously contradictory statements" in my paper on the Stonesfield mammalia, and in my letter to NATURE of May 3. The object of my remarks on the primitive mammalian tooth in my paper, was to show that that part of the "tritubercular theory" (as lately set forth by Profs. Cope and Osborn) which seeks to explain the tubercular-sectorial tooth as having arisen—within the mammalian phylum—from a single cone through a triconodont stage is beset with weaknesses and improbabilities which render it untenable. The view there expressed that the Pro-mammalian molars "were of an indefinite multituberculate pattern," or, in other words (used in my letter), that they were "provided with many cusps not placed in one line," is *not* inconsistent with the admission that the common ancestors of the Marsupials and Placentals—and even (if we accept Prof. Osborn's latest statement) of the so-called "multituberculata"—may have already developed tubercular-sectorial lower molars, and perhaps tritubercular upper molars. Dr. Forsyth Major, whose careful observations deserve great consideration, has argued, in his letter of May 31, very forcibly against this "working hypothesis." I think it only right to say that the views expressed by him are identical with those which have been urged on me privately, and also expressed in lectures, by Prof. Lankester, under whose direction I made my investigation of the Stonesfield jaws.

The theory I support, then, merely comes to this: that many-cusped teeth of indefinite pattern (such as those of Ornithorhynchus?) gave rise to tubercular-sectorial lower and, perhaps, tritubercular upper teeth, some of which in turn gave rise to many-cusped teeth of definite serially tuberculated pattern (Polymastodon, &c.). Prof. Osborn declared that he had evidence of the latter step. The one mistake to which I plead guilty is that of having apparently endorsed in my letter Prof. Osborn's view on this latter point. In reality I wished to be understood as admitting temporarily—and until further evidence comes to hand—a statement which I was not in a position to combat by the use of my own observations.

Oxford, June 4. E. S. GOODRICH.

A Review Reviewed.

I AM rather astonished at the criticism of my use of the term mineraliser in my book on the "Economic Geology of the United States," made by a reviewer in a recent number of NATURE. Surely the sanction of the Century, Webster, and Worcester dictionaries, besides several scientific works, should be considered as warranting my use of the term, unless some very serious objection can be urged.

Since I am writing on the subject, I may say what perhaps should have been said in my preface, that the mineralogical part of the book, to which exception is taken by the reviewer, was not intended to teach mineralogy, but to call attention to a new aspect of the subject—the economic. The students for whom the book was mainly written, those at Cornell University, have, when they begin the study of economic geology, already studied determinative mineralogy and blowpipe analysis, and they have also studied rock-forming minerals from the geological standpoint. Here is the third standpoint, and experience in teaching shows that the plan is not superfluous.

Objection is also made to the absence of illustrations. But this is intentional, for I believe the class-room is the place for these. There we can use large illustrations, lantern-slides, and original maps and sections, which are vastly better than text-book diagrams.

I wish also to make an acknowledgment. As the reviewer points out, and as others have done before him, the chapter on mining terms and methods is weak and in places inaccurate. It was a serious error on my part (for which the book has suffered) not to have submitted this chapter, upon which I have only second-hand knowledge, to some specialist for revision. At present the only thing that can be done is to promise the elimination of the objectionable parts in a second edition, if one is called for. RALPH S. TARR.

Cornell University, Ithaca, N.Y., June 29.

I WILL reply *seriatim* to the various points of Prof. Tarr's letter.

(1) *Term "Mineraliser."*—I still think the word objectionable in the sense used by Prof. Tarr. To most people it probably conveys the idea of something which converts or helps to convert another substance into a mineral. How can sulphur be said to "mineralise" silver by combining with it? Both the elements already exist as minerals in nature; and one might just as well say that the silver mineralised the sulphur.

(2) *Mineralogical part of the book.*—Prof. Tarr states that the object of this part of the book is not to teach mineralogy, but to call the attention of students to the economic side of the question; but this is no excuse for loose and careless writing, instances of which are far too numerous. We read on page 16: "When a metal is combined with silica (SiO_2), a silicate is formed." "Ores considered from the economic standpoint occur in beds or in veins" (p. 17); this would lead the student to infer that no other modes of occurrence are known. Iron pyrite "grades into copper pyrite, but when there is much copper present the colour becomes more golden" (p. 18) "Grade" as a neuter verb does not appear in my edition of Webster, but it probably is intended to mean "gradually passes into." This reading is confirmed on page 22, where we find "copper pyrites, which is in reality a sulphide of iron and copper combined, the proportion varying from an exceedingly cupriferous variety (chalcopyrite) to pure iron pyrites." Limonite is spoken of as "the rust of hematite" (p. 19). Tin ore "is found both as tinstone, in coarse granites or pegmatites, and as stream-tin" (p. 25). Is not stream-tin a form of tinstone, and may not tin ore be found in *fine-grained* granite and in slate?

Judging from the paragraph on page 20, the author is unaware of the existence of any oxidised ore of nickel. The student does not obtain a correct idea of dolomite by being told that it is carbonate of lime "combined chemically with magnesium" (p. 10). I think that these instances, and others might be quoted, justify my remarks.

(3) *Paucity of illustrations.*—If Prof. Tarr had adhered to

his original intention of merely writing lecture-notes for his class, there would have been some force in his excuse; but when he sends forth his work as "a text-book, with the hope that it may find a wider field," he cuts the ground from under his feet. He must recollect that the majority of his readers will never have the opportunity of seeing his lecture diagrams and lantern-slides. If illustrations are out of place in a text-book, why did the author take the trouble to insert twenty-nine? Surely he is not ashamed of his beautiful and instructive frontispiece.

(4) *Mining chapter.*—After Prof. Tarr's candid confession, I will not say another word likely to cause him pain or annoyance; but will merely express the hope that Professors of Economic Geology, while examining mineral deposits, will take the trouble to notice how they are worked, and so render themselves independent of any second-hand aid when writing upon the art of mining.

THE REVIEWER.

Halo of 90° with Parhelia.

ON July 11 the halo of 90°, intersecting a primary halo of the usual size, but intensely brilliant in colouring, was visible at West Newton, Cumberland, for about four hours—9 a.m. to 1 p.m. The sun shone brilliantly all the time. Light strips and wreaths of cirrus and minute mottled cirro-cumulus marked the upper sky. There were several mock suns, not all equally distinct. The halo of 90°, a very unusual phenomenon, was of a pale grey-blue tint, showing no prismatic colours, except in a very slight degree at the point furthest removed from the sun.

This system of halos formed a splendid sight for about four hours, indicating a vast sheet of ice-crystals. I have observed that parhelia sometimes precede heat, as well as stormy weather.

The intensely vivid colouring of the part of the two (almost concentric) halos, where they intersected above the sun, was most striking.

Rate of the Flight of Birds.

I SHALL be glad if any of your readers can inform me whether the rate of the flight of any birds other than Homing Pigeons has been accurately measured, and what attempts, if any, have been made to employ birds belonging to other families in place of Homing Pigeons.

F. W. HEADLEY.

Haileybury, July 15.

THE UNIVERSITY OF LONDON AND THE REPORT OF THE GRESHAM COMMISSIONERS.

THE University of London is beyond question the Institution most nearly concerned with the recommendations of the Commissioners appointed to consider the draft charter for the proposed Gresham University in London. These proposals, as was pointed out in NATURE in March last (vol. xlix. p. 405), involve the reconstruction of the present University and the formation of a Senate and Convocation having powers differing considerably from those at present possessed by them. Importance would, under any circumstances, attach to the attitude assumed by either body towards the Report, and in the present case it is in no way lessened by the fact that in the charter of 1863 it is ordained that Convocation—that is, those graduates of the University who have attained a certain seniority and paid certain fees—shall have "the power of accepting any new or supplementary charter for the University, or consenting to the surrender of this our charter, or of any new or supplemental charter," the consent of the Senate being also requisite before either acceptance or surrender becomes operative. This power of veto was exercised by Convocation in 1891, when a draft charter proposed by the Senate was rejected by a large majority, and the way made clear for University and King's Colleges to proceed with their petition for a separate University.

The preparation of a scheme for engrafting teaching on the present examining functions of the University of London did not originate with the Senate. To Convocation belongs the distinction of being the first to advocate this enlargement of the scope of the University, and its proposals were embodied in a scheme as long ago as 1886, while in a later scheme submitted to the Commissioners it indicated in still further detail the lines on which in its opinion a solution of the question might be found. The inability of each body to accept the schemes of the other, the chronic division of opinion between the Senate and Convocation on the Teaching University question, did not augur well for a joint assent to any scheme resulting from the labours of the Commissioners appointed in 1892.

This contingency evidently presented itself to a large majority of the Commissioners, since, with a wisdom which seems likely to be justified by events, they have gone beyond the terms of reference, which contemplated "the establishment under charter of an efficient Teaching University for London," and say that "in view of the failure of previous attempts to settle this question, and of the difficulty and delay which must inevitably attend an alteration of the constitution of the University through the action of the University itself, we are of opinion that, in accordance with the precedents followed in other cases of University reform, the changes which we recommend should be effected not by charter, but by legislative authority, and by the appointment of a Commission with statutory powers to settle, in the first instance, arrangements and regulations in general conformity with the recommendations which we are about to submit to your Majesty."

The latest project for the inevitable extension of University education in London was speedily recognised by many as a well-considered and feasible plan for meeting the requirements of the case. Highly desirable as it was that it should be accepted by, and not forced upon, Convocation, yet at first the outlook was anything but bright. The Annual Committee of Convocation—the body of graduates elected every year "to advise Convocation upon any matter affecting the interests of the University"—undertook the preparation of a report on the scheme of the Commissioners for presentation to Convocation. While this was under discussion an interview took place between it and the Committee of the Senate charged with the consideration of the Commissioners' Report, and it may be inferred that exception was taken to the revocation of the veto and to the mode of procedure proposed by the Commissioners, since the Chancellor (Lord Herschell), in the course of his reply, is reported to have said: "If the proposals of the Commissioners were generally considered to be for the public good, and a reasonable solution of the problem that had been referred to them, it would scarcely rest with this University, either through the Senate or through Convocation, to veto the plan; nor should the remodelling of the constitution of a public body, with a view to its further efficiency, be regarded as a penal abrogation of its charter."

Disregarding this statesmanlike view of the situation, the Annual Committee the same evening adopted a Report wholly adverse to the proposals of the Commissioners, and drew up five resolutions which they recommended Convocation to adopt. Space will only permit reference to the first: "That Convocation protests against the withdrawal without its consent of the charter of the University of London as proposed by the Gresham Commission . . . ." and the fourth: "That Convocation therefore, although it would regret the establishment of a second University in London, is of opinion that it would be less disastrous to establish such a University with a distinctive title than to carry into effect the scheme of the Gresham Commissioners." These will sufficiently indicate the Annual Committee's views.

Convocation's method of conducting business, it may be hoped, is peculiar to itself. Although an extraordinary meeting was convened on April 10 "to consider the Report of the Commissioners appointed to consider the draft charter of the proposed Gresham University in London, and also the Report of the Annual Committee thereon," it was debarred from expressing its opinion, either by discussion or vote, on the Commissioners' Report *as a whole*, and directed to confine itself to such matters as arose out of whichever resolution of the five might be under debate. After much fruitless discussion the resolutions proposed by the Annual Committee were unanimously set aside in favour of a motion which, "with a view to the speedy and satisfactory reconstitution of the University," referred "the whole question of the constitution of this University to the Annual Committee with power to nominate members of a Joint Consultative Committee of the Senate and Convocation."

This motion, agreed upon at the close of a protracted meeting and devoid of any express instructions to the effect that delegates should be selected so as to represent interests and not individuals, and that the Commissioners' scheme should form the basis of conference, was no doubt unfortunately worded, but the use to which it might be put was certainly not foreseen at the time of its adoption. In its seconder's opinion, as stated in a letter to the *Times*, "should such a Committee arrive at a workable result, this may be embodied in a new charter which may be accepted without resort to a Statutory Commission, such as the Annual Committee objected to," in other words, the Consultative Committee might be the means of indefinitely postponing the settlement of the question of University reform. And the Annual Committee, having failed to carry its resolutions, must have taken much the same view, since its delegates were, with one exception—that of a theologian—chosen entirely from its own body, while on points of order raised by two of its members in connection with the motion, discussion on the Commissioners' Report at the ordinary meeting of Convocation on May 8 was again prevented, although a notice of motion expressing general approval of the scheme was allowed to appear on the *agenda*.

Tactics such as these not infrequently meet with the reward they deserve. University reform in London has waited too long for an obstructive and dilatory attitude, whether arising out of questions of "dignity" or of inability to take a broad view of the problem, on the part of a few, to be tolerable, and fortunate it is that a salutary change has taken place in Convocation itself. A movement in favour of the Gresham scheme took definite shape a few days after the extraordinary meeting on April 10; a Committee of Graduates was formed and a circular sent out to elicit from members of Convocation an expression of general approval of its provisions, and a direct vote in Convocation on the scheme being prevented, its adherents took the only course open to them, turned out the old Annual Committee on May 8, and replaced it by one almost wholly favourable to the Commissioners' proposals. Although not a direct vote in favour of the scheme, it has with good reason been regarded as tantamount to this, since the meeting which elected the new Annual Committee would certainly have expressed general approval of the Report had not the motion to this effect been ruled out of order by the chairman.

Since May 8, events have moved rapidly. The delegates appointed by the late Annual Committee, with one exception, resigned their seats on the Joint Consultative Committee as a result of the vote adverse to themselves, and the Joint Consultative Committee with its endless opportunities for delay has been shelved. The circular issued by the Committee of Graduates just mentioned obtained 856 replies, many of them from the best known and most influential members of Convocation, expressing "general approval of the Commissioners' Report"; and this fact with a list of signatories was embodied in a memorial praying the Senate to "use all its influence to induce the Government to appoint a Statutory Commission forthwith." At its meeting on June 13, the Senate, happy in its opportunity, passed almost unanimously a resolution in which general approval of the proposals of the Commissioners was expressed, and instructions given to its special Committee to consider suggestions for the terms of reference to the Statutory Commission. A fortnight later the Annual Committee and other invited graduates met the Special Committee of the Senate in conference, and on behalf of the former it was urged "that it is desirable to memorialise Government to take immediate steps for the appointment of a Statutory Commission to frame statutes in general accordance with the Report of the Gresham Commission, with full power to make such modifications as they may see fit, after conference with Convocation and other bodies affected." Further, four delegates from the Annual Committee attended the meeting on June 30, of representatives from nearly all the institutions which, according to the Commissioners' proposals, will form constituent colleges of the reorganised University, and concurred in the resolution of similar character, which, as reported in NATURE (this vol., p. 227), was passed unanimously by those having the right to vote as delegates. And now the welcome news has transpired that at its meeting on July 11 the Senate passed a resolution urging the immediate appointment of a Statutory Commission with power to modify details of the Gresham Commissioners' scheme if judged expedient after conference with the bodies concerned, and that copies of the resolution were forwarded to the Lord Chancellor, the Lord President and the Vice-President of the Council, and the Home Secretary.

The unexpected, therefore, has happened. In every way in which it has been permitted to do so, Convocation, like the Senate, has expressed general approval of the Commissioners' proposals, and the University of London instead of being placed, by divided counsels, in a position deplorable to all friends of higher education in London, is now at the head of the movement for a University worthy of the greatest city of the world. Now that extensive approval of the Report by the great majority of the institutions concerned has satisfied the condition laid down by the Home Secretary as one to be complied with before action could be taken by the Government, it may be hoped that before Parliament is prorogued an Act appointing the Statutory Commission will be added to the legislative achievements of the Session.

W. Palmer Wynne.

THE OXFORD MEETING OF THE BRITISH ASSOCIATION.

Since the last account of the preparations for the meeting of the British Association on August 8 appeared in these columns, the local arrangements have made steady progress, and the arrangements for the Sectional and other meeting rooms are nearly complete. It may be well to explain that only a few of the Sectional meeting rooms can be darkened for the use of a lantern. It has been found impracticable to darken the large writing rooms in the Examination Schools in which Sections E and F will meet: and the same may be said of Hertford College Hall (Section C) and Keble College Hall (Section F). The Clarendon Laboratory Theatre (Section A), the Anatomical Theatre and Laboratory (Sections D and H), and the Physiology Theatre, are provided with dark blinds; and the large Lecture Theatre in the Museum will be available for meetings of Sections in which the lime-light is indispensable. The dates and hours at which this room will be available must be settled by the Recorders of Sections during the meeting.

The arrangements for excursions in the neighbourhood are now complete. The list is not as long as has been the case in some recent meetings, as the localities of general interest which are accessible from Oxford are few in number. On the Saturday afternoon parties will be taken to Dorchester and Wallingford, to Abingdon, to Blenheim Palace and Woodstock, and to the Roman remains at Silchester, and Prof. Green will take a geological party through Fawler to the classical grounds of Stonesfield. On the Thursday, whole day excursions are arranged for Windsor and Eton, Warwick and Stratford-on-Avon, Compton Wynyates, Broughton and Wroxton, Reading, and the Great Western Railway Works at Swindon.

The total number of those who have up to the present signified their intention of attending the meeting amounts to a little over 1500. As the Sheldonian Theatre, on the most liberal estimate, will not accommodate more than 1800 persons, and as it is very probable that the number of applicants for places will be greater than this, members and associates are recommended to apply for places in the Theatre for the President's address and evening lectures as early as possible. The allotment of seats will begin on Monday, August 6.

Up to the time of writing, but little information has been received respecting the work of the various Sections. In Section D (Biology) the President, Prof. J. Bayley Balfour, will deal in his address with the aspects of forestry in Great Britain, and among other papers which will be read to the Section, Prof. Ray Lankester will make a communication on chlorophyll in the animal kingdom, Prof. A. A. W. Hubrecht will read a paper on the Didermic blastocyst, and Mr. J. T. Cunningham on the specific and generic characters of the Pleuronectidæ.

In Section E the President, Captain W. J. L. Wharton, R.N., will deal in his address with our present knowledge of the physical conditions of the sea. And among other papers which will be read at the meeting are the following:—Colonel Godwin Austen, on Bhotan; Mr. Osbert H. Howorth, on the Sierra Madre of Mexico; Miss Baildon, on a visit to New Guinea; Mr. D. G. Hogarth, on a recent journey in Asia Minor; Mr. W. H. Cozens Hardy, on Montenegro and Albania; Dr. H. Schlichter, on the natural wealth of British East Africa; Mr. G. G. Chisholm, on the orthography of Place-names; Mr. J. Theodore Bent, on Hadramut; Mr. A. Montefiore, on the equipment of the Jackson-Harmsworth Arctic Expedition; Mr. H. N. Dickson, on the physical condition of the North Sea; M. A. Delbecque, on the lakes of France, and Dr. H. R. Mill, on the geography of the English lakes. The proceedings of the other sections will be announced as soon as they are communicated.

THE BIOLOGICAL INSTITUTION IN BERGEN, NORWAY.

LAST autumn a biological institution was opened in Bergen. It forms part of the museum, the library and collection of which the students are at liberty to use.

The building is of wood, two storeys high. On the ground floor there is one large hall surrounded on three sides by aquaria, which are open to the public on payment of a small entrance fee. Then there is the pump-room, and other rooms, one of which is used for experiments in hatching, and in the others the collected matter is examined and studied, and the dredges and other instruments are kept. There are two hatching apparatus, each containing eight hatching-boxes. A hatching apparatus for fresh water is much required, so that the biological questions in connection with the salmon-fishing may be worked out.

Fig. 1 is the plan of the ground floor.

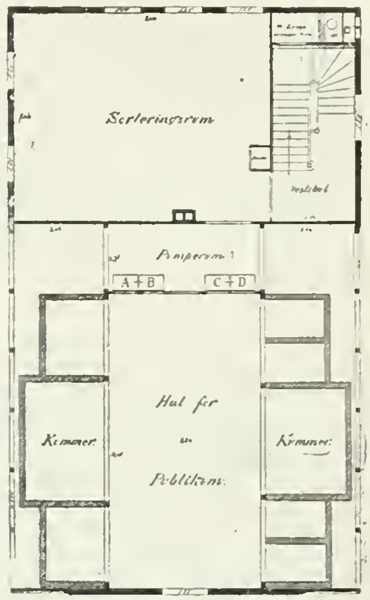

FIG. 1.—Ground floor

The first floor is set apart for scientific work, and consists of two large rooms, the smaller of which is used for chemical work, and is furnished with all necessary apparatus.

The larger room has four windows on each side; those on the east are separated by wooden partitions, curtained off from the rest of the room, thus forming four small work-rooms, each of which is furnished with a microscope and writing-table and other conveniences for the work of one person. In front of the windows on the west side, there are tables (L, M, N, O, Fig. 2).

Altogether ten work-tables are provided in the institute. In the middle of the larger room there is a long low sink (E, F, G, H, Fig. 2), which has a small channel in the middle connected with a waste-pipe. On each side of this sink, but raised slightly above it, there is a shelf running the whole length of it, and wide enough to hold the small experimental aquaria, which consist of glass bowls. Above the shelves are pipes from the sea-water reservoir, with numerous taps, thus supplying flowing water when necessary.

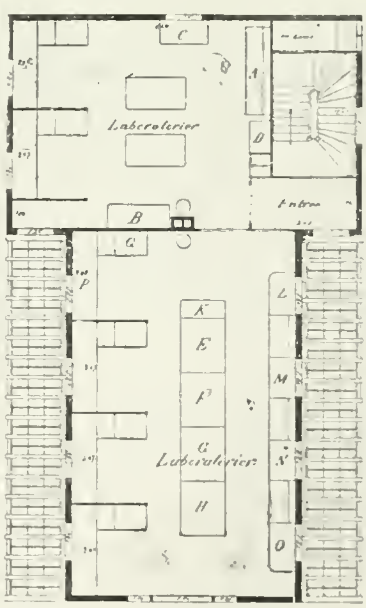

FIG. 2.—First floor.

The sea-water supply is conveyed to the pump-room by means of a long pipe from the middle of the Paddefjords, at a depth of ten metres; from here it is pumped up to the reservoir, which is on the top storey, whence it supplies the laboratories.

The fauna is very rich; the flora has not yet been much studied.

The biological institution is for foreign as well as Norwegian students. The monthly cost for the use of one of the work-tables is twenty-five kronen. This includes the necessary reagents, the free use of all the apparatus and the museum, also the use of the boat, with the men, for private explorations, and liberty to take part in the weekly steamer excursions to the distant parts of the fjords.

The institution is open every day all the year round; the fjords are never quite frozen, and at the coldest time the temperature is never more than a few degrees from zero.

The institution is under the supervision of Herren Dr. A. Appellöf, G. A. Hansen, and T. Brunchorst. It is almost entirely supported by voluntary contributions. A certain sum, however, is granted by the State, which unfortunately is not sufficient to permit the institution to have a resident zoologist; but as the Norwegian Government is always so liberal in matters of a scientific nature, it is hoped that the required amount will soon be granted.

PROFESSOR DR. FISCHER.

By the death of Prof. Dr. Fischer, which took place on May 17 last, the Königliche Preussische Geodätische Institut and the Central-bureau der Internationalen Erdmessung lose a very ardent and devoted chief who has done much, not only to keep up the high standard of these institutions, but to bring them, if possible, to a higher grade of perfection.

Born in the year 1836, on December 10, at Deutsch-Leippe, near Grottkau, in Schlesien. Amand Fischer began his first studies at the Mathias-Gymnasium in Breslau, occupying his attention, among other things, with mathematics and science (*Astr. Nach* Bd. 135, No 3235); he graduated in 1866, the subject of his dissertation being the Comet III. of 1860. In the following year he entered in the Central-bureau der Mitteleuropäischen Gradmessung, and two years later in the Königliche Preussische Geodätische Institut, in which he commenced his great activity, which he continued up to the end. From July 1877 he conducted the sections relating to Geodesy.

Among the numerous valuable works brought before the public will be remembered the "Rheinische Dreiecksnetz," in which were a great number of Fischer's measurements, made at the majority of the stations employed. He found occasion also to busy himself with lateral refraction, and he made an interesting contribution on "Lothabweichungen in der Umgebung von Berlin" (1889), which was valuable in the discussion regarding the relation between Geodesy and Geology.

At a somewhat earlier date, in an article that appeared in the *Astr. Nach.* (Bd. 88), entitled "Die Gestalt der Erde und die Pendelmessungen," he brought forward the interesting deduction that the variation, which Ph. Fischer had calculated from the measures of gravity, could be traced back to geological causes, a deduction which agrees very nearly with our present ideas.

The publication of the "Berliner Basisnetzes" (1891) absorbed a great amount of his activity, as he paid special attention to this piece of work. In the measurements made in the Strehlen, Berlin, and Bonn base-lines operations, he took, finally in the capacity of director, a prominent part. We have to thank him, also, for some important thermoelectrical researches on the expansion of the rods used for base-line determinations. (*Astr. Nach.* Bd. 103.) He determined, also, the difference of longitude between Wangeroog and Schillig by means of optical signals, during the time of the operations on the trigonometrical survey of the North Sea islands and the mainland, with the computation of which he busied himself.

We are indebted to him for a great number of astronomical observations made at several stations for the trigonometrical work in which he was employed.

In order to get some idea of his dexterity and care, and more especially of his love for work and his self-sacrifice, one must not only look at the literary side of Fischer's activity, but at that in which his capacity as an observer was a very prominent feature.

Besides a host of numerous friends who mourn his loss, he leaves behind a widow and three children.

NOTES.

The subjects for 1895 for the results of original research, upon which the Royal Society of New South Wales offer their medal and £25, are as follows:—(1) On the Silver Ore Deposits of New South Wales. (2) On the Physiological Action of the Poison of any Australian Snake, Spider, or Tick. (3) On the Chemistry of the Australian Gums and Resins. The communications are to be sent in not later than May 1, 1895. The subjects for 1896 are also announced as follows:—(1) On the Origin of Multiple Hydatids in Man. (2) On the Occurrence of Precious Stones in New South Wales, with a description of the deposits in which they are found. (3) On the Effect of the Australian Climate on the Physical Development of the Australian-born Population. The Society emphasise the condition that the award will not be made for a mere compilation, however meritorious it may be.

The Council of the Royal Society of New South Wales have awarded the prize given by the Hon. Ralph Abercrombie for the best essay on "Southerly Bursters" on the east coast of Australia, to Mr. Henry A. Hunt, second meteorological assistant in the observatory at Sydney. The essay contains the results obtained from a study of all the bursters that visited the east coast from 1863 to 1893, and is illustrated by weather charts, cloud photographs, and diagrams showing the monthly and hourly distribution of these wind storms, as well as diagrams showing instrumental conditions in typical cases.

Manuscripts competing for the De Candolle Prize for 1895, offered by the Geneva Physical and Natural History Society, for the best unpublished monograph of a genus or family of plants, must be sent in by January 15, 1895. They may be written in Latin, French, German, English, or Italian. The value of the prize is 500 francs.

Liverpool is fortunate in having citizens who testify their interest in the scientific welfare of the city by munificent generosity. We have previously noted the endowments, by the Earl of Derby and Mr. George Holt, of chairs in anatomy and pathology at the University College, Liverpool. We now learn, from the *British Medical Journal*, that the Rev. S. A. Thompson Yates has presented the College with the sum of £15,000 in order to build physiological and pathological laboratories.

The Danish Government has undertaken, during the years 1895 and 1896, a deep-sea exploration in the Greenland and Icelandic waters. The expedition will be accompanied by a botanist.

One of the last acts of the late President Carnot, a few hours before his assassination, was to confer on the well-known botanist Dr. Saint-Lager the dignity of Officer of Public Instruction.

Dr. V. Schiffner has sent to the Botanical Institute of the German University of Prag a very large collection of dried plants and spirit-material from Western Java. He is intending also to visit Eastern Java and Sumatra.

The antiquities, ranging from prehistoric down to Roman times, lately discovered by Prof. Flinders Petrie in the temple of Koptos in Upper Egypt, will be exhibited to the public in the Edwards Library, University College, Gower Street, from July 23 to September 1.

THE death is announced of Dr. Adolph Hannover, at Copenhagen, at eighty years of age, and of Dr. J. Hyrtl, of Vienna University, at the age of eighty-four.

THE first annual meeting of the Australasian Institute of Mining Engineers, recently held at Ballarat, Victoria, appears to have been a very successful one. The inaugural meeting of the Institute was held last year at Adelaide, when Sir Henry Ayres, the President of the Legislative Council of South Australia, was chosen as its first president. Among the speeches delivered at that time was a very pointed one by the Hon. James Martin, the head of the engineering firm bearing that name. In the course of his remarks he said: "Science is much needed in mining, for without it mining cannot go along. We have been blundering too much by rule of thumb, which has done much to injure the mining industry and those who are willing to take some risks in mining. It has been the want of knowledge of the men who have been placed as mining managers that has ruined so many concerns. We want to bring science, experience, and knowledge to bear upon mining, so that we will be able to bring wealth from the earth without a waste of labour." Mr. James Stirling, the present president of the Institute, took the "Mineral Wealth of the Colony of Victoria" as the subject of his address at the Ballarat meeting. A variety of papers on mining topics were read and discussed, and visits were made to a number of mines and engineering works. The Institute has accepted an invitation from the Premier of Tasmania to hold the annual meeting in Hobart, Tasmania, next year, at which time the mining exhibition will be open.

UNDER the conductorship of Major Lamorock Flower, a meeting of the Essex Field Club was held last Saturday on the River Lea, the Conservancy Board having placed their steam-barge at the disposal of the club for the occasion. About sixty members embarked at Hertford and steamed down the river as far as Tottenham. Many well-known scientific men were present and gave addresses during the course of the day. Major Flower, after welcoming the party on behalf of the Conservancy Board (to which he is sanitary engineer), gave an account of the river and of his own work in connection with the improvement in its condition. After lunch at Broxbourne, Mr. J. E. Harting read a short paper on Izaak Walton's association with the river, and exhibited a most interesting set of prints in illustration of his remarks. Mr. G. J. Symons, F.R.S., later in the day, gave an account of the watershed, and explained the connection between the rainfall and the water supplied to the river. Mr. Howard Saunders followed with an address on the birds of the Lea Valley, and Mr. T. V. Holmes concluded with a paper on the geology of the district, explaining how the river had in the course of time shifted its bed generally in an easterly direction, leaving gravel deposits to the west often a mile or more from the present stream. As the result of a most enjoyable meeting, it was generally conceded that the river above the intake of the East London Waterworks Company at Ponder's End was in a very good condition, but great regret was expressed at the accumulation of heaps of the most evil-smelling garbage which here and there greeted the party on their way down. This refuse, as Major Flower explained, is brought from London in barges, and is heaped by the river banks under certain legal powers permitted by an Act of Parliament passed in 1868, and which the Conservancy Board has therefore at present no power of preventing; but it is to be hoped that the general advance of sanitary science will soon be such that public opinion will lead to legal restrictions as to the placing of decomposing refuse on the banks of any stream of which the water is used for human consumption.

ACCORDING to press telegrams, the cholera epidemic which has recently appeared at St. Petersburg is assuming an alarming character, being much more severe than that of last year. It is officially reported that 875 cases of cholera, and 294 deaths have occurred in St. Petersburg alone from the 8th inst. up to Saturday last. In Cronstadt, also, the disease has become epidemic, and other parts of Russia are seriously affected. A number of deaths from cholera are reported from the province of Galicia, in Austria-Hungary. Zaleszczki, in Galicia, has been declared to be a centre of the epidemic, and the necessary precautions have been taken to prevent communication with the infected district. Cases of cholera have also occurred in Sparta, near Adalia, Asia Minor, in the Prussian part of the Vistula, and at Liège and several surrounding villages, and an isolated case with choleraic symptoms has been notified at Paris.

FURTHER particulars with regard to the earthquake in Turkey last week show that it was of a very serious nature. No official return of the real number of victims has yet been published, but Reuter reports that the death-roll in Stamboul alone is known to exceed two hundred. According to Press telegrams, the damage to property in Constantinople is estimated to amount to £T6,000,000. There is scarcely a street in that city which does not show signs of the destructive effects of the earthquake, many of the old Turkish houses in Stamboul and the suburbs having been completely wrecked. The Grand Bazaar suffered severely. The vaulted roof of the jewellers' arcade fell in, causing a scene of great panic and confusion. Reuter's telegrams state that, at Prinkipo, the Greek Orthodox Church and a large number of houses were destroyed or seriously damaged. On the island of Halki nearly all the houses have been rendered uninhabitable. A portion of the Great Ottoman Naval College also collapsed, six students being killed and several injured. On the island of Antigoni not a house has been left intact, with the exception of the monasteries. At Pera four houses fell in, and many were damaged, the number of victims being five. The village of Galateria, near St. Stephano, has been completely destroyed. The shock was felt in the interior of Anatolia at a distance of 236 miles from Constantinople. Nearly all the railway stations have been damaged, and the town of Jalova, in the Gulf of Ismidt, has been almost totally destroyed. During the first shock at the island of Halki and the village of St. Stephano the sea retired over 200 yards, leaving many boats and vessels high and dry. The waters then returned with such force and violence that they overflowed the quay, hurling the boats on to the shore far above sea-level, and causing great damage. It is reported that shocks continue to be felt at intervals, but the movements of the ground are barely perceptible. The point from which the surface disturbances proceeded is said to be in the Sea of Marmora, somewhere between Jolava on the Asiatic side, and Stephano on the European side.

A PRIVATE telegram to the Royal Geographical Society has brought bad news of the Wellman polar expedition, the departure of which for Spitzbergen was noticed in NATURE, vol. l. p. 57. The steam-yacht *Saide*, belonging to Captain Townley-Parker, of the Royal Yacht Squadron, called at Danes Island, in the north-east of Spitzbergen, on July 6, and found the geologist of Mr. Wellman's party, Mr. Oyen, alone in charge of the house and stores. The expedition had reached Danes Island safely on May 7, and after landing Mr. Oyen, set out for Seven Islands on the 10th, promising to send back the steamer for Mr. Oyen in a week's time; but she had never returned. The *Saide* at once attempted to go in search of the missing vessel, but was stopped by ice off Hakluyts Head in 80° 10′ N., and compelled to return. No trace of the ship had been seen by the Norwegian walrus-hunters who are cruising off Spitzbergen, and the inevitable conclusion is that she has been beset by the ice and probably foundered. It is hoped that Mr. Wellman and his party of fifteen men had left the vessel and started on their northward journey before this happened; and if that be so, there is no reason why they should not return safely to Danes Island. Spitzbergen is now visited so frequently during the summer months, that little anxiety need be felt as to their return to civilisation should they be able to regain the island; but since the provisions in store are only sufficient to supply eight men for six months, it is important that additional supplies should be sent to provide for emergencies.

We have received from Prof. Guido Cora a copy of a short paper communicated by him to the Italian Geographical Congress of 1892, in which he strongly urges the importance of a more complete and detailed study of the minute geography of Italy, proposing the formation of a special committee to elaborate and carry out the scheme. It is a subject no less pressing in England than in Italy, for to a properly qualified geographer there is no part of the world riper for investigation and more deserving of study than those countries of Europe in which the ground for a solid constructive geography has been laid by complete topographical and geological surveys.

The State of Minas Geraes in Brazil has recently established a Geographical and Geological Commission, entrusted with the rectification of the topographical map and with the geological survey of the State. The first *Boletim* of this Commission has just been published at Rio de Janeiro by Señor A. de Abreu Lacerda, chief engineer. It contains an account of the objects of the Commission, which are to delimit the State and lay down the boundaries of the subordinate political divisions, to determine the nature of the rocks, minerals, and cultivable soils, to fix the altitudes of important places, and to make a triangulation of the State. The work is modelled on that of the United States Coast and Geodetic and Geological Surveys, and there are several Americans engaged on the operations.

The lectures to intending travellers on various aspects of science, given at the Natural History Museum in Paris, continue, and are reported fully in the *Revue Scientifique*. The most recent were on Palæontology, by M. Marcellin Boule, and on "Metrophotography" by M. Laussedat. The latter is particularly interesting, and shows that the use of photography in surveying is a natural development of a method which Beautemps-Beaupré introduced more than fifty years ago. He utilised panoramas sketched by means of a camera lucida at opposite ends of a measured base-line, and by an ingenious arrangement of the two views on a plane-table plotted the map without any calculations. In this method photography simply facilitates the production of the pictures, the rest of the process remaining the same. The calculation of vertical heights from the photographs is simple when the correct relative distances of the objects are laid down on a map, and thus the simple operation of taking a photograph of the same object from two points suffices for the construction at any future time of a contoured map.

From a circular received from Prof. Dr. Coloman Muller, we note that the preliminary arrangements of the Eighth International Congress of Hygiene and Demography, to be held at Budapest from September 1 to 9, 1894, are nearly completed. The Congress promises not only to be a worthy successor of its predecessors, but also to be in some respects superior to them. Up to the present time a total of 725 papers have been notified, of which 593 belong to the Hygienic, and 132 to the Demographic groups of the Congress. Besides this, 26 Governments with 92 delegates, 91 Public Corporations with 163 delegates, 41 Universities with 65 delegates, and last, but not least, 132 learned Societies with 300 delegates, have expressed their intention of being represented at the Congress. The following are among the subjects of promised communications:—Mr. Ernest Hart, on protection against cholera in the Orient, and the hypothesis of its epidemic diffusion; Prof. Dr. E. Leyden (Berlin), on provisions made by large towns for consumptives; Prof. Dr. George Mayr (Strassburg), on statistics and social science; Baurath Herzberg, C.E. (Berlin), the civil engineer's work in hygiene; Prof. E. Levasseur (Paris), the history of Demography; Prof. Dr. E. T. Erisman (Moscow), the struggle with death; Prof. Dr. C. Lombroso (Turin), the criminal.

The Congress of the British Institute of Public Health, to be held in London from July 25 to 31, under the presidency of Prof. W. R. Smith, promises to be an important one. About 1500 delegates have already been appointed, and if two-thirds of the number attend the meetings the organisers at King's College will have a difficulty in accommodating them. The Congress will be divided into five sections as follows:—(A) Preventive Medicine; (B) Chemistry and Climatology; (C) Municipal and Parliamentary; (D) Engineering and Building Construction; (E) Naval and Military Hygiene. Among the subjects which will be brought up for discussion in the first section are:—The mode of spread and methods of prevention of diphtheria; the dissemination of disease by river-water; the self-purification of rivers; and the alleged aerial diffusion of smallpox. In the second section the subjects for discussion include the chemical and bacteriological examination of water; the purification of sewage; and the micro-organisms in sewer air. In Section D discussions have been arranged on electric lighting from the point of view of public health; on a system of softening public water supplies; sewage disposal; and other matters. There will be conferences on "The Housing of the Working Classes" and "The Provision of Isolation Hospitals," and on Saturday, the 28th inst., Prof. E. M. Crookshank will deliver a popular lecture on "Microbes and the Spread of Infectious Diseases." A number of visits will be made to places and institutions of interest from a public health point of view.

In a memorandum on the mitigation and prevention of insect ravages in India, forwarded a short time ago to the Department of Revenue and Agriculture of the Government of India, the Hon. J. Buckingham, C.I.E., pointed out the necessity for a staff of entomologists, and suggested a scheme for the organisation of an entomological department. Though crops to the value of millions of rupees are destroyed annually in India by insect pests, the Government had not until recently seriously set to work to modify these ravages. In the United States, as also in Canada and parts of Australia, the Government has taken up the matter, with the result of the introduction of new methods of treatment which in some cases have effected an enormous saving. The memorandum calls attention to the fact that in the United States, besides entomological advisers attached to individual States, a strong section of entomology is kept up as a branch of the Agricultural Department of the Central Government. Attached to the entomological section are some fourteen trained entomologists, who visit all parts of the country in order to study and report upon destructive insects. The great importance of collecting information personally upon the spot is so fully recognised that the travels of the investigators are not confined to the limits of the United States, but representatives are even occasionally despatched to distant parts of the world. At the time when the memorandum was drawn up, however, all that had been done was to empower one of the officers of the Indian Museum in Calcutta to report upon insects which were submitted by planters, officials, and others, and to publish the results. Doubtless in this way a considerable amount of information has been collected, and the nature of a large number of the more destructive species of blights have been ascertained; but, as the memorandum urged, what was wanted was a specialist free to move about the country, and supported by laboratory assistants in some fixed place. To render the work of practical value, it is essential that it should be carried on continuously from year to year, so that the observations made in one season may be supplemented and verified by those made in the next, and that a record may be kept up of the increase or decrease of particular blights, so that the planting and agricultural community may be warned in time of impending danger. For the sake of Indian agriculture, we are glad to see that the scheme put forward by the Hon. J. Buckingham has been favourably considered. The Government of India has expressed a readiness to appoint two or three entomologists for the benefit of agriculturists throughout the country. It is not, of course, supposed that the appointment of this small staff of entomologists will result in the suppression of every destructive insect; but there can be no doubt that careful local investigations would, in many cases, lead to the development of improved methods of fighting the evil. In connection with the subject of the memorandum, it is worth remark that the Planters' Association of Ceylon have recently made the modest request for one entomologist to study the insects which attack tea and other plants under cultivation there. Dr. Trimen, of the Royal Botanic Gardens, Peradeniya, has, however, informed the Colonial Secretary at Colombo that, while he would support the appointment of an entomological assistant for the Colombo Museum, who would pay special attention to injurious insects, he could not recommend the appointment of an entomologist for the agricultural community alone. Mr. A. Haly, the Director of the Museum, also thinks that a special officer is not needed for the small area covered by Ceylon, and suggests that the case would be fully met by the appointment of an entomological referee.

THE *Illini* informs us of the establishment on the Illinois River, at Havana, of a biological station devoted to the systematic and continuous investigation of the plant and animal life of the waters of that region. This establishment, authorised by the trustees of the University in March, is under the direction of Prof. S. A. Forbes, with Mr. Frank Smith in immediate charge of the work. The field work is done from a cabin boat, chartered for the summer, which carries the seines, dredges, surface nets, plankton apparatus, and other collecting equipment, together with microscopes, reagents for the preservation of specimens, a small working library, a number of special breeding cages for aquatic insects, and a few aquaria. This boat is provided with sleeping accommodation for four men, and with a well-furnished kitchen. In Havana itself are office and laboratory rooms supplied with running water and electric light, and provided with the usual equipment of a biological laboratory, consisting of first-class microscopes, microtomes, biological reagents, &c., and tables for five assistants. The boat is established in Quiver Lake, an elongated bay of the Illinois, two and a half miles above Havana. From the lake and the river, selection has been made of a number of typical situations, and from these, and from Phelps and Thompson lakes, a little distance away, collections of all descriptions are made at regular intervals for a comparative study of the organic life—the relative abundance of the species at different seasons of the year, and the general system of conditions by which it is affected. We understand that this is the first inland aquatic biological station in America manned and equipped for continuous investigation; and the first in the world to undertake the serious study of the biology of a river system.

WE learn from the *Lancet* that an admirably appointed biological station, modelled upon that at Naples, has just been opened at Dröbatt, on the Christiania Fiord, not far from Christiania. It is said that the international element so wisely encouraged in the Neapolitan institution, by which, in return for an annual subsidy, the universities of the world are entitled to avail themselves of its facilities, will also be recognised at the Norwegian station.

THE report for 1893 of Dr. S. Schönland, the Curator of the Albany Museum, Grahamstown, to the Committee of the museum, has been issued. We learn from it that the institution has largely increased in popularity, the number of visitors having been over 22,000, or more than 2000 in excess of those of 1892. Its value as an educational institution has also been widely appreciated. The Committee dwells on the necessity of the appointment of an assistant who would take over the Entomological Department, the work having become too great for the Curator. It is also urged that, as the grant hitherto accorded to the institution by Parliament is insufficient, even with the greatest economy, to meet urgent requirements, a suitable increase will be made. As many as 7660 specimens were added to the collection in the museum during 1893, all of them being of South African origin.

THE changes of plumage in the Red Grouse (*Lagopus mutus*) have long attracted the attention of ornithologists. Mr. W. R. Ogilvie-Grant gives, in *The Annals of Scottish Natural History* for July, an interesting account of these changes, the nature of which he has described in vol. xxii. of the Catalogue of the birds in the British Museum. In that publication it was conclusively shown that both the male and female of the Red Grouse have two distinct moults during the year, but whereas in the male they occur in autumn and winter, in the female they take place in spring and autumn; the former having no distinct spring, and the latter no distinct winter, plumage. These seasonal variations are clearly explained in the paper referred to, and the principal changes, moults, and varieties are illustrated in two beautifully coloured plates, the feathers of each sex being shown separately.

DR. R. HANITSCH, of Liverpool, has done a most useful and, we need scarcely say, laborious piece of work in his revision of the generic nomenclature and classification in Bowerbank's "British Spongiadæ" (Trans. Liv. Biol. Soc., viii. 1894, pp. 173–206). His paper consists of two parts, dealing with the nomenclature and classification respectively. In the first section are given parallel columns of Bowerbank's and the revised nomenclature; and in the second a list of the British sponges described by Bowerbank, classified in accordance with recent research. Definitions of all British genera of Monaxonida are given. *Lissomyxilla*, for the reception of Bowerbank's *Tethea spinosa*, is new. For the most part, however, the author's arrangement is compiled from the revisions and work of Ridley and Dendy, Sollas, Topsent, Von Lendenfeld and Vosmaer.

A NEW form of phonograph of a particularly simple construction has been described before the Electro-chemical Society of Berlin by Herr A. Kœltzow. In this instrument, which in consideration of its low price appears suited to many purposes, at any rate in those countries where patent rights will not prevent its introduction, the cylinder on which the record is made is composed of a hard kind of soap. Each cylinder, which costs about three shillings, admits of being used for recording 250,000 words, since an arrangement allows of the removal of a very thin layer from the surface when this has been covered. Thus the cost of the cylinders for registering any number of words is not more than the cost of the paper which would be required if they were written down.

The village of Gossau, situated about ten kilometres from St. Gall in Switzerland, was recently the scene of a curious electrical phenomenon. This village is lighted by a supply station situated at a distance of twelve kilometres, which supplies the current at high tension to transformers at the village. During a thunderstorm, which lasted several hours, the supply wires were struck by lightning, all the electric lamps being extinguished, while bright sparks passing between the aërial wires lighted up the whole village. These phenomena were particularly brilliant at the chief transformer sub-station, where the sparks continued to pass for more than an hour, and only stopped when the circuit was broken at the generator station.

The current number of *Science Progress* contains a paper by Mr. Chree, the Superintendent of the Kew Observatory. In this paper, which is entitled "The most recent Values of the Magnetic Elements at the Principal Magnetic Observatories of the World," the author points out the importance of the continuous records of the different magnetic elements made at some of the observatories, both for the purpose of applying the correction for secular change to the charts and maps used by travellers by land and sea, and for allowing observers engaged on a magnetic survey to correct their observed results by allowing for any disturbance of the observed element from its mean value at the moment at which the observation was made. The possibility of making this correction depends on the fact that the diurnal change as well as the small irregular disturbances occur simultaneously, and similarly over considerable tracts of country. This fact is very markedly shown by superposing the photographic traces obtained at Kew and Falmouth, when it will be found that every little undulation is faithfully reproduced. The paper also contains a "popular" account of the different observations made, and the methods by which the photographic curves are obtained and the results reduced. A most useful table of the magnetic elements at the different observatories, which we see from an editorial note is to be continued from year to year, is appended. This table contains besides the latitude and longitude of the observatory, the mean declination, dip, horizontal force and vertical force for the last year for which data are available. A very useful addition to the table would be four additional columns giving, where possible, the secular change.

We have received from T. Homén, of the University of Helsingfors, a work entitled *Bodenphysikalische und meteorologische Beobachtungen*, which has been carefully compiled from all available sources, and also from a long series of observations made by the author, with especial reference to night frosts and their effect upon vegetation in the spring and autumn. The observations and conclusions refer more particularly to northern Europe, but will be found of practical use to agriculturists generally. The work is divided into six sections; the first three deal with the temperature and the conductivity of the earth's surface, and at various depths, with different kinds of soil, with the formation of dew, and with evaporation, while the last three chapters deal with the phenomena of night frosts, the methods of their prediction, and a discussion of the various means which may be adopted to prevent or lessen their injury to vegetation. The chapter relating to the conditions under which frosts usually occur is instructive, and shows that they chiefly depend upon the tracks taken by barometric depressions, the positions of areas of high barometer, and on the amount of the radiation from the surface of the earth. The method sometimes adopted of predicting frost from the position of the dew-point in the evening is shown to be very unsafe, especially for ground temperatures. The protection caused by burning wet straw or moss, and so preventing radiation by means of smoke, is fully discussed; but the plan is not likely to come into general use, owing to the large area over which fires have to be lighted, and the probability of the smoke being drifted away by currents of air. The experiments have been made at a considerable cost of labour and money, part of the necessary funds having been contributed by the authorities of the University.

A paper on the "Geology of Torres Straits," from the combined points of view of Profs. A. C. Haddon, W. J. Sollas, F.R.S., and G. A. J. Cole, was read before the Royal Irish Academy two years ago, and has just been published in the Society's *Transactions* (vol. xxx. part XI.). This is the first time that any detailed description has been given of the islands between Queensland and New Guinea. One of the chief conclusions arrived at, from a close study, is that no recent movements of elevation of the shores of Torres Straits have taken place. "As our knowledge grows" (the authors state) "we the more distinctly see in Australia and its islands the ruins of a great southern continent, fractured and submerged, possibly during the great Alpine Himalayan revolutions, and now in process of resurgence, as the vast folds of the earth's crust roll slowly inwards upon the central continental mass."

A copy of Dr. Sykes' report on the cause of the increase of mortality from diphtheria in London, prepared at the instance of the Health Department of the Vestry of St. Pancras, has been sent to us. Dr. Thorne Thorne, who has also drawn up a report on the same subject, concludes that increased school attendance has had a material influence in increasing the spread of diphtheria, and Dr. Sykes regards this conclusion as irresistible. Again, the increase in cases described as diphtheritic may be also due to variation in nomenclature, most forms of infectious sore-throat being now regarded as diphtheria, whereas formerly the term was restricted to typical cases. Dr. Sykes is, however, also of opinion that the variation in nomenclature may very possibly be due to a change of type in disease of the throat, brought about by increased density of population in our great towns, and the effects of increased personal infection consequent upon the greater aggregation in schools. But does this explain why London should be singled out from all our great cities for such a disastrous epidemic of diphtheria as has unfortunately prevailed over such a long and continuous period? Why should not these causes apply with equal force to Glasgow, Manchester, Birmingham, or any of our great centres of industry?

Frank, and afterwards Schloesing and Laurent, showed that soil containing bacteria and algæ can fix free nitrogen in large quantities; their experiments, however, did not decide whether algæ alone are capable of doing this. In order to answer this question Kossowitsch has estimated (*Botanische Zeitung*, May 16, 1894) the amount of nitrogen present in a nutritive soil before and after the growth of pure cultures of two kinds of algæ, *Cystococcus* and *Stichococcus*. In neither case was any sensible increase of nitrogen detected; so that it appears that neither of these algæ alone have the power of fixing free nitrogen. *Cystococcus*, even when mixed with pure cultures of the bacteria which enable the Leguminosæ to assimilate free nitrogen, was found powerless in this direction; whereas a mixture of soil-bacteria and *Cystococcus*, which also contained a small amount of other algæ, had the power of fixing free nitrogen to a large extent. The same author also describes a number of experiments with heterogeneous mixtures of algæ and bacteria, and shows how in each case the capability of fixing free nitrogen is greatly increased by the addition of dextrose to the nutritive substratum. From this and also from the fact that such mixtures of algæ and bacteria which are capable of fixing free nitrogen when exposed to light cannot be shown to assimilate it in the dark, he concludes that although in no case has it been proved that algæ by themselves possess the power of fixing free nitrogen, yet they are in a symbiotic relationship with the nitrogen-fixing bacteria, and he regards it as probable that these latter draw on the assimilation-products of the algæ to supply the carbon they require in growth.

MR. BERNARD QUARITCH, Piccadilly, has issued a new list (No. 143) of the old and valuable books he has for sale. The list contains a number of rare books of travel, and many important works on botany, entomology, and ornithology.

MESSRS. HENRY SOTHERAN AND CO. will shortly issue a second and cheaper edition of Mr. J. G. Millais' "Game Birds, and Shooting Sketches," with illustrations by the author, and a frontispiece by Sir J. E. Millais, Bart.

WE have received a copy of "Bourne's Handy Assurance Manual" for 1894, now edited by Mr. William Schooling. The volume differs from its predecessors in several important respects, and some of the tables in it may be found useful to students of demography.

THE first volume of "The Royal Natural History," edited by Mr. Richard Lydekker, F.R.S., has been published by Messrs. Frederick Warne and Co. It is illustrated with numerous coloured plates and engravings, and forms a desirable addition to any library. We look forward with pleasure to the publication of the remaining volumes of Mr. Lydekker's important work, a work that possesses scientific interest and has a high educational value.

THE frontispiece of the July number of the *Monist* is a portrait of the late Dr. Romanes. Accompanying it and a short obituary notice, are two stanzas from a memorial poem addressed by the deceased investigator to Charles Darwin, and embodied in a volume printed for private circulation. The number also contains, among other matter, a paper entitled "The Non-Euclidean Geometry Inevitable," by Prof. G. B. Halsted; one on "Leonardo da Vinci as a Pioneer in Science," by Mr. W. R. Thayer; and another on "Monism in Arithmetic," by Prof. Hermann Schubert.

IN the *Journal of Botany* for July is "A Tentative List of British *Hieracia*," which affords a remarkable instance of the tendency to "splitting" displayed by botanists who devote themselves to monographing genera or families. Hooker's "Student's Flora" enumerates 10 British species of *Hieracium*, the eighth edition of Babington's "Manual" 33. The present list comprises no less than 103 specific names, besides varieties. Of these species 36 are attributed to two English botanists who have made the genus their special study, Mr. W. R. Linton and Mr. F. J. Hanbury.

AS in previous years, the *Photographic Annual* for 1894, edited by Mr. Henry Sturmey, contains a number of excellent pictures illustrating various systems of photographic and photo-mechanical reproduction. Some of these illustrations are extremely fine. We are specially interested in four figures reproduced from photographs of microscopic objects, obtained by Mr. Frederick Iles in a novel manner. By a method of stereoscopic illumination, not described, he has procured "stereo-micrographs" showing objects in beautiful relief, and which greatly disparage pictures obtained with ordinary illumination. Plant sections, medical sections, crystals, and other translucent objects are found by Mr. Iles to furnish good results. Judging from the photographs reproduced, the method may have important scientific applications. The text of the *Annual* includes records of the progress, during 1893, of photographic chemistry, by Mr. C. H. Bothamley; photographic optics, by Mr. Chapman Jones; and an admirable summary of work in astronomical photography, by Mr. Albert Taylor. The *Annual* also contains the usual complement of articles on practical photography, and information on recent novelties in photographic apparatus, appliances, and processes.

THE first edition of the late Sir Andrew Ramsay's well-known "Physical Geology and Geography of Great Britain" (Edward Stanford) appeared in 1863. Between then and 1878 five editions of the work were issued, and a sixth has just been published. This edition has been prepared by Mr. H. B. Woodward, and his "restoration" has been admirably done. It is a difficult task to enter thoroughly into the spirit in which an investigator like the late renowned geologist indites a book, but Mr. Woodward has allowed his personality to merge into that of the lamented author, and the result is that the work begins a new life in all its original freshness and vigour. More than thirty years ago, Sir Andrew delivered the lectures out of which the book has grown. The object of the course was "to show how simple the geological structure of Great Britain is in its larger features, and how easily that structure may be explained to, and understood by, persons who are not practised geologists." Some of the author's theoretical views have been called into question, but others have served to establish his perspicuity on geological matters. Throughout the book, however, controversial subjects are fairly treated in the light of latter-day evidence. The part in which the greatest changes have been necessary is that referring to Archæan rocks. Considerable changes had to be made in order to bring this section of the book into touch with current opinion. Not only have such necessary emendations been made, but most of the more or less uninteresting details inserted in the fifth edition have been omitted or condensed. Where the author's theories have been entirely controverted, the accepted views have been substituted for them, but opinions still *sub judice* have been left in their original form. Several changes have been made in the excellent little geological map which forms the frontispiece, especially in the northern part of Scotland. All the revision has been in the direction of improvement, and we have no doubt that numerous readers will appreciate the careful manner in which it has been done.

THE additions to the Zoological Society's Gardens during the past week include two Lesser White-nosed Monkeys (*Cercopithecus petaurista*, ♂ ♀), a Campbell's Monkey (*Cercopithecus campbelli*, ♀), a Brush-tailed Porcupine (*Atherura africana*) from West Africa, presented by Mr. W. H. Boyle; a Mona Monkey (*Cercopithecus mona*, ♂) from West Africa, presented by Mr. Charles Gardiner; two —— Tortoises (*Testudo*, sp. inc.) from the Aldabra Island, presented by Rear-Admiral W. R. Kennedy; a Crowned Lemur (*Lemur coronatus*, ♀) from Madagascar, deposited; an Eland (*Oreas canna*, ♂) from South Africa, a Livingston's Eland (*Oreas canna livingstonii*, ♀) from the Transvaal, two Short-toed Hedgehogs (*Erinaceus brachydactylus*) from Somaliland, purchased; a Thar (*Capra jemlaica*), a Japanese Deer (*Cervus sika*, ♀), a Wapiti Deer (*Cervus canadensis*, ♀), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

VARIATIONS OF LATITUDE.—Since 1885, the fifteen polar stars of which the apparent places are given in the *Connaissance des Temps*, have been regularly observed at Lyons Observatory. The materials thus obtained are used by M. F. Gonnessiat, in the *Bulletin Astronomique* (vol. xi. June and July 1894), for an investigation of the variations of latitude. The calculations show that from one maximum to the next the mean interval is 1·185 years; while the mean interval between two successive minima comes out as 1·178 years. In round numbers, therefore, the variation has a period of 1·18 years, that is, 431 days, which agrees with that found by Mr. Chandler. The mean amplitude of the oscillation is 0"·44. As to the annual variation, M. Gonnessiat is inclined to think that it has no real existence. He points out that one batch of observations discussed by Mr. Chandler, was like those made at Lyons, and hence refraction and errors of delineation introduce apparent annual changes in the results. In the case of observations made in the prime vertical by Horrebow's method, it is argued that refraction would show itself in the results, not only by its effects on the zenith distance of the same star in the course of a year, but also on the same day, when the connection between the groups observed is established. It is further remarked that the intensity of gravity, which determines the phase of the annual term, is far from being constant at any single place, and that its variation with the longitude does not appear to have been established. For these reasons M. Gonnessiat holds that it is necessary to exercise "une certaine réserve à l'égard du second terme de la formule de M. Chandler."

PHOTOGRAPHS OF THE MOON.—At the meeting of the Paris Academy of Sciences on July 9, MM. Lœwy and Puiseux exhibited some marvellous photographs of the moon, obtained by means of the great *coudé* equatorial of the Paris Observatory. In the communication which accompanied the photographs, the advantages of multiplying good lunar photographs were pointed out, and the various methods employed in the work were passed in review. One of the enlargements on paper, shown to the Academy, represented the moon on a scale of 1·80 metres for its diameter, and five lunar pictures on glass were exhibited at the same time. Some years would be required to make a drawing showing all the details visible on one of the plates obtained with an exposure of about a second. The negatives are larger than those obtained with the Lick telescope, and they bear considerable magnification without loss of definition. But such negatives cannot always be obtained. MM. Lœwy and Puiseux say that, of fifty or sixty evenings employed in lunar photography, only four or five gave really first class results. A complete series of negatives, tracing the moon through its phases, has not yet been obtained at Paris, but what has been done has furnished material for experiments in making enlargements. This part of the work is really as important as that of taking the negatives. From the results, MM. Lœwy and Puiseux conclude that a complete lunar atlas of the dimensions proposed by Prof. S. P. Langley can be made by means of the great *coudé* telescope at the Paris Observatory without the expenditure of much time and work. A comparison of the enlargements with previous representations of the same regions shows that real progress has been made. Another great step in advance will have been made when all the phases of the moon have been reproduced photographically in pictures so clearly defined as those just obtained.

FURTHER CONCERNING THE NEW IODINE BASES.

A FURTHER contribution to the chemistry of their recently discovered iodonium bases, by Prof. Victor Meyer and Dr. Hartmann, will be found in the present issue of the *Berichte*. In their two former communications, an account of which will found in NATURE, vol. xlix. pp. 442 and 467, in addition to the free parent base $(C_6H_5)_2I.OH$, descriptions were given of the iodide $(C_6H_5)_2I.I$, the chloride $(C_6H_5)_2I.Cl$, the bromide $(C_6H_5)_2I.Br$, and the pyrochromate $[(C_6H_5)_2I]_2Cr_2O_7$. Several new salts are now described, most of which crystallise well, and several are endowed with properties of a particularly interesting character. The similarity to the salts of thallium becomes even more apparent as the reactions of the derivatives are elaborated. The hydroxide has already been shown to be an easily soluble and an alkaline substance; the carbonate is likewise soluble in water and exhibits an alkaline reaction, and the halogen compounds are similar in colour, solubility, and other physical properties to the corresponding thallium salts.

The *nitrate*, $(C_6H_5)_2I.NO_3$, is obtained as a white crystalline precipitate when a concentrated solution of the free base is neutralised with concentrated nitric acid. It is readily soluble in hot water, and crystallises on cooling in the form of small plates or under particular conditions of concentration in compact spear-like crystals. It melts at 153°–154° to a clear liquid which soon commences to decompose with evolution of gas. When larger quantities are heated they explode with some violence. The nitrate is also produced when the chloride is treated with fuming nitric acid; upon the addition of twice as much water and allowing the liquid to cool, well-formed crystals of the nitrate are deposited.

The *acid sulphate*, $(C_6H_5)_2I.HSO_4$, is produced in solution when a moderately concentrated solution of the base is feebly acidified with concentrated sulphuric acid. Upon evaporation to small bulk over a water-bath and allowing to cool the salt crystallises in compact aggregates. It is so largely soluble in water that it cannot be recrystallised from that liquid, and in order to free the salt from adhering sulphuric acid the crystals are dissolved in the minimum quantity of alcohol and a quantity of ether added, which precipitates the salt in clear colourless crystals. It reacts acid to litmus, and the crystals melt like those of the nitrate at 153°–154° to a clear liquid which decomposes at a higher temperature.

The *acetate*, $(C_6H_5)_2I.OC_2H_3O$, has been obtained under somewhat peculiar circumstances. It was shown in the previous communication that iodobenzene was attacked by caustic soda after agitation of the mixture for some little time, and that the solution, which contained the iodonium base, yielded a white precipitate with acetic acid. This precipitate consists of the impure acetate of the base. If the liquid is filtered immediately after the addition of the acetic acid, when it is quite warm (about 30°) owing to the heat of the reaction, the clear filtrate deposits crystals of the pure acetate, which melt with decomposition at 120°.

The *periodide*, $(C_6H_5)_2I.I.I_2$.—This interesting compound, analogous to the iodine addition products of the alkyl ammonium iodides, is obtained by mixing the iodide of the base with a little alcohol and triturating with an alcoholic solution of iodine. The combination occurs almost instantaneously with production of a brownish-red precipitate, which crystallises from alcohol in magnificent dark red, almost black, and exceptionally lustrous crystals which melt at 138°.

Double salts.—The chloride forms characteristic double salts with mercuric chloride, gold chloride, and platinic chloride. The mercuric chloride compound, $(C_6H_5)_2I.Cl.HgCl_2$, is obtained as a white precipitate upon the addition of corrosive sublimate solution to a solution of the chloride of the base. It crystallises from water in highly refractive colourless needles which melt at 172° with decomposition. The gold salt, $(C_6H_5)_2I.Cl.AuCl_3$, obtained by precipitation with gold chloride, crystallises from hot water in yellow needles melting at 134°–135° with decomposition. The platinochloride, $[(C_6H_5)_2I.Cl]_2PtCl_4$, is obtained by use of chloroplatinic acid as a flesh-coloured precipitate which is very difficultly soluble even in boiling water, and only crystallises from the solution in microscopic needles. Its melting point is 184°–185°, and decomposition occurs upon fusion.

Sulphides.—It was a point of considerable interest to ascertain whether the similarity of the iodonium bases to thallium would be carried as far as the formation of insoluble sulphides. This is indeed found to be the case, and the sulphides are in external appearance most remarkably similar to the freshly precipitated sulphides of lead, thallium, and antimony. When a solution of the free base is mixed with ammonium sulphide a bright orange-red precipitate, very similar to antimony sulphide, is produced. If the experiment is carried out with ice-cold solutions and the product is maintained at 0°, the precipitate is quite stable. If it is performed at the ordinary temperature, however, in a very short time the orange precipitate begins to hiss and seethe, white clouds of vapour are projected out of the liquid, and the solid precipitate rapidly changes to a mobile oil. Analyses and fractional distillations show that the solid orange precipitate is the trisulphide of the base

$$(C_6H_5)_2I.S.S.S.I(C_6H_5)_2,$$

and that this substance decomposes at the ordinary temperature into phenyltrisulphide and iodobenzene.

$$[(C_6H_5)_2I]_2S_3 = 2C_6H_5I + (C_6H_5)_2S_3.$$

The normal sulphide, $(C_6H_5)_2I.S.I(C_6H_5)_2$, has been obtained by the action of sodium sulphide, Na_2S, which precipitates it as a bright yellow precipitate. It rapidly changes at the ordinary temperature, in the same manner as the trisulphide, to a colourless oil consisting of iodobenzene and ordinary phenyl sulphide.

$$[(C_6H_5)_2I]_2S = 2C_6H_5I + (C_6H_5)_2S.$$

Reduction of the free base is brought about by the action of sodium amalgam in the cold, a molecule of the base decomposing into benzene, water, and hydriodic acid, which latter precipitates a second molecule of the base as the insoluble iodide.

$$2(C_6H_5)_2I . OH + 4H = (C_6H_5)_2I . I + 2C_6H_6 + 2H_2O.$$

The solution of the free base precipitates solutions of the salts of the heavy metals exactly like ammonia or the fixed alkaline hydrates.

The physiological action of the chloride of the base has been studied in detail by Dr. Gottlieb, of the Heidelberg Pharmakologisches Institut. The salt has been found to be very poisonous, and its mode of action upon the animal muscles, membranes and nerves, combines the characteristics of the action of lead and thallium salts with those of ammonia and the ammonium bases. A. E. TUTTON.

WOMEN AND SCIENCE.[1]

THIS little volume is to all intents and purposes a charming and eloquent appeal in support of the claims of women to effectual recognition in the scientific world. In reality it purposes only to give in brief outline the lives of half a dozen women who have rendered important service to mathematical science. But although brief the sketches are so clever that the various characters depicted could scarcely appear more living or real, whilst there is not a single dull sentence to be found in the book.

One of the most interesting of the short studies, because so closely connected with the present, is that of the gifted and fascinating Sophie Kowalevski, who only died three years ago, and who commenced her study of mathematics at the age of fourteen, and at eighteen married Kowalevski, "parce qu'il n'était permis qu'aux dames de suivre les Cours des Universités!" On the presentation of three original theses, the University of Gottingen hastened without further examination to confer the degree of Doctor of Philosophy upon her, and later in life she was appointed to a chair of mathematics in Stockholm. But Sophie Kowalevski was not only a gifted mathematician of whom Kronecker declared "l'histoire des mathématiques parlera comme d'une des plus rares investigatrices," but an accomplished *littérateure*, and the author of numerous books, one of which is entitled "Souvenirs sur George Eliot," whilst "Les Souvenirs d'enfance" is described as a fine bit of psychological study worthy of Tolstoi, or of the new "Immortal" Bourget.

The place of imagination in science, so forcibly insisted upon by Mr. Goschen some years ago in his rectorial address at Edinburgh, is beautifully put in a letter to a novelist friend astonished at her pursuing science and letters simultaneously. "People frequently regard mathematics as a dry and barren science. In reality the pursuit of mathematics demands a great deal of imagination, and one of the greatest mathematicians of our century said, with justice, that it is impossible to be a good mathematician without at the same time having a touch of the poet."

Some sixty or seventy years earlier we read of another highly gifted mathematician, Sophie Germain, who at the same time distinguished herself by her contributions to philosophy. M. Rebière tersely summarises her claims to distinction by thus closing his memoir: "Pour construire la tour Eiffel, les ingénieurs ont utilisé l'élasticité des métaux. On a inscrit sur la tour les noms de 72 savants; on a oublié celui d'une fille de génie, la théoricienne de l'élasticité!"

England is represented by Mrs. Somerville in a very bright and sympathetic little notice, whilst Italy sends her contribution in the shape of "la nobile fanciulla" Marie Agnesi, who Pope Benedict XIV. nominated Professor of Mathematics in the University of Bologna, writing—"It is not you who should thank us; on the contrary, it is we who owe all our thanks to you. From the most remote times Bologna has heard of people of your sex occupying its public chairs. It belongs to you to worthily perpetuate the tradition." In commenting upon this distinction M. Rebière cannot resist telling us of some of the numerous women who have at various times held professorial appointments at Bologna. The list is instructive, and we quote it in full, for we cannot afford to admit women as fellows of any of our learned societies even!—"In languages, philosophy, and theology: Priscopia Cornaro, 'maîtresse des arts libéraux'; Clotilde Tambroni, hellenist, who had Mezoffanti as a pupil. In law: Dotta, daughter of Accurse; Biltizia Gozzadini, in connection with whom a pamphlet was published, *De mulierum doctoratu*; the two sisters, Bettina and Novella Calendrini. It appears that Novella was so beautiful, that it was necessary, in order to avoid distracting the students, to draw a slight curtain between her and the audience. In natural science and medicine: Alexandra Gigliani, Maria Petraccini, Anna Manzolini, and Sybille Mérian. The latter, who was a German, went to study insects at Surinam; she published an important work, and left her collections to the School of Bologna. In physics and mathematics: Laure Bassi, who married Dr. Verati, and who whilst teaching physics during forty years was a model wife and mother; the two astronomers, Thérèse et Madeleine Manfredi, sisters of the Director of the Observatory, who published a volume entitled 'Astronomy for Women.'"

The bust of Marie Agnesi was subsequently placed by Cardinal Dumini in his gallery of distinguished Lombards, and on her tomb these words were inscribed: "Fille remarquable par sa piété, sa science et sa bienfaisance."

We are introduced to a very different woman and mathematician in the person of Madame la Marquise du Châtelet, the friend of Voltaire, and whom the Prince Royal of Prussia familiarly addressed as Vénus Newton!

M. Rebière tells us that she had preserved, in spite of her studies, "une certaine frivolité. Son goût pour la parure et les diamants était très vif. Et puis elle riait de si bon cœur aux marionnettes!" But whilst indulging in diamonds and puppet-shows, the Marchioness found time to translate Newton's "Principia" from Latin into French, and produced besides numerous learned memoirs, one of which, "Institutions de Physique," was dedicated to her sons in words which, although written more than a century and a half ago, might have been uttered yesterday—"J'ai toujours pensé que le devoir le plus sacré des hommes était de donner à leurs enfants une éducation qui les empêchât dans un âge plus avancé de regretter leur jeunesse, qui est le seul temps où l'on puisse véritablement s'instruire." We find her returning to the same theme in a little essay, "Traité du bonheur," a curious mixture of feelings reflecting very vividly the varying moods of this remarkable woman:—"Nous n'avons rien à faire en ce monde qu'à nous procurer des sensations agréables," she writes; whilst on another page we read, in an eulogistic commentary on the benefits of study more especially to women—"Quand, par hasard, il s'en trouve quelqu une née avec une âme assez élevée, il ne lui reste que l'étude pour la consoler de toutes les exclusions et de toutes les dépendances auxquelles elle se trouve condamnée par état," M. Rebière does not omit to include amongst his memorable women Hypatia, with whose memoir the volume in fact opens.

In conclusion, M. Rebière devotes a couple of pages to suggestions for the making of a book which we fancy would be with difficulty kept within the modest limit of eighty pages, which the little pamphlet before us embraces. "Un livre à faire" remains, says M. Rebière, in which the influence direct and indirect exerted by women on the progress of science might be recorded, a book catholic enough not only to include the *savantes professionnelles*, but the *simples curieuses* or amateurs in science, amongst which George Sand finds a place, the *collaboratrices*, and finally those whose munificence and public spirit have earned for them the well-deserved title of *les protectrices*, instances of which we in this country have fortunately little difficulty in recalling. But possibly the most eloquent tribute which has ever been paid to any woman, and which might appropriately have found mention in M. Rebière's little volume, is that which was so pathetically inscribed by John Stuart Mill on the first page of his essay on "Liberty."

We are glad to learn that meanwhile M. Rebière is compiling a second and more elaborate volume in which women's relation to science will be discussed, upon which subject M. Rebière asks us to mention that he will gratefully receive any notes and suggestions. G. C. FRANKLAND.

THE ELECTRIFICATION OF AIR.[1]

§ 1. THAT air can be electrified either positively or negatively is obvious from the fact that an isolated spherule of pure water, electrified either positively or negatively, can be wholly evaporated in air.[2] Thirty-four years ago it was pointed out by one of us[3] as probable that in ordinary natural atmospheric conditions, the air for some considerable height above the earth's surface is electrified,[4] and that the incessant variations of electrostatic force which he had observed, minute after minute, during calms and light winds, and often under a cloudless sky, were due to motions of large quantities of positively or negatively electrified air in the immediate neighbourhood of the place of observation.

§ 2. It was proved[5] by observations in the Old College of Glasgow University that the air was in general negatively electrified, not only indoors, within the old lecture room[6] of Natural Philosophy, but also in the out-of-doors space of the College Court, open to the sky, though closed around with high buildings, and between it and the top of the College Tower. The Old College was in a somewhat low situation, surrounded by a densely-crowded part of a great city. In the new University buildings, crowning a hill on the western boundary of Glasgow, similar phenomena, though with less general prevalence of negative electricity in the air, have been observed, both indoors, in the large Bute Hall, and in many other smaller rooms, and out-of-doors, in the court, which is somewhat similar to the courts of the Old College, but much larger. It is possible that the negative electricity found thirty years ago in the air of the Old College, may have been due to its situation, surrounded by houses with their fires, and smoking factory chimneys. In the New College much of the prevalence of negative electricity in air within doors has, however, been found to be due to electrification by the burning lamp[7] used with the quadrant electrometer; and more recent observations with electrification by flame absolutely excluded, throw doubt on the old conclusion, that both in town and country negative electrification is the prevailing condition of natural atmospheric air in the lower regions of the atmosphere.

§ 3. The electric ventilation found in the Old College, and described in § 299 of "Electrostatics and Magnetism," according to which air drawn through a chink, less than ½-inch wide, of a slightly open window or door, into a large room, showed the electrification which it had on the other side of the chink, whether that was the natural electrification of the open air, or positive or negative electrification produced by aid of a spirit lamp and electric machine in an adjoining room, has been tried again in the New College with quite corresponding results. It has also been extended to the drawing in of electrified air through a tube to the enclosure represented in Fig. 1 of the present paper; with the result that the water-dropping test indicated in the sketch, amply sufficed to show the electrification, and verify that it was always the same as that of the air outside. When the tube was filled with loosely packed cotton-wool the electrification of the entering air was so nearly annulled as to be insensible to the test.

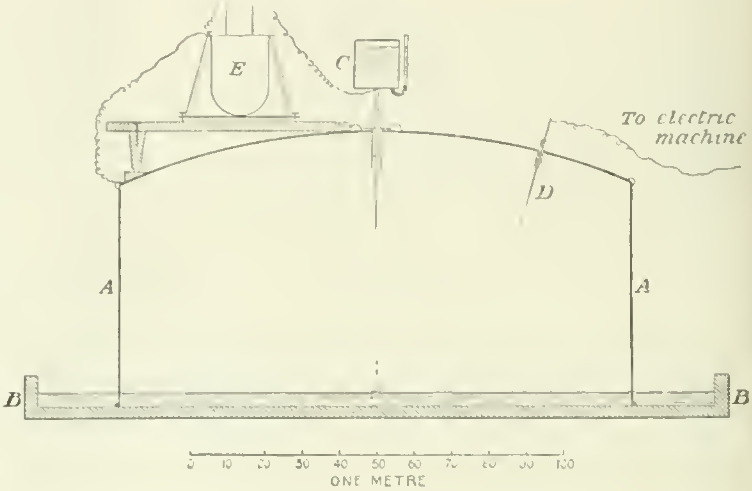

Fig. 1.

§ 4. The object proposed for the experiments described in the present communication was to find if a small unchanged portion of air could be electrified sufficiently to show its electrification by ordinary tests, and could keep its electrification for any considerable time; and to test whether or not dust in the air is essential to whatever of electrification might be observed in such circumstances, or is much concerned in it.

§ 5. The arrangement for the experiments is shown in the diagram, Fig. 1. A A is a large sheet-iron vat inverted on a large wooden tray B B, lined with lead. By filling the tray with water the air is confined in the vat. There are two holes in the top of the vat: one for the water-dropper C, and one for the charging wire D. Both the water-dropper, and the charging wire, ending with a pin-point as sharp as possible, are insulated by solid paraffin, which is surrounded by a metal tube, as shown in half size in Fig. 2. To start with they were supported by pieces of vulcanite embedded in paraffin. But it was found that after the lapse of some days (possibly on account of ozone generated by the incessant brush discharges), the insulation had utterly failed in both of them. The vulcanite pieces were then taken out, and solid paraffin, with the metal guard-tube round it to screen it from electrically influencing the water-dropper, was substituted. This has proved quite satisfactory: the water-dropper, with the flow of water stopped, holds a positive or a negative charge for hours.

§ 6. A quadrant electrometer I (described in "Electrostatics and Magnetism" §§ 346-353) was set up on the top of the vat near the water-dropper, as shown in Fig. 1. It was used with lamp and semi-transparent scale to indicate the difference of potential between the water-dropper and the vat. The sensibility

[1] A Paper by Lord Kelvin, P.R.S., and Mr. Magnus Maclean, read at the Royal Society on May 31.

[2] This demonstrates an affirmative answer to the question, Can a molecule of a gas be charged with electricity? (J. J. Thomson, "Recent Researches in Electricity and Magnetism," § 36, p. 53) and shows that the experiments referred to as pointing to the opposite conclusion are to be explained otherwise.

Since this was written, we find in the *Electrical Review* of May 18, on p. 571, in a lecture by Elihu Thomson, the following:—"It is known that as we leave the surface of the earth and rise in the air, there is an increase of positive potential with respect to the ground. . . . It is not clearly proven that a pure gas, rarefied or not, can receive and convey a charge. If we imagine a charged drop of water suspended in air and evaporating, it follows that, unless the charge be carried off in the vapour, the potential of the drop would rise steadily as its surface diminished, and would become infinite as the drop disappeared, unless the charge were dissipated before the complete drying up of the drop by dispersion of the drop itself, or conveyance of electricity by its vapour. The charge would certainly require to pass somewhere, and might leave the air and vapour charged."

It is quite clear that "must" ought to be substituted for "might" in this last line. Thus the vagueness and doubts expressed in the first part of the quoted statement are annulled by the last three sentences of it.

[3] "Even in fair weather the intensity of the electric force in the air near the earth's surface is perpetually fluctuating. The speaker had often observed it, especially during calms or very light breezes from the east, varying from 40 Daniel's elements per foot to three or four times that amount during a few minutes, and returning again as rapidly to the lower amount. More frequently he had observed variations from about 30 to about 40, and back again, recurring in uncertain periods of perhaps about two minutes. These gradual variations cannot but be produced by electrified masses of air or cloud, floating by the locality of observation."—Lord Kelvin's "Electrostatics and Magnetism," art. xvi. § 282.

[4] The out-of-doors air potential, as tested by a portable electrometer in an open place, or even by a water-dropping nozzle outside, two or three feet from the walls of the lecture room, was generally on these occasions positive, and the earth's surface itself therefore, of course, negative—the common fair weather condition—which I am forced to conclude is due to a paramount influence of positive electricity in higher regions of the air, notwithstanding the negative electricity of the air in the lower stratum near the earth's surface. On the two or three occasions when the in-door atmospheric electricity was found positive, and, therefore, the surface of the floor walls and ceiling negative, the potential outside was certainly positive, and the earth's surface out-of-doors negative, as usual in fine weather."—*Ibid.* § 300.

[5] *Ibid.* Q 2, § 2[illegible]3. [6] *Ibid.* §§ 296-300.

[7] "Electrification of Air by Combustion," Magnus Maclean and Makita Goto, Philosophical Society of Glasgow, November 20, 1889: "Electrification of Air by Water Jet," Magnus Maclean and Makita Goto, *Philosophical Magazine*, August 1890.

of the electrometer was 21 scale divisions (half-millimetres) per volt, and as the scale was 90 centimetres long, difference of potentials up to 43 volts positive or negative, could be read by adjusting the metallic zero to the middle of the scale. A frictional plate-electric machine was used, and by means of it, in connection with the pin-point, the air inside the vat could be electrified either positively or negatively.

§ 7. The vat was fixed in position in the Apparatus Room of the Natural Philosophy Department of the University of Glasgow on December 13, 1893, and for more than three months the air inside was left undisturbed except by discharges from the pin-point through the electrifying wire, and by the spray from the water-dropper. Thus the air was becoming more and more freed of dust day by day. Yet at the end of the four months we found that the air was as easily electrified, either positively or negatively, as it was at the beginning; and that if we electrify it strongly by turning the machine for half an hour, it retains a considerable portion of this electrification for several hours.

§ 8. Observations were taken almost daily since December 13; but the following, taken on February 8, March 12, and April 23, will serve as specimens, the results being shown in each case by a curve. At all these dates the air must have been very free from dust. Both during the charging and during the observations the case of the electrometer and one pair of quadrants are kept metallically connected to the vat. During the charging the water-dropper and the other pair of quadrants were also kept in connection with the vat. Immediately after the charging was stopped the charging-wire was connected metallically to the outside of the vat, and left so with its sharp point unchanged in its position inside the vat during all the observations.

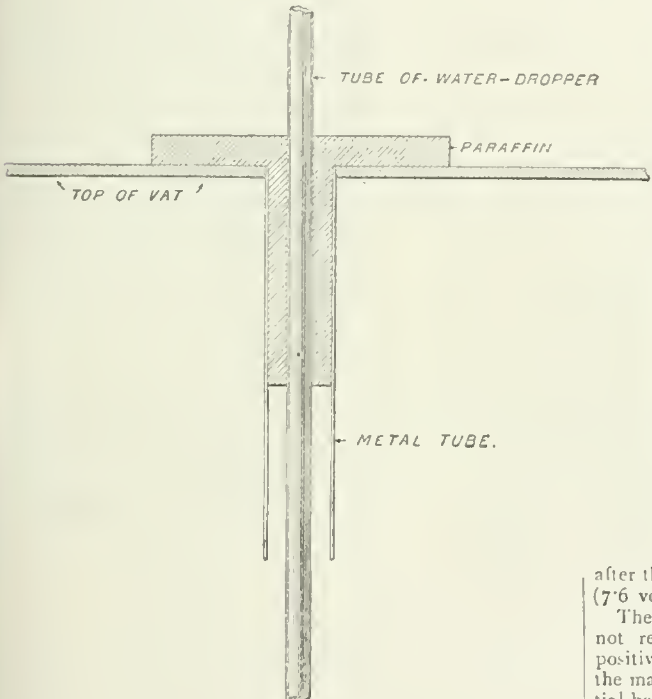

FIG. 2.

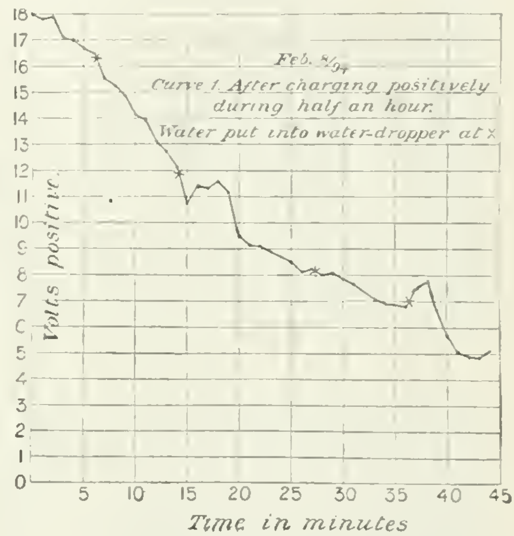
§ 9. *Curve* 1. *February* 8, 1894.—The friction-plate machine was turned positive for half an hour. Ten minutes after the machine stopped the water-dropper was filled and joined to one pair of quadrants of the electrometer, while the other pair was joined to the case of the instrument. The first reading on the curve was taken four minutes afterwards, that is, fourteen minutes after the machine stopped running (18 volts).

Curve 2. *March* 3, 1894.—The friction-plate machine was turned positive for five minutes. The water-dropper was filled and joined to the electrometer immediately after the machine stopped turning. The spot was off the scale, and nine minutes elapsed before it appeared on the scale. The first reading on the curve was taken one minute afterwards, or ten minutes after the machine stopped turning (35·25 volts).

Curve 3. *March* 12, 1894.—A Voss induction machine was joined to the charging wire, and run by an electric motor for four hours nineteen minutes. A test was applied at the beginning of the run to make sure that it was charging negatively; and a similar test when it was disconnected from the charging wire in the vat showed it to be still charging negatively. The water-dropper was joined to the electrometer, and the spot appeared on the scale immediately. The first reading on the curve was taken half a minute after the machine was disconnected (30·65 volts).

Curve 4. *April* 23, 1894.—The friction-plate machine was turned positive for thirty seconds, with water-dropper running and joined to the electrometer. Twenty seconds after the machine stopped the spot appeared on the scale, and the reading one and a half minutes after the machine stopped turning is the first point on the curve (7·3 volts).

Curve 5. *April* 23, 1894.—The friction-plate machine was turned negative for thirty seconds, with the water-dropper running and joined to the electrometer. Ten seconds afterwards the spot appeared on the scale, and the reading seventy seconds



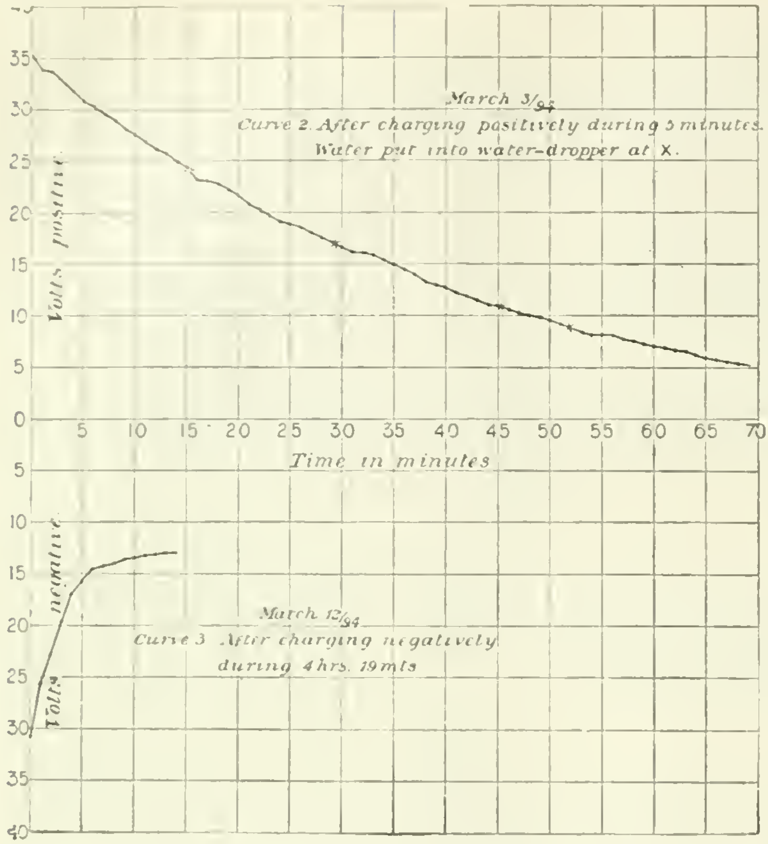
after the machine stopped turning is the first point on the curve (7·6 volts).

The curves show, what we always found, that the air does not retain a negative electrification so long as it retains a positive. We also found, by giving equal numbers of turns to the machine, that the immediately resulting difference of potential between the water-dropper and the vat was greater for the negative than for the positive electrification; though the quantity received from the machine was probably less in the case of the negative electrification, because the negative conductor was less well-insulated than the positive.

§ 10. On March 21, two U-tubes were put in below the edge of the vat, one on either side, so that it might be possible to blow dusty, or smoky, or dustless air into the vat. To one tube was fitted a blowpipe bellows, and by placing it on the top of a box in which brown paper and rosin were burning, the vat was filled with smoky air. Again, several layers of cotton-wool were placed on the mouth of the bellows, so as to get dustless air into the vat. The bellows were worked for several hours on four successive days, and we found no appreciable difference (1) in the ease with which the air could be electrified by discharges from the wire connected to the electric machine, and (2) in the length of time the air retains its electrification.

But it was found that, as had been observed four years ago with the same apparatus,[1] with the water-dropper insulated and connected to the electrometer, and no electrification of any kind to begin with, a negative electrification amounting to four, five, or six volts gradually supervened if the water-dropper was

[1] Maclean and Goto, *Philosophical Magazine*, August 1890.



the equal and opposite quantity on the inner boundary of the enclosing metal; and we therefore have the formula:—

$$V = 4\pi \int_0^a \left(\frac{r^2}{r} - \frac{r^2}{a}\right)\rho\, dr,$$

where V denotes the potential indicated by the water-dropper, a the radius of the spherical hollow, and ρ the electric density of the air at distance r from the centre. Supposing now, for example, ρ to be constant from the surface to the centre (which may be nearly the case after long electrification as performed in our experiments), we find $V = \frac{2}{3}\pi\rho a^2$; whence $\rho = 3V/2\pi a^2$.

To particularise further, suppose the potential to have been 38 volts or 0·127 electrostatic c.g.s. (which is less than the greatest found in our experiments) and take $a = 50$ cm.: we find $\rho = 2{\cdot}4.10^{-5}$. The electrostatic force at distance r from the centre, being $\frac{4}{3}\pi\rho r$, is therefore equal to $10^{-4} r$. Hence a small body electrified with a quantity of electricity equal to that possessed by a cubic centimetre of the air, and placed midway ($r = 25$) between the surface and centre of the enclosure experiences a force equal to $2{\cdot}4.10^{-9}.25$, or 6×10^{-8}, or approximately 6.10^{-5} grammes weight. This is 4·8 per cent. of the force of gravity on a cubic centimetre of air of density 1/800.

§ 14. Hence we see that, on the supposition of electric density uniform throughout the spherical enclosure, each cubic centimetre of air experiences an electrostatic force towards the boundary in simple proportion to distance from the centre, and amounting at the boundary to nearly 10

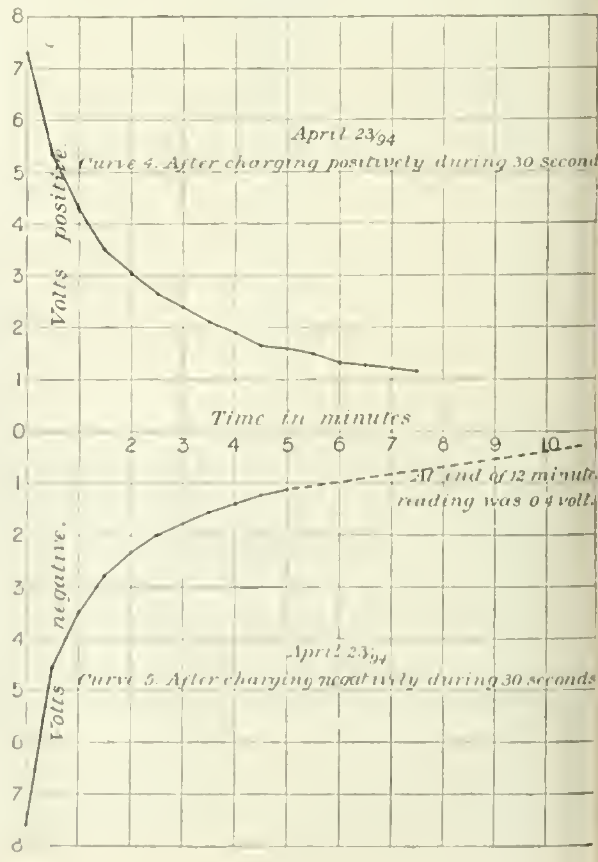
kept running for 60 or 70 minutes, through air which was dusty, or natural, to begin with. It was also found, as in the observations of four years ago, that no electrification of this kind was produced by the dropping of the water through air purified of dust.

The circular bend of the tube of the water-dropper shown in the drawing was made for the purpose of acting as a trap to prevent the natural dusty air of the locality from entering the vat when the water-dropper ran empty.

§ 11. The equilibrum of electrified air within a space enclosed by a fixed bounding surface of conducting material presents an interesting illustration of elementary hydrostatic principles. The condition to be fulfilled is simply that the surfaces of equal electric "volume-density" are surfaces of equal potential, if we assume that the material density of the air at given temperature and pressure is not altered by electrification. This assumption we temporarily make from want of knowledge; but it is quite possible that experiment may prove that it is not accurately true; and it is to be hoped that experimental investigation will be made for answering this very interesting question.

§ 12. For stable equilibrium it is further necessary that the electric density, if not uniform throughout, diminishes from the bounding surface inwards. Hence, if there is a portion of non-electrified air in the enclosure it must be wholly surrounded by electrified air.

§ 13. We may form some idea of the absolute value of the electric density, and of the electrostatic force in different parts of the enclosure, in the electrifications found in our experiments, by considering instead of our vat a spherical enclosure of diameter intermediate between the diameter and depth of the vat which we used. Consider, for example, a spherical space enclosed in metal of 100 cm. diameter, and let the nozzle of the water-dropper be so placed that the stream breaks into drops at the centre of the space. The potential shown by the electrometer connected with it, being the difference between the potentials of the air at the boundary and at the centre, will be the difference of the potentials at the centre due respectively to the total quantity of electricity distributed through the air and



per cent. of the force of gravity upon it; and electric forces of not very dissimilar magnitudes must have acted on the air electrified as it actually was in the non-spherical enclosure used in our experiments. If natural air or cloud, close to the ground or in the lower regions of the earth's atmosphere, is ever, as in all probability it often is, electrified to as great a degree of electric density as we have found it within our experimental vat, the natural electrostatic force in the atmosphere, due as it is, no doubt, to positive electricity in very high regions, must exercise an important ponderomotive force quite comparable in magnitude with that due to difference of temperatures in different positions.

It is interesting to remark that negatively electrified air over negatively electrified ground, and with non-electrified air above it, in an absolute calm, would be in unstable equilibrium; and the negatively electrified air would therefore rise, probably in large masses, through the non-electrified air up to the higher regions, where the positive electrification is supposed to reside. Even with no stronger electrification than that which we have had within our experimental vat, the moving forces would be sufficient to produce instability comparable with that of air warmed by the ground and rising through colder air above.

§ 15. During a thunderstorm the electrification of air, or of air and the watery spherules constituting cloud, need not be enormously stronger than that found in our experiments. This we see by considering that if a uniformly electrified globe of a metre diameter produces a difference of potential of 38 volts between its surface and centre, a globe of a kilometre diameter, electrified to the same electric density, reckoned according to the total electricity in any small volume (electricity of air and of spherules of water, if there are any in it), would produce a difference of potential of 38 million volts between its surface and centre. In a thunderstorm, flashes of lightning show us differences of potentials of millions of volts, but not perhaps of many times 38 million volts, between places of the atmosphere distant from one another by half a kilometre.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Council of the Owens College has, on the recommendation of the Senate, made the following appointments to Fellowships in the College:—Bishop Berkeley—Dr. A. W. Crossley in Chemistry, A. H. Jameson in Engineering; Honorary Research—Wilmot Holt, junr., in Chemistry.

MR. ANDREW J. HERBERTSON, of Edinburgh, has been appointed Lecturer on Geography at the Owens College, Manchester, in succession to Mr. Yule Oldham.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xvi. 3. (Baltimore: July 1894.)—A class of uniform transcendental functions, by Dr. T. Craig (pp. 207–220), gives another mode of forming a certain transcendental function first introduced by M. Picard (*Comptes Rendus*, 1878), and which does not seem to have been subsequently discussed. M. G. Humbert (pp. 221–253), writing "Sur les surfaces de Kummer elliptiques," after mentioning that Cayley's *tetrahedroid* is a particular case of a Kummer surface with six double points, applies himself to the problem of determining whether any other of these surfaces possess similar properties.—Mr. Basset contributes a memoir on the deformation of thin elastic plates and shells (pp. 254–290). The origin of the investigation appears to be the dissatisfaction Mr. Basset has felt with Mr. Love's treatment of the theories of thin plates, shells, and wires in the second volume of his book on "Elasticity."

Jahrbuch der k. k. geolog. Reichsanstalt Wien. Bd. xliii. Heft 3 and 4, March 1894.—Although Graz is one of the few localities in the Central Alps in which palæozoic strata are present containing good fossils, the exact age of these strata and their parallelism with the Silurian and Devonian strata of extra-Alpine regions have remained uncertain. The richly fossiliferous Coral-limestone of the Graz succession was determined as mid-Devonian by Suess, Stache, and others. Hoernes, on the other hand, thought it Lower Devonian. Now, for the first time, the Corals have been made the subject of a detailed study.—Dr. K. A. Penecke contributes a paper to the *Jahrbuch*, "On the Devonian strata of Graz," in which he proves that the "Coral limestone" and the "Calceola horizon" immediately above it are the uppermost bed of the *Lower Devonian* series. The age of the palæozoic strata of Graz ranges, according to Dr. Penecke, from the oldest Silurian to the youngest Devonian, and may possibly include a part of the Lower Coal Measures.—The monograph of the Raibl strata, by Baron von Wöhrmann, marks a considerable advance in our knowledge of Alpine Trias. The author's previous papers on the Raibl fauna in North and South Tyrol, have paved the way for this general paper. All the Raibl facies known in the Alps are described, the species contained in them reviewed, the indications of the geographical conditions discussed, and comparative references made to extra-Alpine seas in the same period. The subject is one of the most complex, but its treatment is searching, concise, and exhaustive. We note, almost with relief, the entire absence of the speculative method and wordy argument too frequently seen of late in matters concerning the Alps.

Bd xliv. Heft 2, June 1894.—"On the newer literature of the Alpine Trias," by Dr. A. Bittner. The personal and polemical tone of this paper renders it somewhat remarkable. By way of reviewing the terminology and literature of the Alpine Trias, Dr. Bittner exposes scathingly the fashion of new name-giving on insufficient grounds, the prejudice and obstinacy with which a name once given is apt to be retained, and the danger to science of subsequent attempts to modify the original meaning of a name, and prop a deservedly falling fabric. The writings of Mojsisovics are those which specially come under the whip. We are told, for example, that in studying "the Cephalopoda of the Hallstadt Limestone," one of the greatest works of Mojsisovics, we must read everywhere—instead of Mediterranean Trias, Alpine Trias; instead of Juvavic horizon, Noric horizon; instead of Noric horizon, Ladinian horizon; the author of the work himself having entirely departed from the geological conceptions for which the names were created! Dr. Bittner's paper is, to say the least, breezy; but, on the principle of the old proverb, "It's an ill wind, &c.," there is no doubt it will have a healthful effect in blowing away some of the cobwebs of tradition from a study which nature had already made so difficult and so fascinating.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 10.—"The Composition of Atmospheres which Extinguish Flame." By Dr. Frank Clowes, Professor of Chemistry, University College, Nottingham.

The statements usually published, as to the proportion of carbon dioxide in air necessary to extinguish a candle flame, vary widely. The present investigation was undertaken with the object of fixing the minimum proportion of carbon dioxide and of nitrogen gas, which, when mingled with air, will extinguish flame; and with the further object of ascertaining also the minimum proportion of each of these gases, which is necessary to extinguish the flames of different combustible substances, including those of certain gases.

The method of experimenting, which was devised, prevented the introduction of errors arising from the incomplete mixture of the gas with the air, from the solubility of carbon dioxide in water, and from the effect of carbonic dioxide produced from the flame during its combustion. The proportions of gas and air in the mixtures used were checked by analysis and were shown to be accurate, and duplicate experiments agreed in their results closely.

A preliminary series of experiments proved that, within the wide limits selected, the extinctive proportion of carbon dioxide was independent of the *size* of the flame of any particular combustible which was introduced into the mixture.

An extended series of experiments was then made to ascertain the minimum extinctive proportion of carbon dioxide for flames of very various description. The results arrived at showed that the flames of very different combustibles which were burnt from wicks, required a strikingly similar proportion of carbon dioxide in the air for their extinction. Thus the percentage of carbon dioxide necessary for the extinction of the flames of the following combustibles were: for absolute alcohol, 14; for methylated alcohol, 13; for paraffin oil, 15; for mixed colza and petroleum, 16; and for a candle, 14.

The extinctive proportions of the gas for the flames of various gases burnt from a jet, on the other hand, showed wide differences. The minimum percentages of carbon dioxide gas in air required for the extinction of the various flames of gases were as follows: for hydrogen, 58; for carbon monoxide, 24; methane, 10; ethylene, 26; and for coal-gas, 33. These numbers show no relation, as they might have been expected to do, to the volume of oxygen necessary for the combustion of the different gases.

A second series of experiments was then undertaken to ascertain the minimum proportion of nitrogen which must be added to the air in order to render it extinctive of the various flames already specified. It was found necessary in every case to add nitrogen in larger proportion than carbon dioxide to the air, in order to secure the extinction of a flame. The superior extinctive power of carbon dioxide over that of nitrogen is probably connected with its higher specific heat, and with its greater density.

Characteristic differences were noticed between the behaviour of wick-fed flames and flames supplied with gas from a jet, during the process of their extinction. The wick-fed flame gradually *diminished* in size until it ultimately dwindled away. The gas-fed flame, on the other hand, rapidly *increased* in dimensions, at the same time becoming more and more pale; and it became so pale at last as to be often visible with difficulty, so that it was not easy to mark the moment of its extinction. Probably the extinction of both classes of flames was primarily due to the lowering of their temperatures. In the case of the wick-fed flames, however, the reduction of their temperature led to the diminution of the supply of gaseous and vapourous fuel to the flame, and the flame ultimately died because it was starved. In the case of gas-fed flame the supply of fuel, being independent of the flame, was maintained, and the flame perished from lowering of temperature only; in its effort to obtain an adequate supply of oxygen in the diluted air, however, it expanded its surface, and it thus undoubtedly hastened the reduction of temperature which led to its extinction.

The very high proportion of carbon dioxide in air which is necessary for the extinction of the hydrogen flame has received an important and interesting application. One of the most serious troubles to which the miner is exposed when using his safety-lamp, is the extinction of its flame by air containing carbon dioxide. In most mines the lamp cannot be relighted with safety, since a naked flame would cause danger in the possible presence of inflammable gas. The loss of the flame therefore implies the necessity of the miner moving in darkness often through a considerable distance to a place where the wick may be relighted without risk. The safety-lamp for delicate and accurate gas-testing, which has been already described by the author (*Roy. Soc. Proc.* vol. lii. p. 486), provides the means of avoiding this inconvenience and possible danger. Without opening this lamp it can be made to burn either an ordinary oil-flame alone, or a hydrogen flame alone, or both these flames may be made to burn side by side. If the miner is approaching a part of the mine in which the proportion of carbon dioxide may be extinctive of his oil-flame, he would turn on the hydrogen-flame as an auxiliary. If the oil-flame becomes extinguished, he has proof that he has entered air containing at least fifteen per cent. of carbon dioxide; but he can withdraw from it with his hydrogen-flame still burning, and in purer air the hydrogen-flame will at once rekindle the wick and give him his illuminating flame once more. Under certain circumstances he might even with safety pass though the foul air, and in a similar way regain his oil flame. It is even possible to arrange the hydrogen-jet so close to the wick, that the oil-flame is more or less perfectly maintained by the hydrogen-flame even in the presence of much carbon dioxide.

The question has been raised whether it is safe to enter air which contains sufficient carbon dioxide to extinguish a candle-flame. This question is usually answered in the negative. But recent experiments made by J. R. Wilson (*Amer. Journ. Pharm.* 50, No. 12), seem to prove that rabbits can breathe for an hour with entire immunity from harm or even discomfort air containing 25 per cent. of admixed carbon dioxide, and that when the air contains 50 per cent. of the gas it is by no means immediately fatal to a rabbit which is immersed in it. Now air containing 15 per cent. of carbon dioxide at once extinguishes an ordinary candle-flame or oil-flame. Hence it appears that air may contain a considerably larger proportion of carbon dioxide than that which is necessary to extinguish the flame of a lamp or candle, and yet be competent to maintain life when it is breathed. This statement is fully supported by experiments made by Dr. Angus Smith, as well as by the experience of miners and others.

The following conclusions may be drawn from the experiments referred to above:—

(1) That the extinction of a flame depends not only upon the *quantity* but also upon the *quality* of the extinctive gas present in the air; carbon dioxide uniformly exerting a more powerfully extinctive effect than nitrogen.

(2) That wick-fed flames burning different combustibles show a remarkable uniformity in the minimum proportion of an extinctive gas in air necessary for their extinction.

(3) That this uniformity is not shown by flames fed by a gas burning from a jet; and no simple relation is apparent in the case of the gas-fed flames between the proportion of oxygen present in the diluted air and the proportion of oxygen requisite for the complete combustion of the gas.

(4) That the hydrogen flame requires for its extinction the presence in air of a very high proportion of extinctive gas; it may therefore be advantageously used as an auxiliary flame for maintaining an oil-flame in the foul air of a mine or other locality.

(5) Since an ordinary candle-flame or oil-flame is extinguished by the presence of about 15 per cent. of carbon dioxide in air, and air containing over 25 per cent. of carbon dioxide has been breathed with perfect safety for more than an hour, the extinction of an ordinary oil- or candle-flame in any particular atmosphere must not be taken as proof that that atmosphere contains so much carbon dioxide as to be dangerous to life when it is breathed.

(6) A more satisfactory indication of the presence of a dangerous proportion of carbon dioxide is furnished by the change of colour of the hydrogen flame from reddish to blue-grey. This change begins when 2 per cent. of carbon dioxide is present in the air; it becomes very pronounced as the proportion of the gas present increases. When 30 per cent. or upwards is present the flame is of a pronounced blue colour and also increases in height with the increased proportion of the gas, to an extent which is easily measured on a scale.

May 31.—"Note on the Possibility of obtaining a Unidirectional Current to Earth from the Mains of an Alternating Current System." By Major P. Cardew.

June 21.—"Degenerations consequent on Experimental Lesions of the Cerebellum." By Dr. J. S. Risien Russell.

The paths which degenerate after ablation of one lateral lobe of the cerebellum, and after extirpation of its middle lobe, are discussed in this paper.

Degenerated fibres are found in all the peduncles on the same side after the former operation, and in the superior peduncle of the opposite side. The position occupied by these degenerated fibres, in this peduncle, is that of fibres which degenerate in both superior peduncles after the cerebellum has been divided into two lateral halves by a mesial incision. The degenerated fibres in the superior peduncle of the side of the lesion decussate in the posterior quadrigeminal region, and pass to the opposite red nucleus and optic thalamus. Those fibres which degenerate in the middle peduncle pass chiefly to the grey matter of the opposite side of the pons. Of the fibres which degenerate in the inferior peduncle, the majority occupy the lateral region of the medulla, becoming more and more scattered as they pass down. These can no longer be said to form a tract below the level of the superior pyramidal decussation; but a few scattered fibres occupy the antero-lateral region of the cervical cord, beyond which none can be traced. Degenerated fibres pass to both inferior olives from this peduncle; but no well-marked tract to the opposite inferior olive was found.

After extirpation of the middle lobe of the cerebellum, degenerated fibres were found in all the peduncles. Those in the superior peduncle decussate in the region of the posterior corpora quadrigemina, and terminate in the opposite red nucleus. The degenerated fibres in the middle peduncle behave much as do those which result from ablation of one lateral lobe of the cerebellum; and the same may be said with regard to the degenerated fibres in the inferior peduncle.

No degeneration was found in the fillet, posterior longitudinal bundles, pyramids, ascending root of the fifth nerve, the roots of the cranial and spinal nerves, and in the spinal cord, forming an antero-lateral tract throughout its whole length.

Physical Society, June 22.—Prof. W. E. Ayrton, F.R.S., Past-President, in the chair.—Captain Abney, before exhibiting his photographs of flames, demonstrated that a candle flame contains solid particles by passing a beam of polarised light though it, the track of the beam through the flame being clearly seen in one direction, whilst in a direction at right angles it was practically invisible. The same thing was also shown by passing the light through a turbid liquid. Photographs of argand and candle flames with pencils of sunlight and electric light passing through, were then exhibited showing similar phenomena. Several series of photographs of flames of candles and various forms of gas-burner taken with diminishing exposures were then shown in order to illustrate the different luminosities at different parts of the flame. Those taken with long exposures showed the bright parts nearly equally white, but as the time of exposure diminished only the most luminous portions were recorded on the plate. From the photographs the author concluded that when used with a slit as a photometric standard the argand burner was unsuitable, for portions of different luminosity come into view when the slit is approached or receded from. The ordinary fish-tail burner was better in this respect. Questions were asked and remarks made by Prof. S. P. Thompson, Prof. Perry, and Mr. Trotter, in reply to which Captain Abney said dropped shutters with slits from one inch to one-sixteenth inch wide had been employed, and some of the exposures were only a few thousandths of a second. The displacement caused when the object was not stationary could easily be allowed for when the velocity of the shutter was known.—Prof. O. Henrici read a paper on an elementary theory of planimeters. Considering the generation of areas by the motion of straight lines, the author defined the sense in which such areas are to be taken. Choosing the positive sense of a line O T of variable length as outwards from the centre O about which it turns, and the positive direction of rotation as counter-clockwise, the following rule for determining the sense of an area was given. Imagine yourself standing at a point P, and looking along the positive sense of O T, whilst it passes over P, then the area near P will be swept out in *a positive sense if O T crosses you from right to left*, otherwise it will be negative. Applying this rule to closed curves of any shape, it was shown that if T goes once round the boundary, any area outside the curve was necessarily swept over as many times in the negative sense as in the positive sense, therefore these areas cancelled, and also that the sense of any part of an area depends on the sense of its boundary. Passing on to the consideration of areas generated by a line (or rod) of fixed length, which moves anyhow in a plane and returns to its initial position, Prof. Henrici showed by taking instantaneous centres, that the same rule regarding the sense of the areas holds, and that the area generated by the rod is equal to the difference between the areas of the two closed curves traced by its ends. In the particular case where one end of the rod moves forwards and backwards along the same path the area swept out by the rod is equal to that of the closed curve traversed by the other end. This is the theory of Amsler's planimeter, for the area of the curve whose boundary is traversed by the tracer is the same as that swept out by the rod carrying the tracer when the pole is outside the closed curve. By resolving small motions of the rod in two component parts, a translation parallel to itself, and a rotation about the point in which the plane of the registering wheel cuts the rod, the author showed that the areas swept out by the translations were registered by the wheel, whilst the sum of those generated during the rotations cancel. Cases where the pole is inside the curve were next considered, and the constant then to be added to the wheel reading determined. Instead of registering the translation by a wheel whose axis is parallel to the rod, a knife-edged wheel which slides and turns freely on an arm perpendicular to the rod would serve the same purpose. This is the principle of Hine and Robertson's planimeter. In the actual instrument, however, the arm is inclined at about 10° to the rod, and is therefore inaccurate. In the "hatchet" planimeter a bent rod terminates at one end in a tracing point, and at the other in a convex knife-edge or "keel," whose plane contains the point. The area of the curve whose boundary is traversed by the point is approximately equal to twice that of the sector included between the initial and final positions of the rod. The approximation results from the fact that the area of the curve traced by the keel is not zero. At the meeting the question of reducing the area of the keel curve was discussed at some length, the author showing that in the case of a curve symmetrical about a line, it was possible to reduce this area practically to zero. Even for unsymmetrical curves one could obtain a symmetrical one of double the area by drawing a line, cutting the curve, and supposing the area turned over about this line. Prof. Perry inquired if the author's conclusion was that the "hatchet" planimeter and the Hine and Robertson instrument were inaccurate? If so, he was at a loss to understand why the latter gave results more nearly correct than Amsler's. Mr. Blakesley pointed out that if both arms of a jointed planimeter be simultaneously moved over curves the total reading should give the sum of the two areas traced out if taken in the proper senses. Mr. A. P. Trotter directed attention to an article by the inventor of the "hatchet" in the current number of *Engineering*. Dr. Macfarlane Gray said he had examined the proof given in *Engineering*, and found no error. He then showed how the Amsler planimeter could be explained in a simple geometrical manner by drawing radial lines through the pole and intersecting the curve. Moving the tracer along these radii added nothing to the area; motion along the arcs was the important component. Mr. O. G. Jones and Prof. Thompson also took part in the discussion.—Mr. F. W. Hill made a communication on the "hatchet" planimeter. In this paper the author takes a point within the area to be measured, and divides the area into elementary triangles with this point as apex. The tracing point of the planimeter is then supposed to start from the apex and trace out one of the triangles. The inclination between the initial and final positions of the "hatchet" is then expressed in terms of the angle at the apex, the radius vector, and the length of the planimeter. By expanding and integrating the expression, it is shown that twice the area between the initial and final position of the planimeter, after tracing all the triangles, is represented by an infinite series of terms, the first of which is the area of the curve, the second is proportional to the moment of inertia of the area about the point, the third proportional to its first moment about the same point. The higher terms are usually small enough to be neglected. Starting the tracer at the centroid of the area causes the third term to disappear, and the second has its minimum value, so that this is the starting-point recommended. The magnitude of the errors caused by neglecting the various terms are discussed in some detail. In the author's opinion, the instrument can never be strictly accurate; but usually the errors are within the limits of observation. Prof. Henrici did not agree with the statement that the instrument was necessarily inaccurate, and thought geometry might aid analysis to find the proper starting-point. For a symmetrical curve he had shown that a point existed, starting from which the area traced by the hatchet end was zero. Dr. Macfarlane Gray thought Prof. Henrici's latter argument was vitiated by his figure not being correctly drawn; but this Prof. Henrici disputed. Mr. O. G. Jones said Prof. Henrici's construction was not obvious, for the cusp curves traced by the "hatchet" end depended on the starting-point. Mr. Yule suggested that by shortening the planimeter it might be possible to bring the third and second terms of Mr. Hill's formula into greater prominence, and, by going round the curve more than once, determine the first and second moments. —A paper on a new integrating apparatus, by Mr. A. Sharp, was taken as read. The paper describes an improved form of harmonic analyser, giving the amplitude and epoch of each constituent term, the mechanism of which is an inversion of that described in a communication made to the Society on April 13. Numerous drawings accompany the paper, showing the various parts in detail. The mechanism is also shown to be applicable for integraphs, and by suitable modification may be employed for mechanically integrating differential equations of various forms. A paper on magnetic shielding by a hollow cylinder, by Prof. Perry, and another on "Clark's cells," by Mr. S. Skinner, were postponed.

Geological Society, June 20.—Dr. Henry Woodward, F.R.S., President, in the chair.—On deep borings at Culford and Winkfield, with notes on those at Ware and Cheshunt, by W. Whitaker, F.R.S., and A. J. Jukes-Browne. Four borings at Culford, Winkfield, Ware, and Cheshunt were described in detail, so far as the specimens examined would permit; these were few in the case of Culford, but many from the other borings. The interest of the Culford boring centred in its striking the Palæozoic floor at the small depth of 637½ feet; but the age of the slaty rocks cannot be determined. Although only 20 miles east of Ely, no Jurassic rocks exist, and the Lower Cretaceous series is only about 32 feet thick, the beds differing greatly from those of Cambridgeshire, but resembling those of the same age in the Richmond boring. The Winkfield boring (3½ miles west-south-west of Windsor) was remarkable for having been successful in obtaining water from the Lower Greensand, and for the great depth (1243 feet) to which it was carried for this purpose, the Gault being unusually thick. The boring at Ware was for the first time described in detail, and former accounts were corrected from specimens preserved by the New River Company. By this means, and with the assistance of Mr. W. Hill, the authors were able to give a fairly complete account of the rocks, and to determine the limits of the divisions of the Upper Cretaceous series. They denied the existence of Lower Greensand at this locality. Of the boring at Cheshunt a complete account was given, based on information and specimens supplied by Mr. J. Francis, the engineer of the New River Company. The paper concluded with a tabular view of all the borings in the East of England, showing the level below ordnance datum at which the Palæozoic floor occurs in each. The President, Prof. Boyd Dawkins, Prof. Judd, and Mr. Topley spoke upon the subject of the paper, and Mr. Whitaker briefly replied.—The Bargate Beds of Surrey and their microscopic contents, by Frederick Chapman. This was an attempt to correlate the Bargate Beds of Guildford and its vicinity with the members of the Lower Greensand as known elsewhere in the south-east of England. Mr. T. Leighton, Prof. Judd, Mr. Whitaker, Dr. G. J. Hinde, Mr. Topley, and Prof. T. Rupert Jones offered some remarks upon the paper.—On deposits from snowdrifts, with special reference to the origin of the loess and the preservation of mammoth-remains, by Charles Davison. When the temperature is several degrees below freezing-point, snow recently fallen is fine and powdery, and is easily drifted by the wind. If a fall of snow has been preceded by dry frosty weather, the interstitial ice in the frozen ground is evaporated, and the dust so formed may be drifted with the snow and deposited in the same places. The snowdrifts as a rule are soon hardened by the action of the sun or wind, and the dust is thus imprisoned in the snow. As the snow decays, by melting and evaporation, a coating of dust is extruded on the surface of the drifts, and, increasing continually in thickness as the snow wastes away, is finally left upon the ground as a layer of mud, which coalesces with that of previous years. The deposit so formed is fine in texture, unstratified, and, as experiments show, mica-flakes included in it are inclined at all angles to the horizon. The author described several such deposits both in this country and in the Arctic regions; and suggested (1) that the loess is such a deposit from snowdrifts, chiefly formed when the climate was much colder, but still very slowly growing; (2) that mammoths suffocated in snowdrifts are subsequently embedded, and their remains preserved in the deposits from them; and (3) that the ground-ice formation of Alaska, &c., is the remains of heavy snowdrifts when the coating of earth attained a thickness greater than that which the summer heat can effectually penetrate. Mr. Davison's theory did not find much support. During the discussion upon it, Mr. Oldham said that he happened to have a personal acquaintance with the deposits left after the melting of snow and with the loess. The former were found in sheltered spots on the ridges of the Himalayas, which are annually covered with snow, but (so far as his experience went) they were denser and more compact than the true loess; they were, in fact, dried muds, while the true loess was a dust. In the hills of the western frontier of India, where loess was largely developed and still in course of formation, the distribution, surface-contour, and constitution showed it to be a wind-blown dust deposit, though it passed into deposits which had been rearranged by water. Part of this lay at altitudes where snow fell each year, but it was equally well and typically developed below the level at which snow usually fell, and where it was not preceded by a long frost nor lasted long enough to form extensive drifts. He did not think that the true loess could originate from the solid matter left by melting snow, and it could certainly be formed without the aid of snow. Prof. Blake, Prof. Boyd Dawkins, and Dr. W. F. Hume also spoke.—Additions to the fauna of the *Olenellust*-zone of the north-west Highlands, by B. N. Peach, F.R.S. New material obtained by the officers of the Geological Survey having been placed in the author's hands, he was enabled to add information concerning the species of *Olenellus* previously described by him (*O. Lapworthi*); he also described a new variety of this species, three new species of the genus, a new subgenus of *Olenellus*, and a form provisionally referred to *Bathynotus*. He discussed certain theoretical points based upon the study of the remains described in the paper, and stated that these make it probable that the dispersal of the Olenellids was from the Old World towards the New. Dr. Hicks and Dr. G. J. Hinde spoke upon the subject.—Questions relating to the formation of coal-seams, including a new theory of them: suggested by field and other observations made during the past decade on both sides of the Atlantic, by W. S. Gresley. A number of new facts were described, and the bearing of these and of previously recorded facts upon the origin of coal was discussed, special reference being made to the Pittsburgh coal. He maintained that the evidence pointed to the formation of coal on the floor of an expanse of water, by vegetable matter sinking down from floating "islands" of vegetation, which may have been of very large size, and enumerated cases of such "islands" or "rafts" of vegetation which have been described as existing in modern times.—Observations regarding the occurrence of anthracite generally with a new theory as to its origin, by the same author. After discussing Dr. J. J. Stevenson's theory of the origin of anthracite, the author described the nature and mode of occurrence of the anthracites of Pennsylvania, and gave his reasons for concluding that the de-bituminisation of coal was not produced by dynamic metamorphism during mountain-building, but rather by previously-applied hydrothermal action. He further discussed the applicability of his theory to other cases of anthracite, including that of South Wales and Ireland. In the discussion that followed, Prof. Boyd Dawkins pointed out that the anthracite-fields of South Wales and of Ireland are exactly in those places where the coal-seams have suffered most from crushing and faulting, and that therefore there is distinctly a connection between the exertion of dynamical force and the anthracitic condition. This also applies to the Irish fields. In some cases a coal-seam can be traced into an anthracite seam. In his opinion the author's views would not explain the presence of anthracite in this country.—The igneous rocks of the neighbourhood of Builth, by Henry Woods.—On the relations of some of the older fragmental rocks in north-west Caernarvonshire, by Prof. T. G. Bonney, F.R.S., and Miss Catherine A. Raisin. In a recent paper on the felsites and conglomerates between Bethesda and Llanllyfni, North Wales, it was argued that, in the well-known sections on either side of Llyn Padarn, a great unconformity separates the rocks into two totally distinct groups. The authors of the present communication discussed at the outset the great physical difficulties involved in this hypothesis; a subject which, in their opinion, was passed over too lightly by the author of that paper. They further affirmed, in the course of a description of the sections, which are most clear and afford the best evidence:—(1) That the strike in both the supposed rock-groups is generally similar. (2) That the same is true of the dips. (3) That very marked identity of lithological characters may be found in rocks on either side of the alleged unconformity, specimens occasionally being practically indistinguishable. (4) That in no case, which has been examined, can any valid evidence be found in favour of the alleged unconformity, and that in the one, which is supposed to to the most satisfactory proof of it, the facts are wholly opposed to this notion. Prof. Blake, Dr. Hicks, and Mr. Whitaker discussed these views, and Prof. Bonney replied.

Royal Microscopical Society, June 20.—Mr. A. W. Bennett in the chair—Dr. J. E. Talmage described his method for mounting and staining the brine shrimp, *Artemia fertilis*.—Dr. W. H. Dallinger called attention to a stereoscopic photomicrograph of injected muscle which had been presented by Dr. W. C. Borden.—Dr. Dallinger exhibited and described a new form of mechanical stage for the microscope, which had been produced by Messrs. Swift. Further remarks were made by the chairman, Messrs. Comber, Swift, More, and Beck.—Mr. J. H. Harvey described a method of mounting opaque objects so that they could be moved in all directions whilst under examination.—Mr. T. Comber read a paper on the unreliability of certain characters generally accepted for specific diagnosis in the Diatomaceæ. A discussion ensued, in which the chairman, Prof. F. J. Bell, and Mr. J. Badcock took part.—Prof. Bell gave a *résumé* of Mr. F. Chapman's sixth paper on the Foraminifera of the Gault of Folkestone.

DUBLIN.

Royal Dublin Society, June 20.—Dr. W. Frazer in the chair.—Dr. Telford Smith and Prof. D. J. Cunningham, F.R.S., gave a lantern demonstration of two microcephalic brains. One of these weighed 352 grammes; the other 559 grammes. The authors contrasted these specimens with the brains of the ape and the quadruped. The cerebrum in each had not passed in its development beyond the quadrupedal stage. The initial growth disturbance must therefore have occurred about the fourth month of fœtal development. With the aborted occipital region there was associated a marked convolutionary disturbance. The arrangement of the gyri and sulci did not correspond with that present at any period of fœtal life. It resembled the simian more than the human type; and what was most remarkable was the mixture of low-ape and high-ape characters. In some respects, therefore, the convolutionary pattern resembled that of a baboon, and in others that of a chimpanzee or an orang. The authors referred to the various theories which had been put forward to account for the condition, and upon the whole seemed to favour that of Karl Vogt, although the arguments they brought forward were of a totally different character. The results at which the authors have arrived will shortly appear in the Society's *Transactions*.

PARIS.

Academy of Sciences, July 9.—M. Lœwy in the chair.—The death of M. Mallard, member of the Mineralogy Section, was announced.—On the photographs of the moon obtained with the great *coudé* equatorial of the Paris Observatory, by MM. Lœwy and Puiseux. (See our Astronomical Column.)—On some of the work done at Nice Observatory, by M. Perrotin. In connection with photographic exploration, the author observes that, in the sky regions examined, (1) the number of new asteroids (magnitudes 7–13) is much less than the number previously known; (2) only in the case of asteroids of the 13th magnitude are more now discovered than had been previously observed; (3) the total number of asteroids increases with decreasing magnitude as far as the 12th mag.—On new derivatives from benzoylbenzoic acid, by MM. A. Haller and A. Guyot.—Experimental production of the contagious peripneumonia of cattle by the aid of cultures. Demonstration of the specific character of *Pneumobacillus liquefaciens bovis*. Note by M. S. Arloing. The author concludes from his results quoted that (1) the virulent agent in contagious peripneumonia is an ordinary microbe, and (2) this microbe is the *Pneumobacillus liquefaciens bovis*.—Comparative researches on the products of the combustion of lighting-gas given by an Argand burner and an Auer burner, by M. N. Gréhant. The combustion products from the Auer burner yielded evidence of the presence of carbonic oxide to the extent of 1 in 2580, those from the Argand burner a trace only, estimated at 1 in 75,000.—Special images of the sun given by the simple rays corresponding to the dark lines of the solar spectrum, by M. H. Deslandres. The author gives the first results of a study of the surface layers of the sun by means of images formed by light from selected parts of the spectrum.—On the calorific radiations included in the luminous part of the spectrum, by M. Aymonnet. The following conclusions are deduced from a study of the spectra given by the Bourbouze and Drummond lamps and by the sun: (1) the eye does not perceive all the radiations between the red and violet; (2) the eye is not acted on by rays intercepted by water; (3) when the medium between the radiant source and the measuring apparatus contains water, there is an imperfect concordance between the distribution of heat and that of light in the same region of the spectrum; (4) the bright lines or bands which we can observe in a spectrum are only those or a part of those which pass through water.—On the polarisation of light diffused by roughened surfaces, by M. A. Lafay.—On the relation between the density of a saline solution and the molecular weight of the dissolved salt, by M. Georges Charpy. The density of a saline solution augments proportionally to the molecular concentration if it be admitted that the molecular weight of water at 0° is about 3×18. The densities of equally concentrated solutions of analogous salts are nearly proportional to their molecular weights.—On a new glucosane, lævoglucosane, by M. Tanret.—Syntheses by means of cyanacetic ether. Phenylcyanacetic ethers, by M. T. Klobb.—On paraphthalodicyanacetic ether, by M. J. Locher.—On pine tar, by M. Adolphe Renard.—The quantitative composition of creosotes from beech and oak, by MM. A. Béhal and E. Choay. Beechwood creosote is richer in guaiacol than that from oak.—Inuring ferments to antiseptics and the influence of this hardening on their chemical work, by M. J. Effront.—The nature of onychomycosis, demonstrated by culture and by inoculations, by M. J. Sabrazès.—On the coexistence of the sternum with the shoulder-girdle and lungs, by M. Alexis Julien. The sternum varies in its composition, form, and texture, in its development and even in its connections. Notwithstanding this great variability, certain constant features may be distinguished. The sternum always coexists with the shoulder-girdle and lungs, that is to say, all vertebrates which have a sternum have also lungs and shoulder-girdles, but the converse is not true.—On the insertion of the membrane of Corti, by MM. Coyne and Canniew.—On the topography of the attached urethra, studied on sections of frozen subjects, by M. L. Testut.—On the measurement of the absorption of water by roots, by M. Henri Lecomte.—On the petrographic nature of the summit of Mont Blanc and the neighbouring rocks, by MM. J. Vallot and L. Duparc.

BERLIN.

Physical Society, June 1.—Prof. du Bois Reymond, President, in the chair.—Prof. König described a repetition of H. Müller's experiments on the part of the retina in which the sensation of light takes its origin, using, however, monochromatic light. Müller, as is well known, had localised it in the rods and cones by observing that the shadows cast by the blood-vessels of the retina execute movements, when the source of light is moved (Purkinje's experiment), which correspond to the distance between the blood-vessels and the layer of rods and cones. Prof. König had repeated the measurements on the normal eye of Dr. Zumft, whose constants he had accurately determined, using four kinds of monochromatic light, namely, that of the lithium line in the red, of the D sodium line, of the thallium line, and of the line F. He found as a result of fifteen separate determinations that the distance of the light-perceiving elements of the retina from the blood-vessels which give the shadows varies with the varying wave-lengths of the different lights, a result which can only be explained on the basis of Young's theory of colour-vision.—Dr. H. du Bois spoke on the changes of resistance of a bismuth spiral in a powerful magnetic field. This change, discovered by Lord Kelvin, had been measured in the case of bismuth in a magnetic field whose maximum strength was 12,000 C.G.S., and the curve of resistance in the field, compared with that of the resistance outside the field, was found to be at first concave upwards and then straight. The resistance in the field of maximum strength was 1·7 of that in zero field. The speaker, using some very powerful electromagnets which he had recently exhibited to the Society, and which gave an intensity of 38,000 C.G.S., had, in conjunction with Dr. Henderson, measured the resistance of spirals of pure bismuth, and found that the curve pursues a further straight-line course, so that the resistance in the field of greatest intensity is three times as great as in a field of zero intensity. The measurement of the resistances in a magnetic field at different temperatures had yielded interesting results. In weak fields a rise of temperature increased the resistance: in stronger fields the effect was less, and became zero in a field of 7000 C.G.S. In still stronger fields the resistance of the warm spiral was less than that of the cold. The experiments have so far been carried on only for temperatures between 0° and 25°, but will be pushed further up to 100°.—Dr. Pringsheim described an ingenious procedure by means of which he had succeeded in obtaining positives of old manuscripts on which old and faint characters were obscured by newer and dark writing. The positives were obtained by a combination of several photographs, and showed only the older and fainter characters in sharp and clear definition.

June 15.—Prof. von Helmholtz, President, in the chair.—Prof. von Bezold gave an address in memory of Prof. A. Kundt, the Vice-President of the Society, recently deceased, in which he dwelt upon his scientific labours, and in particular upon his distinguished efforts as a teacher.

NEW SOUTH WALES.

Royal Society, May 2.—Prof. Anderson Stuart delivered the presidential address. He gave a detailed account of the poison of *Ornithorhynchus paradoxus* and of the poison of the "Bush-tick," and alluded to that of the Australian varieties of the spider-genus *Lathrodectus*. After describing the present favourable state of the arrangements for an expedition to one of the South Sea atolls, to realise the suggestion of Darwin to bore and bring up a core, and thus probably settle the question of the origin of the atoll, he announced that, acting on behalf of the Committee of the British Association, he had secured the loan of a diamond drill from the Government of New South Wales. He also spoke of the artesian water supply of the colony in reference to the probable limits of its supply, and favoured the naming after Darwin of some place in the Blue Mountains associated with Darwin's visit. He then reviewed certain questions of present importance in the colony, such as the disposal of sewage, the characters of sewer-air, and the backward condition of sanitary legislation in the colony, &c. The Society is maintaining its position very well, in spite of the present extremely adverse circumstances of the colonies. The officers and council were elected for the ensuing year, Prof. R. Threlfall being President.

Linnean Society, May 30.—Prof. David, President, in the chair.—Notes on the methods of fertilisation of the *Goodeniaceæ*, by Alex. G. Hamilton. Three species of *Scævola*, one of *Selliera*, and one of *Brunonia* were dealt with. The writer concluded that although there is an elaborate contrivance in the first four for securing cross-fertilisation by the aid of insects—which was described in detail—yet, if that fails, self-fertilisation occurs. *Brunonia* was said to be anomalous in its methods. The process of fertilisation in the three allied orders—*Lobeliaceæ*, *Goodeniaceæ*, and *Campanulaceæ*—was contrasted, and it was shown that the same end is secured by widely different adaptations of the same organs.—On three highly ornate boomerangs from the Bulloo River, N.S.W., by R. Etheridge, junr.—Note on the tertiary fossils from Hall Sound, New Guinea, by Prof. Ralph Tate. The author's observations were based on an examination of the specimens in the Macleay Museum, obtained during the voyage of the *Chevert*. These were reported on by the late Rev. J. E. Tenison-Woods (*P.L.S.*, N.S.W. 1878, ii. (2), pp. 125 and 267), who referred them "to a very recent tertiary formation, much newer than any of the Murray River or Western Victorian beds." The author concurred in this view, but pressed for a more recent origin than that implied by Tenison-Woods—even Pleistocene. Some critical observations on the specific determination of the specimens were given—a matter of some difficulty in most cases by reason of their imperfect condition.—On the morphology of the muscles of the shoulder-girdle in monotremes, by W. J. Stewart McKay. The author has found a clavicular deltoid present in both *Echidna* and *Ornithorhynchus*; also a pectoralis quartus, teres minor and subclavius. The teres major is single in both forms; the sub-scapularis of great extent. Much attention has been given to the nervous system, and elaborate dissections have been made to trace out "the latent cutaneous nerve of the thorax" (Patterson) and its communication with the intercostal nerves.—Description of a new Australian snake by J. Douglas Ogilby. The habitat of the new species (*Hoplocephalus waitii*), which differs mainly from *H. pallidiceps*, Gunth., in having 21 series of scales round the body instead of only 15, appears to be the central district of N.S.W., whereas *H. pallidiceps* is a North Queensland form.—Fishes new or rare on the Australian coasts. By Edgar R. Waite. The fishes dealt with were from Maroubra, N.S.W., and are either new to Australia or of exceedingly rare occurrence, and with two exceptions obtained for the first time on the coasts of this colony. The species mentioned are:—*Dules argenteus*, Bennett, *Acanthurus triostegus*, Linn., *Psenes whiteleggii*, sp. nov., *Nomeus gronovii*, Gmel., *Schedophilus maculatus*, Gunth., *Glyphidodon brownriggii*, Bennett, *Solenognathus hardwickii*, Gray, *S. spinosissimus*, Gunth., *Monacanthus filicauda*, Gunth., *M. nitens*, Hollard, and *Leptocephalus*. The author expressed the opinion that *Solenognathus fasciatus*, Gunth., is not specifically distinct from *S. spinosissimus*.—Description of a new mite belonging to the genus *Heteropus* found in wasps' nests, by W. W. Froggatt. The name *Heteropus alastori* was proposed for a mite which has been found in great numbers in the clay nests of the solitary wasp, *Alastor eriurgus*, Sauss., in the neighbourhood of Sydney. The gravid female has an immense globular abdomen eight times the length of the head and thorax combined.—On the mode of attachment of the leaves or fronds to the caudex in *Glossopteris*, with remarks on the relation of the genus to its allies, by R. Etheridge, Jun., with note on the stratigraphical distribution of *Glossopteris* in Australasia, by Prof. T. W. Edgeworth David. The fossil plant *Glossopteris*, which formed the predominant type of swamp vegetation in Eastern Australia during the Permo-Carboniferous Period, when the productive coal-measures were being formed, has left records of its former presence almost invariably in the form of leaves only. Only two authentic cases have been recorded of *Glossopteris* leaves having ever been found attached to any kind of stem, previous to the discovery of the specimen found near Mudgee by Mr. J. C. McTaggart, which makes the third specimen ever discovered, and which was described by the authors. The specimen shows that some variety, at all events, of *Glossopteris* in Australia had somewhat the form of a dwarf tree-fern, with a caudex, or stem, at least six inches in length, and surmounted by a clump of closely packed fronds to the number of about eight. The fronds, as proved by the scars on the caudex, were not placed on a verticil, but spirally on the caudex. They are sessile, not petiolate as in the case of the specimen described by Prof. Dana from Illawarra.—Mr. Hedley read the following note:—"From the throat of a *Rallus pectoralis* Mr. J. A. Thorpe of the Australian Museum extracted the snail I now exhibit. This is a specimen of *Chloritis jervisensis*, Quoy and Gaimard, a species common in this neighbourhood, whose almost adult and uninjured shell measures 18 mm. in diameter, and which weighed, shell and animal together, 1·26 grammes. When found by Mr. Thorpe, to whom I am indebted for both facts and specimen, the snail was quite dead; as a test I immersed the animal in strong spirits without inducing contraction: since, however, its consumer had been killed forty hours earlier, the suffocation of the mollusc was to be expected. The bird was shot at Randwick, near Sydney, on May 19, 1894, by Mr. Newcombe, Deputy Registrar-General. In enumerating 'Means of Dispersal,' Darwin observes ('Origin of Species,' 6th ed. p. 372): 'A bird in this interval [eighteen hours] might easily be blown to the distance of 500 miles, and hawks are known to look out for tired birds, and the contents of their torn crops might thus readily get scattered.' In view of the above incident, this suggests a means whereby the geographical range of *jervisensis* might be considerably extended."

MATHEMATICAL GEOLOGY.

Popular Lectures and Addresses by Sir William Thomson (Baron Kelvin), P.R.S., LL.D., D.C.L., &c. In three volumes. Vol. II. "Geology and General Physics." With illustrations. NATURE Series, pp. x. + 599, with index. (London and New York: Macmillan and Co., 1894.)

THIS handy republication of the lighter scientific utterances of Lord Kelvin was begun in 1889, with the volume reviewed in NATURE (vol. xl. p. 433), was continued in 1891, with a volume on "Navigational Affairs," and is now concluded for the present by a volume, nominally the second of the series, which deals mainly with Geological Dynamics, or the application of the physical sciences to the past history of our planet, and likewise includes such later addresses on general physical topics as were not included in the volumes already issued.

The preliminary remarks appropriate before reviewing utterances of leaders in science, were made in connection with the first of the series (vol. xl. p. 433), and need not now be repeated; we will enter straight upon a summary, and perhaps an occasional slight criticism, of the contents.

The first paper is a little article on dew, wherein it is pointed out that the protective action conspicuously exerted on vegetation by invisible aqueous vapour is due not to its "athermancy," as Tyndall imagined, and as text-books teach, but to its infinite heat-capacity. The temperature of bodies which cool only from the surface cannot fall below the point at which dew is being deposited upon them; and naturally the moister the air the higher is this said point.

Then comes a brief note, a kind of text or starting-point for many subsequent addresses, in which the extreme doctrine of geological uniformity is briefly refuted. The refutation consists in the simple arithmetical calculation, that if the observed gradient of temperature in the earth's crust had been uniform for, say, twenty thousand million years back, the amount of heat that must have flowed out from it into space in that time would be enough to heat the whole earth ten thousand centigrade degrees, unless it were made of material very different from surface rock, or unless fresh quantities of heat had been generated by chemical action. In any case, allowing for these possibilities to the uttermost, the past temperature would have been at some such date so excessively high that *ipso facto* no approach to uniformity of other conditions could possibly be maintained or contemplated.

In this simple argument the "mathematics" is but little more severe than that needed in what the author later on (p. 240) calls "a simple effort of geological calculus," whereby it is estimated that 1° per 30 metres is the same as 1000° per 30,000 metres; or (a fairer comparison) that quoted on p. 86, that a deposit at the rate of one inch per century demands ninety-six million years for the deposition of the stratified rocks; yet the simple argument may well be held as more conclusive and convincing than an appeal to Fourier and the laws of distribution of temperature in a cooling sphere. For this reason: an immediate application of Fourier to the gradient of temperature observed in the earth's outer skin is liable to all the uncertainties attaching to very violent extrapolation both in space and time; it has to assume that the sole operative cause is conduction of heat, and always has been conduction of heat, up to a certain past date deduced from the data as the era of reckoning.

Now, it is quite possible to hold that the main mass of the earth consists of metal, chiefly iron, and that the heat, observed in the damp skin or coat of rust on which we live and into which we bore, is being generated *de novo* by the rusting action still going on.

The heat generated by the oxidation of a pound of iron is (I estimate) sufficient to warm an equal mass of rocky material something like three thousand centigrade degrees; so that small confidence can be felt, by those who are impressed with the probability of a meteoric view of the earth's origin, in refined calculations as to successive distributions of temperature in a simply cooling globe started in a molten condition and left to radiate into space undisturbed.

But it is to be observed that the argument of Lord Kelvin contemplates the possibility of fresh generation of heat, but maintains that nevertheless at some by no means infinitely distant date the obvious physical conditions of the earth's surface must have been extremely different from what they are now.

The doctrine of extreme uniformity, which at one time was undoubtedly held by some leading geologists, is now however abandoned, a result due most likely in large measure to the author's calculations and reiterated arguments; and the only reasonable hesitation which can now be felt is as to how far the numerical data available, from observations hitherto made in the earth's outer skin, are sufficient for fixing an upper limit to the age of the earth: especially since these underground thermometer-readings are likely to be disturbed by local and by general chemical action at considerable depths.

The author suggests borings in the African deserts, where moisture is less prevalent than elsewhere, and it may be that observation of underground temperature there conducted will be productive of valuable information; but it is unlikely that these data have already been obtained.

Whatever hesitation may still rationally be felt as to the acceptance of the author's numerical estimate of the earth's age—and he is careful to allow ample margin when he extends the more strictly estimated ten million into a possible hundred million years—yet the reception of his calculations by contemporary palæontological and stratigraphical geologists, as summarised in a controversial address on Geological Dynamics in this volume, will probably be surprising to a more fully informed posterity. Instead of heartily welcoming fresh light on the subject of the earth's past history, from an unexpected quarter, they seem to resent interference from what they are pleased to consider "outside," and their most able advocate, Prof. Huxley, accepts a brief to repel the intruder.

The quotations made by Lord Kelvin from Playfair, from Lyell, from Darwin, and from writers of text-books, are evidences of the natural though exaggerated reaction into scientific uniformitarianism, from the ancient legendary prescientific cataclysmal period, when everything was done in a hurry, and a week was an epoch of serious moment in the earth's history. In the reactionary period, on the contrary, it was customary to airily postulate a few thousand million centuries for any particular achievement; geologists then drew upon "a practically unlimited bank of time, ready to discount any quantity of hypothetical paper." Lord Kelvin by physical reasoning recalled them from this unnecessary vagueness, and put into their hands new data, ascertained by observation of the earth's crust of just as close and valid a character as any inspection of strata or classification of fossil remains, but of a kind more immediately amenable to mathematical calculation; he called for more data from observers, and meanwhile treated in the light of present knowledge the data already available, just as the observing geologists had endeavoured to treat ordinary stratigraphical facts in the light of what they perceived to be at the present time occurring near river-mouths and coast-lines.

And in thus discussing and drawing deductions from terrestrial data, Sir Wm. Thomson was a true geologist. If researches and discoveries concerning the past history of the earth, in respect of age and temperature and physical condition and length of day and exposure to sunshine, are not geology, it is difficult to adduce anything that has a right to that title. Yet Prof. Huxley, in a peroration to an address to the Geological Society of London in 1869, on the subject of Sir Wm. Thomson's address to the Glasgow Society the year before, speaks of "the cry for reform which has been raised from without," says "the case against us has entirely broken down," and concludes with the comfortable assurance: "we have exercised a wise discrimination in declining to meddle with our foundations at the bidding of the first passer-by who fancies our house is not so well built as it might be."

And another more astounding but very characteristic sentence occurs in an earlier part of this forensic speech:—

"I do not suppose that at the present day any geologist would be found to maintain absolute uniformitarianism, to deny that the rapidity of the rotation of the earth *may* be diminishing, that the sun *may* be waxing dim, or that the earth itself *may* be cooling. Most of us, I suspect, are Gallios, 'who care for none of these things,' being of opinion that, true or fictitious, they have made no practical difference to the earth, during the period of which a record is preserved in stratified deposits."

This attitude of "not caring" for the results of scientific investigation in unpopular regions, even if those results be true, is very familiar to some of us who are engaged in a quest which *both* the great leaders in the above-remembered controversy agree to dislike and despise. It is an attitude appropriate to a company of shareholders, it is a common and almost universal sentiment of the noble army of self-styled "practical men," but it is an astonishing attitude for an acknowledged man of science, whose whole vocation is the discovery and reception of new truth.

Certain obscure facts have been knocking at the door of human intelligence for many centuries, and they are knocking now, in the most scientific era the world has yet seen. It may be that they will have to fall back disappointed for yet another few centuries, it may be that they will succeed this time in effecting a precarious and constricted right of entry; the issue appears to depend upon the attitude of scientific men of the present and near future, and no one outside can help them.

I admit that it savours of presumption even to quote in a critical spirit from the utterances of a man of Prof. Huxley's eminence, a man who fought with surpassing eloquence and vigour the battle of free and open inquiry into the facts of the universe before most of us had cut our wisdom teeth; but having been guilty of such an act of presumption, I propose to cap it with another: I shall take permission to say how cordially we recognise the immense service to truth and progress which has been effected by those gladiators who, in despite of fierce hostility, and in face of deadly odds, encountered and overcame the forces of superstition and won for us who follow so great a measure of freedom and friendly countenance as we now enjoy.

It requires an effort of imagination now, or a visit to some stagnant country town, to realise the strength of prejudice which the evolutionary spirit of science had at one time to encounter. It would ill beseem us who are enjoying the peaceful outcome of this struggle to regard with other than the deepest honour those veterans who bore the burden of the fray, even though they sometimes display their fighting front to a left wing of earnest investigators who come heavily marching over the bog and swamps not far removed from those into which the conquered hosts retreated. The morass is difficult and treacherous—it may once more be overwhelming—but if ever secure foothold is gained, and the mud on our clothing has time to dry, the veterans will recognise their own colours and not the colours of their former foes.

Returning to our immediate subject, I pick out from the address on Geological Time the following interesting points. The tides are a case of forced vibration in which the natural period of free swing is *longer* than that corresponding to the forced period; consequently, but for friction, the tidal humps are at right angles to the line of tide-generating force. Were the free period shorter than the forced, the tidal humps would be in the line of force, again excepting friction; and were the two periods the same, the tidal humps, but for friction, would be infinite. The fact that the natural or free period is longer, not shorter, than the lunar or solar day period, as well as the bare fact of appreciable friction itself, are proved by a delay in the occurrence of spring-tide, which again establishes the fact that the lunar tide is more accelerated by friction than is the solar tide; the solar being of slightly shorter period than the lunar, and therefore slightly more discordant with the natural swing.

The effect of friction is to accelerate the tidal phase, and by this acceleration its amount can, or could if the data were good enough, be estimated. It is equivalent to a friction brake applied to the equator, and tightened till it requires a total tangential force equal to the ordinary weight of four million tons to hold it still.

Or, if the earth be supported like a terrestrial globe by a polar axis 100 miles in diameter, that axle must be clamped and subjected to a tangential drag of 320 million tons in order to represent the energy dissipated by tidal friction.

Given this gigantic retarding "couple," it is surprising to remember how slow the consequent lengthening of the day actually is: that the earth, in fact, lags behind a perfect time-keeper only an accumulated few seconds—the estimate in this book is the rather high one of twenty-two seconds—in the course of a century, *i.e.* in the course of 36,500 rotations.

To test or detect this retardation by direct observation is, as is well known, very difficult, because the only other time-keeper available for purposes of comparison is the moon, and she is a very bad and complicated one. Only by efforts of great genius has the astronomical discovery of the diminishing speed of the earth's rotation been made; but if astronomical clocks were as perfect as Lord Kelvin thinks they ought to be, the observation would be comparatively easy. He looks forward to a time when clocks will not be set by the stars, as at present, but when the earth's motion will be rated by a standard clock of extraordinary perfection. At present, or at least in 1868, "astronomical clocks are just as great a disgrace to the mechanical genius of Europe and America as chronometer watches are a credit."

(Incidentally a curious statement is made as to the feasibility of working coal at enormous depths, in spite of the presumably high temperature there—"Suppose there was coal, or rather charcoal, where the strata were red hot, it might be gone into, and that with perfect ease. All that is necessary is plenty of ventilation": the ventilation being conducted on the freezing-machine principle of adiabatic expansion of previously compressed air.)

Other causes affecting the rate of the earth's rotation are likewise considered, such as the deposition of meteoric dust, the redistribution of polar ice and equatorial water, the shrinking of the earth by cooling. If meteoric dust, without initial moment of momentum, were deposited at the rate of one foot in 4000 years it would produce the observed retardation, and likewise the acceleration of the moon's mean motion, without aid from the tides. On the other hand, any redistribution or accumulation and dissipation of polar ice must be a periodic phenomenon, and therefore, though it may exert a distinct effect for some cycles of years, disturbing calculations of eclipses and such like, yet in the long run it must integrate out and be inoperative. As to the accelerative influence of thermal contraction, it is believed by the author to be extremely small, probably not the 1 6000th part of that due to tidal friction.

Concerning the probable antecedent condition of the matter which has fallen together to make the earth, it is interesting to note (p. 121) that "any great degree of *relative* motion of different portions of matter through space renders the chance of their hitting one another very small"; it is probable, therefore, that the heat developed by the falling together of the earth's materials arose simply from their gravitative potential energy, which is fairly calculable, and not from vague stores of unknown initial motions.

On p. 185 a statement is made with respect to Helmholtz' theory of solar heat, to the effect that "this condensation can only follow from cooling." It is rash to question a statement allowed to stand by this author after revision, but perhaps he would look at it again. Surely condensation can, under some conditions, not only generate heat but also elevate temperature?

Towards the end of a Presidential address delivered to the British Association at Edinburgh in 1871, the author, while quoting with "cordial sympathy" a couple of sentences from "The Origin of Species," on the subject of biological evolution, omits an intervening sentence "describing briefly the hypothesis of 'the origin of species by natural selection' because [he] had always felt that this hypothesis does not contain the true [*i.e.* doubtless the complete] theory of evolution . . . in biology. Sir John Herschel, in expressing a favourable judgment on the hypothesis of zoological evolution . . . objected to the doctrine of natural selection, that it was too like the Laputan method of making books [which it may be recollected was something like this: haphazardly composing all the type available, and hoping that of all the random statements thus made the fittest might survive] and that it did not sufficiently take into account a continually guiding and controlling intelligence. This seems to me a most valuable and instructive criticism."

Eliminating the slightly anthropomorphic mode of expression from one sentence of this quotation, it illustrates, what is certainly the truth, that to the interested onlookers from other sciences there already seemed cogent need of a supplement to the fraction of truth contained in Natural Selection, a supplement involving some such treatment of the Origin of Variations as is now attempted in Mr. Bateson's recent work.

In an address to Section A, at Glasgow, 1876, the author goes back to geology and considers the question of a possible shift of the earth's polar axis and of possible temporary alterations in the length of the day, while he entirely repudiates and demolishes the view that the earth's interior can be mainly or even largely liquid. His conclusion from the whole of tidal phenomena is that the earth is now extremely rigid and must be practically solid all through.

He nevertheless contemplates with equanimity Newcomb's bold hypothesis, based on the lunar theory and on apparent irregularities in the moon's motions, that the earth actually went slow and lost seven seconds between 1850 and 1862, and then went fast and gained eight seconds from 1862 to 1872. Lord Kelvin tentatively explains the conceivable possibility of this acceleration by possible changes in the earth's shape, as detectable by changes in sea-level.

"A settlement of 14 centimetres in the equatorial regions, with corresponding rise of 28 centimetres at the poles (which is so slight as to be absolutely undiscoverable in astronomical observatories, and which would involve no change of sea-level absolutely disproved by reduction of tidal observations hitherto made), would suffice. Such settlements must occur from time to time; and a settlement of the amount suggested might result from the diminution of centrifugal force due to 150 or 200 centuries' tidal retardation of the earth's rotational speed."

A paper on Geological Climate continues what we are treating as the geological portion of the volume under review. One of the chief subjects therein discussed is the probable cause of the warm Arctic climate once experienced, so that not only are remains of forest trees found within fifteen degrees of the North Pole, with every evidence of their having grown there, and that not so very long ago, but the return of the Arctic expedition in 1876 brought "evidences of a very warm climate, probably as warm as we have it now in the tropics, within nine degrees of the North Pole"!

For explanation, at any rate of the more moderate pine-forest temperature, we are told to look in the direction indicated by Lyell's twelfth chapter, viz. to a redistribution of land and water.

The Arctic Ocean is a land-locked sea, and the effect of the surrounding coasts is to hem the ice in and prevent free oceanic circulation, while the land itself serves to receive and accumulate snow wherewith to load the neighbouring sea with a thin layer of surface ice.

But now lower the land 2000 feet: the sea would be open, but for a few islands, and the water would be deep enough for plenty of warm currents to flow in, sufficient to clear the ice away and keep it clear. Even now the ice seems to be only 5 feet thick, evidently melting away underneath. It is asserted that the climate of a small island in an iceless circumpolar sea would be probably "temperate and free from frost except in hollows." Considering all the defences, the heat-capacity of moist air, the formation of dew, and so on, it appears that the same defences as protect a large continent in temperate zones from destructive cold during a summer night, would "prevent even so much as hoar-frost on a small island at the very pole during its whole winter six months' night, if it were surrounded by a deep ocean with no land to obstruct free circulation between it and tropical seas."

And in the other direction Lord Kelvin agrees that the simplest cause of the glaciation of India is some 15,000 feet extra elevation. But at the same time "the astronomical cause invoked by Herschel must have had, and must now have, its effect," the well-known fact, namely, of the varying distance of the sun, and the periodic coincidences of its least distance with the northern summer. The sometimes postulated shift of the earth's axis to account for changes in climate does not satisfy Lord Kelvin; he says that there is no evidence, either geological or astronomical, for any considerable shifting of the position of the poles. As to the warmer climate evidenced all over the earth at one time: underground heat is often appealed to, but it is hopelessly inadequate, it can never have sensibly influenced the climate during the period of the stratified rocks. "The earth might be a globe of white hot iron covered with a crust of rock 2000 feet, or there might be an ice-cold temperature within 50 feet of the surface, yet the climate could not on that account be sensibly different from what it is, or the soil be sensibly more or less genial than it is for the roots of trees or smaller plants."

The simple and in every way "almost infinitely probable" hypothesis to account for past high temperature is *a warmer sun*.

Persons who are inclined to imagine a future limit to the duration of life on the earth as in any way dependent on a failure in the supply of heat from below, will do well to note the above strong pronouncement.

The next essay, on "The Internal Condition of the Earth," asserts that on the meteoric theory the earth would once have been just about molten throughout, by reason of the heat of its own formation; but subsequent occurrences must depend on whether solid rock sinks or swims in molten rock. Definite experimental information on this fundamental point appears to be still wanting, but so many facts show that the earth is rigid, that practically the author seems to have little doubt but that it would *sink*. He is careful to point out, however, that the crude notion sometimes met with of a rise of temperature in arithmetic progression at different depths in the crust is certainly false. The law of increase is an asymptotic one, and the temperature at the centre *need* not be higher than two or three thousand degrees. He denies altogether the intensely high temperature often imagined, and thus has no difficulty in accepting the solidity and rigidity otherwise indicated.

Some ingenious arithmetical calculations attempted in Dr. Croll's book on Climate and Time, form the subject of the next paper, on "Polar ice-caps and their influence in changing sea-levels." It is interesting to know that if the ocean were of quicksilver instead of water, it would not spread over the earth as it does, but would accumulate itself entirely at one side. The stability of the ocean depends on the low specific gravity of sea-water as compared with earth. Now, any great piling of material over a large area, such for instance as over the gigantic Antarctic continent, would have the effect of drawing by gravitation some of the ocean toward itself, and thereby lowering the sea-level all over the rest of the earth. And if the material so piled up were itself ice, having been withdrawn by distillation from the ocean itself, the fall of level would be greater still. By the formation of an ice-cap on the Antarctic continent, twelve miles thick, an immense change of sea-level can be produced; the amount of lowering thereby caused in distant parts of the globe being differently estimated as 380 feet, 650 feet, 1140 feet, and 2000 feet.

But Lord Kelvin denies the possibility of a coat of ice twelve miles thick, such as Dr. Croll postulates; the pseudo-viscosity of ice forbids it; but suppose it only a quarter-mile, suppose the thickness varied by 1200 feet from some cause, the area of the Antarctic continent is something like $\frac{1}{40}$th of the whole earth, and so, if such a coat of ice melted off it, the sea-level all over the world would rise twenty-five feet,—sufficient to make many important changes.

The greatest permissible thickness of ice at the South Pole seems to be about 18,000 feet, such a height as that with a gradual slope could stand; and a comparatively small fluctuation in its thickness would have very important geological results. What the actual condition of affairs now is at the South Pole can only be settled by an Antarctic expedition, of which the feasibility and importance are now in some quarters being seriously considered. The thickness of the ice-cap would depend on the annual snowfall and on the rate of viscous sliding down. The internal heat of the earth has nothing to do with the problem—the underground heat could not melt a millimetre of ice thickness per annum. It is singular that an increase in the southern ice-cap tends to increase that of the northern also, by lowering the level of the ocean, and so retarding circulation. Any cause which lessened the Antarctic ice-cap would moderate the rigour of the extreme northern climate, and tend to warm the Arctic Ocean.

So much for the first half of the book under review. The remaining half will be treated in another article.

OLIVER J. LODGE.

ELEMENTARY METEOROLOGY.

Elementary Meteorology. By William Morris Davis, Professor of Physical Geography in Harvard College. (Boston, U.S.A.: Ginn and Co., 1894.)

THE necessity for the production of text-books would seem to diminish with lapse of time, but the examination of publishers' catalogues discloses no diminution in their numbers. If there be any excuse for the writing of new text-books in any branch of science, it might be found in those at present unformed departments, like meteorology, where well-directed and systematic inquiry is constantly enlarging the boundaries of knowledge by the addition of new facts, or the discovery of fresh grounds for the acceptance of facts not yet admitted as demonstrated truths. The science of meteorology is not like that of mathematics, which immediately displays its power, and has nothing to hope or fear from passing time; but appealing as it does to observation and experience, its progress must be gradual and comparative. And if any one be entitled to write text-books, it is those who having been engaged practically in teaching have felt a particular want to be ill-supplied, and who feel themselves qualified by their office and minute acquaintance with the subject to remedy the defect. For these reasons we may welcome the appearance of Prof. Davis' work on "Elementary Meteorology," which originally intended for those engaged in the earlier years of college study, and with whom the author has been brought much into contact, may well be read by others, who wish to keep themselves acquainted with the more recently-acquired facts concerning the behaviour and the processes of atmospheric circulation. In fact, Prof. Davis has had both classes of readers in his mind, as he has prepared this work; and further, recognising how many in his own country are more or less intimately connected with the national and state weather services, he has endeavoured to supply them with a well-digested treatise which may be a supplement to the meagre but precise instructions issued to observers under official authority.

It is not to a text-book of this character that one goes to learn the present position of the more speculative side of meteorology, and since the author excludes from his programme purely mathematical discussion, some of the more recondite inquiries cannot be treated. The qualities that we should look for in a book intended primarily for college students, are exactness of facts and expression, lucidity of description, and orderly consecutive arrangement, carrying the student gradually forward to complete knowledge of the subject, within the limits proposed by the author. And, supposing this to have been the aim of the writer, it seems to have been admirably fulfilled. A text-book embracing the views and the experience of others cannot hope to be original, but it should be thorough, and this on the whole is the opinion we have conceived of the book.

In a few short chapters, we have a description of the atmosphere as a whole, and of the forces that are continually operative, giving rise, by the succession of day and night and summer and winter, to vertical interchanging currents whose behaviour under varying conditions and circumstances embraces the whole province of meteorology. Having thus prepared the way by sufficient reference to the physical processes which influence the temperature of the earth as a whole, it might have been expected that the author would have proceeded naturally to the consideration of local temperatures, and a more minute division of his subject. But, unfortunately, he delays the progress by the introduction of a chapter on the colour of the sky. Doubtless the author can defend himself, but to us, it appears an interruption of the orderly development of the subject, and a defect in the arrangement of the work. It is, however, the only distinct blemish to which we shall have to refer in the plan and conception of the book. We should suspect that the subject of the colour of the sky has had great attraction for Prof. Davis, and that he has over-valued its importance in a book of this nature. But having surmounted that difficulty, there is nothing to stop the consideration of temperature, its measurement, its distribution, and the causes affecting its disturbance, either as a whole by the obliquity of the earth's axis, or locally as by ocean currents, &c. All this is very admirably arranged; and here we may say a word for the sufficiency and clearness of the diagrams. Prof. Davis has apparently had access to a very admirable and complete collection, and his selections are judicious and well illustrative of the points under discussion.

From isotherms the transition to isobars is easy and natural, and though we cannot expect anything original in the description of a barometer, the quality of thoroughness to which we have before alluded is again illustrated. The author does not recommend the correction of the individual readings of the barometer to the sea-level, a practice which is falling more and more into disuse. Unfortunately a definition of sea-level, as understood in America, is not given, at least where we expected to find it. We doubt whether many English readers could supply a correct definition, but the expression may be perfectly clear on the other side of the Atlantic.

Proceeding as far as possible with the discussion of barometric readings, revealing the varying distribution of pressures, the author finds it necessary to introduce the subject of the observation and distribution of the winds. This we consider absolutely in its right place, and assists the gradual progress materially. On the subject of the reduction of wind observations the information is certainly meagre. Wind observations offer one of the most complicated problems in meteorology, one certainly out of the range of the ordinary college student, and this may be a sufficient apology for the author. Here, too, we should have looked for some reference to the recent work of Prof. Langley, indicative of both the difficulty of making exact observations of velocity, and of the important results that may be expected from a complete discussion. But the author is more intent upon describing the general effects of wind circulation as affected by the rotation of the earth, before proceeding to partial and local disturbances. Of course, in this section, the author follows Ferrel, and without employing mathematical illustration, succeeds in fairly well placing before the student an outline of the essential features that mark the work of his distinguished countryman.

This gradual progress of the book seems to throw the question of rain and precipitation far into the work. No inconvenience arises from this, though in many minds, not necessarily scientific, the subject of rain is considered the most important fact in connection with meteorological science. Prof. Davis, however, is not to be hurried. He wishes to approach the subject of cyclones and local storms, and as these are more or less accompanied with rainfall, he finds it necessary, in pursuance of his scheme, to clear away the general features connected with the moisture of the atmosphere, including clouds, dew, frost, and the various forms in which we find water precipitated. In connection with cloud observation, a simple method is mentioned of determining the direction and velocity of cloud movement, which might be worthy of more systematic trial than, it is believed, has yet been accorded to it. The method consists in noting the path of the reflection of a cloud in a horizontal mirror, in which the observer looks through an eye-piece that remains fixed during the observation. If the eye-piece is placed so that the reflection of a certain part of the cloud falls at the centre of the mirror, and after a few seconds a radial arm is turned so as to bring its edge on the position then taken by the cloud, the edge of the arm will lie parallel to the cloud's motion, on the admissible assumption that the cloud is drifting in a horizontal plane. (pp. 181–2.) A slight addition to the apparatus permits the ready appreciation of the relative velocity of the cloud drift, far better than can be estimated by the eye alone.

Having dealt with the general subject of rain and clouds, the author is in a position to treat of cyclonic storms, thunderstorms and tornadoes, and the more violent interruptions of meteorological phenomena. The reason for this section, interesting as it is, being sandwiched in between the description of clouds, &c., and the causes and distribution of rainfall is, however, not so clear. The author probably did not wish to have a greater separation than possible between his chapter on winds and that on cyclones; but we think it would have been better to have finished the subject of rainfall before returning to the motion of the atmosphere. But the writer is clearing the way for the consideration of the "weather," "weather prediction," and climate, with which his book ends. On the subject of weather forecasts, Prof. Davis does not take a very hopeful view. We believe that our authorities at Victoria Street look with a certain degree of satisfaction on the results of their predictions. They are able to point to a percentage of some 90 per cent. of successes, and as far as is known, they, and the public too, consider their existence justified. But listen to Prof. Davis: "The number of stations has grown, and their equipment has been materially improved; the accuracy of various processes preparatory to charting has been increased; a vast body of information has been accumulated for study relative to the kinds and changes of weather; various predicting officers have had extended practice in their art, and while the forecasts are truly made for longer periods than they were at first, and are certainly superior in definiteness and accuracy to those issued twenty years ago, their improvement is not so great as was hoped for. Mistakes in prediction are still made, and of much the same kind as at the beginning of the service." (p. 325.)

In laying aside this book, which we have read with pleasure, and heartily commend to the student, one word of caution may not be unnecessary to the English reader. The book is written for American students, and the use of "our" and "us" is apt to be a little confusing. For instance, "our" damp winter north-easters (p. 145) will scarcely apply to "our" climate, and the statement (p. 269) "that in the six years 1885–1890 there were 2233 buildings set on fire by lightning in this country," is one which must be considered in connection with the area of the country to which it applies. W. E. P.

THE WEALDEN FLORA.

Catalogue of the Mesozoic Plants in the Department of Geology, British Museum. Part I. *Thallophyta—Pteridophyta.* By A. C. Seward, M.A., F.G.S. (London: Printed by order of the Trustees, 1894.)

THIS hand-book serves to show how interesting a monograph of all that is known regarding this mysterious formation would prove. In the folds of the Wealden we imagine the secret of the evolution of angiosperms must be locked. It is as if we stood at the mouth of a great river flowing from an unexplored interior, whose flotsam we anxiously interrogate for clues as to the nature of the unknown hinterland; yet nothing reaches us from beyond the coast-belt, which we have already explored. The Wealden flora is in fact so meagre that it is hard to regard the formation as fluviatile, and one is tempted to believe that it was formed in some brackish lake into which the spoils of the land were rarely drifted.

The first pages afford a comparison of the plants of the English Wealden with those of other countries, but that any of the formations included, especially from beyond Western Europe, are really contemporaneous, must be open to doubt. None of them, however, with trifling exceptions, contain any indications of the presence of angiosperms. Another remarkable fact is the extraordinary geographical range of the English species, only ten out of thirty being peculiar to this country, and these are the most poorly represented. A perhaps unavoidable drawback, to this book and former ones of the series, is that they change established nomenclature so greatly as to render preceding lists of British fossils useless.

A new term, *Algites*, designates the markings which probably represent Algæ. A rather widely distributed *Chara* and a new species under *Marchantites* are important acquisitions; as are the three species of *Equisetum* with tuberous roots, of which one is new. These tubers show that some description of fruit could have been preserved if they had ever been present.

The bulk of the volume is taken up with the Ferns, which are fairly, perhaps over-cautiously, treated. The time-honoured *Sphenopteris Mantelli*, with an enormous range, becomes *Onychiopsis*, representing *Onychium*. A second British form is identified with one hailing from Japan and China; and a new and pretty *Acrostichum*, described as *Acrostichopteris*, completes the list assigned to the vast family of the *Polypodiaceæ*. Tree ferns are more abundant. A remarkable and oft-described species will probably find its final resting-place in *Matonidium*, where it was first placed by Schenk. Another, known from the trunk only, is described under the scarcely satisfactory name *Protopteris*, Presl., preferred by the author to *Caulopteris*. With its marked affinities, it would have been convenient if this, and perhaps two other species, had been given a generic name suggesting relationship with *Dicksonia*.

Sphenopteris is further dismembered by the reference, with a query, of *S. Gœpperti* to the *Schizaceæ*, a family so well represented in the newer Cretaceous and Eocene rocks. It seems again somewhat unfortunate that this species should have received a new generic name (under cover, perhaps, of the query) which in no way reveals its presumably strong affinities with *Anemia*. If nomenclature is to be an aid instead of a stumbling-block, meaningless names should be prohibited. In this particular case Mr. Rufford did not even discover the species, and *Ruffordia* as a generic name will probably disappear when the highly probable close relationship is incontestably established. Moreover, the author's desire to pay Mr. Rufford a well-earned compliment could have been easily gratified among the "genera which afford no trustworthy evidence as to their affinities with existing families," which follow on. Of species falling under this head six are placed in Brongniart's *Cladophlebis*, a provisional genus adopted by some of the best palæobotanists. Two species, one new and the other renamed, represent *Sphenopteris*. The old *Lonchopteris Mantelli* becomes *Weichselia*. It is an abundant but distinctly brittle fern, which may prove to be a *Gleichenia*, a species so abundant in the newer Cretaceous that it could hardly be unrepresented in the Wealden. The remaining forms comprise a number of interesting fragments, the Oleander-like *Tæniopteris*, *Sagenopteris*, two curious net-veined fragments, *Dictyophyllum* and *Microdictyon*, new to the Wealden of England, and which might have come from the Eocene, so closely do they agree. These suffice, at all events, to show that if we could only meet with some fairly representative leaf-beds, such as abound in newer formations, the Wealden would yield a flora, both varied, and of enormous interest. The descriptions conclude with a sufficiently exhaustive discussion of the affinities of that difficult fossil *Endogenites erosa*, which the majority appear agreed to place in *Tempskya*. This, by the by, as an arborescent fern, would have more properly followed the *Cyatheæ*.

The whole result shows that a few species which grew on or near where they are found are abundant in the Wealden, while the rest are rare and fragmentary. A large proportion possessed separate fertile pinnæ, a character maintained in ancient fern-life down to the Tertiaries, and judging from the preponderance of ferns, the Wealden must be still reckoned in the age of Cryptogams. The next part, dealing with Gymnosperms, will be awaited with interest.

OUR BOOK SHELF.

A Monograph of Lichens found in Britain; being a Descriptive Catalogue of the Species in the Herbarium of the British Museum. By the Rev. James M. Crombie, M.A., F.L.S., F.G.S., &c. Part I. (London: Printed by order of the Trustees, 1894.)

MR. CROMBIE'S monograph of the British lichens, of which the volume before us forms the first half, is a valuable addition to that splendid series which, issued by the order of the Trustees, form the "Catalogues" of the vast collections preserved in the British Museum.

Botanists will welcome Mr. Crombie's book, for notwithstanding the works of Leighton and others, the lichens have for the most part been treated with singular neglect. Nor need we seek very far, perhaps, for the reason of this; their isolation, and the tedious difficulties connected with the task of dealing minutely with the group, have all tended to restrain people from a pursuit which is further hedged about with a formidable and unwieldy terminology. Other problems more immediately awaiting, or at least inviting, solution, have attracted the majority of investigators, and this notwithstanding the splendid results yielded by the researches of Schwendener and others into the real nature of these plants. And yet the disregard into which the study of lichens has fallen is really not deserved. It is even possible that a clue to the physiological solution of some of the most interesting questions of morphology may ultimately be found amongst these very plants, which from their composite nature can be constructed or altered at the will of the investigator.

It must, however, be admitted that the taxonomy of lichens is not altogether an inviting study, and Mr. Crombie has rendered a great service in lessening the actual difficulties which necessarily have to be encountered. He begins by providing a glossary (which we think might with advantage have been more extensive), and then, after a synopsis and a conspectus of the groups and genera, occupying a dozen pages in all, he enters at once on the main body of the work.

The diagnoses are extremely good and, in so far as we have tested them, accurate and distinctive. We cannot, however, help wishing that some stand could have been made against the practice of using incorrect, though possibly convenient, "chemical" formulæ (*e.g.* CaCl for chloride of lime) to denote the reagents so often used in determining the different species.

Those who are familiar with the literature will recognise Nylander's influence through the book as a whole, and we do not hesitate to express our satisfaction at this; indeed, in a systematic treatise it is perhaps impossible for some of Nylander's own definitions to be improved on.

Perhaps the only parts of the book which are at all suggestive of weakness, are the illustrations. These are frequently rather diagrammatic, but at the same time we venture to think they are sometimes not as clear as they might have been, and the impressions are unfortunately not seldom lacking in sharpness and definition. Of course the actual preparations of lichens are often neither very clear nor particularly illuminating; but these are precisely the defects which admit of remedy in a diagram or a figure. Apart, however, from this point, the book deserves the very highest praise, and its great merits will assuredly cause it to occupy a distinguished and a permanent position in the literature of lichens.

Travels in a Tree-top. By Charles Conrad Abbott. Pp. 208. (London: Elkin Mathews and John Lane, 1894.)

THE naturalist with poetic fancy, who sees beauty in "all that run, that swim, that fly, that crawl," and publishes his feelings in writings more or less after the style of Richard Jefferies, is very much abroad just now. Sometimes he is more poet than naturalist, but he is always a lover of nature, and though his interpretations are often lacking in scientific accuracy, his observations are generally worth putting on record. Dr. Abbott belongs to this class of nature's disciples. Systematic science has no charms for him. He prefers rather to roam the fields and woods, and watch life in all its varying moods and motions. Ensconced in the branches of a high tree, he has seen sights never vouchsafed to mortals with more limited horizons. He has watched the building of nests, and his observations on the method of working are as valuable as they are interesting. The footprints of various birds, the sinuous traces made by mussels and water-snakes on the ripple-washed sand of a sea-shore, and an infinite variety of similar impressions, have furnished him with objects of study. These are the kind of topics treated in the book, the scene of which, judging from internal evidence, is in Maryland. For the most part, the reading is pleasant gossip, free from rhapsody and tiresome platitude. The title does not, however, clearly express the character of the contents, for it only refers to one of the seventeen papers which make up the volume.

The publishers are famed for their tasteful editions in *belles-lettres*, and they have done their best to give an æsthetic value to Dr. Abbott's musings on sundry phenomena.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Electrification of Air.

As attention is called to this subject by the paper, by Lord Kelvin and Mr. Magnus Maclean, in NATURE for July 19 (p. 280), it may be worth while to point out that two distinct questions, which it is important should not be confused, arise as to the electrification of air. The first question is whether an electric charge can be given to a quantity of dust-free air? In other words, whether a gas can get into a condition in which it can carry a charge of electricity? The evidence derived from the electrification observed in vacuum tubes, &c., seems almost conclusive in favour of an affirmative answer to this question, which is the one considered by Lord Kelvin. The second and quite different question is whether this electrification of the gas is possible unless some of the gas is in a special state, such, for example, as would be produced if some of the molecules were split up into atoms? To adopt a definite theory, for the sake of putting the question clearly: Is the electricity in the charged gas carried by molecules or atoms?

It was the second of these questions, not the first, which I discussed in my "Recent Researches in Electricity and Magnetism," under the heading "Can a *molecule* of a gas be electrified?" The ultimate fate of a charged drop of water, alluded to by Lord Kelvin and Prof. Elihu Thomson, is, as far as I can see, not in any way inconsistent with the view which I advocated, that the *molecule* of a gas can not be electrified. For take the case of a drop of water impure enough to be regarded as an electrolyte, and suppose it negatively electrified. The negative charge will be carried by oxygen ions or atoms; thus, if it were possible to evaporate all the water away, the electricity would be left on these atoms, and there would be no charge on either the *molecules* of water or air. On the other hand, the fact that the water molecules escape from the electrified surface without any electrification, seems in favour of the view that the water molecules can not be electrified. Again, it is worth remembering that a square centimetre of surface, immersed in air at the standard temperature and pressure, is struck by about 10[illegible] molecules per second; yet such a surface will retain for hours, without sensible loss, a charge of electricity, which, as we know from the electrolytic properties of liquids and gases, could be carried by a few thousand millions of particles if these were to receive such a charge as the *atoms* of the gas are able to carry.

J. J. THOMSON.

Cambridge, July 20.

"Testacella Haliotoidea," Drap.

IN NATURE for the 5th inst. Mr. J. Lloyd-Bozward has a note headed "Testacella haliotoidea," of which slug he says that "specimens are not infrequently collected in asparagus-beds, as are also those of the much rarer *T. scutulum*."

It will be allowed that the latter species is often found in such places, those recently recorded from Buckhurst Hill, for instance (*Essex Naturalist*, vol. vii. 1893, p. 46), but exception may be taken to the statement that *Testacella scutulum*, Sow., is much rarer than *Testacella haliotoidea*, Drap.—in fact, it would seem that the opposite is the case.

Until recently every British example of the genus not referable to *Testacella maugei*, Fér., was called *haliotoidea*: however, the late Mr. Charles Ashford in 1885 pointed out to Mr. J. W. Taylor that there were anatomical differences between the form that seventy years before had been called *scutulum* by Sowerby, and the typical *haliotoidea*. The figures in Mr. Taylor's paper (*Journal of Conchology*, 1888, p. 337), which was the outcome of this, were not altogether convincing, and the present writer, in some remarks to the Linnean Society (June 1893), on the method of feeding in Sowerby's species (see *Zoologist*, August 1893) thought it advisable to endorse Mr. Taylor's statements from his own observations. Again, in the following July, Mr. Walter E. Collinge (*Annals and Magazine of Natural History*) gave some very clear figures and descriptions of some anatomical details of the genus, ably supplementing Mr. Ashford's work.

Now that the specific distinctness of *Testacella scutulum* is beginning to be recognised, the records for this species are getting numerous, while those for *haliotoidea* are apparently dwindling, doubt being thrown on existing records, and, as can easily be foreseen, supposed localities having to be struck out in favour of the allied form. Almost all the shells of this genus preserved in the British Collection at South Kensington, on running through them with Mr. Edgar Smith, turned out to belong to *Testacella scutulum*.

Mr. Bozward's record of *Testacella haliotoidea* is interesting, as Tate's list of counties can hardly be reliable now, a catalogue of localities as exhaustive as that given for the other species by Mr. Taylor, in his paper, already referred to, would be most useful. The following are a few records which the writer has been able to lay his hands upon, at short notice, for the *true haliotoidea*.

Horsham.—The first specimen which Mr. Taylor sent to Mr. Ashford, which was really this species, was from here (letter to the writer).

Oxford.—Mr. Taylor mentions having a specimen from Prof. Poulton (in his paper on *T. scutulum*).

Chepstow.—Mr. Taylor mentions this locality (letter to the writer).

Yorkshire and Cornwall.—Mr. Collinge had his specimens chiefly from these counties (letter to the writer).

Ireland.—Dr. Scharff gives Youghal, co. Cork (in "Irish Land and Freshwater Mollusca," *Irish Naturalist*, 1892).

Kew.—The writer collected specimens in the Royal Gardens some years ago.

WILFRED MARK WEBB.

Biological Laboratory, Chelmsford, July 19.

Two Arctic Expeditions in One Day.

THE 7th of July was memorable as the date of sailing of two Arctic expeditions, one from St. John's, Newfoundland, the other from New York. The steamer *Falcon*, having set out from New York in June, and touched at St. John's, made its final departure from that point for Bowdoin Bay, Inglefield Gulf, Greenland, having on board the Peary auxiliary expedition, the intention being to convey Lieut. Peary and his twelve companions back to the United States in September, after their twelve months' sojourn in the Arctic regions. The *Falcon* was saluted in passing by the British man-of-war *Cleopatra*.

The expedition will be gone about ten weeks. Cary Island, Cape York, and Clarence Head will be visited. Various scientific work will be pursued, including the study of glacier systems.

The iron steamer *Miranda*, chartered by Dr. Frederick A. Cook, of Brooklyn, sailed from New York the same afternoon with a party of fifty men of science and pleasure-seekers. Labrador and the west coast of Greenland will be visited. Several of the party will remain in Greenland to prosecute scientific researches. The steamer will then go to Melville Bay, and perhaps visit the quarters of Peary and other explorers, returning about the middle of September.

Among the passengers were ten Eskimo, who had been stationed in the Eskimo camp at the World's Fair in Chicago last year, and are returning home. WM. H. HALE.

Brooklyn.

Rearing of Plaice.

IN NATURE of July 12 (p. 251), there is an interesting note on the rearing of larval plaice at Plymouth, by Mr. J. T. Cunningham, in which it is mentioned that they have been reared to the age of thirty-seven days; but it is not stated how long the incubation went on. It may be interesting to say that at the Fishery Board's Marine Hatchery, at Dunbar, I succeeded in preserving many millions of larval plaice from twenty-four to thirty-three days, counting from the time of fertilisation; and some were reared in jars for longer. On one occasion I kept them in a thriving condition to the forty-seventh day after impregnation of the eggs, at which age they were carried away by an accidental overflow. The eggs were fertilised on April 3, hatched on April 19, and larvæ reared until May 20, when the accident occurred. A description in full will be given in the Fishery Board's report. HARALD DANNEVIG.

Fishery Board's Marine Hatchery, Dunbar, July 17.

Absence of Butterflies.

REFERRING to "Delta's" note, I may say that in the fine weather which we had here in April, the small tortoise-shell butterfly appeared more numerously than ever I had witnessed it at that season, or indeed at any time. I recollect counting a dozen at one time on a small bush of *Andromeda floribunda*, then in flower. Many of them were on wing in the latter days of March, alighting on the willow blossoms. With the fall of temperature in May they disappeared, and only in these recent warm days of July have I again seen them. The first white butterfly of the season was seen here April 21, the glowworm on June 23 (three weeks later than last year), and the horse-fly, *Hippobosca equina*, on June 28. J. SHAW.

Tynron, Dumfriesshire.

THE OXFORD MEETING OF THE BRITISH ASSOCIATION.

WE regret to announce that Mr. W. H. White, C.B., will be unable, through ill-health, to give the evening lecture on "Steam Navigation at High Speeds," announced for Thursday, August 9. The Council of the Association has secured the services of Dr. J. W. Gregory to fill his place, and we believe that the title of Dr. Gregory's lecture will be "Experiences and Prospects of African Exploration."

During the past week further information has come to hand as to the work in some of the Sections. In Section C (Geology) the President, Dr. L. Fletcher, will deal in his address with the progress of mineralogy since Dr. Whewell's report was presented in 1832. Prof. Green will read a paper on the geology of the country round Oxford, with special reference to the places to be visited during the excursions. Prof. Boyd Dawkins will contribute several papers, including one on the probable range of Coal Measures under the newer rocks of Oxfordshire. Amongst others are papers by Mr. H. A. Miers, on a new method of measuring crystals; by Mr. E. P. Culverwell, on an examination of Croll's and Ball's theory of Ice Ages and Glacial Epochs; Mr. W. W. Watts, on barytes in Keuper sandstone; Dr. H. Hicks, on some Lacustrine deposits of the Glacial Period in Middlesex; and Dr. J. Anderson, on some volcanic subsidences in the North of Iceland. There will be a joint meeting of Sections C and H, to discuss the implements of the plateau gravels and their bearing on the antiquity of man.

In Section G (Mechanical Science), the President, Prof. A. B. W. Kennedy, will deal in his address with modern mechanical training, constructive and critical. Sir Frederick Bramwell will read a paper on Thursday, August 9, on Steam Locomotion on Common Roads. On the Friday there is to be a joint discussion with Section A, on Integrators, Harmonic Analysers, and Integraphs, and their applications to physical and engineering problems. This discussion will be opened by Prof. O. Henrici, who is expected to exhibit some valuable models and instruments. On the same day, Lord Kelvin will read a paper on the resistance experienced by solids moving through fluids, which will be followed by a discussion on Flight. Other papers, by Prof. Fuller, Mr. FitzMaurice, and Mr. H. Davey, will follow. On the Saturday, Sir A. Noble, F.R.S., will open with a valuable paper on the measurement of pressures in gun bores; and other papers, by Mr. B. Donkin and Mr. J. Kenwood, will follow. The Monday will be devoted to electrical questions, and among others Mr. W. H. Preece will give two papers on Signalling without Wires, and on the Efficiency of Glow Lamps. On the Tuesday, several papers of mechanical engineering interest will be read by Prof. Unwin, Mr. J. Swinburne, Prof. Capper, and Prof. Hudson Beare.

The programme of Section H (Anthropology) is already a large one, including nearly fifty reports and papers of great interest. Amongst these are papers by Mr. Lionel Decle, on the native tribes of Africa between the Zambesi and Uganda; Dr. A. B. Meyer, on the distribution of the Negritos; M. Émile Cartailhac, on the art and industry of the Troglodytes of Bruniquel (France), and two other communications; Mr. J. Theodore Bent, on the natives of the Hydramoot; Count Goblet d'Alviella, on recent discoveries in prehistoric archæology in Belgium; Prof. Max Lohest, on observations relative to the antiquity of man in Belgium; Mr. Arthur Evans, on the discovery of a new hieroglyphic system and pre-Phœnician script in Crete; and Prof. J. Kollmann, on pygmies in Europe. It must be understood that where dates have been given above, they are only provisional, and that the order in which the papers are to be read is liable to alteration before and during the meeting, due notice of which will be given in the daily journal.

Section I (Physiology) will meet in the fine Physiological Laboratory of the University adjoining the Museum; and, judging from the number and interesting character of the communications which have been already promised, its launch into independent existence should prove most successful. A very large number of the physiologists of Great Britain have announced their intention of being present, and, in addition, the President of the Section, Prof. Schäfer, will have the support of several distinguished foreign physiologists, amongst whom are Prof. Chauveau (of Paris), Prof. Hermann (of Königsberg), Prof. Engelmann (of Utrecht), Prof. Heger (of Brussels), and Prof. Gaule (of Zurich).

The programme of local arrangements is drawn up, but owing to alterations being required, consequent on the withdrawal of Mr. W. H. White's lecture, and other causes, it will not be ready for distribution before the beginning of next week.

The Local Secretaries desire to give notice that all communications should be addressed to them at the British Association Office, the Examination Schools, Oxford, and *not* to the University Museum, as heretofore.

BIG GAME SHOOTING.[1]

WHILE partridges and pheasants, and even hares and rabbits (in spite of the Ground Game Bill) continue to increase and multiply, to the delight of the ordinary sportsman, there can be no doubt that the supply of what is termed "big game" is rapidly and seriously diminishing year by year. In North America the bison or "buffalo" is extinct as a wild animal, and the wapiti is hardly to be met with anywhere within reach. In Europe the steinbock has entirely disappeared, and the chamois is found only in certain districts where it has been carefully preserved. Cashmere, formerly the happy hunting-ground of the Indian officer, is now nearly cleared out, and it is very hard work, we are told, to get one decent "head" of barasingha or ibex in a whole season. As for Africa, the whole of the easily accessible country has been swept clean by the host of "big game" shooters, and it is only by penetrating into such distant places as the swamps of the Luapula, or the torrid deserts of Lake Rudolph, that the larger mammals, which formerly populated its whole surface, can be "got at" in any numbers. Such being the case, it was quite time that an account of what has been for many years one of the great national sports of the British race should be taken in hand. It will help the adventurous spirits of the present generation to share more easily in a pastime that cannot last much longer, and, at the same time, hand down to future ages a record of what were the delights and dangers of slaughtering the extinct mammals of the preceding era.

Of the high qualifications of the editor and those who have assisted him in the present work, there can be no doubt whatever. Mr. Phillipps-Wolley is a recognised authority upon the game of the Caucasus and Western America. The names of Baker, Oswell, Jackson, Pike, and Selous are well known to sportsmen all over the world as those of ardent and intrepid hunters of the past and present generation. In the present work they have all made excellent contributions to the common stock of knowledge on the subject; but, as is usually the case where five or six people join together in writing one book, there is perhaps a little want of a uniform system in the combined product. We may even venture to hint that a little judicious compression and excision might have combined the two volumes into one. On the whole, however, this perhaps would not have been altogether desirable; it might have caused the omission of some of the excellent illustrations which pervade the two volumes, and possibly have interfered with the very plain and legible print now before our eyes.

The first volume of "Big Game Shooting" opens with an essay by Mr. Phillipps-Wolley on the general principles of the subject. No apology, we agree with him, is required for "Big Game Shooting." Man from his earliest origin has been a hunting animal. Even in the most highly civilised races the love of wild sport affects some of the most highly gifted and intelligent of the race, and gives exercise to those masculine virtues which in these days it is so necessary to encourage. The best hunters, moreover, have done much for geography and much for science, although it may be the mere love of hunting that has originally prompted them in their expeditions. In Africa, as Mr. Phillipps-Wolley well puts it, hunting and exploration have certainly gone hand in hand; in America, it was the hunter who first explored and settled the great West; while in India, not the least amongst those latent powers which enable us to govern our Asiatic fellow-subjects, is the "respect won by generations of English hunters from the native shikaris and hillsmen."

Agreeing fully with the author in his vindication of the

Fig. 1. Game animals in British East Africa.

[1] "Big Game Shooting." By Clive Phillipps-Wolley. With contributions by Sir Samuel W. Baker, W. C. Oswell, F. J. Jackson, Warburton Pike, and F. C. Selous. The Badminton Library. Two vols. (London: Longmans, Green, and Co., 1894.)

merits of big game shooting, we will not follow him into the arcana relating thereto, which will be mainly profitable to those who wish to indulge in the pursuit.

The four chapters which follow Mr. Phillipps-Wolley's introduction are devoted to a biography of Oswell, and to a history of his various expeditions in South Africa. These are all of great interest, and will be read by his brother shooters with an affection and reverence correctly due to so renowned a pioneer of their favourite pursuit. But the days of Oswell, alas, are past and gone, and we doubt whether the modern shooter of big game will profit much by the narrative of his hazardous exploits, although they will form excellent chapters for reading round the camp fire—if big game shooters ever have time for such a diversion. Very different is the case with Mr. F. J. Jackson, of Uganda fame, whose eleven chapters occupy the next place. East Africa is now almost the only country in the world where there is still unoccupied space left for the shooters of big game, and where the elephant, the buffalo, the lion, the rhinoceros, the hippopotamus, the giraffe, and a host of antelopes are still to be met with in luxuriant abundance. Mr. Jackson commences with good advice on the proper mode of fitting out an expedition, and on the routes and districts to be traversed with greatest profit.

He then devotes separate chapters to the various animals above mentioned, and gives us altogether what will prove to be a most useful guide-book to the hunter in Eastern Africa. The chapter on antelopes is of very great interest even to the scientific naturalist. The various species are separately enumerated, and discussed under their correct scientific names. Their number, not only as regards individuals, but species, is simply astonishing. Dividing them according to the sportsman's point of view into two categories, Mr. Jackson places eighteen antelopes under the head of those which frequent the open plains, while those which are usually found in the bush make fifteen more, so that not less than thirty-three species of these elegant bovine animals are registered as occurring in East Africa. Had Somaliland been included within East African limits, several more species might have been added. We look upon Mr. Jackson's contribution as the most original and valuable part of the first volume, although Mr. Selous' chapter on the lion and his ways, and Mr. Pike's account of the slaughter of the musk-ox in the barren lands of Arctic America, are likewise of considerable value.

To the second volume of "Big Game Shooting" the contributors are hardly less inferior in fame than those who have written the former portion. Mr. Arnold Pike discourses on Arctic hunting, in which the walrus and the polar bear form the chief subjects of attraction. Mr. Phillipps-Wolley tells us of his adventures in the Caucasus, where the chief mountain game consists of the chamois and two species of ibex, while the slopes on the northern side of the chain are the favourite haunts of the few bison that are left, and of a large stag, termed by Mr. Phillipps-Wolley the red deer. But this stag is more probably the maral (*Cervus maral*) which many years ago was introduced into the Zoological Society's gardens from Circassia, and flourished abundantly for more than ten years.[1] Of the bison, or as it is called in this work, the "Caucasian aurochs," the redoubtable traveller and hunter, Mr St. George Littledale, the only Englishman who has slain this mighty beast in the Caucasus, gives us full particulars. As is now well known, a small district on the northern slope of the Caucasus and one far-distant forest in Lithuania are the only remaining spots on the face of the earth where this splendid animal is still to be met with. Not many centuries ago, no doubt, the European bison pervaded the whole intervening district, and in past ages spread all over Europe, and was abundant even in England. But to call it the "aurochs" is a misnomer, for the true aurochs is the extinct Urus (*Bos primigenius*) which was found in the forests of Germany during the time of Julius Cæsar. Mr. Littledale also gives us a good account of the huge *Ovis argali* of Mongolia, and the corresponding *Ovis polii* of the Pamir, two gigantic sheep, which he was amongst the first of British sportsmen to encounter.

FIG. 2.—Spanish Ibex.

Another well-known hunter, Mr. Baillie-Grohman, writes chapters on the more familiar chamois and stag of the Alps, while Messrs. Chapman and Buck contribute an excellent account of the large game of Spain and Portugal, a subject on which they are well qualified to speak from long personal experience. The picture of the Spanish ibex, taken from Mr. Chapman's sketches, with the lammergeiers floating in the distance, gives us a good idea of the attractions still to be met with in "Wild Spain," which he and Mr. Buck have done so much to

[1] See Mr. Sclater's article on "The Deer, now or lately living in the Society's Menagerie." (*Trans. Zool. Soc.* vii. p. 336.

make known to us. Indian shooting is well treated by Colonel Percy, who goes very fully into the subject. It is, indeed, an ample one, and Colonel Percy enumerates no less than fifty-three animals to be included in the category of big game by the fortunate sportsmen of India. The second volume concludes with good advice about camps, transport, rifles, and ammunition, and with a few hints on taxidermy, showing the way in which the larger animals should be skinned and their heads set up as sportsmen's trophies.

In concluding our notice of this attractive work, we may be permitted again to call notice to the illustrations, which, with few exceptions, are of a high degree of excellence. Two of these, by the kind permission of the publishers, we reproduce on the present occasion. The first of them represents a scene in British East Africa, between Teita and Taveta, in the Kilima-njaro district, where (in September 1886) the country was "literally crawling" with zebra, hartebeest, impala, oryx, and Grant's antelope, besides eland and giraffe, and an occasional steinbok and wart-hog." In those days Taveta was correctly designated the "Hunters' Paradise." The second illustration shows us the haunt of the Spanish ibex, of which we have already spoken.

Before concluding our notice of what will no doubt quickly and deservedly become the big-game-shooters' favourite handbook, we venture to call attention to what is probably a slight slip on the part of Mr. Phillipps-Wolley. General Richard Dashwood, than whom there can be no better authority on the subject, has commented, in an article in *Land and Water* (March 24, 1894), rather severely on some of Mr. Phillipps-Wolley's statements regarding the caribou and moose of North America. It is no doubt incorrect to say that caribou and moose feed upon the same food. As explained by General Dashwood, their tastes are very different. It is also an error to describe the "call-cry" of the female moose as a roar. General Dashwood's experienced ear teaches him to describe it as a "beautiful clear note, rising and falling with a sort of entreaty in the tone and a soft grunt at the end."

POPULARISING SCIENCE.

"POPULAR science," it is to be feared, is a phrase that conveys a certain flavour of contempt to many a scientific worker. It may be that this contempt is not altogether undeserved, and that a considerable proportion of the science of our magazines, school text-books, and books for the general reader, is the mere obvious tinctured by inaccurate compilation. But this in itself scarcely justifies a sweeping condemnation, though the editorial incapacity thus evinced must be a source of grave regret to all specialists with literary leanings and with the welfare of science at heart. The fact remains that in an age when the endowment of research is rapidly passing out of the hands of private or quasi-private organisations into those of the State, the maintenance of an intelligent exterior interest in current investigation becomes of almost vital importance to continual progress. Let that adjective "intelligent" be insisted upon. Time was when inquiry could go on unaffected even by the scornful misrepresentations of such a powerful enemy as Swift, because it was mainly the occupation of men of considerable means. But now that our growing edifice of knowledge spreads more and more over a substructure of grants and votes, and the appliances needed for instruction and further research increase steadily in cost, even the affectation of a contempt for popular opinion becomes unwise. There is not only the danger of supplies being cut off, but of their being misapplied by a public whose scientific education is neglected, of their being deflected from investigations of certain, to those of doubtful value. For instance, the public endowment of the Zetetic Society, the discovery of Dr. Platt's polar and central suns, or the rotation of Dr. Owen's Bacon-cryptogram wheel, at the expense of saner inquiries might conceivably and very appropriately result from the specialisation of science to the supercilious pitch.

It should also go far to reconcile even the youngest and most promising of specialists to the serious consideration of popular science, to reflect that the acknowledged leaders of the great generation that is now passing away, Darwin notably, addressed themselves in many cases to the general reader, rather than to their colleagues. But instead of the current of popular and yet philosophical books increasing, its volume appears if anything to dwindle, and many works ostensibly addressed to the public by distinguished investigators, succeed in no notable degree, or fail to meet with appreciation altogether. There is still a considerable demand for popular works, but it is met in many cases by a new class of publication from which philosophical quality is largely eliminated. At the risk of appearing impertinent, I may perhaps, as a mere general reader, say a little concerning the defects of very much of what is proffered to the public as scientific literature. As a reviewer for one or two publications, I have necessarily given some special attention to the matter.

As a general principle, one may say that a book should be written in the language of its readers, but a very considerable number of scientific writers fail to realise this. A few write boldly in the dialect of their science, and there is certainly a considerable pleasure in a skilful and compact handling of technicalities; but such writers do not appreciate the fact that this is an acquired taste, and that the public has not acquired it. Worse sometimes results from the persistent avoidance of technicality. Except in the cases of the meteorologist, archæologist, and astronomer, who are relatively free from a special terminology, a scientific man finds himself at a great disadvantage in writing literary English when compared with a man who is not a specialist. To express his thought precisely he gravitates towards the all too convenient technicality, and forbidden that, too often rests contented with vague, ambiguous, or misleading phrases. It does not follow that, because, what from a literary standpoint must be called "slang," is not to be used, that the writer is justified in "writing down" as if to his intellectual inferiors. The evil often goes further than a lack of precision. Out of a quite unwarrantable feeling of pity and condescension for the weak minds that have to wrestle with the elements of his thought, the scientific writer will go out of his way to jest jests of a carefully selected and most obvious description, forgetting that whatever status his special knowledge may give him in his subject, the subtlety of his humour is probably not greatly superior, and may even be inferior to that of the average man, and that what he assumes as inferiority in his hearers or readers is simply the absence of what is, after all, his own intellectual parochialism. The villager thought the tourist a fool because he did not know "Owd Smith." Occasionally scientific people are guilty of much the same fallacy.

In this matter of writing or lecturing "down," one may even go so far as to object altogether to the facetious adornment of popular scientific statements. Writing as one of the reading public, I may testify that to the common man who opens a book or attends a lecture, this clowning is either very irritating or very depressing. We respect science and scientific men hugely, and we had far rather they took themselves seriously. The taste for formal jesting is sufficiently provided for in periodicals of a special class. Yet on three occasions recently very considerable distress has been occasioned the writer by such mistaken efforts after puerility of style. One was in a popular work on geology, where the beautiful problems of the past of our island and the evolution of life were defaced by the disorderly offspring of a quite megatherial wit—if one may coin such an antithesis to "etherial." One jest I am afraid I shall never forget. It was a Laocoon struggle with the thought that the huge subsidiary brains in the lumbar region of *Stegosaurus* suggested the animation of Dr. Busby's arm by the suspicion of a similarly situated brain in the common boy. The second disappointment was a popular lecture professing to deal with the Lick Observatory, and I was naturally anxious to learn a little of the unique appliances and special discoveries of this place. But we scarcely got to the Observatory at all. We were shown—I presume as being more adapted to our intelligence—numerous lantern-slides of the road to the Lick Observatory, most of them with the "great white dome" in the distance, other views (for comparison probably) with the "great white dome" hidden, portraits of the "gentlemen of the party on horseback," walks round the Observatory, the head of an interesting old man who lived in a cottage near, the dome by moonlight, the dome in winter, and at last the telescope was "too technical" for explanation, and we were told in a superior tone of foolish things our fellow common people had said about it. For my own part, I really saw nothing very foolish in a lady expecting to see houses on the moon. My third experience was ostensibly a lecture on astronomy, but it was really an entertainment—and a very fair one—after the lines of Mr. Grossmith's. "Corney Grain in Infinite Space" might have served as a title. It was very amusing, it was full of humour, but as for science, the facts were mere magazine *clichés* that we have grown sick of long ago. And as a pretty example of its scientific value I find a newspaper reporter, whose account is chiefly "(laughter)" with jokes in between, carried away the impression that Herschel discovered Saturn in the reign of George the Third.

Now this kind of thing is not popularising science at all. It is merely making fun of it. It dishonours the goddess we serve. It is a far more difficult thing than is usually imagined, but it is an imperative one, that scientific exponents who wish to be taken seriously should not only be precise and explicit, but also absolutely serious in their style. If it were not a point of discretion it would still be a point of honour.

In another direction those to whom the exposition of science falls might reasonably consider their going more carefully, and that is in the way of construction. Very few books and scientific papers appear to be constructed at all. The author simply wanders about his subject. He selects, let us say, "Badgers and Bats" as the title. It is alliterative, and an unhappy public is supposed to be singularly amenable to alliteration. He writes first of all about Badger A. "We now come," he says, "to Badger B"; then "another interesting species is Badger C"; paragraphs on Badger D follow, and so the pavement is completed. "Let us now turn to the Bats," he says. It would not matter a bit if you cut any section of his book or paper out, or shuffled the sections, or destroyed most or all of them. This is not simply bad art; it is the trick of boredom. A scientific paper for popular reading may and should have an orderly progression and development. Intelligent common people come to scientific books neither for humour, subtlety of style, nor for vulgar wonders of the "millions and millions and millions" type, but for problems to exercise their minds upon. The taste for good inductive reading is very widely diffused; there is a keen pleasure in seeing a previously unexpected generalisation skilfully developed. The interest should begin at its opening words, and should rise steadily to its conclusion. The fundamental principles of construction that underlie such stories as Poe's "Murders in the Rue Morgue," or Conan Doyle's "Sherlock Holmes" series, are precisely those that should guide a scientific writer. These stories show that the public delights in the ingenious unravelling of evidence, and Conan Doyle need never stoop to jesting. First the problem, then the gradual piecing together of the solution. They cannot get enough of such matter.

The nature of the problems, too, is worthy of a little attention. Very few scientific specialists differentiate clearly between philosophical and technical interest. To those engaged in research the means become at last almost as important, and even more important than the end, but apart from industrial applications, the final end of all science is to formulate the relationship of phenomena to the thinking man. The systematic reference of *Calceola*, for instance, *Theca*, the Lichens, the Polyzoa, or the Termites, is an extremely fascinating question to the student who has just passed the elementary stage, and so too is the discussion of the manufacture and powers of telescopes and microscopes; morphological questions again become at last as delightful as good chess, and so do mathematical problems. But it must be remembered that morphology, mathematics, and classification are from the wider point of view mere intellectual appliances, and that to the general reader they are only interesting in connection with their end. To the specialist even they would not be interesting if he had not first had their end in view. The fundamental interest of all biological science is the balance and interplay of life, yet for one paper of this type that comes to hand there are a dozen amplified catalogues of the "Cats and Crocodiles" description. I find again, presented as a popular article, a long list of double stars with their chief measurements. Now, to a common man one double star is as good as a feast. Again, the botanist, asked to write about leaves, will get himself voluminously entangled in the discussion whether an anther is a lamina, or in an exhaustive and even exuberant classification of simple and compound, pinnate and palmate, and the like, making great points of the orange leaf and the barberry. But the kind of thing we want to have pointed out to us is *why* leaves are of such different shapes and so variously arranged. It is a thing all people who are not botanists puzzle over, and a very pretty illustrated paper might be written, and remains still to be written, linking rainfall and other meteorological phenomena, the influence of soil upon root distribution and animal enemies, with this infinite variety of beautiful forms.

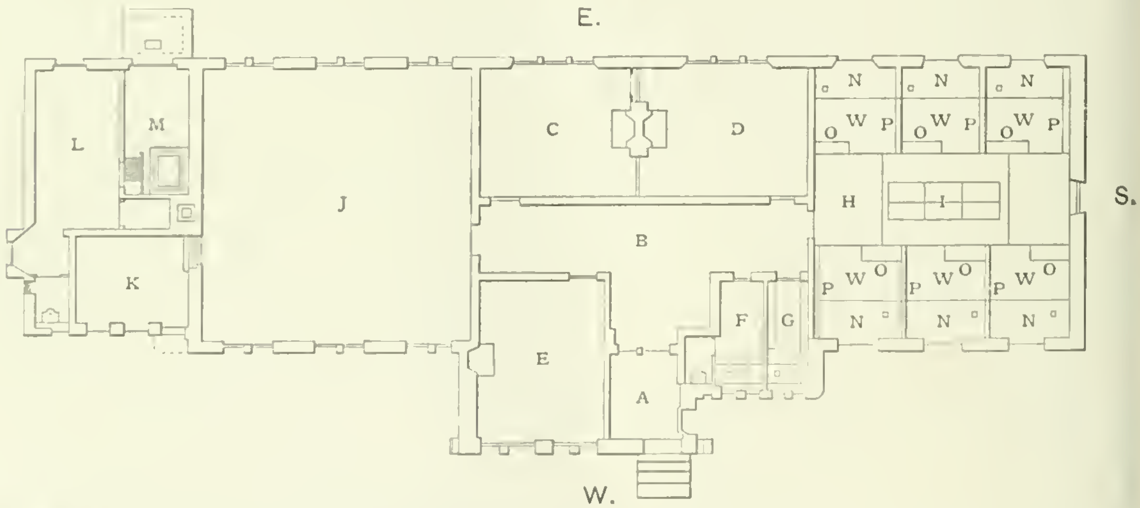
Enough has been said to show along what lines the genuine populariser of science goes. There are models still in plenty; but if there are models there are awful examples—if anything they seem to be increasing—who appear bent upon killing the interest that the generation of writers who are now passing the zenith of their fame created, wounding it with clumsy jests, paining it with patronage, and suffocating it under their voluminous and amorphous emissions. There is, I believe, no critical literature dealing generally with the literary merits of popular scientific books, and there are no canons for such criticism. It is, I am convinced, a matter that is worthy of more attention from scientific men, if only on the grounds mentioned in my opening paragraphs.

H. G. Wells.

ON THE NEW BUILDINGS FOR THE ST. ANDREWS (GATTY) MARINE LABORATORY.

That St. Andrews had not one of the oldest marine laboratories was the result of an accident. Nevertheless it has the oldest marine laboratory in Britain, since it was opened early in 1884, though since 1882 the practical laboratory in the College had been used for this purpose; and it could not well be otherwise, since it was within a stone's cast of the bay—so rich in a varied fauna and flora. For ten years the work of the laboratory has been carried on under considerable difficulties in a wooden building originally erected as a temporary fever-hospital, and the walls and roof of which were neither wind- nor water-tight. This structure was situated on a spit of sand near the harbour, and most conveniently placed for easy access to the fishing-boats and the beach; but it was on a public common, and though for nearly two years every effort has been made to get the new laboratory erected on the same site, it was found to be impracticable, and a new site was therefore chosen on University ground, about 300 yards further south, and close to the beach. This site affords ample space, and, besides, a small fresh-water stream flows through it.

The new laboratory is the munificent gift of Dr. Charles Henry Gatty, of Felbridge Place, East Grinstead, who has placed £2500 at the disposal of the University of St. Andrews for its erection. The building will face the west, with the back towards the east and the sea, and will be for the most part of one storey. From its eastern or sea face the windows command an extensive view of the picturesque bay, with the Forfarshire coast terminating in the steep rocks of the "Red Head" on the left, and on the right the well-known cliffs from which the "Rock and Spindle" and "Maiden Rock" stand out boldly, while here and there a more gentle slope gives a patch of bright green sward. The western face or front has a view embracing the fine old ruins of the cathedral, the southern suburbs of the city, and a wide stretch of Fife, including such eminences as Drumcarro Craig and Clatto Hill. It has a frontage of 125 feet, and the building is in the Scottish style of architecture—unpretending externally, but comfortable and convenient internally.



A, Vestibule; B, Hall; C, Director's Room; D, Library; E, Room for Specimens; F, Cloak Room and Lavatory, G, Chemical Room; H, Research Room, I, Tanks of Room; W, Workers' Compartments; O, Workers' Cabinets; P, Workers' Bookshelves; J, Tank Room; K, Receiving Room; L, Engine and Pumps; M, Heating Chamber.

The entrance is in the projecting block on the west, leading into a vestibule (A), and a spacious hall (B), with lobbies leading right and left. In this block are situated three official rooms, viz. the Director's room (C), the library (D), and the room for specimens (E), the two former looking into the bay, the latter to the west. Besides these are a cloak-room with lavatory (F) and a chemical room (G). The lobby on the right leads to the research room (H), which is 30½ ft. × 30 ft., and contains compartments (W) 10 ft. square, with partial partitions about 8 ft. in height, for six workers. Each of these has at the window a large and convenient table (N) with sink, mirror, and other fittings, on the right wall a series of shelves (P) for books and other things, while behind is a cabinet of drawers (O) for storage of delicate apparatus and specimens. From the position of the building three of these windows look to the sea, and three to the west; while a seventh admits light from the southern end of the building. In the centre of the room is a series of tanks of sea-water, six in number (one for each worker), besides various shelves for smaller glass aquaria, and the necessary pipes and nozzles for distributing sea-water as required. A fireproof compartment for long-continued use (all night) of the hot bath occurs at one end, while each worker has a separate small paraffin apparatus in his compartment.

The lobby on the left leads to the tank-room (J) or aquarium, 30 ft. 6 in. × 30 ft., and with three windows on each side (east and west) for illuminating the tanks—of slate and glass—ranged round the room, as well as placed in the centre. While that part of the building already described has wooden floors, the aquarium is paved with concrete. A door at the northern end leads by a few steps to the receiving-room (K), with its long table and sink, where the specimens procured by the boats are arranged by the attendant before being introduced into the tank-room or distributed to the workers. The outer door to this room is on the western face of the building (front), and above it is a large storage-tank for sea-water. In this block are the apartments for the engine and pumps (L), a store and the heating-chamber with accessories (M), all these being entirely separated from the tank-room by a thick wall of stone.

The main apartments are heated by hot-water pipes, with the exception of the three in the centre (viz. Directors' room, library, and museum), which have fire-places for gas.

The laboratory is capable of easy extension should that ever be necessary, and it is readily reached from the class-rooms of the University. Moreover, being in direct connection with the latter, the workers have the advantage of free access to the University library and museum, besides that communication with those of similar tastes, which is so congenial as well as profitable to the naturalist, and which cannot be compensated by mere richness of fauna and flora, if these are in an isolated locality or difficult of access.

Further, in addition to its connection with the University, the laboratory from the first has been under the control of the Fishery Board for Scotland, who administered the Parliamentary grant given in 1884 for its equipment, and who maintain the attendant and defray certain other expenses.

Ample space exists for the formation of large external ponds and tanks, and certain portions of the tidal rocks in the neighbourhood are fitted for enclosure, so that young fishes and crustaceans may be reared from the post-larval stages onward, under conditions as closely approaching nature as possible. In the same way the culture of useful mollusks can be experimented with.

The beach at St. Andrews is remarkably adapted for marine researches, since it combines extensive reaches of sand with their special forms, and on which a vast variety of materials in a fresh state are stranded by storms, with great stretches of tidal rocks and rock-pools so rich in littoral animals and plants. The valuable mussel-bed in the estuary of the Eden, the proximity of the Forth and the Tay, the constant stream of specimens brought by the fishing-boats, and the plenitude of life in the bay itself—all combine to render it classic ground to the naturalist. For example, amongst the rarer forms at St. Andrews are *Corymorpha*, *Cerianthus*, *Pennatula*, *Asterias Mülleri*, *Echiurus*, *Magelona*, *Tornaria Mitraria*, swarms of Appendicularians (*Oikopleura*), *Pelonaia*, *Actinotrocha*, the Pteropods *Clione* and *Spirialis*, the Nudibranch *Idalia*, and the Tectibranch *Aplysia*.

The greatly improved facilities for research which the munificence of Dr. Gatty has granted to St. Andrews cannot but increase the results in regard to marine biological science and the fisheries, and render the old University city even better known in this connection in the future than in the past. Yet there are those still living who remember the glee of Edward Forbes as he picked up the living spoon-worms (*Echiuri*) on the west sands, and who listened to a short course of lectures he gave in the University on star-fishes, before the publication of his work on this group, and who were familar with the figure of John Reid as he descended the steps at the Baths to hunt for *Hydra tuba*, and watch the scyphistoma-stage of *Aurelia*, which he independently worked out there. It is unnecessary on the present occasion to allude to the names of more recent workers, but they are many, and include continental and American, as well as those of our own country.

W. C. M.

NOTES.

All who take an interest in science will be glad to hear that the health of Prof. von Helmholtz has been improving of late, and that he has regained partial use of his paralysed side.

The resignation of Prof. Dana, from the position he has so long occupied at Yale University, is announced. Dr. Dana was appointed, in 1850, Silliman Professor of Natural History and Geology at Yale, and now at the age of eighty-one years he is compelled to abandon further active work by reason of feeble health. We hope that many years of well-earned rest remain to him.

Prof. H. S. Williams, formerly of Cornell University, has been appointed Prof. Dana's successor at Yale University.

The sixty-second annual meeting of the British Medical Association will take place at Bristol, from July 31 to August 3, under the presidency of Dr. E. Long Fox. The report which the council has to present is, we understand, a very favourable one, and shows that the membership of the Association has increased from 14,703 to 15,090, and the total investments to £41,789. Dr. Long Fox is to deliver his address on Tuesday, July 31, and during the meeting the following addresses will be delivered:—On Medicine, by Prof. Sir T. Grainger Stewart; on Surgery, by Prof. Greig Smith; and on Public Medicine, by Sir Charles Cameron.

The Société Industrielle de Mulhouse has issued a programme of the prizes to be awarded next year. The prizes are open to all, whether natives of France or not, and works competing for them must reach the President of the Society before February 15, 1895. Most of the awards consist of medals only, but some carry with them prizes varying from one hundred to five thousand francs. A complete programme can be obtained by applying to the Secretary of the Society, Mulhouse.

The twenty-third meeting of the French Association for the Advancement of Science will be opened at Caen on August 9, under the presidency of Prof. Mascart. The work of the Association will be divided into four groups, each containing from three to five sections. The first group (Sciences Mathématiques) will be devoted to mathematics, astronomy, and geodesy, mechanics, navigation, civil and military engineering. To Group II. (Sciences Physiques et Chimiques) belong physics, chemistry, meteorology, and terrestrial physics. In the third group (Sciences Naturelles et Médicales) will be found geology and mineralogy, botany, zoology, anatomy, physiology, anthropology, and medical sciences. The fourth group (Sciences Économiques) is concerned with agriculture, geography, political economy and statistics, pedagogy, hygiene, and public health.

The next annual meeting of the Italian Botanical Society will take place at Palermo, in 1895. For the present year a botanical excursion is arranged, on September 25 and the three following days, to the Island of Giglio, the largest of the Tuscan Archipelago, except Elba, the flora of which has been but imperfectly explored. Botanists desirous of taking part in the expedition should communicate, not later than September 15, with the President, Prof. Arcangeli, 19 Via Romana, Florence.

Information has come to hand respecting an International Exhibition of Arts, Industries, &c., which is to be held at Bordeaux in 1895. The exhibition, which is the thirteenth held at Bordeaux, will be opened on May 1, and will be divided into some ten Sections, as follows:—Section I. Education. II. Arts (Liberal, Industrial, and Decorative; Medicine, Hygiene, &c.). III. Social Sciences. IV. Agriculture, Horticulture. V. Wines and Spirits. VI. Industries (Mineralogical, Mechanical, Chemical, &c.). VII. Habitation (Furniture, Dress, &c.). VIII. Transport, Civil Engineering, and Military Art. IX. Electricity. X. Commerce and Colonies. England, Belgium, Italy, Portugal, Spain, and Switzerland are invited to contribute.

The seventeenth annual meeting of the Midland Union of Natural History and Scientific Societies will take place on August 3 and 4, at Ellesmere, under the auspices of the Ellesmere Natural History Society and Field Club. A strong programme has been arranged, and after the business meetings of August 3 a conversazione will be held at St. Oswald's College. The following day will be taken up by three excursions: one to Chirk, Llangollen, and Valle Crucis for the archæologists, led by Mr. A. T. Jebb; a second, round the Meres and Peat Mosses of the neighbourhood for the biologists, under the leadership of Messrs. Peake, Jennings, and Thompson. The third, for the geologists, will be under the guidance of Dr. Callaway, who will conduct his party to Hawkstone and Grinshill. We understand that the Ellesmere Society hope that many of the visitors will be able to stay in the neighbourhood over the Bank-holiday, when further excursions may be arranged, and they are perfecting the arrangements in a most generous and hospitable spirit.

We hear, with much regret, of the death, at the age of seventy-nine years, of Dr. Daniel Cornelius Danielssen, who has been since 1864 president of the Directors of the Bergen Museum, and of Prof. Michele Lessona, President of the Royal Academy of Science at Turin.

THE death is announced of Mr. Alfred Williams, who for many years has been closely identified with the branch of his profession relating to gas engineering. Mr. Williams was one of the founders of the Society of Engineers, and has acted as its honorary secretary and treasurer since its inauguration in 1854.

THE Accademia dei Lincei at Rome held its annual meeting on June 3, the President, Senator Brioschi, being in the chair. The King of Italy always attends these meetings, and this year the Queen accompanied him. The magnificent Palazzo Corsini, which compares with the rooms of the Royal Society very much as the consideration shown to men of science in Italy does with the neglect of science by the powers that be in England, was *en fête*, and the sitting, already recorded at length in the *Atti*, was a most interesting one. The President referred to the work done by the Society, and the constant sympathy of the King with its affairs; and Prof. Ferraris, of the Turin Industrial Museum, gave a discourse on the electric transmission of energy.

WE have often in these columns had to complain of the backwardness of the Government of this country to recognise the value of men of science and the work in which they are engaged, and a fresh instance of this slowness of vision is furnished in a recent number of the *Electrical Review*. It seems that of the deputations sent last year to the International Congress at Chicago, the delegates who represented France and Germany had the whole of their expenses paid, and were rewarded according to their several merits with decorations, honours, and with courteous thanks. The representatives of Great Britain alone have been ignored entirely: and, so far from their services receiving remuneration or thanks, it is doubtful whether her Majesty's Government even know the names of those who looked after British interests and maintained the credit of Britain on this most important occasion. Yet they were all men of the highest eminence, who sacrificed much time and trouble to this thankless business. According to our contemporary, among them was one whose labours have been rewarded abroad with every kind of honour and acclaim, whose work has wrought incalculable benefit, whose inventions are in constant universal use, who gave his greatest discovery freely to the world and who has never in his own country received the smallest official recognition or distinction. Truly, a prophet is not without honour save in his own country and among his own people.

SOME sensational paragraphs have appeared in evening papers as to all hope of the Wellman arctic expedition being abandoned; but this is not the case. There is serious cause for anxiety, but the probability that Mr. Wellman had left the *Ragnvald Jarl* before she was lost, is at least as great as that he was on board at the time. During the next month there will be frequent communication with Spitzbergen, and the position of Mr. Oyen on Danes Island will not be one of utter desolation. Colonel Feilden writes to the *Times* from Lerwick on July 21, correcting some of the extravagant rumours which had been published. He states that none of Mr. Wellman's party had any previous experience of Arctic work, and that the conduct of the expedition, so far as known, showed ignorance of the risks they would have to run.

THE American Museum of Natural History have commissioned Prof. Rudolph Weber to organise an expedition to Sumatra, for the purpose of scientific exploration and the collection of specimens. Mr. Weber will leave New York on the 28th inst., and will study for a short time in Germany, thence proceeding to Sumatra, where he will collect and equip a force of natives for the expedition.

WITH reference to the note in our last number, respecting the Rev. S. A. Thompson Yates's gift to the University College, Liverpool, a correspondent writes:—"The Thompson Yates Laboratories are to be exclusively devoted to physiology and pathology; and since of no two subjects can it be said with more truth that "aliud ex alio clarescet," it is to be hoped that both will largely benefit by the fact of their being housed in the same building. Many of the requirements are identical, so that the proposed new laboratories, whilst providing the separate accommodation for such teaching and research as the study of the subjects requires, will be as far as practicable dovetailed, so as to avoid the reduplication of costly special rooms. It is hoped that such combined laboratories may prove of value by bringing into intimate association pathological and physiological scientific workers, and it is certain that a building complete in itself, which provides for both departments, must lend itself most advantageously to economical maintenance. The building will be situated in the ample grounds of the College, and will form a block to which, at some subsequent date, the Medical faculty hopes to add further new buildings for other departments of its Medical School."

BY permission of the postal authorities, the wires between St. Margaret's and the General Post Office, London, were, on Sunday afternoon and evening last, used for the purpose of some experiments with the teleautograph, the invention of Prof. Gray, of New York; the time for the experiments being selected owing to the wires being comparatively idle on Sundays. The experiments took place between the General Post Office, London, and Cable Hut, St. Margaret's Bay, through which the London and Paris telephone passes. Special instruments were fixed up at both ends, and as this was the first time that long distance experiments in teleautography have taken place in this country, they were watched with unusual interest. The results were excellent, the messages transmitted being in every respect most successful, and the instruments working without the slightest hitch over a distance of 83 miles. Messages were both sent from and received at St. Margaret's Bay. The principle of the instrument is that it automatically records an exact *facsimile* of the writing contained in messages. In the experiments on Sunday the receiving pencil recorded with ease and clearness different handwritings, giving thick and thin strokes, dotting i's, and crossing t's very correctly.

THE current number of the *British Medical Journal*, in a leader on "Cholera Prospects," laments the fact that "there are half-a-hundred places in England where, if cholera were to be introduced to-morrow, it would, unless at once detected, spread, and not only so, but spread to the danger of communities around, and which, by reason of gathering grounds of their water supply, or the like, are at the mercy of some rural body whose sole aim as a body seems to be to cut down the rates at the expense of the public health." The outlook, as far as this country is concerned, is not of the brightest, and health bodies would certainly do well to take to heart the advice of our contemporary, and bestir themselves betimes to the proper fulfilment of the duties devolving upon them.

CONFIRMATION of the wisdom of the old adage, "There is nothing new under the sun," is to be found in the *Lancet* for July 21, which details from the "Newes" of 1665 a series of precautions employed in combating the plague of London in that year. "These include the appointment of parochial examiners to investigate cases of sickness and to take measures for their isolation if needful and the employment of watchmen to ensure this result and of chirurgeons to certify the presence of plague. Notification of this disease was the duty of householders; every infected house was marked in the manner with which we are all familiar and underwent a quarantine of longer or shorter duration, and disinfection was carried out by airing with fire and by medicated fumigation. Nurses on the termination of a case were subject to twenty-eight days' seclusion, and visitors were forbidden the house of sickness." We of to-day could do worse than act upon much of the advice here given.

IN the report of the Puffin Island Biological Station, just received, we find a history of the station since its vacation by the Liverpool Biological Society for their new home at Port Erin. The laboratory was taken over in 1892 by a number of members of the staff of University College, Bangor, and other residents in the neighbourhood; and a committee of management was formed, with Mr. P. J. White, who also edits the report, as director of the station. The contributors to the present report of thirty-two pages deal briefly with special points of interest in the terrestrial fauna and flora and the archæology of the island, and the director offers some suggestions in regard to the improvement of the sea-fisheries (shell-fish) of the district.

THE *Compte Rendu* of the fifth session of the International Geological Congress, held at Washington in 1891, has just appeared. The general arrangement of the book closely follows that of the report of the London Congress (1888), but it is printed on larger paper. The formal reports of discussions, &c., are printed in French, but these occupy only a small portion of the book; the greater part consists of descriptive papers and of fuller reports of some discussions, mainly in English. The description, by C. R. van Hise, of the pre-Cambrian rocks of the Lake Superior region, and the geological guide-book to the Rocky Mountain Excursion, edited by S. F. Emmons, are interesting portions of the report. Some notes and sketches by "visiting geologists"—Prof. T. McK. Hughes and Dr. Fr. Frech—are appended. We may also here note that Dr. F. Wahnschaffe has published detailed descriptions of the Western districts in *Naturwissenschaftliche Wochenschrift*. The Rocky Mountain Guide-book is by numerous contributors, and we have received a separate copy of that part relating to the Yellowstone Park, by A. Hague.

WE have received part i. of the twelfth annual report of the Fishery Board for Scotland, being for the year 1893. Following the practice of previous years, the report will be issued in three parts. The third part deals with the scientific investigations conducted under the direction of the Board, and in it the hatchery established at Dunbar for the propagation of marine food-fishes will be described. We learn from the present part that the establishment consists of a small tidal pond, in which a limited number of spawning fishes may be collected and preserved; a large concrete spawning tank, in which the fishes at maturity are placed; a chamber for the automatic collection of the fish eggs, and for the filtration of the water; a hatching room, in which the special hatching apparatus is fitted up; together with the necessary pumping apparatus. The whole of the expenditure, amounting to about £1600, has been met from the ordinary vote for scientific investigations. So far, the operations have been limited by the want of a sufficiently capacious sea-water enclosure. Nevertheless, over 25,000,000 eggs of the plaice have been hatched in the establishment, and arrangements are in progress with the view of obtaining a supply of adult turbot and soles, so as to admit of these fishes being propagated on a large scale, and the fry placed on the fishing grounds. The opinion is expressed that when large sea-water ponds or enclosures are added, it will be possible to retain the young flat fish until they have assumed the habits of the adults, and thus greatly increase the usefulness of the establishment to the fishing industry.

A REPORT on the cultivable land on Kilimanjaro, with special regard to its climate and healthfulness, is published by Dr. Brehme in the last number of the *Mittheilungen aus Deutschen Schutzgebieten*. The fertile land may be taken as the zone between 3700 and 7000 feet of elevation; this zone, strictly speaking, measures only 500 square miles, but several thousand square miles of the neighbouring country may be included as fit for settlement. The soil is the result of the weathering of volcanic rocks mixed with the humus formed by decaying vegetation; it is from 1 to 3 metres thick on the lower slopes, and of great natural fertility. The water supply is good, from melting snow, as well as from the discharge of the clouds which usually hang over the upper part of the mountain. Rains or wet mists occur frequently at all times of the year. The healthfulness of the slopes watered by rapid streams is in contrast with the fever-haunted marshes of the plain at the base of the mountain, where the slope of the land is insufficient for natural drainage. One very important circumstance is that the water of the mountain streams may be drunk unboiled without any risk. At the station of Marangu (1430 metres), meteorological observations, taken from October 1892 to December 1893, the highest monthly mean temperature at 7 a.m. was 17°·9 C. in December 1892, and the lowest 13° C. in August 1893. The mountain is exposed to the trade winds, the south-east trade blowing from April to October, and the north-east from the end of October to March; but the local winds are modified by a general up-hill wind during the day-time, and a down-hill wind at night. The illnesses most common on the cultivable zone of the mountain are much more frequently due to cold than to malaria. In addition to the banana, sorghum, and maize, all European cereals and vegetables grow readily. There seems to be no reason why the experiment of settling European farmers on the temperate uplands of the mountain should be unsuccessful if fairly tried.

IN the last number of the *Scottish Geographical Magazine*, Prof. Otto Pettersson continues his memoir on recent Swedish hydrographic research in the Baltic and North Seas. In this instalment, which is profusely illustrated with coloured charts and sections, he shows how the observations have thrown new light on the Baltic Current in the Skagerack and North Sea. The outflowing and inflowing currents which traverse the Skagerack can readily be distinguished by the different salinity of the water, the inflowing current containing more than 3·2 per cent. and the outflowing less than 3·0 per cent. of salt. In winter, when the outflowing current, or Baltic Stream, is reduced to its minimum by the freezing of the rivers, it shrinks to the dimensions of a narrow current along the coast, the Skagerack resembling a whirlpool with still water in the middle, and the moving water flowing along the coasts. The water is everywhere warmer than the air, but most so in the centre. Thus, while the air at or below 0° C. is in contact with water of nearly the same temperature off the Swedish coast, in the centre of the Skagerack it rests on water the surface temperature of which may be as much as 5°; thus a central mass of relatively warm air is produced, surrounded by concentric layers which are colder and colder. This not only affects the climate of the Swedish coast, but is favourable to the formation or attraction of cyclones. In spring the cold Baltic Stream overspreads the warm central waters of the Skagerack with a fresher and colder layer, destroying the conditions favouring the formation or passage of cyclones, and thus produces the typical dry and cold spring weather which prevails in Sweden.

IN a letter to the *Electrician*, Prof. Elihu Thomson mentions a curious and rather amusing illustration of the principle upon which the instrument for detecting the presence of electric oscillations, devised by Prof. Oliver Lodge, and called by him the "coherer," is based, which came under his notice lately. It will be remembered that the "coherer" depends on its action on the alteration in the resistance of a "bad contact" between an aluminium plate and an iron wire when electric oscillations are set up in the circuit containing the coherer. It was reported to Prof. Thomson that a certain electro-plater at Philadelphia had found that he could not pursue his silver-plating operations during a thunderstorm, and that if he left his plating over-night, and a thunderstorm came on, the work was invariably ruined. Prof. Thomson says :—"I was disposed to be thoroughly sceptical, and expressed my disbelief in any such effect. Being urged, however, I went to the silver-plater's shop, which was a small one, and questioned the silver-plater himself concerning the circumstances which had been reported. While it was evident that he was not a man who had informed himself electrically, I could not doubt that he had indeed stated what was perfectly true, namely, that when his plating operations were going on and a thunderstorm arose, his batteries, which were Smee cells, acted as though they were short-circuited, and the deposit of metal was made at too rapid a rate. The secret came out on an inspection of his connections. The connections of his batteries to his baths were made through a number of bad contacts, which would not fail to be of high resistance under ordinary conditions. I could readily see that virtually he was working through a considerable resistance, and that he had an excess of battery power for the work. Under these circumstances a flash of lightning would cause coherence of his badly-contacting surfaces, and would improve the conductivity so as to cause an excessive flow of current, and give a too rapid deposit. The incident suggests the employment of Dr. Lodge's ingenious instrument in the study of the waves which are propagated during thunderstorms, of which waves we have practically little or no information."

PROF. R. LEPSIUS, of Darmstadt, is preparing a new geological map of Germany, which will give a valuable summary of our knowledge of that area. It is founded upon the various national surveys and upon other good authorities. The scale is 1 : 500,000. The map will be complete in twenty-seven sheets, each measuring 15¾ inches by 13 inches. Four sheets in the south-western areas are published (by J. Perthes, Gotha); these are :—Sheets 17, Koln ; 22, Strassburg ; 23, Stuttgart ; 25, Mülhausen. The sheets are completed beyond the German boundary. The meridian of the map is Paris, but the longitude east of Greenwich is also indicated on the upper margin of each sheet. A new point in this map is that a complete index is printed with each sheet, but only those rock-divisions indicated on the sheet are coloured. The subdivisions shown may be grouped as follows :—Post-Tertiary, 4 ; Tertiary, 4 ; Secondary, 11 ; Palæozoic, 10 ; Metamorphic, 2 ; Volcanic and Plutonic, 7. The "Silur System" includes Cambrian, Lower Silurian, and Upper Silurian. The map is unusually bright and clear; this is partly due to the black printing (topography, &c.) having been done last, over the colours. Like many other geological maps recently published, the price is small: two marks for one sheet, or three marks for each Lieferung containing two sheets.

THE generous manner in which reports on scientific matters are prepared and published in the United States has frequently been commented upon in these columns. In 1891 the sum of two thousand dollars was voted by Congress for investigations respecting the advisability of establishing a fish-hatching station in the Rocky Mountain region in the States of Montana and Wyoming, and also a station in the Gulf States. The results of these investigations are contained in a *Bulletin* (vol. xi. 1891) recently received from the U.S. Fish Commission. Prof. B. W. Evermann carried out the chief of the investigations. In looking for a suitable site for a fish-cultural station, the following requirements for the successful operation of such a station were kept in mind :—(1) There should be a constant supply of not less than one thousand gallons a minute, at a temperature never exceeding 50° or 55°, and free from any possibility of contamination. (2) There should be twenty to thirty acres of ground conveniently near the source of water supply. There should also be sufficient fall between the source of water supply and the hatchery building to permit a gravity supply. (3) The location should be central with reference to the region to be stocked, and should also afford good railroad facilities. Prof. Evermann and his party visited fourteen of the most promising localities, and the explorations were very satisfactory, both from the economic and scientific points of view. It was eventually decided that the region most nearly filling all the natural requirements was Horsethief Springs. These springs, situated in Montana, near the north-west corner of the Yellowstone National Park, are among the largest and most remarkable to be found anywhere in the United States.

WE are glad to see, from the "Abstract of Proceedings of the South London Entomological and Natural History Society" for the years 1892 and 1893, which has just reached us, that the condition of the Society is still a very satisfactory one, although the membership is slightly lower now than a year ago. The Society now numbers 192 members. The volume contains, in addition to reports of the various meetings held, the addresses of the respective presidents for 1892 and 1893.

THE London Matriculation Directory for June has just been issued by the University Correspondence College, and contains the papers set for the Matriculation Examination, June 1894, and solutions to the same.

A SECOND edition has been issued of the catalogue of the "Bibliothèque du Jardin Botanique de Buitenzorg," Java. The edition has been prepared by Dr. Brutel de la Rivière, and it is much more complete and better arranged than the first. We are requested to state that naturalists desiring to obtain a copy of the catalogue, should communicate with M. Treub, the Director of the State Botanic Garden, and the volume will be sent without delay.

THE July part of the *American Naturalist* contains, besides general notes, articles on "Animal Mechanics," by Dr. Manly Miles; "The Meaning of Tree-Life," by H. L. Clarke; "Lepidosirenids and Bdellostomids," by Theodore Gill; and "The Origin of Pelagic Life," by Prof. W. K. Brooks.

THE Quarterly Statement of the Palestine Exploration Fund for July contains many items of interest, among which we notice a translation of a paper by M. Th. Barrois, "On the Depth and Temperature of the Lake of Tiberias."

MESSRS. MACMILLAN AND CO. have just published a new edition, revised and enlarged, of "Arithmetic for Schools," by Rev. J. B. Lock.

THE Seventeenth Annual Report of the Connecticut Agricultural Experiment Station has just been issued at New Haven, and tells of a vast amount of work done during 1893.

AN interesting mode of converting oxide of iron into small but perfect crystals of hæmatite, exhibiting the characteristic forms of the naturally occurring mineral, is described by Prof. Arctowski, of Luttich, in the current number of the *Zeitschrift fur Anorganische Chemie*. The experiment simply consists in passing partially or totally dissociated ammonium chloride vapour over the oxide heated to a particular temperature. The oxide is placed in a combustion tube closed at one end, and at the closed end a quantity of ammonium chloride. The portion of the tube containing the latter is placed in a combustion furnace, and that containing the ferric oxide in an air bath, so constructed that the reaction within the tube can be observed, in order to be able to attain any desired temperature. When the ferric oxide is heated to about 600° in the stream of ammonium chloride vapour small glittering crystals commence to form after the expiration of a few minutes, the remainder of the oxide increases considerably in volume, and ammonium chloride is rapidly absorbed. No fusion occurs, so that the absorption is a mechanical one; the ammonium chloride condenses upon the exterior of the particles, eventually converting the powder into a white mass. Upon subsequent microscopic examination of this white product large numbers of the small brilliant crystals of hæmatite are observed interspersed among the whitened particles. When the experiment is performed at 700°, the whole of the ferric oxide is converted into miniature crystals of hæmatite; it is probable that the ammonium chloride is totally dissociated at this temperature. The crystals exhibit all the peculiar crystallographic properties of hæmatite. The fundamental rhombohedron possesses the characteristic angle of 86°, and the subsidiary forms developed, including those of the scalenohedron, are precisely those exhibited by the natural mineral and are developed to about the same extent. This mode of synthesising hæmatite is very probably intimately connected with that described by M. Sainte Claire Deville in 1861. The latter method consisted in heating ferric oxide to redness in an indifferent atmosphere into which traces of hydrochloric acid gas were admitted. As the ammonium chloride in the experiment at 700° was most probably completely dissociated into hydrochloric acid and ammonia, it is extremely likely that the crystallising action was due to the free hydrochloric acid. The synthesis of hæmatite by means of partially or totally dissociated ammonium chloride vapour is interesting, however, as throwing light upon the mode of formation in nature, for the vapours evolved by the fumaroles in volcanic districts always contain a certain proportion of sal-ammoniac, and it is usually observed that the fissures through which these vapours pass are more or less covered with crystals of specular iron and hæmatite. There is every probability, therefore, that the formation of the crystals is due to the partially dissociated sal-ammoniac, just as in the artificial experiments above described.

THE additions to the Zoological Society's Gardens during the past week include a Moustache Monkey (*Cercopithecus cephus*) from West Africa, presented by Mr. Clayton Pickersgill; a Leopard (*Felis pardus*) from East Africa, presented by Mrs. J. R. W. Pigott; a Lioness (*Felis leo*) from East Africa, presented by Major Oweo; two Tiger Cubs (*Felis tigris*) from Pehang, Malay Peninsula, presented by Lieut.-Colonel Sir Charles B. H. Mitchell, K.C.M.G.; a Common Jackal (*Canis aureus*) from India, presented by Mr. Gerard Gurney; a Monk Seal (*Monachus albiventer*) from Madeira, presented by Mr. C. F. R. Blandy; a Cockateel (*Calopsitta novæ-hollandiæ*) from Australia, presented by Miss Sloane Stanley; six South African Francolins (*Francolinus afer*), a Puff Adder (*Vipera arietans*) from South Africa, presented by Mr. J. E. Matcham; a Smooth Snake (*Coronella lævis*) from Hampshire, presented by Mr. Willingham F. Rawnsley; a Long-eared Fox (*Otocyon megalotis*) from Somaliland, a Geoffroy's Terrapin (*Platemys geoffroyana*) from the Argentine Republic, a Ceylonese Terrapin (*Clemmys trijuga*) from Ceylon, an Ocellated Monitor (*Varanus ocellatus*) from Lake Tanganyika, two Black and White Snakes (*Pituophis melanoleucus*) from New Jersey, U.S.A., a Black-winged Peafowl (*Pavo nigripennis*) from Cochin China, deposited; a Muscat Gazelle (*Gazella muscatensis*) from Muscat, received in exchange; two Collared Fruit Bats (*Cynonycteris collaris*), four Mandarin Ducks (*Æx galericulata*), six Australian Wild Ducks (*Anas superciliosa*), two Slender Ducks (*Anas gibberifrons*), a Magellanic Goose (*Bernicla magellanica*), a Black-headed Gull (*Larus ridibundus*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE RESULTS OF IMPRUDENT SOLAR OBSERVATIONS.—Dr. George Mackay, of the Royal Infirmary, Edinburgh, has sent us a pamphlet "On Blinding of the Retina by Direct Sunlight" (J. and A. Churchill), being a study in prognosis, based chiefly upon accidents incurred during the observation of partial solar eclipses. Tyros in observations of the sun, and also many incautious astronomers, have sustained more or less permanent injury to the sight by looking at it or its image without the interposition of a dark glass, or similar absorber, of sufficient thickness. During the progress of partial solar eclipses, the laity often make incautious observations, and the results of gratifying such curiosity have furnished Dr. Mackay with the chief part of the clinical material for his study. The paper, which originally appeared in the *Ophthalmic Review*, opens with a historical survey of the few cases of ocular injury from exposure to sunlight, recorded in historical literature. There is a tradition that Galileo seriously impaired the sight of his right eye by his solar observations, but Dr. Mackay has not been able to trace the story to its origin. It is well known that, in his later years, Galileo became quite blind, but the loss of sight was apparently caused by an affection of the cornea, and not by injury to the retina. The earliest precise description of the subjective sensations consequent upon focussing solar rays upon the retina is due to Reid, a Professor of Moral Philosophy in the University of Glasgow. He observed the transit of Venus in May 1761, without taking any precautions to modify the intensity of sunlight, and the result was that he was afflicted with metamorphosia; that is, objects appeared to him in distorted forms. Very few other cases of similar ocular injury have been described. Fortunately for Dr. Mackay, the partial eclipse of the sun in June 1890, and that of June 1891, both visible at Edinburgh, furnished him with seven new cases of "Eclipse Blinding," all of which he examined with great care, both with the ophthalmoscope and with type and colour-tests. The patients suffered from an impairment of visual acuteness, and, to most of them, dark spots appeared in their fields of vision. Sometimes these spots were fixed, and in other cases they oscillated rapidly. Dr. Mackay says that complete recovery from the injury, even in cases of only slight failure for test-type, is exceptional if investigated by sufficiently refined methods. It is pointed out that the treatment ought to be preventive: smoked and coloured glasses of the feeble shades ordinarily used by the public to view solar phenomena are quite insufficient. Experience shows that, to view the sun with impunity, even in January, it is necessary to use a glass so dark that no object illuminated by diffuse daylight is visible through it.

A NOVEL METHOD OF SOLAR OBSERVATION.—Dr. Deslandres made an important communication to the Paris Academy of Sciences on July 9. In December 1893, he suggested that separate photographs of the sun should be taken by means of the light of individual dark and bright lines in the solar spectrum. The success with which Prof. Hale has done this with the light of the K line shows that striking results may be expected from the development of the method. An ordinary photograph of the sun is mainly produced by the action, upon the sensitive plate, of the bright intervals between dark lines. Dr. Janssen's marvellous pictures of the sun are produced by using only light of high actinic power, and covering but a small region of the spectrum, to act upon his photographic plate. By carrying this principle still further, there can be no doubt that solar physics will be considerably advanced. The dark lines in the solar spectrum are only dark by contrast. Both Prof. Hale and Dr. Deslandres have shown that sun pictures can be produced by the light from them alone. Hence, by isolating a line due to any element, and using it to act upon a sensitive plate, a photograph is obtained of the layer of the sun in which that particular element predominates. Dr. Deslandres exhibited to the Paris Academy some of the photographs obtained in this way. His first results were produced by means of the light from the bright interval between two dark lines. The pictures thus obtained showed the photosphere with spots and faculæ much the same as

Janssen's photographs. One point confirmed by the pictures is that the difference between the brightness of the solar disc and that of the spots and faculæ is more marked the greater the refrangibility of the light employed. The bright lines due to the vapour of calcium, gave a different set of results. Such reversed lines do not represent incandescent solid or liquid, as in the preceding case, but are emitted by gaseous calcium at a higher level. Their light therefore imprints the image of the chromosphere upon the photographic plate. Dr. Deslandres' photographs of this kind agree with those previously mentioned as regards disposition and general forms of faculæ, but they differ in the fact that they show faculæ near the centre of the disc as clearly as faculæ near the edge, and also by greatly extending the areas of these bright patches. Using the light from a portion of the dark and wide calcium line, and exposing the photographic plate a little longer than when the bright reversal in the middle of the line was employed, a curious and altogether different result was obtained. The same faculæ appear upon the photograph, but they are not so clearly marked, and are of less extent. On the other hand, spots are shown very distinctly, with their penumbræ sharply defined. Dr. Deslandres has obtained similar photographs by using absorption lines of iron, aluminium, and carbon, which are wide enough to permit them to be isolated by means of his spectrograph. The results of further work in this direction will be awaited with interest.

THE ROYAL BOTANIC GARDEN, CALCUTTA.[1]

THE ponderous and important *Annals of the Royal Botanic Garden, Calcutta*, are known to all students of Indian flora. We have from time to time referred in terms of praise to these solid monuments of Dr. King's industry, and to the skill of the native lithographers and printers. The fourth volume of the *Annals* is before us, and is of equal excellence to the preceding ones. It is concerned with "The Anonaceæ of British India," a family of about six hundred species of woody plants. Although Dr. King, in an admirable introduction, gives an outline of the arrangement of the whole family, the present monograph only contains "a detailed account of those species which are indigenous to British India proper, to that part of the Malayan Peninsula which is under British protection, to the Islands of Singapore, Pangkore and Penang, and to the Nicobar and Andaman groups. This is the geographic area covered in the latter volumes of Sir Joseph Hooker's *Flora of British India*; and it may in the broad sense be considered for botanical (though not for political) purposes as *British* India, as distinguished from *Dutch* or *Netherlands* India, which consists of the Malayan Archipelago. The majority of the species indigenous to the British Indian area have already been dealt with by Sir Joseph Hooker and the late Dr. T. Thomson in that splendid fragment their *Flora Indica* (published in 1855), and still more recently by Sir Joseph Hooker in the first volume of his *Flora of British India*. It is with no idea of improving upon the work of these distinguished authors that I have re-described the same species in the following pages, but chiefly in order that the species which have been discovered since the order was dealt with by them may be described, and that the relations of the new to the older species may be understood." Dr. King points out that the Malayan Peninsula remains even now but partially explored, and that its complete examination must bring to many new *Anonaceæ*. But as there was an opportunity of printing a fully illustrated account of the family at the present time, and as there is no knowing when the mountain range which forms the backbone of the Peninsula may be explored, it was decided to publish the monograph, and risk the charge of having done so prematurely.

The great importance of such a work as that under notice can only be adequately judged by botanical experts. Altogether there are 220 lithographic plates, a figure of each species being given. These are accompanied by 169 pages of text, in addition to an index and the useful introduction, to which reference has been made. For the immense labour involved in the publication of such a volume, Dr. King deserves the thanks of all systematic botanists, and the Government of Bengal has done a great service to science by enabling the work to be published.

The hundredth anniversary of the death of Colonel Kyd, the founder and first superintendent of the Royal Botanic Garden at Calcutta, occurred last year, and Dr. King has taken advantage of the occasion by putting on record as much as can be traced of the early history of the Garden, and the career of its founder. The volume is dedicated to Colonel Kyd (of whom a portrait is also given), and prefaced with an interesting account, from which we have taken the following extracts:—

"Robert Kyd belonged to an old Forfarshire family, several members of which had preceded him in the service of the Honourable East India Company. He was born in 1746. At the age of eighteen he became a cadet of the Bengal Engineers, and on October 27, 1764, he received his commission as Ensign in that corps. His promotion to the rank of Lieutenant followed in the year after. Two and a half years later he became Captain, getting his majority on May 29, 1780, and his Lieutenant-Colonelcy on December 7, 1782. He died at Calcutta on May 26, 1793. From the fragmentary evidence which is still extant it appears that Colonel Kyd was a man of wide and varied sympathies and experience, and that, during the later years of his service he attained a position of so much influence that his suggestions on various weighty matters were not only listened to but promptly acted upon. Himself a keen gardener, he had brought together, round his country house at Shalimar, a collection of various plants of economic and horticultural interest which had been sent to him, partly by correspondents in the interior of the country, but which had chiefly been brought to him by Captains of the Company's ships returning from their voyages to the Straits and to the Malayan Archipelago. Colonel Kyd conceived the idea of supplying the Company's Navy with teak timber grown near the ports where it could be used in ship-building, and of increasing their commercial resources by introducing into India the cultivation of the spices which, in those days, formed so important an item in their trade, but for supplies of which they had to depend on their factories in Sumatra and Penang. He communicated this idea to the Governor-General of the day; and, in a letter written on June 1, 1786, he officially submitted a scheme for the establishment of a Botanical Garden, or Garden of Acclimatisation, near Calcutta. This scheme also included proposals for introducing, into territories subject to the Company, the cultivation of cotton, tobacco, coffee, tea, and various other commercial products. To have suggested to the local representatives of what was then practically a trading Company, the provision (at a considerable annual cost) of facilities for the pursuit of pure, as distinguished from economic, botany would probably not have increased the chances of the acceptance of the Garden scheme. The scientific aspect of the matter was therefore, with commendable sagacity, excluded from mention in the original proposal. So much, in fact, were the local Government impressed with the advantages of Colonel Kyd's proposed scheme that, without waiting for a reply to this letter from the Board, they secured land for the Garden 'in anticipation of sanction'; and, in a letter dated July 27, 1787, they reported this action to the Directors. This second letter, however, must have crossed a dispatch, dated London, July 31, 1787, in which the Board not only conveyed their sanction to the formation of the Garden suggested by Colonel Kyd, but warmly approved his action in bringing the proposal to their notice.

"Colonel Kyd's country house and garden stood near the village of Sibpur, on a promontory round which the Hooghly bends in passing the site of the present Fort William (at that time only recently completed), and which was known then (as it is now) as Shalimar. And it was land in the vicinity of Shalimar, and separated from his own private garden only by a ditch, which Colonel Kyd selected for the proposed Botanic Garden. The piece of land thus selected measures more than three hundred acres in extent, and is of rather irregular shape. It consists of a rather narrow strip running along the right bank of the Hooghly for about a mile and a half, but expanding towards its lower extremity into a large square block.

"Colonel Kyd, whose office at this time was that of Military Secretary to Government, was appointed Honorary Superintendent of the Garden, a post which he retained until his death. He never lived within the Garden. In fact, there was no dwelling-house within its limits until his successor, Dr. Roxburgh, built the present Superintendent's house in 1795.

[1] *Annals of the Royal Botanic Garden, Calcutta*, vol. iv. The Anonaceæ of British India. By Dr. George King, F.R.S., &c., Superintendent of the Garden, Calcutta. (Printed at the Bengal Secretariat Press, 1893.)

Colonel Kyd probably, as was the fashion of the day, had a town house in Calcutta. But he appears to have passed a good deal of his time at Shalimar; and in his will he directed that he should be buried in his garden there. The part of the Botanic Garden nearest to Colonel Kyd's house was devoted to the planting of teak trees, in accordance with the Company's earnest desire to supply themselves with timber for ship-building. The experience of thirty-four years having shown that good teak timber cannot be successfully raised on the muddy soil of the Gangetic delta, this part of the garden (extending to about forty acres) was in the year 1820 given up by Government to the Lord Bishop of Calcutta (Dr. Middleton) as the site for a Christian college. The Garden was thus reduced to its present area of 270 acres."

SCIENTIFIC SERIALS.

Bulletin of the New York Mathematical Society, vol. iii. No. 9, June 1894. (New York: Macmillan.)—Prof. E. W. Brown, under the heading "The Lunar Theory" (pp. 207-215), gives an admirable abstract of vol. iii. of Tisserand's "Théorie de Mécanique Céleste, Perturbations des Planètes d'après la Méthode de Hansen; Théorie de la Lune." Herein he opens with the remark: "It is somewhat strange that a subject like the lunar theory, which has received so much attention since its first principles were given by Newton, should be allowed to pass its second centenary before the appearance of a treatise like the present one." His opinion is that, notwithstanding a few defects, the book will take a high rank amongst the many classic treatises on celestial mechanics.—Students of the Theory of Numbers have recently been gratified by the publication (1892) of Bachmann's "Die Elemente der Zahlentheorie." An analysis of its contents, with a brief consideration of the parts which call for special remark, is given by Dr. J. W. A. Young (pp. 215-222).—Prof. Conant (pp. 223-224) calls attention to a work which occupies a unique place among translations, viz. "Memoirs on Infinite Series." These are classic memoirs by Lejeune-Dirichlet (2), Abel, Gauss, and Kummer. The book is brought out, under the auspices of the Tokio Mathematical and Physical Society, by Japanese professors.

IN the numbers of the *Journal of Botany* for June and July, Mr. A. B. Rendle describes new species of Asclepiadeæ and Convolvulaceæ from Tropical Africa, including a new genus of the former order *Odontostelma*, which is also figured.—A new British *Rubus*, *R. Rogersii*, n. sp., is described by Mr. E. F. Linton.—Mr. F. J. Hanbury contributes "A Tentative List of British *Hieracia*," numbering upwards of 100 species.

IN Nos. 5-7 of the *Bullettino della Societa Botanica Italiana* are two papers on fungus diseases of cultivated trees, by Sig. P. Baccarini. The "petecchia" or "vaiolo" (pock) of the orange has been ascribed to various causes. It is always accompanied by a number of fungi, but these are apparently saprophytic, and not pathogenic. The true cause appears to be a bacillus. The "mal nero" of the vine is also attributed to a microbe, *Bacillus vitivorus*, n. sp.—Sig. S. Sommier has two papers on the little-known flora of the Island of Giglio, near to Elba.—Sig. A. Jatta completes his paper on the lichens of Italy, of which he enumerates 1407 species.

THE number of the *Nuovo Giornale Botanico Italiano* for July is occupied by three papers:—"On the Roman Flora," by Sig. A. Terracciano; "On the Flora of Sicily," by Sig. L. Nicotra; and "On the Disease of the Strawberry caused by *Sphærella Fragariæ*," by Sigg. E. Baroni aud G. Del Guergio.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 24.—"On the Influence of certain Natural Agents on the Virulence of the Tubercle-Bacillus." By Dr. Arthur Ransome, F.R.S., and Sheridan Delépine.

June 7.—"The Influence of Intra-Venous Injection of Sugar on the Gases of the Blood." By Dr. Vaughan Harley.

In a previous paper (*Roy. Soc. Proc.* 1893), he showed that the intra-venous injection of grape sugar caused an increase in the lactic acid in the circulation. It appeared probable that the lactic acid had combined with the bases of the carbonates in the blood, having driven out the carbonic acid.

Experiments were made on dogs to see what changes were produced in the gases of the blood after intra-venous injections of sugar.

It was found the quantity of carbonic acid was diminished, it being most markedly so during the first hour after the sugar injection, and still somewhat so three to five hours later. These results support the view that the lactic acid drives the carbonic acid from the sodium salts and replaces it.

In the next place, the changes met with in the quantity of oxygen in the blood were investigated. It was found the oxygen was markedly diminished during the first hour after the sugar injection. During the third and fifth hours the quantity in arterial was that usually found in venous blood. The explanation of this cannot up to the present be explained.

June 21.—"Researches on Explosives. Preliminary Note." By Captain Sir A. Noble, K.C.B., F.R.S.

The researches on which I, in conjunction with Sir F. Abel, have been engaged for very many years, have had their scope so altered and extended by the rapid advances which have been made in the science of explosives, that we have been unable to lay before the Society the results of the many hundreds of experiments under varied conditions which I have carried out. We are desirous also of clearing up some difficulties which have presented themselves with certain modern explosives when dealing with high densities and pressures, but the necessary investigations have occupied so much time that I am induced to lay a few of our results before the Society, trusting, however, that before long we may be able to submit a more complete memoir.

A portion of our researches includes investigations into the transformation and ballistic properties of powders varying greatly in composition, but of which potassium nitrate is the chief constituent. In this preliminary note I propose to refer to powders of this description chiefly for purposes of comparison, and shall devote my attention principally to gun-cotton and to those modern explosives of which gun-cotton forms a principal ingredient.

In determining the transformation experienced during explosion, the same arrangements for firing the explosive and collecting the gases was followed as are described in our earlier researches,[1] and the gases themselves were, after being sealed, analysed either under the personal superintendence of Sir. F. Abel, or of Prof. Dewar, and to Prof. Dewar's advice and assistance I am indebted, I can hardly say to what extent.

The heat developed by explosion, and the quantity of permanent gases generated were also determined as described in our researches, but the amount of water formed plays so important a part in the transformation that special means were adopted in order to obtain this product with exactness.

Numerous experiments were made to ascertain the relation of the tension of the various explosives employed, to the gravimetric density of the charge when fired in a close vessel, but I do not propose here to pursue this part of our inquiry, both because the subject is too large to be treated of in a preliminary note and because approximate values have already been published[2] for several of the explosives with which we have experimented.

With certain explosives, the possibility or probability of detonation was very carefully investigated. In some cases the explosive was merely placed in the explosion vessel in close proximity to a charge of mercuric fulminate by which it was fired, but I found that the most satisfactory method of experiment was to place the charge to be experimented with in a small shell packed as tightly as possible, the shell then being placed in a large explosion vessel and fired by means of mercuric fulminate. The tension in the small shell at the moment of fracture and the tension in the large explosion vessel were in each experiment carefully measured.

It may be desirable here to explain that I do not consider the presence of a high pressure with any explosive as necessarily denoting detonation. With both cordite and gun-cotton I have developed enormous pressures, close upon 100 tons per square inch (about 15,000 atmospheres), but the former explosive I have not succeeded in detonating, while gun-cotton can be detonated with the utmost ease. It is obvious that if we suppose a small charge fired in a vessel impervious to heat, the rapidity

[1] *Phil Trans.* vol. clxv. p. 61.
[2] Noble, "Internal Ballistics," 1892, p. 33; *Roy Soc. Proc.* vol. lii. p. 128.

or slowness of combustion will make no difference in the developed pressure, and that pressure will be the highest of which the explosive is capable, regard being of course had to the density of the charge. I say a small charge, because, if a large charge were in question and explosion took place with extreme rapidity, the nascent gases may give rise to such whirlwinds of pressure, if I may use the term, that any means we may have of registering the tension will show pressures very much higher than would be registered were the gases, at the same temperature, in a state of quiescence. I have had innumerable proofs of this action, but it is evident that in a very small charge the nascent gases will have much less energy than in the case of a large charge occupying a considerable space.

The great increase in the magnitude of the charges fired from modern guns has rendered the question of erosion one of great importance. Few, who have not had actual experience, have any idea how rapidly with very large charges the surface of the bore is removed. Great attention has therefore been paid to this point, both in regard to the erosive power of different explosives and in regard to the capacity of different materials (chiefly different natures of steel) to resist the erosive action.

The method I adopted for this purpose consisted in allowing large charges to escape through a small vent. The amount of the metal removed by the passage of the products of explosion, which amount was determined by calibration, was taken as a measure of the erosive power of the explosive.

Experiments have also been made to determine the rate at which the products of explosion part with their heat to the surrounding envelope, the products of explosion being altogether confined. I shall only briefly allude to these experiments, as, although highly interesting, they have not been carried far enough to entitle me to speak with confidence as to final conclusions.

Turning now to ballistic results. The energies which the new explosives are capable of developing, and the high pressures at which the resulting gases are discharged from the muzzle of the gun, render length of bore of increased importance. With the object of ascertaining with more precision the advantages to be gained by length, the firm to which I belong has experimented with a 6-inch gun of 100 calibres in length. In the particular experiments to which I refer, the velocity and energy generated has not only been measured at the muzzle, but the velocity, and the pressure producing this velocity, have been obtained for every point of the bore, consequently the loss of velocity and energy due to any particular shortening of the bore can be at once deduced.

These results have been obtained by measuring the velocities every round at sixteen points in the bore and at the muzzle. These data enable a velocity curve to be laid down, while from this curve the corresponding pressure curve can be calculated. The maximum chamber pressure obtained by these means is corroborated by simultaneous observations taken with crusher gauges, and the internal ballistics of various explosives have thus been completely determined.

Commencing with gun-cotton, with which a very large number of analyses were made, with the view of determining whether there was any material difference in the decomposition dependent upon the pressure under which it was exploded, two descriptions were employed: one in the form of hank or strand, and the other in the form of compressed pellets. Both natures were approximately of the same composition, of Waltham Abbey manufacture, containing in a dried sample about 4·4 per cent. of soluble cotton and 95·6 per cent. of insoluble. As used, it contained about 2·25 per cent. of moisture.

[Tables were given showing the results of the analyses of the permanent gases.]

From my very numerous experiments on erosion I have arrived at the conclusion that the principal factors determining its amount are: (1) the actual temperature of the products of combustion; (2) the motion of these products. But little erosive effect is produced, even by the most erosive powders, in close vessels, or in those portions of the chambers of guns where the motion of the gas is feeble or *nil*; but the case is widely different where there is rapid motion of the gases at high densities. It is not difficult absolutely to retain without leakage the products of explosions at very high pressures, but if there be any appreciable escape before the gases are cooled they instantly cut a way for themselves with astonishing rapidity, totally destroying the surfaces over or through which they pass.

Among all the explosives with which I have experimented I have found that where the heat developed is low the erosive effect is also low.

With ordinary powders, the most erosive with which I am acquainted is that which, on account of other properties, is used for the battering charges of heavy guns: I refer to brown prismatic powder. The erosive effect of cordite, if considered in relation to the energy generated by the two explosives, is very slightly greater than that of brown prismatic, but very much higher effects can, if it be so desired, be obtained with cordite and, if the highest energy be demanded, the erosion will be proportionally greater. There is, however, one curious and satisfactory peculiarity connected with erosion by cordite Erosion produced by ordinary gunpowder has the most singula effect on the metal of the gun, eating out large holes and form ing long rough grooves, resembling a ploughed field in minia ture, and these grooves have, moreover, the unpleasant habit o being very apt to develop into cracks; but with cordite, so fa as my experience goes, the erosion is of a very differen character. The eddy holes and long grooves are absent, and th erosion appears to consist in a simple washing away of th surface of the steel barrel.

Cordite does not detonate; at least, although I have mad far more experiments on detonation with this explosive tha with any other, I have never succeeded in detonating it. Wit an explosive like cordite, capable of developing enormous pres sures, it is, of course, easy, if the cordite be finely comminuted to develop very high tensions, but, as I have already explained a high pressure does not necessarily imply detonation.

[The velocities and energies developed by the new explosiv were shown by the aid of diagrams.]

"The Rotation of the Electric Arc." By Alexander Pelha Trotter.

In the course of experiments made with the view of realisin as a practical standard of light, the method of using one squa millimetre or other definite area of the crater of the positiv carbon of an electric arc,[1] the author has found that the effecti luminosity is not as theory would predict,[2] either constant o uniform. By the use of a double Rumford photometer, givin alternating fields, as in a Vernon Harcourt photometer, h attention was called to a bright spot at or near th middle of the crater. The use of rotating sectors accidental revealed that a periodic phenomenon accompanied the appea ance of this bright spot, and although it is more marked wi a short humming arc, the author believes that it is alwa present.

An image of the crater was thrown on a screen by a phot graphic lens; and a disc having 60 arms and 60 openings of 3 and rotating at from 100 to 400 revolutions per minute, w placed near the screen. Curious stroboscopic images we observed, indicating a continually varying periodicity seldo higher than 450 per second, most frequently about 100, diffic to distinguish below 50 per second, and becoming with a lo arc a mere flicker. The period seemed to correspond with t musical hum of the arc, which generally breaks into a hiss at note a little beyond 450 per second. The hum is audible in telephone in the circuit, or in shunt to it. The current w taken from the mains of the Kensington and Knightsbrid Electric Light Company, often late at night, after all t dynamos had been shut down. The carbons were, of cours not cored; six kinds were used.

A rotating disc was arranged near the lens, to allow the bea to pass for about 1/1000th of a second, and to be cut off f about 1/100th of a second. It was then found that a brig patch, occupying about one quarter of the crater, appeared be rapidly revolving. Examination of the shape of this pat showed that it consisted of the bright spot already mentione and of a curved appendage which swept round, sometim changing the direction of its rotation. This appendage seem to be approximately equivalent to a quadrant sheared ec centrically through 90°. Distinct variations in the luminos of the crater are probably due to the fact that this is only approximation.

The *à priori* theory of the constant temperature of the cra is so attractive, that the author is inclined to attribute t phenomenon, not to any actual change of the luminosity of t

[1] J. Swinburne and S. P. Thompson, discussion on paper by the aut "Inst. Electrical Eng.," vol. 21, pp. 384 and 4[illegible].

[2] Abney and Festing, *Phil. Trans.* 1881, p. 890; S. P. Thompson, *Arts. Journ.* vol. 37, p. 32.

crater, or to any wandering of the luminous area, as is seen with a long, unsteady arc, but to the refraction of the light by heated vapour. All experiments, such as enclosing the arc in a small chamber of transparent mica, or the use of magnets, or an air blast, have failed to produce any effect. A distortion of the image of the crater while the patch revolves, has been looked for, but nothing distinguishable from changes of luminosity has been seen.

An unexpected difficulty is thus introduced in the use of the arc as a standard of light, and one which may interfere with its use under some circumstances as a steady and continuous source of light. The author is further examining this phenomenon, with the view of ascertaining its nature, and of finding practical conditions under which it is absent or negligable.

"On the Viscosity of Water as determined by Mr. J. B. Hannay, by means of his Microrheometer." By Robert E. Barnett.

In a paper entitled "On the Microrheometer," published in the *Phil. Trans.* for 1879, Mr. Hannay described an apparatus which he devised for measuring the rate of flow of liquids through a capillary tube, and gave the times of flow of water at various temperatures, and of certain aqueous salt-solutions which he had observed by its means. The capillary was 21 mm. long, and 0·0938 mm. in diameter; the bulb had a capacity of 4·053 c.c., and the pressure employed was that of 1 metre of water at 20°. In order to compare the results with those of other observers, the author has converted the measurements of time of flow recorded by Mr. Hannay for water into viscosity-coefficients by means of the formula :—

$$\eta = \frac{\pi r^4 pt}{8Vl} - \frac{V\rho}{8\pi lt}.$$

The figures thus obtained are given in tabular form, and on comparison with the results given by Poiseuille, Slotte, Sprung, and Thorpe and Rodger, are seen to yield discordant values for the viscosity of water. Not only is the value at 0° far below that of any known liquid, but it diminishes so rapidly that at 6° and above it is a *minus* quantity. This paradoxical result is due to the fact that Mr. Hannay's experimental figures are inconsistent. It is physically impossible to pass such a volume of water under the stated pressure through a capillary tube of the dimensions given, in the times recorded. At 20°, for instance, the time of flow required under these conditions would be about 4600 seconds, instead of 131·3 seconds, as stated. The author has attempted in several ways to account for the discrepancy, but without success.

"On the Singular Solutions of Simultaneous Ordinary Differential Equations and the Theory of Congruencies." By Prof. A. C. Dixon.

PARIS.

Academy of Sciences, July 16.—M. Lœwy in the chair.—New researches on chromium, by M. Henri Moissan. Chromium has been prepared in large quantity by means of the electric furnace. Pure chromium has the density 6·92 at 20° C. It is more infusible than platinum, and has, apparently, no action on a magnetic needle. It is practically unacted on in moist air, but burns at 2000° C. in oxygen. It readily combines with silicon and carbon, to form very hard compounds; the silicide scratches the ruby. The pure metal is not nearly so hard, and readily takes a fine polish. It is hardly attacked by acids, resisting aqua regia, and is not acted on by fused potash, though oxidised by fused potassium nitrate or chlorate.—On the two ourang-outangs which have recently died at Paris, by M. A. Milne-Edwards.—On the mechanism of the murmurings caused by the passage of air in tubes; determination of the moment when a soundless flow, transformed instantaneously into a murmuring flow, becomes sonorous in the different points of the tube, by M. A. Chauveau.—On the necessity for ostriches, and most birds, to swallow hard bodies which remain in the pyloric region of the stomach, and which play the part, as regards foods, of masticatory organs, by M. C. Sappey.—On dimethylamidobenzoylbenzoic acid, diethylamidobenzoylbenzoic acid, and dimethylanilinephthalein, by MM. A. Haller and A. Guyot.—Note on some biological variations of *Pneumobacillus liquefaciens bovis*, the microbe of contagious peripneumonia of cattle, by M. S. Arloing. The author describes a non-liquefying variety of this microbe, and shows that it is not an independent species.—Studies on central actions: general laws relative to the effect of media, by M. F. P. Le Roux.—On interferences due to mean difference of path, by M. Georges Meslin.—Direct autographic record of the form of periodic currents by means of the electrochemical method, by M. P. Janet. A battery of fifteen steel styles, connected with fifteen points of the circuit taken, so that the difference of potential between consecutive points was about four volts, gave traces on prepared paper which indicated the characteristics of the discharge through the circuit.—Coefficient of self-induction of n equal and equidistant parallel threads of which the sections are distributed on a circumference, by M. Ch. Eug. Guye. The coefficients calculated for two selected definite systems by means of a formula quoted agree with the experimental values within about one per cent.—On the equation of discharges, by M. R. Swyngedauw.—Separation and estimation of tin and antimony in an alloy, by M. Mengin. The oxides are obtained as usual by means of nitric acid acting on the alloy of tin and antimony, and the metal antimony is reduced therefrom by means of a plate of pure tin and hydrochloric acid, and weighed separately.—On rotatory powers variable with the temperature; a reply to M. Colson, by M. A. Le Bel.—Synthesis of mesoxalic acid and bismuth mesoxalate, by M. H. Causse. The acid has been obtained by oxidation of glycerine by means of nitric acid in presence of bismuth nitrate. Insoluble bismuth mesoxalate is formed and, by virtue of its insolubility, the mesoxalic acid is removed from the field of action and escapes further oxidation.—Contribution to the study of some amido-acids obtained by the condensation of vegetable proteid substances, by M. E. Fleurent. On some derivatives of the propylamines, by M. F. Chancel. The preparation and properties are described of the compounds (1) propylpropylideneamine, (2) monopropylacetamide, (3) dipropylacetamide, and (4) tetrapropylurea.—On some points in the anatomy of the ourang-outang, by MM. J. Deniker and R. Boulart.—On the male genital apparatus of the ourang-outang (*Simia satyrus*, L.), by M. E. de Pousargues.—On the osteology of the ourang-outang, by M. P. Delisle.—Researches on the excitability of rigid muscles and on the causes of the disappearance of cadaveric rigidity, by M. J. Tissot. The author shows that the relaxation of the cadaveric rigidity of muscles is not due to putrefaction, which only sets in after the rigidity disappears.—Physiological mechanism of egg-laying among Orthopterous insects of the family of the Acridii. The *rôle* of the air as a mechanical agent, and multiple functions of the genital apparatus, by M. J. Viala and G. Boyer.—On the carved ivories from the Quaternary station of Brassempouy (Landes), by MM. Ed. Piette and J. de Laporterie. An account of five statuettes or parts of statuettes of human figures, found among cinders and numerous bones of the rhinoceros, mammoth, aurochs, horse, and hyæna.—On the Constantinople earthquake. An extract from a letter from M. Moureaux to M. Mascart.

AMSTERDAM.

Royal Academy of Sciences, June 30.—Prof. van der Waals in the chair.—Prof. Behrens, Delft, gave some particulars concerning the detection of alkaloids by microchemical methods. A good method must give slides, showing the alkaloids pure or well crystallised combinations, from which the pure alkaloid can be set free by simple and trustworthy reactions. Such slides can be kept any time as documents for comparing with standard slides and further experiments, while the colour-tests in current use generally destroy the alkaloid. Volatile alkaloids are the most easy to isolate. Thus, from 0·3 mgr. of tea, and from 1 mgr. of coffee, by extraction with lime water and with alcohol, and subsequent sublimation, characteristic needles of theine were obtained without any difficulty. Cocoa must be extracted with weak acetic acid. After purifying with acetate of lead and concentrating, the liquid is dried with an excess of sodium carbonate, and sublimed at 300° C. Powdery theobromine is obtained, giving characteristic prisms with silver nitrate, and, later on, needles, resembling theine, more volatile than theobromine and more soluble in water. Their angle of extinction is 0°, and their chloromercurate is easily soluble. For theine, angle of extinction 45°, chloromercurate thrown down as long needles.

Two mgr. of cocoa are sufficient for showing both alkaloids. Among alkaloids that are not volatile, quinine may be cited, treated with success by the author six months ago. As another example, strychnine and brucine may be taken. For tracing strychnine the limit was found by de Vry and van der Burg at 0·001 mgr. With the aid of microchemical methods, well-defined crystals of strychnine can be obtained down to 0·0002 mgr. in the presence of as much brucine; afterwards the latter is made to crystallise as chloroplatinate. The actual limit is found at a fourth of this quantity. A detailed paper will be published next year.—Mr. Bakhuis Roozeboom discussed the graphical representation of heterogeneous equilibrium in systems of one to four substances. For systems of one substance we have only p, t lines which encounter each other in triple points. Systems of two substances may be represented in space between two parallel plans, by points which indicate p, t and the composition. For systems of three components the composition may be expressed in an equilateral triangle, and in a direction perpendicular to this plan, either p, or t. For systems of four substances the composition only can be expressed for one single temperature and pressure by points in a tetrahedron. The author discussed the conditions for a right selection of the components, and demonstrated that, in systems which admit single or double substitution, the number of components is one inferior to that of the apparent components.—Prof. J. A. C. Oudemans presented a note on the geographical position of the Astronomical Observatory at Utrecht, revised by him on a request from the editor of the British Nautical Almanac. The latitude = 52° 5′ 9″·5. Using Leiden-Greenwich, as newly found by telegraph, and Utrecht-Leiden, geodetically determined, he deduced 20m. 31s.·00, practically the same result as given by the old observations of Hennert, van Utenhove, Wagner, van Beeck, Calkoen, and Keyzer, from 1778 to 1820.—Prof. C. A. J. A. Oudemans exhibited two new fungi, viz. *Septoria dictyotæ*, found on *Dictyota obtusangula*, a submerged *Rhodophycee*, detected by Miss Weber in the neighbourhood of Malacca, and *Ustilago Vuyckii*, discovered by Mr. Vuyck, in Leiden, in the ovary of *Luzula campestris*.—Prof. Kamerlingh Onnes commented on (1) the coefficients of viscosity of fluids in corresponding states, calculated by Mr. de Haas. They generally agree with the formula deduced from his theorem that the moving molecular systems in corresponding states are mechanically similar. Great deviations are shown by the fatty acids, and especially the alcohols. (2) The further experiments made by Dr. Kuenen, in the Leiden Laboratory, on the abnormal phenomena observed by Galitzine near the critical point. Dr. Kuenen proved that they are to be ascribed to impurities, and in particular to air. Gas can be originated at one side of the tube by heating a part of it, just as during the process of scaling. The gas being transferred to the opposite side of the tube, the density at this side changes in accordance. By admitting air at one side, anomalies such as were observed by Galitzine are obtained.—Mr. Jan de Vries presented an article on triple equations. He showed that the roots of such equations of degrees 7 and 9 cannot satisfy a symmetrical trilinear relation. This property is also verified for two distinct sorts of triple equations of degree 13; it has not yet been decided whether these are the only possible systems of this degree.

Netherlands.

Entomological Society, June 9.—Mr. A. van den Brandt in the chair.—Mr. Everts exhibited a fine collection of specimens illustrating the biology of the honey bee; Mr. Leesberg, specimens of the rare *Doryatoma chrysomelina*, new for the Dutch fauna; Mr. Snellen, both sexes of *Euplæa martinii* de Nicéville, and a bread specimen of *Meliana flammea*, Curt.; Mr. J. C. H. de Meyere, several rare and interesting indigenous Diptera; Mr. F. J. M. Heylaerts, specimens of *Coleophora* and *Psychidæ*; Mr. H. A. de Vos tot Nederveen Cappel, *Agrotis dahlii*, *Boarmia abietaria*, and a very curious variety of *Taeniocampa incerta*; Mr. A. J. F. Fokker, specimens of two rare indigenous Hemiptera, *Eurygaster maura* and *hottentotta*. The latter stated that the name of *Pedops horvathi*, a species which was not long ago described by him in the Dutch *Tijdschrift*, had been previously given by Distant to a Japanese species, and was therefore changed by Dr. Bergroth into *P. subalpina*.—Mr. H. J. Veth described the liquids emitted by the coxæ of several Coleoptera (Coccinellidæ and others), and which, according to Leydig, was a secretion of blood. A renewed chemica[l] inquiry into its nature, however, seems to be desirable.—Mr A. J. van Rossum gave a further account of his breedings o[f] *Cimbex fagi* and *saliceti*.—Mr. J. Th. Oudemans exhibited a[n] apparatus for setting Lepidoptera, and adapted to be use[d] during long journeys.

LORD KELVIN ON GENERAL PHYSICS.[1]

Popular Lectures and Addresses by Sir William Thomson (Baron Kelvin), P.R.S., LL.D., D.C.L., &c. In three volumes. Vol. II. "Geology and General Physics." With illustrations. NATURE Series, pp. x. + 599, with index. (London and New York: Macmillan and Co., 1894.)

II.

AT the present time, when the need for a fully-equipped and well-manned National Physical Laboratory for expensive and for secular observations is sometimes discussed, it is interesting to quote from Lord Kelvin's Presidential address to the British Association at Edinburgh in 1871 as follows:—

"The success of the Kew Magnetic and Meteorological Observatory affords an example of the great gain to be earned for science by the foundation of physical observatories and laboratories for experimental research, to be conducted by qualified persons, whose duties should be, not teaching, but experimenting. Whether we look to the honour of England, as a nation which ought always to be the foremost in promoting physical science, or to those vast economical advantages which must accrue from such establishments, we cannot but feel that experimental research ought to be made with us an object of national concern, and not left, as hitherto, exclusively to the private enterprise of self-sacrificing amateurs, and the necessarily inconsecutive action of our present Governmental Departments and of casual Committees."

"On the Continent there exist certain institutions, fitted with instruments, apparatus, chemicals, and other appliances, which are meant to be, and which are made, available to men of science, to enable them, at a moderate cost, to pursue original researches."

"The physical laboratories which have grown up [in Universities] show the want felt of Colleges of Research; but they go but infinitesimally towards supplying it, being absolutely destitute of means, material or personal, for advancing science except at the expense of volunteers, or for securing that volunteers shall be found to continue even such little work as at present is carried on."

And in connection with the still urgently pressing need for a systematic abstract of papers and of a central comprehensive report of annual progress in physics, such as is already satisfactorily accomplished by our friends the chemists, the following quotation from the same address is likewise of interest:—

"A detailed account of work done and knowledge gained in science Britain ought to have every year. The *Journal of the Chemical Society* and the *Zoological Record* do excellent service by giving abstracts of all papers published in their departments. The admirable example afforded by the German *Fortschritte* and *Jahresbericht* is before us; but hitherto, so far as I know, no attempt has been made to follow it in Britain. It is true that several of the annual volumes of the *Jahresbericht* were translated, but a translation . . . cannot supply the want. An independent British publication is for many obvious reasons desirable. The two publications, in German and English, would, both by their differences and their agreements, illustrate the progress of science more correctly and usefully than any single work could do."

From the same address I cull the following detached morsels:—

"Our knowledge of the dark lines is due to Fraunhofer. Wollaston saw them but did not discover them." "The old nebular hypothesis supposes the solar system . . . . to have originated in the condensation of fiery nebulous matter. This hypothesis was invented before the discovery of thermodynamics, or the nebulæ would not have been supposed to be fiery."

In amongst the more geological portion of the book there comes a Presidential address to the Society of Telegraphic Engineers, from which it may be useful to extract the following compact statements concerning atmospheric electricity:—

"In fair weather the surface of the earth . . . . is always found negatively electrified. . . . The more common form of statement is that the air is positively electrified, but this form of statement is apt to be delusive. . . . . The surface of the earth is negatively electrified, and positive electrification of the air is merely inferential, ... the lower regions of the air [such air as comes in through windows] are negatively electrified. . . . . It is not always negative, however. I have found it positive on some days. In broken weather . . . . it is sometimes positive and sometimes negative. Now hitherto there is no proof of positive electricity in the air at all in fine weather; but we have grounds for inferring that probably there is positive electricity in the upper regions of the air."

Opening the book now at page 360, we find a paper which might well have been included in the volume on "Navigational Affairs," being on the subject of the Rate of clocks and chronometers as influenced by the mode of suspension. It is rather surprising to learn that the rough and ready conditions of a pocket by day and a pillow by night give a watch a better chance of going correctly than many other modes of support, such as hanging on a nail or even lying flat on a table. If a correctly-going watch be hung up by a single long thread normal to its plane it begins to gain, and if its case has n times the moment of inertia of the balance-wheel, it gains one in $2n$ swings; a watch actually tried, whose n was 650, gained more than a minute (67 seconds) in a day when so suspended. Suspend it by a bifilar suspension and gradually move the threads further apart, so as to increase the natural rate of swing of the case, and the watch gains more and more, until, when the periods of case and wheel coincide, it gains furiously, and then either stops altogether or else begins to lose equally furiously. Separate the threads a little more still, and the losing rate begins to diminish, until ultimately, when the constraint is great, it begins to keep correct time again. Thus by suspending a chronometer judiciously it can be adjusted to time without touching the hands; but if it be suspended so as to have a quick natural period of swing, it cannot be expected to keep good time. If placed on a cushion to protect it from jars, its case is not unlikely to have a quick swing-period;

[1] (Continued from page 293.)

it should be firmly fixed to something with a considerable moment of inertia, and then placed on its cushion. Any fairly regular motion of the case is fatal to good going. And as to astronomical clocks, they should be fixed to stone piers with the same sort of care as is bestowed on transit instruments.

Another paper, "On a New Astronomical Clock," notes the defects of Graham's dead-beat escapement, and suggests a new one, wherein the escapement wheel is carried by a loose friction collar at a rate a trifle faster than the proper rate, so that its pellets engage the pendulum only occasionally, receiving the necessary check and maintaining the motion of the pendulum sufficiently, even though they only touch once a minute or so.

In a paper "On Beats of Imperfect Harmonies," of date 1878, Lord Kelvin virtually lends his support to the view advocated by Koenig, that in the appreciation of harmony the ear detects phase-differences and is not limited to analysis of a complex note into simple harmonic constituents. For instance, a harmony of even and odd vibration numbers (like 2 : 3) will have one kind of phase relation, while a harmony of two odd numbers will have another kind, the most obvious feature of these phase relations being the way successive maxima and minima coincide or oppose. In general the shape of the curve representing the composition of two notes varies in appearance, as is well known, according to the phase in which they are compounded. If one of the constituents is out of tune there will be a gradual transition from one of these phase-relations to another. "In favourable circumstances . . . a variation of the sound recurring periodically in the successive cycles is distinctly heard. . . . It is this variation which is called the 'beat' on the imperfect harmony."

Lord Kelvin has made experiments on pure tuning-fork tones, and his experience is "that in every case the ear does distinguish the two halves of the period of each beat. . . . The ear distinguishes the quality of the sound represented by the sharp-topped and flat-hollowed curve from that represented by the flat-topped and sharp-hollowed curve. In the one case the pressure of air close to the ear rises very suddenly to, and falls very suddenly from, its maximum, and (as in cases of tides in which there is a long hanging on low water) there is a comparatively slow variation of pressure for a few ten-thousandths of a second on each side of the instant of minimum pressure; in the opposite phase-relation there is a slow change before and after the time of maximum pressure, and a rapid change before and after the time of minimum pressure."

The ear is thus found able to distinguish between a push and pull on the tympanum; or the receiving apparatus is not symmetrical on either side of zero. This is equivalent to saying that second order of small quantities must affect the sound as heard, and on this can be based the usual theory of the difference and summation tones of Helmholtz.

But the mode of expression adopted by Lord Kelvin is not that of interference of any resultant simple tones; he prefers to think of the actual phase changes as directly detected by the ear, and says that "a *revolving character* which I perceive in the beat is to me certainly distinct enough to prove that the ear does distinguish between these configurations, which are one of them the same as the other taken in the reverse order of time."

According to his experiments it is singular how very faint is the disturbance necessary to bring out these beat tones: much less than would appear to be necessary on Helmholtz' theory of difference tones, whose amplitude is proportional to the product of the constituent amplitudes. Thus, "if when the approximate harmony C E is being sounded, with the E slightly out of tune and the beats on it heard, the faintest sound of G is produced by a very gentle excitation of the fork by the bow, instantly a loud beat at half speed is heard. . . . It is marvellous how small an intensity of the sound G is required to give a smooth unbroken loud beat in the double period." This practical method of tuning a major third, by addition of the minor third above it, completing the common chord, is of course well known; but the ordinary Helmholtz explanation, of beats between the C E difference tone and the E G difference tone, scarcely seems to fit the above observed facts.

Again, if the notes C E G are sounded and one of the notes (say C) is flattened, the beats are not only very audible but "the sound dies beating, the beats being distinctly heard all over a large room as long as the faintest breath of sound is perceptible. The smooth melodious periodic moaning of the beat is particularly beautiful when the beat is slow (at the rate, for instance, of one beat in two seconds or thereabouts), being, in fact, sometimes the very last sound heard when the intensities of the three notes chance at the end to be suitably proportioned."

Incidentally an inconvenient usage of musical nomenclature is mentioned in a note. The word "tone," which is now coming to be used to mean a pure sine curve disturbance or simple note, means in music the interval of the major or minor or tempered second.

Those who have to do with acoustics must have often experienced the inconvenience of the ordinary childish nomenclature of intervals—a fourth, a third, a seventh, and so on—especially when these intervals are being numerically expressed at the same time. To call the interval 2 : 3 a fifth, 3 : 4 a fourth, and 1·25 a third, is often confusing. Might I suggest that these intervals, when true, might be named readily and intelligibly as respectively a do-sol, a sol-do, or if preferred a do-fa, and a do-mi; similarly a minor third would be a mi-sol; a major and a minor tone would be a do-re and a re-mi respectively; and so on.

It might be convenient to drop the *l* in sol, so as to make all the syllables of two letters; and then the flattening or sharpening of notes might be indicated readily by a final *a* or *e*: thus a flattened major tone would be a do-rea (the same as a re-mi), and a sharpened one a do-ree.

On the tempered scale the intervals could be called *cg*, *gc*, *ce*, *eg*, &c., with perfect ease.

Again, the ordinary musical notation, with its various clefs, if it were not hallowed by usage, would seem a barbarous piece of stupidity. Undoubtedly a couple of lines should have been understood as missing between the bass and treble clefs, instead of only one; so that the F label could be affixed to the top line of the bass instead of to the second from the top (see fig.); or rather, since the second line from the bottom is G, the same as in the treble, no labelling would be wanted, and one clef would serve for all instruments—a change which would

surely save a Conductor something? I wonder if it is too late now to make the change! This, however, is a digression, and Lord Kelvin is not to be held responsible for any of these musical notation heresies.

The remaining parts of the book consist, for the most part, of Presidential addresses and a couple of Royal Institution lectures. The first R.I. lecture, "On the origin and transformation of motive power," is now of only historical interest. It is of date 1856, and in it the energy of motion is called "dynamical" or "actual" energy, though in a note the author says that he very soon after suggested the name kinetic.

It is followed by the address to Section A at York in 1881, on the practical utilisation of wind and water power; and then begin the quite recent articles. First, an article on the Dissipation of Energy for the *Fortnightly Review* of 1892, wherein the author points out how near Carnot was to an appreciation of the second law of thermodynamics, and justifies his own limitation of its statement to "inanimate material agency" by the following:—

"My statement of this axiom was limited to inanimate matter because not enough was known either from the natural history of plants and animals or from experimental investigations in physiology to assert with confidence that in animal or vegetable life there may not be a conversion of heat into mechanical effect not subject to the conditions of Carnot's theory. It seemed to me then, and it still seems to me, most probable that the animal body does not act as a thermodynamic engine in converting heat produced by the combination of the food with the oxygen of the inhaled air, but that it acts in a manner more nearly analogous to that of an electric motor working in virtue of energy supplied to it by a voltaic battery. . . . It is, however, conceivable that animal life might have the attribute of using the heat of surrounding matter, at its natural temperature, as a source of energy for mechanical effect, and thus constituting a case of affirmative answer for Carnot's last thermodynamic question.[1] The influence of animal or vegetable life on matter is infinitely beyond the range of any scientific inquiry hitherto entered on. Its power of directing the motions of moving particles, in the demonstrated daily miracle of our human free-will, and n the growth of generation after generation of plants rom a single seed, are infinitely different from any possible result of the fortuitous concourse of atoms."

"Considerations of ideal *reversibility* . . . have no place in the world of life."

In an address on the opening of the Physical and Chemical Laboratories of the North Wales College, Bangor, it is stated that there is no philosophical division whatever between chemistry and physics; both "investigate the properties of matter." I would suggest that properties common to many kinds of matter belong to Physics, while the properties whereby one kind of matter differs from other kinds belong to Chemistry. Of course there can be no sharp line of demarcation, but instinctively we are conscious of a difference; and wherever the investigation is concerned essentially with specific varieties of matter, it is felt that the interest attaching to it is a chemical interest. Properties of matter in general, in its different states indeed but without regard to whether the matter is pure or impure simple or compound—those usually belong to Physics.

In this Bangor address there are some interesting reminiscences of the old building of Glasgow University, and of the early days of students' laboratory work there, where under the inspiration of their unique teacher, even theological students worked away at practical experimental physics. And an excellent training too! The modern system of different curricula for each class of professional students, even in the early stages of their degree course, is probably not half so wise as the old Scotch system, where everyone had a year at natural philosophy as well as a year at metaphysics; and the course for everyone up to a degree standard was the same, whatever he was going to be. Specialisation at an early stage is now largely advocated, but I believe that our descendants will regard it as a mistake; or certainly that in effecting a partially required reform we are running now too far into an opposite extreme.

A good wholesome uniform range of subjects, with sufficient variety for different tastes but no reprieve from any course, is the best pregraduate course for all but intellectual weaklings; and for weaklings to attempt to specialise, as they sometimes do now, because it is easier to pass a high stage badly than a low stage well, cannot be really useful or satisfactory.

Those who are incompetent to go deep, and are necessarily superficial, let them try to give their surface breadth; and for those who can go deep, let them spread wide too. A liberal culture and wide information can hurt nobody of decent ability, and it need not be inconsistent with any depth to which a man's genius can carry him. True depth is an affair of genius. Training has chiefly to do with breadth. (This is another digression.)

Of the author's brief annual addresses as President of the Royal Society, the first is on the recently observed slight shift of the earth's polar axis, and on the Faraday centenary; the second on terrestrial magnetism, and the conceivable modes by which the sun may be able to disturb it. The following sentence may be quoted: "I find it unimaginable but that terrestrial magnetism is due to the greatness and rotation of the earth." And on the hypothesis that magnetic disturbances are caused by the direct action of the sun acting as a variable magnet, he says:—"In eight hours of a not very severe magnetic storm, as much work must have been done by the sun in sending magnetic waves out in all directions through space as he actually does in four months of his regular heat and light. This result, it seems to me, is absolutely conclusive against the supposition that terrestrial magnetic storms are due to magnetic action of the sun; or to any kind of

[1] This question was:—"Is it possible to derive mechanical effect from heat of average temperature?"

dynamical action taking place within the sun, or in connection with hurricanes in his atmosphere, or anywhere near the sun outside.

"It seems as if we may also be forced to conclude that the supposed connection between magnetic storms and sun-spots is unreal, and that the seeming agreement between the periods has been a mere coincidence."

The next year's address is on electric radiation, the experiments of Hertz, and electric discharge in gases: with a reference to Mr. Crookes' discovery of vacuum-stresses as an outcome of experimental troubles experienced in his weighing of thallium, and with a characteristic foot-note by Lord Kelvin to the word "troubles":—"Tribulation, not undisturbed progress, gives life and soul, and leads to success when success can be reached, in the struggle for natural knowledge." It is followed by the speech delivered at the unveiling of Joule's statue in Manchester Town Hall on December 7, 1893, and by the Royal Institution lecture on Isoperimetrical Problems; this last being an attempt at popularising the calculus of variations! From how to surround a maximum acreage with a given boundary subject to certain conditions, and how to plan a railway route with a minimum of expense, the author ascends to recent researches in the problem of three bodies, and to the geometrical representation of problems of dynamical stability by the method of geodetics. The most curious part of this lecture is not scientific but social, viz. the treatment accorded to that unfortunate hero, "Horatius Cocles." The representation of Dido as a cute Phenician adventuress successfully wheedling a reasonable plot of ground out of a sarcastic African chief is fair enough, but the spectacle of the stout old warrior with his wounded leg scrambling after a plough along a single furrow from morning till night over all kinds of country, in order to secure as much of the public cornland as possible at the hands of his grateful countrymen, is an odd reading of the legend. That he was awarded a piece of land such that it would take two oxen the whole of a day to plough it, is a statement poetic perhaps in its terms but more precise in its meaning than if expressed in some extinct units of measurement; but to suppose that it was to be ploughed round, and that Horatius must guide the plough, and guide it with a constant eye to secure the maximum of benefit for his minimum of service, is hardly fair either to the memory of the patriot or to the spirit of the Romans in their early and wholesome days.

It can hardly be said even now to represent the attitude of any nation with respect to the services of its military or political heroes, but it may very well be held as a typical illustration of the way in which most countries at present attempt to reward their inventors through the medium of their patent laws.

Whether the author half intended the Horatian episode as a satire, or whether (as is more probable) he is taking the story as a myth for whose social significance or historical bearing he cares nothing, it serves as a popular introduction to what else would be rather an abstruse subject—a subject, indeed, which few people would have ventured to use as the basis for a Friday evening discourse.

These, then, are the varied and highly readable contents of this small book. May the author long live with undiminished vigour, and give us many more of these recreations of a great mind.

OLIVER J. LODGE.

THE FLORA OF CEYLON.

A Handbook to the Flora of Ceylon: containing Descriptions of all the Species of the Flowering Plants indigenous to the Island, and Notes on their History, Distribution and Uses. By Henry Trimen, M.B. (Lond.), F.R.S., Director of the Royal Botanic Gardens, Ceylon. With an Atlas of Plates illustrating some of the more interesting Species. Part i. Ranunculaceæ—Anacardiaceæ. 8vo. pp. xvi. 327, with plates i.-xxv. (4to). Part ii. Connaraceæ—Rubiaceæ. pp. 392, with plates xxvi.-l. (Published under the authority of the Government of Ceylon. London: Dulau and Co., 1893-94.)

WHEN Dr. Trimen left England at the beginning of 1877 to undertake the directorate of the Ceylon Gardens, he had already formed the determination to elaborate the flora of Ceylon, and to publish a descriptive handbook of its botany. Those who knew him knew that this work would only be undertaken after due preparation and without undue haste, but that it would be pushed forward steadily and with all reasonable speed to a satisfactory consummation: and the two instalments now before us amply justify such a conclusion.

Dr. Trimen was fortunate in having had so careful a predecessor as G. H. K. Thwaites, whose "Enumeratio Plantarum Zeylaniæ," published in 1858-64, he rightly describes as "an extremely accurate and most valuable work," rendered more useful by the extensive series of illustrative specimens distributed by Thwaites to the principal herbaria of the world. The first work of the new Director was to bring this up to date, which he did in a "Systematic Catalogue," published in 1885, and arranged in accordance with the "Genera Plantarum." In the course of a visit to England in 1886, Dr. Trimen found time to examine the invaluable Ceylon Herbarium of Hermann, preserved in the British Museum, upon which Linnæus based his Flora Zeylaniæ; and he published a complete enumeration and identification of the plants therein contained, with notes, in vol. xxiv. of the *Journal of the Linnean Society*. Various new species have from time to time been published by Dr. Trimen in the *Journal of Botany*; and these, with the results of the rest of his work, are embodied in the "Handbook."

In his younger days, Dr. Trimen was known as a painstaking British botanist, and the "Flora of Middlesex," issued in 1869, for which he was mainly responsible, initiated a new departure in works of the kind. It was marked by thoroughness and accuracy; every page showed care and research: and these qualities are abundantly manifest in this Ceylon "Handbook." A careful correlation of the work of predecessors in the same field is another characteristic shared by each book; and in each there was need for this, for Middlesex plants have been recorded since the days of William Turner, while the Cingalese flora has been treated of by various authors from Hermann (1717) downwards.

The opening sentence of the brief introduction strikes the key-note of the work, with which the two volumes before us are in perfect harmony. "One principal object of this Handbook is to enable observers in Ceylon to ascertain the name of any plant they may find growing wild. When this is arrived at, they are in a position to learn all that may have been written about it in botanical and other literature, to appreciate its relationships to other plants, to trace its distribution in other lands, and to intelligently investigate its properties and uses." The book being intended as a guide to the flora of Ceylon, the descriptions have been made wholly from Ceylon specimens, and the information given under each species is restricted to what affects it as a Ceylon plant. Technicalities have been avoided so far as this could be done consistent with accuracy, and the definitions of orders and genera are only such as are shown by the species found in Ceylon.

The same restriction is carried out in the references to published books and papers, which are almost entirely limited to those wherein the species is noticed as a Ceylon plant. The Latin name is followed by the vernacular names when known, in Cingalese and Tamil. Thwaites's distributed numbers are always quoted, and figures of the species, preference being given to such as are known to have been made from Ceylon specimens, are referred to. After the description, made wherever possible from living specimens, come the general distribution and comparative frequency in Ceylon, and notes as to the times of flowering and colour of the flowers—points which are not always to be found in works of this kind, but which are very useful to the field botanist, especially if he be a beginner. In addition to these matters, information is frequently added on peculiarities in structure, or on the properties, products, and uses of the plants, with brief notes on the history and nomenclature of the species. The diagnostic description of each order is followed by keys for the rapid determination of the genera and species. Dr. Trimen has wisely refrained from the startling novelties in nomenclature which are to be met with in various transatlantic local floras, where they are more than usually out of place; and lays down dogmatically that "no botanical name in the modern taxonomic sense can be of earlier date than 1753, when Linnæus first definitely published his binominal nomenclature."

Our colonial floras are for the most part so largely drawn up from dried specimens by botanists unacquainted with the plants in a living state, that their usefulness in the field must be considerably diminished. Their value for herbarium work is undoubted, a fact of which one is continually reminded by the absence of any enumeration for some countries, and the unfortunate incompleteness of most of those which have been set on foot. New Zealand and Australia are well provided for, although the unflagging zeal of Baron Ferdinand von Mueller and his many helpers has already added so much to our knowledge that the "Flora Australiensis" is by no means up to date. Africa, both South and Tropical, is less fortunate, the "Flora Capensis" remaining where it was at the death of Harvey in 1866, and the "Flora of Tropical Africa," although now once more in progress, having come to a standstill in 1877. Thanks to the energy of Sir Joseph Hooker, we are within reasonable distance of the completion of the "Flora of British India"; and the useful "Index Floræ Sinensis," although not a descriptive flora in the sense of those mentioned, is proceeding steadily. But we greatly need floras for the South American continent; and Mr. Hemsley's handsome Botany of the "Biologia Centrali Americana" can hardly be considered exhaustive for the region of which it treats. To take a much more limited area, we have no compendium for Madagascar, and our knowledge of its wonderful flora has to be gleaned from a large number of scattered papers.

The existing floras, however, do not contain in any great degree descriptions drawn from living material; and it is fortunate that the small area to which Dr. Trimen is restricted has enabled him to treat his plants in this rational manner. It is to be regretted that his aims will be to some extent frustrated by the unnecessarily bulky form which his "Handbook" has assumed. The two volumes already issued contain between seven and eight hundred pages, and at least as many more must be occupied by the remainder of the work. The paper employed is much too thick, and by a different arrangement of type considerable saving of space might have been effected, without materially detracting from the appearance of the volumes. It may well be, however, that when the work is completed, Dr. Trimen will issue an abridgement for use in the field, which would occupy to the present handbook the position which Mr. Hayward's "Botanist's Pocket-book" holds with regard to our larger British manuals.

A word must be said in praise of the excellent quarto plates which accompany the "Handbook." They are selected from a series of several thousand drawings, begun in 1823, when Mr. Moon was Director of the Gardens, and preserved in the library. These are entirely the work of three members of one family. Haramanis de Alwis, who has just died at a very advanced age, held the post of draughtsman to the Gardens for thirty-eight years, and was succeeded by his sons, one of whom has held the post for twenty-seven years. Most of the drawings here reproduced are his work.

James Britten.

OUR BOOK SHELF.

Biskra and the Oases and Desert of the Zibans. By Alfred E. Pease, F.R.G.S. Pp. 112. (London: Edward Stanford, 1894.)

Having spent six months in Biskra, Mr. Pease thought it worth while to use the knowledge gained during this period to supplement the comparatively slight information given in handbooks to the provinces of Oran, Algeria, Constantine, and Tunisia.

Biskra, Biskra-en-Nokkel, or Biskra aux Palmiers, is a beautiful green oasis, from which visits can be conveniently made to neighbouring oases in the Sahara. The oasis is about five kilometres in length, and its width ranges from one hundred to seven hundred metres. The town is situated 111 metres above sea-level in lat. 34° 52′ N., and long. 5°42′ E. Upon the oasis flourish 160,000 date palms, 6000 olive trees, as well as fig, orange, citron, and lemon trees. The people are kindly and unsophisticated, and the climate is delightful during most of the year, being specially suitable for persons suffering from pulmonary complaints. Tourists who like to leave the beaten track, and seekers after a refuge from an English winter, will be attracted to Biskra if they read Mr. Pease's little book.

Practical Photo-Micrography. By Andrew Pringle. (London: Iliffe and Son, 1894.)

WORKERS in this fascinating branch of science will no doubt be well acquainted with the author's large treatise, a book which is suitable, more especially, for those who wish to devote themselves very considerably to this kind of work, and to enter into all the details connected with it. The publication of the present book will not appeal so much to the interest of this class of readers, but will be welcomed more by those who wish to get a good working idea of photo-micrography. With this intention this manual has been kept within very reasonable limits, is decidedly explicit, and thoroughly practical. In the seventeen chapters the reader is led through all the manipulations, from the choice of instruments to suit his purse, kinds of plates to use, colour treatment of objects, and general photographic procedure, &c., to those dealing with good hints on lantern-slides, cover-glass preparations, and section cutting and staining. The text is accompanied with numerous well-chosen illustrations, and the get-up of the book is all that could be desired. It may interest our readers to know that in the above pages we are informed that no apparatus is recommended on hearsay, or is any statement made or step suggested "outside the knowledge and practice of the writer."

Twelve Charts of the Tidal Streams on the West Coast of Scotland. By F. Howard Collins. Small folio. (London: J. D. Potter, 1894.)

MR. COLLINS has elaborated the work of the Hydrographic Office by producing a set of charts showing the direction of the tidal streams on the west coast of Scotland at intervals of one hour from the time of high water at Greenock. The twelve charts are prefaced by a note describing how they should be used, and a tide-table. The sources of his information are duly acknowledged, and the work was carried out with the assistance of Captain Wharton, the hydrographer. The work is similar in scope and method to the atlas of tides in the North Sea by the same author. It is a serious defect that no method has been adopted for distinguishing the velocity of the tidal streams, or at least of indicating the furious tidal races which occur in many channels and off many headlands. So far as the direction of the streams is concerned, this compact set of charts should be useful to yachtsmen, and is not without interest for oceanographers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On Some Methods in Meteorology.

IS it not a *desideratum* in our rainfall records that they should give, with the amount of rain, not mere rain-days (or days' rain), but the exact time (or as near an approximation to that as possible), during which rain has fallen? This might at least, surely, be expected from our observatories and better equipped stations. Some of our continental neighbours are before us in this respect. Thus, the Geneva record, for more than thirty years, has contained as one of its items, "hours of rain." May we not then ask why an institution like that at Greenwich, goes on giving the number of days on which rain fell; a momentary sprinkle being thus put in the same category with an incessant downpour of twenty-four hours?

One might here remark on the great fulness of detail and excellence of arrangement in records of the weather at various continental stations (*e.g.* Pola); which are apt to lead us into invidious comparisons.

With regard to measurement of bright sunshine, the burning-glass method leaves much to be desired from a scientific point of view, and the photographic method seems likely to supplant it increasingly. But might not the concentrated rays be got to produce some other physical effect (metal-expansion?) than burning paper, yielding a more exact record of the amount of sunshine?

Again, may it not be said that the graphic method is far too little utilised in meteorology? Probably nine persons out of ten would agree that they apprehend a truth of statistical nature, a numerical variation, much better every way—more quickly, more clearly, more retentively—through a graphic curve, than through a column of figures, or a verbal description. Yet we have only to turn over the pages of our meteorological publications (and others dealing with figures) to see that this method is used very sparingly. And it is easy to pick out cases where the want of it is felt very plainly. I can recall one such case in a valuable paper by one of our ablest meteorologists (Dr. Buchan), published a short time ago in the Scottish Society's *Journal*, on mean temperature in the neighbourhood of London during 130 years. Here we find paragraph after paragraph, over several pages, describing how certain smoothed values of temperature had varied, now above, now below the line of average. This imposes a considerable strain on the imagination, proves, I am afraid, somewhat tedious reading, and leaves, perhaps, no very distinct impression after all. A simple diagram, giving the curves themselves, would here be an effective labour-saving contrivance, both to the author and his readers.

But to multiply diagrams means great expense, it will naturally be urged. Now the cost of a well-finished diagram (and we all like such) is no doubt considerable. But with the aid of photography diagrams can now be reproduced very cheaply; and it seems to me open to consideration whether we might not do well to sacrifice a little fineness and finish, for the sake of a freer and more frequent use of the method, and the greater clearness of comprehension which that would ensure. Moreover, such diagrams are not to be regarded as a mere addition, and therefore requiring more space; they may even mean an economy of words and space. There are frequent cases in which it is not necessary to give all the figures involved; the object being merely to point out a relation, the salient features of a curve. And if the diagram can be relied upon for accuracy, little need be said about it, in some cases; it tells its own tale. Then again, the photographic reproduction of an author's diagram may even prove a gain in accuracy; some intermediate perils are avoided. I believe, in fine, that the graphic method has a great future before it, not only in science, but in other domains; and the sooner we set about developing its capabilities to the utmost, the better.

A. B. M.

Magnetism of Rock Pinnacles.

IT is well known that the Riffelhorn powerfully affects the compass, and the like has been observed on other peaks in Switzerland; but I have never seen any record of similar observations in this country.

Four years ago, on a visit to the Lizard, accident drew attention to a strong influence on the compass exhibited by a crag on the moors near Kynance. I have taken the opportunity of a visit this year to ascertain whether that were a solitary case. I find that such influence, though not general, is by no means uncommon. Most of the rocks in which it was observed were serpentine; it occurred also in hornblende schist; there were no sufficient opportunities of testing the other rocks of the district. The influence was exhibited only in rather prominent crags, but among them often in lower adjacent blocks, as well as in the absolute summits. At a few yards' distance it was always imperceptible.

I saw no traces in any case of the crag having been struck by lightning. This was the only point to which I gave attention; but it would be natural also to inquire if all kinds of rock can possess the property, if wet or weather affects it, and if it be temporary or permanent.

I used a common pocket compass, taking the bearings of some distant object, first a few feet off, then in four surrounding positions as near as the compass could be held to the stone I was testing. The effects varied from no deviation or slight, to cases where the needle swung completely round while still a foot or two away. Among the strongest noted were some crags north of Kynance Cove, and some on a headland about a quarter of a mile south of Coverack, both consisting of serpentine. Any one whose holidays take him to a rocky neighbourhood, may find interest in carrying out similar observations.

Cockfield, July 28. E. HILL.

The Aurora Australis.

THE following report of a brilliant Aurora, seen in the Indian Ocean, will be interesting to many of your readers :—

THE AURORA AUSTRALIS.—When sailing along the Indian Ocean from the Cape of Good Hope to Australia, and in about the vicinity of St. Paul's Island, longitude 76° 17′ east, latitude 4 1°22′ south, an Aurora Australis of remarkable grandeur was seen by those on board the ship *Isle of Arran*. Describing it yesterday, Captain Carse said his chief officer and he had a beautiful view of the phenomenon on two nights (April 28 and 29). It was a very fine sight, the streams of light in spraylike form shooting upward for fully thirty degrees, lighting up with wonderful brightness the whole southern part of the heavens. Some very bad weather was experienced by the ship in the locality of St. Paul's. High confused seas prevailed with a strange continuance of easterly winds.—*Herald*, May 23.

No report was received that this was seen in any part of Australia, and I have seen no report that the brilliant Aurora seen in the northern hemisphere on March 30 was seen in this part of the world. H. C. RUSSELL.

P.S.—I got position and date from Captain Carse.

Absence of Butterflies.

THE most common butterflies—as, for instance, *Pieris Brassicæ, Coleas Rhamni, Vanessa Urticæ*—were very rare hereabouts this spring too (*cf.* NATURE, vol. l. p. 225), and the same has been observed at Frankfort-on-Maine. As for *Pieris*, this scarcity might have been predicted with certainty last autumn, as, here and at Frankfort, the cabbage-plants in fields and gardens were almost exempt from their usual ravagers, the caterpillars of the said species. If the extraordinary dryness of last year's summer should be connected with these facts, it cannot have acted through the damage done to the food-plants, but must have operated more directly upon the insects themselves. D. WETTERHAN.

Freiburg, July 28.

A STRANGE LIGHT ON MARS.

SINCE the arrangements for circulating telegraphic information on astronomical subjects was inaugurated, Dr. Krueger, who is in charge of the Central Bureau at Kiel, certainly has not favoured his correspondents with a stranger telegram than the one which he flashed over the world on Monday afternoon :—

"Projection lumineuse dans région australe du terminateur de Mars observée par Javelle 28 Juillet 16 heures Perrotin."

This relates to an observation made at the famous Nice Observatory, of which M. Perrotin is the Director, by M. Javelle, who is already well known for his careful work. The news therefore must be accepted seriously, and, as it may be imagined, details are anxiously awaited ; on Monday and Tuesday nights, unfortunately, the weather in London was not favourable for observation, so whether the light continues or not is not known.

It would appear that the luminous projection is not a light outside the disc of Mars, but in the region of the planet not lighted up by the sun at the time of observation. The gibbosity of the planet is pretty considerable at the present time. Had there been evidence that the light was outside the disc, the strange appearance might be due to a comet in the same line of sight as the planet. If we assume the light to be on the planet itself, then it must either have a physical or human origin ; so it is to be expected that the old idea that the Martians are signalling to us will be revived. Of physical origins we can only think of Aurora (which is not improbable, only bearing in mind the precise locality named, but distinctly improbable unless we assume that in Mars the phenomenon is much more intense than with us), a long range of high snow-capped hills, and forest fires burning over a large area.

Without favouring the signalling idea before we know more of the observation, it may be stated that a better time for signalling could scarcely be chosen, for Mars being now a morning star, means that the opposition, when no part of its dark surface will be visible, is some time off.

The Martians, of course, find it much easier to see the dark side of the earth than we do to see the dark side of Mars, and whatever may be the explanation of the appearances which three astronomers of reputation have thought proper to telegraph over the world, it is worth while pointing out that forest fires over large areas may be the first distinctive thing observed on either planet from the other besides the fixed surface markings.

THE INTERNATIONAL GEOLOGICAL CONGRESS.

THE sixth meeting of this Congress will be held at Zurich, commencing on August 29. The Congress was founded at Philadelphia in 1876, the first meeting being held at Paris in 1878 ; subsequent meetings have been—Bologna, 1881 ; Berlin, 1885 ; London, 1888 ; Washington, 1891. As one result of discussions at the Paris meeting, committees were appointed in different countries to draw up reports on classification, nomenclature, &c. At Bologna these reports were received and discussed, the greater part of the time being thus spent. An additional committee was then appointed to prepare a geological map of Europe ; this work is still in progress, but the committees on nomenclature, &c., have practically lapsed, and but little attention has been paid to such subjects at the more recent meetings. At the Washington Congress a committee was appointed to report on the Bibliography of Geology. Lists of bibliographies for each country were to be prepared, and printed in the report of the Washington meeting ; but the volume has recently appeared without such lists. It is hoped that the committee will submit a report on this important subject at Zurich.

Prof. E. Renevier, of Lausanne, is nominated President of the Zurich meeting. He has been an active member of the Congress from the commencement, and the excellent arrangements for the forthcoming meeting are no doubt largely due to his powers of organisation. Prof. A. Heim, of Zurich, is Vice-President ; Prof. H. Golliez, of Lausanne, is Secretary ; M. C. Escher-Hess, of Zurich, is Treasurer. This apparently exhausts the list of officers of the organising committee, democratic Switzerland dispensing with "president of honour," "honorary members of committee," &c., which have largely figured in the lists of previous Congresses, even in that of Washington. Not having such honorary lists upon which to draw for funds, the subscription for membership is double that previously charged, but is even now only 25 francs.

The arrangements made for the Zurich meeting differ somewhat from those of previous sessions. There will be no formal discussion on nomenclature, classification, &c. ; but, after transacting general business, the Congress will divide into three sections, meeting simultaneously. The subjects for discussion will be : (1) General and Tectonic Geology ; (2) Stratigraphy and Palæontology ; (3) Mineralogy and Petrography. Amongst the papers promised are: K. von Zittel, Palæontology; M. de Bertrand, Structure of the Western Alps; A. Heim, Geology of the Environs of Zurich; A. Michel-Lévy, the Unification of Petrographical Nomenclature; E. Suess, Tectonic Geology. There will also be papers on glacial geology; and Captain Marshall Hall will submit a proposal for an international survey and record of glaciers.

At the Zurich meeting, however, papers and discussions will form but a comparatively small part of the work. Excursions have always played a prominent part in the arrangements for the various meetings; but hitherto they have been mainly made after the close of the Congress. At Zurich the Congress will practically divide into five excursion sections, starting on September 3, traversing the Alps in different directions, and all converging on Lugano, where the closing meeting will be held on September 14. These excursions would alone make the Zurich meeting memorable; they have been planned to include the most interesting districts of the Swiss Alps, and to facilitate the study of many intricate problems concerning the structure of the mountains and the petrographical nature of the rocks. After investigation of the northern flanking ranges of folded secondary rocks, the central crystalline zone will be crossed, and in some cases glacial phenomena can be well studied. Prof. Heim will conduct a party over the country which he has so well described, starting from St. Gall and crossing the Alps of Glarus, the Vorder Rhein, and the eastern Lepontine Alps; Prof. Schmidt will conduct the party from Schwtz over the St. Gotthard; Prof. Baltzer, starting at Lucerne, will take a line some miles further west; Prof. Schardt, starting at Bulle, will traverse the western end of the Bernese Alps and part of the Pennine Alps, and will reach Lugano by the Simplon. These four excursions are for pedestrians only, and those only are invited who are accustomed to long walks and climbing, hard beds, and frugal living. A more elaborate circular tour in the Alps will be conducted by MM. Ruffieux and Ruchonnet, of Lausaunne; this will traverse a wider district, and the work will be done with less fatigue. Profs. Renevier and Golliez will be the scientific directors of this tour.

Supplementary excursions will start from Lugano after September 14, one of which, conducted by Profs. Bruckner, Du Pasquier, and Penck, will study the glacial phenomena of the Italian Lakes, thence by the Tyrol to Munich, and finally to the Lake of Constance.

Before the Congress there will be excursions in the Jura—five for pedestrians—as follows: French Jura, M. Schardt; Vaudois Jura, M. Jaccard; Bernese Jura, M. Rollier; Bâle and the Argovian Jura, M. C. Schmidt; Argovian Jura and Soleure, &c., M. Murlberg. There will also be a long circular tour in the Jura by MM. Ruffieux and Ruchonnet, with MM. Renevier and Gollitz as scientific directors; the latter part of this will be much devoted to glacial questions, and will therefore be preparatory to the special glacial excursion starting from Lugano.

Arrangements have been made for inclusive charges for all these excursions. For the pedestrian tours, they are 50 or 60 francs for the Jura excursion of five or six days each, and 300 francs for the circular Jura tour of fourteen days.

For the longer excursions in the Alps, after the Congress, the prices are from 150 to 250 francs for the pedestrian tours of eight to thirteen days, and 400 francs for the circular tour of thirteen days.

A guide-book to the various excursions is in preparation. This will contain about 300 pages of text, and will be amply illustrated by plates and sections; it will form a most useful handbook to the geology of Switzerland. A new geological map will also be published, on the scale of 1 : 500,000; this will be a reduction of the official maps of the Swiss Geological Survey, which is now completed.

Special guide-books to the important geological collections at Lausanne and Zurich are in preparation. As usual at such meetings, geological maps and other publications, photographs, specimens, &c., will be exhibited.

W. TOPLEY.

THE DISCS OF JUPITER'S SATELLITES.

THE discussion which is now taking place between two well-known observers—namely, Profs. Pickering and Barnard—as to the forms which the satellites of the planet Jupiter assume at various times, is one not only of absorbing interest, but, moreover, of a nature somewhat delicate, for the bodies in question are so minute as to baffle any but the very best and trustworthy observers. Such observations, then, to be of any value at all, must be either made in the clearest of atmospheres with a moderately large aperture, or in a moderately clear atmosphere with a very large aperture. Considering these two conditions, one would doubtless think that the larger the instrument the more chance there would be of finding out the shape of a body, and with a very clear atmosphere in addition these chances would be very greatly increased. On the other hand, however, we have the facts still in our mind of Schiaparelli's wonderful observing powers, which enabled him to notice the doubling of the canals of Mars with his small aperture long before they were declared "double" by other observers. In this case one would have thought that such an observation would have been more easily observed with large apertures than with the small telescope which was at his disposal.

Let us, however, turn to the facts at hand with regard to the satellites that are now under discussion; but first a few words with regard to the instrumental equipment employed and the observing stations.

Prof. Pickering's observations have been made at the Observatory that is situated near Arequipa, in Peru, at an altitude of more than eight thousand feet, where the sky during a large part of the year is nearly cloudless. The telescope employed has shown that there is a remarkable degree of steadiness in the atmosphere, and night after night atmospheric conditions prevail, which, as he says, "occur only at rare intervals, *if ever*, in Cambridge." Several of the diffraction rings surrounding the brighter stars are visible, close doubles in which the components are much less than a second apart are readily separated, and powers can be constantly employed which are so high as to be *almost useless* in Cambridge. In fact, he says that in many researches the gain is as great as if the aperture were doubled. The aperture of the refractor employed is 13 inches.

Prof. Barnard has made his observations, on the other hand, with the now well-known 36-inch refractor of the Mount Hamilton Observatory, a description of which here would be unnecessary; suffice it to be mentioned that Prof. Burnham has increased the number of double stars by about 200 during his brief use of this instrument, most of which are beyond the reach of the majority of telescopes.

Turning now to the observations of the satellites themselves, we find the first account of Prof. Pickering's observations in the March number of *Astronomy and Astro-Physics* for the year 1892.

On October 8, a series of measurements was made of the diameters of the satellites. On the next evening it was noticed that the disc of the first was not circular but very elliptical. Early observations on the tenth confirmed the measurements made on the eighth, but after an examination of the other satellites the first was again measured, when, as Prof. Pickering says, "to my astonishment, instead of showing an elliptical disc, it showed one that was perfectly circular, precisely like the other satellites." He further goes on to say that the disc gradually began to lengthen again and assume the elliptical form. From these observations it was concluded that the first satellite had the form of a prolate spheroid or ellipsoid, or, in other words, was egg-shaped. A week later each of the other satellites had been recorded to some extent elliptical. Curious to relate, the three outer satellites, according to the observations, appeared *shortened* equatorially, not *lengthened*, showing that they did not seem to revolve round their minor axes.

It was not surprising to notice that Prof. Pickering was at first rather sceptical about the truth of these observations, and assuming that they might be produced optically or otherwise, he employed every method which would eliminate such ambiguity. These researches gave a negative result. It occurred to him, also, that the effects seen might be due to light and dark spots, suitably placed upon the surface, but during the time of the satellites' transits, and when they were about to disappear, no such spots were seen, although some surface markings on the first, third, and fourth satellites have been discovered.

The results to be gathered from the observations made up to this time may be summed up as follows :—

(1) The first satellite is a prolate ellipsoid revolving about one of its minor axes in a period of 13h. 3m. ; and (2) the discs of the second, third, and fourth satellites at regular intervals assume the forms of ellipses, and these periodic changes are presumably produced, as is thought, by rotations upon their axes.

The second contribution on the form of the satellites appeared in the May number of the same journal for the following year, and Prof. Pickering opens with the statement that "what have appeared to be most natural suppositions have been found so frequently to be contradicted by the facts, that it seemed best to take nothing for granted with regard to them." The observations here deal first with the direction and period of rotation, giving as a result a probable retrograde motion of rotation for the first satellite.

With regard to the change of forms, it was noticed that the first satellite on January 13 appeared distinctly shortened equatorially when at its minimum phase, the phenomenon lasting thirty-four minutes ; while the second satellite is occasionally described as appearing long, like the first. At the maximum phase the second, like the two outer satellites, has appeared round ; and the third, at some of its minima retains the elliptical phase for a longer time than at others. Thus, for instance, it remained short for the three days, January 13, 14, and 15, consecutively.

The next account of further observations are contained in a long paper entitled "The Rotation of Jupiter's Outer Satellites," which appeared in the following June number. The observations here are given more in detail, but we will confine ourselves to the main points, commencing with those relating to the largest and most easily observed of the group, *i.e.* the third. This satellite, according to Prof. Pickering, presents an elliptical phase twice during its revolution in its orbit at an interval of about thirty-four hours after passing conjunction. When on the eastern side it presents an elliptical disc, and the inclination of the major axis to the orbital planes is clearly marked and has been measured on several occasions, the mean value being $-10^{\circ}\cdot5$ P. angle. We have here also some important observations of details visible on this disc of the satellite, which, as Prof. Pickering says, "can without much difficulty be made out."

A careful study shows that the marking usually appears forked, and is sometimes turned to the right and sometimes to the left, and at other times it is seen double, appearing like the letter X turned on one side. Another appearance of the markings on the surface of the same satellite is as if an equatorial belt on one side had been drawn out in both directions of the poles, its breadth increasing as the limb is approached, being in fact trumpet-shaped. A measurement of the position angle of the axis of the belt gave $+15^{\circ}\cdot5$.

Special precautions were taken to find out whether the belt were a genuine phenomenon, or an illusion due either to the instrument or the observer, but these resulted in it being declared real. The observations for the determination of the rotation of this satellite implied a period of rotation coinciding with that of the revolution of the satellite in its orbit.

A recapitulation of the facts relating to the third satellite observed up to this time may be made here :—

Two observers see the disc flattened at regular intervals, and agree upon direction of flattening. Both see a belt in same position, direction, and character of detail, and both remark that the observations are not very difficult, but quite evident when attention is called to them.

The details in the other satellites seem to be more difficult to see than those on the third. The direction of the bands (one or two) in the first satellite lies in an approximately north and south line, while on only one occasion there was detail detected on satellite II., and this consisted simply of a small patch or spot.

The observed facts with regard only to the forms of these discs are :—

The shape of the first is elongated. The regularly recurring changes of shape of the discs of the outer satellites (caused apparently by rotation). The change of position angle of the major axis of the third, and probably of the fourth in different parts of their orbits.

The peculiar behaviour of satellite III., which in October and November was recorded as shortened in the polar direction, but which was afterwards recorded upon two nights as perfectly round, when it should have exhibited its maximum ellipticity. The frequently recorded lengthening (equatorially) of satellite II., which is not corroborated by recent observation. Apparent irregularities in period and ellipticity of the second and, perhaps, the fourth, and the occasional irregular non-elliptical shape of the disc of the third.

Such, then, is the sum total of the observations which up to that time had been made by Prof. Pickering, and we will now turn our attention to the re-examination of the satellites by Prof. Barnard with the help of the great Lick refractor. (*Astronomy and Astro-Physics* for April, 1894).

He commences by telling us that the satellites I., III., and IV. often undergo singular transformations of apparent form during certain stages of their transits across the face of Jupiter, but he had never "seen any of these moons other than round when off the disc of the planet."

In the latter end of the year 1893 to the beginning of 1894, with a power of 1000 diameters, and sometimes higher, he made numerous observations, with the object of detecting, if present, deviations from the disc forms.

The results showed that no such deformations were observed, and Prof. Barnard is inclined to think that the surface markings of the satellites themselves, when near the edges of the discs, might readily cause apparent distortions in these satellites, as they certainly do so when the satellites are in transit, especially when very high magnifying powers on a small telescope are employed. It is curious, he adds, that such deformations should escape detection with our great telescope, even with the most casual observations, considering how conspicuous are the distortions recorded at Arequipa. It is of interest to note one or two remarks accompanying some of the observations, thus :—

	h. m.	
1893 Dec. 3	...	I. is near transit, following, it appears slightly elongated towards Jupiter.
1893 .. Dec. 11	9 18	... I., II., III., each is round, IV. seems a little deficient on following side, as if a slight phase existed, &c.
1894 ... Jan. 28 ...	6 50	... I., II., III. are round, IV. is slightly deficient on following side, as if a slight phase or a dark area existed in it.

The time referred to above is Standard Pacific time, 8 hours slow on Greenwich.

The notes, however, are generally of the following type, a few of which may be mentioned here.

	h. m.	
1893 ... Aug. 28 ...	14 30	... All four are round.
Sept. 3 ...	13 0	... All four are round.
Sept. 24 ...	12 48	... III. is perfectly round.
Sept. 25 ...	15 0	... All four are round and clearly defined.
Oct. 1 ...	16 40	... I. and III. perfectly round.
Nov. 6	11 54	... III. is beautifully round.
	14 40	... III. is perfectly round.
Dec. 10 ...	9 25	... All four are round. North Pole of III. is white.

These observations show that either the satellites on the whole appear generally round, or that the Lick observers have been so unfortunate as to observe them just at those times when the circular discs were to be seen. This seems at first thought to be very improbable, for the reason, as Prof. Barnard himself remarks, that the Arequipa observations indicate distortions that are apparently so very conspicuous.

In the June number of *Astronomy and Astro-Physics* (p. 423), Prof. Pickering gives in reply a short note to the observation made by Prof. Barnard. There are here, also, some measures of the position angle of the elongation of the first satellite as secured by himself and Mr. Douglas upon six different nights, a copy of which is below.

I. Satellite.

Time	P.A.	Dev.	Obs.	Diff.	Corr.
				°	
1892, Nov. 28 ..	100·5	3·7

		± 4·8		+ 7·1	± 2·2

Each measure is the mean of six readings, taken alternately in opposite directions. These measures show that the observations are fairly concordant, only that there seems to be a mean personal correction of about 7°·1. The first column gives the date of observation, the second the observed position-angle of the major axis of the disc, the third the average deviation of the readings which combined give the individual measures, the fourth the observers, the fifth the differences between these results, and the sixth these differences corrected by the constant angle 7°·1.

In the last column, the mean 2°·2 indicates the average difference between the corrected measure of the two observers upon any night, which shows a remarkable accordance between the measures.

There can be no doubt that there was some peculiarity about this satellite that was under measurement at the time, a peculiarity which, as Prof. Pickering says, was apparent when it was not in transit, but which vanished at regular intervals of 6h. 32m. Why Prof. Barnard has not been able to witness what seems to be a very distinct phenomenon, if it be not really "personal," seems to raise considerable surprise. Although Prof. Pickering does not deny the existence of the equatorial belts, yet he will not accept it as an explanation of the changes of form noticed, for he says, "such a belt could not have produced the effects observed by us in Arequipa."

A further investigation on the forms of the discs has recently been made by Prof. Schaeberle (*The Astronomical Journal*, No. 321, p. 70), with the intention of detecting, if possible, the rapid change of phase which Prof. Pickering's observations so strongly advocate. The results showed, however, that, by tabulating the ratios of the measured major and minor axes of the several elliptical discs, a practically constant form for the outline was always obtained. We may mention here that to Profs. Campbell and Schaeberle the first satellite appears round only when "it is near to or projected on the disc of Jupiter, and elongated in the direction of the planet's equator in all other positions."

In judging between the weights that ought to be applied to observations made at Arequipa and Mount Hamilton, a fact here is mentioned that is by no means insignificant in showing the superiority, in this case at any rate, of the Mount Hamilton observations over those made at Arequipa.

The observations in question relate to the abnormal forms of the shadows of the satellites, the true forms of which were observed at the Lick Observatory by Prof. Schaeberle and by other observers at different places and times.

The shadows of these satellites as they pass before the disc of Jupiter become at times apparently distorted to observers on the earth's surface, owing to the oblique illumination of the satellites in some positions of the earth, and to the spherical nature of Jupiter's surface.

These distortions reach sometimes very considerable proportions, more considerable, in fact, than the changes of shapes of the satellites, as observed by Prof. Pickering. This being so, it is curious indeed that from Arequipa we have, as far as is known, no mention of such shadow distortions at all, and as Prof. Schaeberle remarks, "one would naturally suppose that an observer, after having discovered, as he believed, a periodic variation in the form of a satellite, would seek to verify his results by examinations of the satellite's shadow during its transit across the disc of the planet"

An idea of the size of the distortions alluded to may be gathered from Prof. Schaeberle's statements that, at the time of the Arequipa observations in January of last year, the longest (longitudinal) diameter of every shadow just after the ingress on the visible disc of Jupiter was "more than twice the breadth of the shadow, while at egress just the reverse condition of things existed."

Such, then, is the present state of affairs. Prof. Pickering sees these small bodies regularly changing their shapes; Prof. Barnard sees them always perfectly round; while Profs. Schaeberle and Campbell see them only round when near to or projected on the disc, and at all other times constantly elongated.

The only conclusion that can be drawn, if one is at liberty to draw any at all, is that in the estimation of the shapes of such small bodies a great amount of personal error is liable to creep in, and the estimation of such must be left for future determination.

It would be interesting, however, to know how the observations would differ, if Prof. Barnard and Schaeberle had the use of the Arequipa instrument at a favourable opportunity, and Prof. Pickering the Mount Hamilton refractor.

W. J. S. LOCKYER.

GEOLOGY AND SCENERY IN IRELAND.[1]

MR. R. WELCH, of Belfast, well-known as a photographer of Irish scenery, has of late years utilised his intimate knowledge of the country, and his keen judgment as an artist, in the preparation of special series of photographs illustrating archæological and scientific features. The brilliant exposures of volcanic and sedimentary rocks along the coast of Co. Antrim have led him to form a group of pictures which might serve as a companion to any ordinary text-book of geology; and he is rapidly extending the series by additions from the counties of Down, Donegal, and even from the far south-west. As I have had the pleasure of assisting Mr. Welch in the production of his first geological catalogue, I can make no comment on its character as a publication; but I need not hesitate to point out what valuable aid is being given to science by the recording of the physical features of Ireland, not haphazard in a series of general landscapes, but with a special geological eye. The excursions of the Belfast Naturalists' Field Club have been the means of calling attention to exposures in places outside the ordinary tourist-track; and the officers of the Geological Survey of Ireland have always been willing to give information as to suitable illustrative localities.

Two samples will show something of the detail and the range of these photographic records. Fig. 1 shows one of the fine quarry-sections on Cave Hill, Belfast. The chalk below, with lines of flints, and the basaltic lavas of the upper plateau, are always an effective contrast; but at this point dykes of dolerite are numerous, cutting through both series. The large one in the centre of the picture is columnar in its upper portion, and has a somewhat wavy course. A smaller sinuous dyke climbs towards it from the right. In the left of the original photograph, a delicate bifurcating intrusive sheet is clearly seen near the top of the horizontal lavas. Fig. 2 is a still more specialised illustration. The whole stream of Glenariff is seen pouring into a pot-hole some four feet across, and the smooth sides of the hole, and the swirl of waters in its still active portion, have been admirably rendered. On the left, the rock, which is a red Triassic sandstone, shows the grooving and smoothing action of the stream. It would be interesting to photograph this spot again after an interval of twenty years.

FIG. 1.—A Quarry Section on Cave Hill, Belfast.

The reproduction of such views as these in the form of lantern-slides makes them still more valuable to teachers. It is pleasant to know that Co. Antrim has its geological features now recorded for us more completely than those of any other county in the British Isles: and Mr. Welch may be congratulated on undertaking this and other scientific missions in the midst of more immediately popular professional work. The recen

[1] A Catalogue of Geological Irish Views, by R. Welch, 49 Lonsdale Street, Belfast.

visit of the Geologists' Association to Ireland did much to direct attention to the geological features, as well as to the scenic beauties, of the eastern coast; it may be hoped that Mr. Welch's photographic series will form an introduction and an inducement to another visit, this time to the fascinating variety of igneous rocks and Mesozoic strata in the north.

GRENVILLE A. J. COLE.

FIG. 2 — Pot-Hole excavated in Triassic Sandstone, Glenariff.

NOTES.

WE are pleased to learn that Prof. Prestwich, F.R.S., has been made Foreign Member of the R. Accademia dei Lyncei, Rome, for geology and palæontology.

WE regret to hear of the death, from typhoid fever, of Prof. G. H. Williams, of Baltimore. The United States has of late years produced a band of admirable petrographers, amongst whom Prof. Williams has long held a foremost place. His early death will be lamented by a large circle of friends in Europe.

WE are sorry to have to record the death, at the age of sixty-six, of the Rev. Edward Hale, who had been for some years the senior science master of Eton College. Mr. Hale died on July 25.

THE annual meeting of the Institution of Mechanical Engineers was opened at Manchester on July 31, and is proceeding. Prof. Kennedy is presiding.

THE sixty-second annual meeting of the British Medical Association is taking place at Bristol under the presidency of Dr. E. Long Fox, who delivered his presidential address at the evening meeting of Tuesday last.

THE British Pharmaceutical Conference began its annual meeting at Oxford on Tuesday, July 31, when Mr. N. H. Martin, of Newcastle-on-Tyne, took the chair, and delivered an address.

THE autumn meeting of the Iron and Steel Institute of Great Britain, which this year takes place at Brussels, from August 20 to 24, will probably be very well attended, about 500 members having already intimated their intention of being present. The arrangements for the meeting are being organised by an influential local reception committee, of which M. Gillon, president of the Society of Engineers of Liege, is chairman, in conjunction with the general secretary of the Institute, Mr. Bennett H. Brough. During the meeting, excursions will be made to the Antwerp Exhibition, the Mariemont Collieries, the Couillet Steel Works at Charleroi, the works of the Cockerill Company at Seraing, and the Angleur Steel Works at Liege. The programme of papers to be read and discussed is a long one, there being no less a number than ten arranged for. The first on the list is, "On the Use of Caustic Lime in the Blast Furnace," by Sir Lowthian Bell. Other papers are to be contributed by Messrs. R. A. Hadfield, T. W. Hogg, H. C. Jenkins, W. G. M'Millan, John Parry, and D. Selby-Bigge, respectively, and there are to be two papers of local interest, written by Belgian engineers. Their titles are, "On the Coal-Mining Industry of Belgium," by M. Briart, President of the Society of Engineers of Hainaut; and "On the Iron and Steel Industries of Belgium," by M. A. Gillon, President of the Society of Engineers of Liège.

THE Medical Congress which is to be held in Calcutta from December 24 to 29 next, and to which we briefly referred in our issue of July 5, is, according to present arrangements, to be divided into six sections, viz.: I. Medicine and Pathology. II. Surgery, including Ophthalmology. III. Obstetrics and Diseases of Women and Children. IV. Public Health. V. Medico-legal Medicine and Insanity. VI. Pharmacology. It is hoped that medical men from countries other than India will co-operate to make the Congress a success. Special efforts are being made to secure the comfort of visitors.

THE programme of the one hundred and eleventh meeting of the Yorkshire Naturalists' Union has been issued. The meeting will be held on August 6, at South Cave, for the investigation of the neighbourhood of Drewton Dale, Weedley Springs, and Wold Dale. The sciences of geology, botany, vertebrate zoology, entomology, and conchology will be officially represented by members told off for the purpose; and if the weather be favourable, the meeting will, no doubt, prove as popular as those on former occasions.

THE eighth meeting of the International Ophthalmological Congress will be held at Edinburgh in the second week of this month, under the presidency of Dr. Argyll Robertson. It is thought that about 300 ophthalmic surgeons will be present. The last meeting took place at Heidelberg in 1888.

THE spring of next year will see established at Earl's Court an exhibition, on a large scale, devoted to the products of India.

THUNDERSTORMS occurred over the southern and midland parts of England on Sunday, accompanied by heavy falls of rain, amounting to nearly one inch in several places. Over the southern and south-western parts of England, as well as in the south of Ireland, the total rainfall during July has greatly exceeded the average, in many places being double the usual amount, while at Jersey the total was about seven inches, which is nearly three times the average for July, and it is the heaviest fall in that month during the last twenty-nine years. In the east of Scotland and north-east of England the rainfall for the month was rather less than the average.

WE have received from Dr. W. Doberck, a copy of the observations and researches made at the Hong Kong Observatory in the year 1893. The meteorological observations are given for every hour, while the means and various deductions from them have been carefully arranged in tables in a convenient form for future use. The mean temperature during the last ten years was 71°·3, the maximum was 93°·9, and the minimum 32°·0. The average rainfall for a period of thirty years was 90·17 inches; rain mostly falls between May and August. Dr. Doberck gives a useful summary of the climate investigated from ten years' observations. There is a well-marked variation of climate; the winter is cool, its mean temperature being about 60°, while in summer it rises a little above 80°; at this season Europeans suffer much from the excessive dampness of the air. The solar radiation is very considerable in all months; the maximum during 1893 was 154°, in August. Much attention is paid to the study and prediction of typhoons; telegrams giving information about them were issued on eighty-seven days, and with a view to the systematic study of these storms, observations are regularly extracted from ships' logs. During the year no less than 672 logs with entries during typhoons were received, and these were supplemented by observations made at about forty land stations. These various useful researches, in addition to the regular astronomical and magnetical observations, try the powers of the small staff to the utmost, and Dr. Doberck states that the work is much hampered by want of sufficient office accommodation.

THE *Lancet* states that Dr. Bornand, the eminent Swiss consultant lately deceased at Berne, bequeathed his fortune (which was considerable) to the Académie de Lausanne for the endowment of a chair of Embryogeny in that school. His *armamentarium chirurgicum* and his microscopical instruments he also presented to the Académie, while his magnificent library become property of the *bibliothèque cantonale* of his native Canton de Vaud.

WE learn from the *Academy*, that the Pengelly Memorial Fund now amounts to about £1360; and the committee have determined to proceed immediately with the erection of a lecture theatre, as part of the proposed addition to the Natural History Museum at Torquay, of which Mr. Pengelly was the founder.

A CIRCULAR has been sent to us announcing the proposed formation of a society, whose headquarters are to be located at Sydney, to be called "The Palæographical Society of Australasia." The following are among the objects which the society is being established to promote:—"To collect, illustrate, and place on record, examples of all systems of old time written characters, whether in the form of pictograms, symbolisms, or phonograms, as also representations of the various mnemonic aids to memory used by so many savage and barbarous peoples. To undertake the collection and formation of a library, to consist of works treating of or connected with Palæography and kindred sciences, as also collections of photographs and other exact copies and illustrations of rock inscriptions, cave paintings, &c. To afford a means of communication and co-operation between those interested in the science of Palæography, who are now unable to obtain this mutual aid. To assist students as far as possible in the work of deciphering new or unknown characters." The Society will, it is announced, be formed as soon as the initial membership reaches a hundred; when, therefore, that number of intending members send in their names, &c., to one or other of the gentlemen named below, a meeting will be called for the purpose of electing officers, passing of rules, &c. The subscription fee is to be one pound per annum. It is intended to establish a periodical as organ of the society, in which will appear original articles on the science of Palæography, with illustrations of various scripts. Further particulars may be obtained from Dr. A. Carroll, Kogarah, Sydney, N.S.W.; or Mr. Elsdon Best, Wellington, New Zealand.

A NUMEROUSLY attended meeting of the Essex Field Club was held last Saturday, in the Navestock district, under the conductorship of the Rev. S. Coode Hore and Prof. R. Meldola, F.R.S. Alighting at Brentwood Station, the party were driven to the site of an ancient entrenchment, which the conductors had identified with the "alate temple of the Druids," described by Dr. Stukeley in the last century. A *fac-simile* of Stukeley's figure, made by Mr. Walter Crouch, was handed round for inspection. Nothing of these ancient remains is now to be seen, excepting a circular depression, and a fosse connected with it, situated in a field bordering the road. From this spot the party proceeded to Navestock Park, the estate of Lord Carlingford, where they were most hospitably entertained at luncheon by Mr. and Mrs. D. P. Sellar, of Dubrook. An ordinary meeting of the Club was held after luncheon, and a discussion took place respecting the proposed cession of certain Essex parishes to Hertfordshire and Cambridgeshire, under the Parish Councils Act. A resolution protesting against this cession was unanimously passed, and a copy ordered to be sent to the Essex County Council and to the Essex Members of Parliament. The members next proceeded to inspect an ancient earthwork in a wood near the park, which earthwork is entered as a camp in the ordnance map. It consists of a well-defined rampart and ditch, and is of an oblong form, with a spur at one angle. The site is now known as "Fortification Wood," but was formerly known as the "Defence of Navestock." The party next proceeded towards the Roding Valley, and were conveyed to Curtismill Green, an outlying fragment of old Hainhault Forest, which, with Epping Forest, formerly constituted the Forest of Waltham. Here they were shown an upright stone, which the conductors had identified as "Richard's Stone," one of the boundary stones set up at the time of the perambulation of the Essex Forest in 1641-1642. Standing by this stone, marking the extreme north-eastern extension of the old forest, Prof. Meldola gave a short account of the history of the perambulation, and stated that with his colleague, Mr. Coode Hore, and Mr. William Cole, the hon. secretary, and his brothers, they had now found five out of the seven boundary stones referred to in the perambulation. The fragment of primitive forest between "Richard's Stone" and the "Navestock Stone" was much admired, as far as time permitted an inspection, and a desire was expressed that steps should be taken for securing the permanent preservation of all these interesting boundary marks, the more especially as the forest of Hainhault has, with the exception of a few isolated patches, been entirely cultivated out of existence. From "Richard's Stone" the party drove through some of the most picturesque parts of the county to South Weald, where, at the "Tower Arms," tea was awaiting them. After tea another meeting was convened for the purpose of hearing a most interesting paper by Mr. Coode Hore, in which he gave a series of notes on the history of Navestock in Saxon and Norman times, and made reference to the prehistoric remains visited in the course of the day.

THE annual report of the Director of the Royal Botanic Garden, Calcutta, for the year 1893-94, has just reached us. During the year the Herbarium was enriched by more than 16,000 specimens, and the Garden in return sent out numerous specimens to various botanical institutions in different parts of the world. Reference is made to a great storm which raged for nearly the whole of three days in the month of May, and the damage done was so great that for about six weeks after its occurrence the whole of the out-door labour staff was engaged in making repairs. A more suitable platform for Colonel Kyd's monument was erected, the roads in the grounds were generally improved, and the gardens are reported to have been maintained in a high state of efficiency.

M. L. CAYEUX (*Bull. Soc. Géol. France*) describes radiolarians from rocks in Brittany which are generally admitted to be pre-Cambrian. They occur in siliceous bands in the "Phyllades de Saint Lô." The evidence for the pre-Cambrian age of these beds is stated by Dr. Barrois. Many of the radiolarians described belong to the genera still existing.

A PAPER on the "Shasta-Chico Series," of N. California and Oregon (*Bull. Geol. Soc. Amer.*), by Messrs. J. S. Diller and T. W. Stanton, is interesting as discussing the limits of the Cretaceous and Jurassic formations on the Pacific Coast. The series has a maximum thickness, on Elder Creek, Tehama Co., California, of 30,000 feet; the whole set of beds graduating into one another as one continuous series. It was formerly supposed that the lower (Knoxville) beds graduate into the Mariposa beds—the highest Jurassic; the authors contend that there is both a physical and palæontological break between them. The highest Cretaceous rocks are not here represented, and the Téjon beds, which probably are not the oldest Eocene, rest unconformably upon the Chico series. In Middle and Southern California the Téjon beds are believed to be conformable to the Chico beds.

PROF. H. F. OSBORN discusses the characters and faunal relations of the Laramie Mammals (*Bull. Amer. Mus. Nat. Hist.* vol. v., p. 311), and shows that they are more nearly related to the Puerco (Eocene) mammals than they are to those of the Jurassic series. This is specially illustrated by the evolution of the teeth. In the same volume, there are papers by Prof. Osborn, Dr. J. L. Wortman, and Ch. Earle, on the Lower Miocene mammalia of North America. The White River deposits have a maximum thickness of about 800 feet, and they represent a great period of time, during which the Titanotheriidæ, Rhinocerotidæ, Equidæ, and Oreodontidæ underwent considerable modification, amounting in some cases to changes of true generic significance.

A NEW design for large spectroscopic slits is described by Mr. Wadsworth in the current number of the *American Journal of Science*. Of the various forms of double motion spectroscope slits which have been designed, the two forms in most common use are the parallel ruler form, as fitted to most German instruments, and that form in which the jaws slide in guides, and are moved simultaneously in opposite directions by a right and left hand screw. The first form is convenient but somewhat bulky, and makes it difficult to determine the exact width of the slit. The second form, in which the screw is necessarily at one side of the jaw, gives rise to a twisting strain tending to make the slit wider at one end than at the other, an objection which becomes very serious in slits above 5 cm. in length. The author's new form, designed for Prof. Langley, has the advantage of giving a central thrust on both jaws while keeping the slit accurately centred. This is accomplished by making the milled head move the whole jaw system along the slit plate by means of a nut screwed to the latter, while another screw on the same shaft, but of double the pitch, moves the nearer jaw independently in the opposite direction. Thus the centre of the slit remains fixed, the jaws opening out from it. A spring provides for the return motion, and takes up all back lash in the screw. The graduated head gives by its motion over a graduated drum the whole number of turns and fractions of a turn, enabling the width of the slit to be determined at a glance. The thrust being central, there is no tendency to twist the jaws in their guides. The slit has a clear opening of 10 cm.

IT appears that the public in Brooklyn, U.S.A., are making use of the stray current from the electrical tramways, driving motors and lighting lamps, by connecting the terminals to the metallic framework of the overhead railways and to the water-pipes; while it is proposed in one of the suburban telephone exchanges to utilise the above current, and do away with the batteries. The loss of energy on the American lines where the current is supplied by a trolley wire, and the return takes place by the rail, is very considerable, and the above use of the stray current is much more likely to draw the attention of the tramway companies to these losses than the corrosion of the water- and gas-pipes, the damage to which we have on previous occasions referred.

ACCORDING to the *Pioneer Mail*, Allahabad, the anthropometrical system of identification has already proved of practical use in Bengal. Previous convictions against six men, who had been sentenced in districts beyond Calcutta, were traced by its means.

Engineering for July 27 is a special number, and is, for the most part, taken up with a description (with illustrations) of the various mills and appliances used in the manufacture of cotton at or near Manchester, in which city the Institution of Mechanical Engineers is at present holding its summer meeting. This section of the number is, in fact, specially designed for the use of those who are taking part in the meeting of the Institution.

PART 2 of vol. xv. of the *Journal* of the Sanitary Institute contains, besides Proceedings of the Institute, notes on sanitation abroad, &c., an article by Dr. Louis Parkes, entitled "The Possibility of the Spread of Disease through the River Waters supplied to London," being a review of the evidence given by the bacteriological witnesses before the Royal Commission on Metropolitan Water Supply, 1893.

THE August number of *Natural Science* contains the following articles:—"The Evolution of the Thames," Dr. J. W. Gregory; "Some Account of the Gall-making Insects of Australia," W. W. Froggatt; "Books of Reference in the Natural Sciences," C. Davies Sherborn; "Some Reforms in the Oxford University Museum," E. S. Goodrich; "Hertwig's 'Preformation or New Formation,'" P. Chalmers Mitchell; and a special illustrated supplement on "Taxidermy as a Fine Art." The process illustrations in this supplement, and in the article by Mr. Goodrich, are for the most part very successful.

THE "Proceedings of the Physical Society of London," vol. xii. part 4, has just been issued.

THE August part of *Science Gossip* has a portrait of Dr. Ludwig Mond, F.R.S., the munificent donor of the new laboratory for physical and chemical research in connection with the Royal Institution, to which we referred at length in our issue of July 5.

ANOTHER remarkable nitrogen compound, nitramide NO_2NH_2, is described in the current *Berichte* by its discoverers, Drs. Thiele and Lachman, of Munich. A short time ago, these chemists showed that by the action of sulphuric and nitric acids upon urethane a nitro-derivative, nitrourethane $NO_2 . NHCOOC_2H_5$, was produced. When this substance is dissolved in water, and the concentrated solution is mixed with a large excess of a concentrated solution of caustic potash in methyl alcohol, and the mixture cooled by ice, a potassium salt of the composition $NO_2 . NK . COOK$ is deposited in crystal plates. If these crystals are placed in water they instantly decompose with great rise of temperature into potassium carbonate and nitrous oxide. If, however, they are placed in a mixture of ice and sulphuric acid, carbon dioxide is evolved, and the new substance nitramide is produced. It may be extracted by means of ether, and upon evaporation of the latter it is left behind in the form of clear colourless prisms. The crystals melt at 72°, but the least trace of moisture lowers the melting point very considerably. Nitramide is readily soluble in water, ether, and alcohol, but difficultly soluble in benzene. The aqueous solution reacts strongly acid. Nitramide is volatile, considerably so even at the ordinary temperature. It is an unstable substance, and decomposes on mixing with copper oxide or lead chromate, or even on admixture with powdered glass, great rise of temperature occurring in each case. The products of decomposition are nitrous oxide and water. When heated rapidly above its melting point it explodes. Nitramide is instantly decomposed by alkalies, not only by caustic alkalies but also by carbonates, ammonia, borax, and even sodium acetate, in the cold, with evolution of nitrous oxide. It would thus appear to be incapable of forming salts, at any rate in solution. The crystals explode violently, with production of flame, when a drop of caustic soda or potash is allowed to fall upon them. The ethereal solution of the crystals yields with ammonia a precipitate of an ammonium salt, but it decomposes almost immediately with evolution of gas. Concentrated sulphuric acid or hot water similarly provoke violent decomposition. Upon reduction a substance endowed with powerful reducing properties is produced, which would appear to be hydrazine $\begin{matrix} NH_2 \\ | \\ NH_2 \end{matrix}$. The discoverers of this interesting substance are continuing the study of its reactions, and are attempting to prepare it in a purely inorganic manner.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*), a Hygian Snake (*Elaps hygiæ*) from South Africa, presented by Mr. J. E. Matcham; a Macaque Monkey (*Macacus cynomolgus*) from India, presented by Mr. J. A. Brand; a Common Paradoxure (*Paradoxurus typus*) from India, presented by Mr. E. Stallard; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Miss Champneys; an Indian Cobra (*Naia tripudians*) from India, presented by Mr. Angus M. Kinloch; two Slowworms (*Anguis fragilis*), British, presented by Mr. T. E. Gunn; two —— Opossums (*Didelphys*, sp. inc.) from South America, a Common Cassowary (*Casuarius galeatus*) from Ceram, a Hawk-headed Parrot (*Deroptyus accipitrinus*) from Brazil, two Hamadryads (*Ophiophagus elaps*) from India, deposited; a Pleasant Antelope (*Tragelaphus gratus*), bred in Germany, purchased; a Thar (*Capra jemlaica*), a Red Deer (*Cervus elaphus*), three Cairo Spiny Mice (*Acomys cahirinus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SPECTROSCOPIC VELOCITIES OF BINARIES.—The determination of the elements of double-star orbits from spectroscopic measurements has been attempted by two methods. That due to Dr. Wilsing, which is a very convenient one, is only applicable to cases of small eccentricities; another method, developed by Dr. Rambaut, is not subject to this limitation, but is rather elaborate. In No. 3242 of the *Astronomische Nachrichten*, Prof. R. Lehmann-Filhés works out a method somewhat akin to that of Dr. Rambaut, but which he claims to have discovered independently, and which does not require difficult calculations or constructions. If both components of a spectroscopic double are bright enough to give a measurable spectrum, as is the case with β Aurigæ and ζ Ursæ Majoris, the velocities as determined from the displacement of the lines in the spectrum are taken as relative, and the investigation then deals with the motion of one mass with respect to the other considered as stationary. If, on the contrary, only one of the components gives a measurable spectrum, as in the case of Algol and α Virginis, the motion must be referred to the centre of gravity of the system, the radial velocity of which must be determined and subtracted from the observed velocities. The period of the star is easily determined by observing a considerable number of periodic variations, and all observations can then be reduced to a single revolution by adding or subtracting multiples of the period. These spectroscopic velocities are then plotted as ordinates with the times as abscissæ, and a wavy curve is thus obtained showing the maximum and minimum velocities relative to the solar system. If these velocities are referred to the centre of gravity of the system, the areas of the curve above the axis of abscissæ must be equal to those below, *i.e.* the total displacements must neutralise each other. This gives a condition which the curve must fulfil, and which serves to control the observed velocities. Another condition is that the area intercepted between the maximum positive ordinate and the next point of intersection with the axis of abcissæ must be equal to the area of the curve between that point and the maximum negative ordinate, this representing the motion of the star from the ascending to the descending node. Prof. Lehmann-Filhés gives simple formulæ for determining the various elements of the orbit from the corrected curve. Comparing his method with that of Dr. Rambaut for the case of β Aurigæ, he finds 0·158 for the eccentricity, where the latter found 0·156, and 57°·93 for the longitude of the ascending node, against Dr. Rambaut's 57°·43, showing differences which are well within the errors of observation. The real daily motion is found to be 90°·726, corresponding to a period of 3·968 days. The apparent semi-major axis of the orbit comes out as 7,516,000 English miles, which agrees very closely with the value obtained by Dr. Rambaut, viz. 7,500,000.

THE INSTITUTION OF NAVAL ARCHITECTS.

THE annual summer meeting of the Institution of Naval Architects was held last week, at Southampton, commencing on Tuesday, July 24, and concluding on the Friday following.

The President of the Institution, Lord Brassey, occupied the chair during the sittings, which were held in the theatre of the Hartley Institute. There were only seven papers set down for reading during the three sittings that were held for business purposes, the meeting being, perhaps, rather more of a social nature than usual. The following is a list of the papers:—

(1) "On the Harbour and Docks of Southampton," by John Dixon, Dock and Marine Superintendent of the London and South Western Railway Company.

(2) "On the Importance of Economy of Fuel in very Fast Vessels, and on the advantages to be derived from Heating the Feed-water," by J. A. Normand, of Havre.

(3) "On the Influence of Circulation on Evaporative Efficiency of Water Tube Boilers," by J. I. Thornycroft.

(4) "On the Design of Mail Steamers, with special reference to their use for War Purposes," by J. H. Biles.

(5) "On a Rapid Method of Calculating Wetted Surfaces," by Archibald Denny.

(6) "Recent Experience with Cylindrical Boilers and the Ellis and Eaves Suction Draught," by F. Gross.

(7) "The Ventilation of Steamships, with special reference to the Removal of Explosive and Foul Gases from Bulk Oil Steamers," by S. H. Terry and J. F. Flannery.

Mr. Dixon's paper does not call for extended reference at our hands; it was intended chiefly as a guide to members who were about to visit the Southampton Docks in the afternoon, and was excellently designed for this purpose. Perhaps the most generally interesting part of the paper was contained in the appendices, in which a brief history was given of the various steamship companies that used the docks at Southampton. In a note attached to the paper, some interesting historical details were given. Although Southampton is a very ancient town, its importance was not great in the early days of this century. In the year 1811, we learn that the chief trade was with Jersey, Guernsey, Alderney, and Sark. Several sloops were running between these islands and Southampton. There was also a carpet and a silk manufactory, as well as mills for manufacturing blocks and pumps for the Navy. The number of houses in the town then was 1582, and the population was under 8000. The ship-building industry, however, goes back to very early days, Mr. Dixon stating that in the reign of Henry V. the famous ships *Grace Dieu* and *Holy Ghost* were built at Southampton; this was about the year 1414. One of the vessels was built by Robert Berd, and the other by William Soper; and it is curious to notice that one of the well-known yacht-designers of the district is now a Mr. Soper. Each of the ships referred to cost about £500. During the last century, and in the early days of this century, a very large number of ships for the Royal Navy were built in this district. At a small place called Bucklers Hard, now seldom heard of, a number of famous ships were constructed. This is on the little river Exe, which flows through the New Forest and past Beaulieu Abbey to the Solent. Three ships of the British Fleet which were at Trafalgar, were built there, the most celebrated being Nelson's *Agamemnon* and the *Swiftsure*. Another interesting historical fact stated by Mr. Dixon, was that the timbers of the celebrated American frigate *Chesapeake* were used, when that vessel was broken up, in the construction of a mill at Wickham, near by. The building still exists, and is known as "Chesapeake Mill." The late Admiral of the Fleet, Sir Provo W. Parry Wallis, who died only a short time ago, in 1813 took the *Chesapeake* into Halifax, after her encounter with the *Shannon*.

M. Normand's paper was one of considerable value, and, though short, contained a good deal of useful information. The well-known scientific attainments of French naval architects are excellently represented in M. Normand's firm, and from the Havre yard have been turned out some of the torpedo boats which have been most worthy to be placed in competition with the productions of the Thames builders, Thornycroft and Yarrow. M. Normand is an original designer, his conclusions being based on scientific deduction. He is not content, as some other constructors of fast vessels are, to simply follow the lead of others, ignorantly copying whatever they may see to be successful. As is usually the case with scientific workers, M. Normand is generous in giving information to others, even to his competitors; although he would probably be the first to acknowledge his indebtedness in this respect to the two leading torpedo boat-builders of this country. Indeed, the interchange of information in this way across the channel has always been a pleasant feature in the rivalry of the builders of these beautiful little craft. Torpedo boats are not supposed to be economical vessels, and it has been said that "the mission of a torpedo boat is to run a trial trip." There certainly was a great deal of truth in this remark in the old days of premium for speed, when a boat might earn for her builders several thousand pounds over her contract price if she could scramble through her six runs on the mile without breaking down. In such a case, as there was no restriction in regard to coal burned, economy of fuel was little thought about, and indeed in the ultimate work for which torpedo boats are designed, should they ever be brought to the stern realities of war, it would be a small matter whether much or little coal were burned to attain the high speed. To get to the scene of operation, however, a torpedo boat might have to run a long distance, and in that case her radius of action in regard to coal stowage would be a serious consideration. Moreover, trial trips of torpedo boats now extend over a considerable length of time, and the amount of coal that has to be carried has become an important factor in regard to the total weight, which, of course, in turn governs the speed to a large extent. M. Normand has recognised these facts; he tells us that in his last torpedo boats he has found, by the official trials, that the coal burned per I.H.P. per hour ranged from 1·1 lb. up to 15 knots, and to somewhat less than 2 lb. at 25 knots. These figures seem very low, and the author is certainly within the mark in saying that the consumption is not more than two-thirds of that of a number of similar craft. Another interesting and valuable piece of information, given us by M. Normand, is that the total weight of engines and boilers of the boats above alluded to, is about 48 lb. per maximum I.H.P. and even this extremely light machinery is further reduced in weight, notably in the case of the *Forban*, now under construction at Havre; a vessel, it will be remembered, which is expected to reach a speed of 30 knots an hour, although we believe the contract speed is 29 knots. It may be mentioned here, that Mr. Yarrow has under construction, for the Russian Government, a vessel which is guaranteed to make 30 knots. M. Normand further tells us in his paper, that in high-speed vessels a reduction in the weight of any part of the ship allows the whole displacement to be reduced by about 4½ times the weight saved, if the speed, steaming distance, weight of armament, and general conditions remain unchanged. The author attributes the remarkable economy of his engines to several causes, but more particularly to the feed-heater that he uses. This, he informs us, gives an economy in fuel of at least 20 per cent. The figures seem somewhat startling, but they are vouched for by the author, and have been obtained on official trials. The principle of this feed-heater was enunciated for the first time in 1886 by the author's brother, M. Benjamin Normand. It is a direct application of the first law of thermodynamics. The heating steam is taken, in the ordinary compound engine, at mid-stroke from the low-pressure cylinder by a special valve. In three or four stage expansion engines it is taken direct from the low-pressure casing, all the work previously given in the engine by the heating steam being a direct gain. The author ascribes the economy of 20 per cent., before mentioned, to two causes, viz.: (1) That which results from the number of thermal units saved by using, for heating the feed, steam which has already done work. This may amount to from 10 per cent. to 14 per cent., according to the pressure. (2) That which results from the better circulation of the water in the boiler, a greater proportion of that water being at a boiling temperature. As a practical example of the advantages of this heater, it may be stated that simply by putting it into use, the revolutions of the engine in one vessel were increased from 305 to 335 per minute.

A short discussion followed the reading of this paper, in which both Mr. Thornycroft and Sir Nathaniel Barnaby took part. The chief point of interest was the statement by Mr. Thornycroft, that in the case of the *Daring*, a torpedo boat destroyer recently built by his firm, he believed the weight of machinery per I.H.P. was even less than that stated by M. Normand.

Mr. Thornycroft's paper, like that which preceded it, contained a good deal of valuable information in a small compass.

It dealt especially with one feature in the boiler which has been invented by the author. This steam generator, it will be remembered, consists chiefly of three horizontal cylinders arranged, in cross section, in the form of a triangle. Two of the cylinders are placed in the wings of the furnace, whilst the third, which is above, at the apex of the triangle, the fire-grate forming the base. The top cylinder is connected to the two wing cylinders by two series of curved pipes, which are so arranged as to deliver into the top cylinder at its upper part; they thus deliver above the water-level of the boiler, which is about half-way up the top cylinder. Connecting the top cylinder with the two wing cylinders, respectively, are two external pipes; the whole, of course, is enclosed by a smoke-jacket, and the steam generation occurs in the connecting pipes. The method of working of the Thornycroft boiler is as follows:—The heat from the furnace playing on the pipes or tubes, which connect the top cylinder to the two wing cylinders, causes generation of steam, the flow of which is upwards. As is nearly always the case when steam is generated in small pipes, a great deal of water is also carried upwards with the steam. This water is delivered into the top cylinder, and from thence is free to flow downwards to the two wing cylinders, from whence it can rise again through the generating tubes, and so on in continuous cycle so long as there is water to be evaporated. The success of a water-tube boiler in practical working may be said to be dependent on its circulation, so that when rapid evaporation takes place, and water is quickly driven away from the heating surface, other water should be there to flow in to take its place. Mr. Thornycroft has always claimed that this circulation is most effectually attained by having the steam-generating tubes deliver in the upper part of the top cylinder. The principle has been questioned, and in order to set the matter at rest experimentally, the author had made a boiler purely on his system, and also one in which the design was so modified as to bring the generating tubes into the top cylinder below the water surface. If we have made our explanation clear, it will be seen, as stated by the author, that in either boiler, pressure in the lower vessel is that due to the full depth of water in the boiler, in addition to the steam pressure, and reduction of density in the generating tubes will be available for causing circulation; whilst reduction in pressure in the wing cylinder below that due to the head of water in the boiler, will reduce the circulation. In fact, the circulation of water in the boiler is governed by variations of pressure. In order, therefore, to measure these variations, Mr. Thornycroft had recourse to a water gauge connecting the top and bottom cylinders, the height of the column of water showing the greater or lesser pressure in the wing cylinder. The results of the trials were shown by a diagram in which curves were assigned to each series of experiments. When the steam-generating tubes were arranged as in the normal Thornycroft boiler, as the rate of evaporation increased, the height of the water in the gauge-glass showed a steady and comparatively small pressure in the wing cylinder. Thus, when the evaporation was increased from 3 lb. to 20 lb. per square foot of heating surface per hour, from and at 212° Fahr., the fall was about 2 inches of water. With the boiler having tubes delivering below the water-level when the evaporation was raised from 3 lb. per hour per square foot of heating surface to about 15 lb., the fall in pressure in the wing cylinder was from 3 inches to 7 inches, roughly. Thus it will be seen that the circulation of water in a boiler of this class, where the tubes deliver above water-level, must be more energetic than when the tubes deliver below water-level. In both of these experiments, what are called the down-comer tubes, that is to say, the two tubes at the ends of the cylinders provided for completing the circuit of circulation, were in use. The utility of these tubes has, however, been questioned, and in order to throw light on this point, Mr. Thornycroft next made a series of experiments with a boiler in which the tubes delivered below the water-level, and the down-comer tubes were out of use. The results were interesting and instructive. The reduction in pressure in the wing cylinder was extremely rapid as the evaporation increased; after a time, however, the curve reached its lowest point, and then suddenly bent upwards, showing an increase in the pressure. This last phenomenon Mr. Thornycroft attributed to the fact that the steam, instead of rising uniformly in the tube, as it would when the evaporation was moderate, was driven out at the lower end; and this, of course, would tend still more to check the circulation. The diagram is well worthy of study on the part of those interested in any class of boiler design, and it may be found in the *Transactions* of the Institution.

In the discussion which followed the reading of this paper, the most interesting feature was a description, by Mr. Pilcher, of the device used by Mr. Maxim in making the boiler of his flying machine. This boiler, it may be stated, is a marvel of lightness. It is a Thornycroft boiler with very small generating tubes about ⅜ inch in diameter; it is said to have given off steam equivalent to 300 I.H.P. at a pressure of 300 lb. to the square inch; the weight of the boiler itself being but 3 lb. per I.H.P. With the small diameter tubes it was found impossible to keep up circulation sufficient to prevent the destruction of the boiler, and, in order to aid the natural circulation, Mr. Maxim introduced what may be described as injector circulation. He carried the feed-pipe of the boiler into the down-comer tube, covering the orifice of his feed-pipe by a conical valve, which was attached to a long spindle, and, working through a stuffing-box, was carried outside the pipe. The valve was kept closed by means of an external spiral spring, so adjusted as to give a pressure of 50 lb. to the square inch on the valve. The feed-pump naturally would overcome this additional pressure, so that the pressure in the feed-water on the boiler side of the pump would be 50 lb. above the boiler pressure, and thus 350 lb., the boiler pressure being 300 lb. It will be seen, therefore, that, on the hydraulic pressure opening the valve, the feed-water would be injected with some velocity into the boiler, and thus would set up a circulating current. In this way it was found that the boiler in the flying machine could be made to work very perfectly.

Prof. Biles, in his paper, described a method by which he proposed to transform mail steamers into war vessels in the event of hostilities. Details were worked out by the author, and given in the paper; but into these we need not enter. The most noticeable feature was a long recess in the side of the ship, into which the author proposed to pack an armoured belt when the vessel was required to take up its warlike *rôle*.

The scope of Mr. Denny's paper is described by its title. Mr. Morrish, of the Admiralty, in the discussion which followed, gave a formula used by Mr. Froude at Haslar, which appeared to us even more simple than the method described by Mr. Denny. We must refer our readers to the *Transactions* for these formulæ.

Mr. Gross gave details of certain trials made with the system of burning fuel in steam boilers, referred to in the title of his paper. A very good result in regard to economy of fuel was obtained with one vessel referred to; the consumption being 1·3 lb. per I.H.P. per hour of South Wales coal for the main engines. We fail to see, however, in what respect "suction" draught differs from "forced" draught in regard to economy. As Sir Edward Harland humorously stated in the discussion: "If one wishes to remove a person from a certain position, it does not much matter whether one gives him a pull by the nose, or applies pressure from behind." There may, of course, be some occult virtue in "suction" as compared to pressure, but we certainly have never heard it satisfactorily accounted for.

The last paper was read by Mr. Terry. It is remarkable how those tank steamers which carry oil in bulk may be freed from the insidious vapours which always arise whenever a little of these hydrocarbon oils are present. Mr. Terry tells us—and he is confirmed in this by Mr. Martell, Lloyd's chief surveyor, who has naturally had thorough opportunities of seeing these matters in practical work—that, in the same spaces that have been occupied by petroleum, rice, and other perishable food, cargoes have been carried without detriment. So successful have the results been, that it is now proposed to carry even tea in these tank steamers.

We cannot deal with the many pleasant excursions that were really the leading feature of the meeting. The proprietors of the various mail steamers, the London and South-Western Railway Company, and those gentlemen who had estates in the neighbourhood, seemed to vie with each other in entertaining the members of the Institution. On Friday morning a visit was paid to Portsmouth Dockyard, where many interesting features were shown by Admiral Fane, the superintendent, and the officers of the permanent staff. In the afternoon an excursion was made round the Isle of Wight, on board the *Frederica*, a vessel of 1509 tons, and about 6000-h.p., which had been lent by the London and South-Western Railway Company for the purpose.

ON THE NEWTONIAN CONSTANT OF GRAVITATION.[1]

I.

IT is probably within the knowledge of most of those present that Sir Isaac Newton, by his great discovery of gravitation and its laws, was able to show that a single principle, ideally simple, viz. that every particle in the universe attracts any other particle towards itself with a force which is proportional to the product of their masses divided by the square of the distance between them, would completely and absolutely account for the three laws of planetary motion which Kepler had given to the world.

Newton also showed that a spherical body, whether uniformly dense or varying in density according to any law from the centre to the surface, would attract bodies outside with the same force that it would do if it could all be concentrated at its centre, *i.e.* that all the attractions varying in amount and direction produced by particles in all parts of a sphere need not be considered separately, but may be treated in this simple way.[2]

Nevertheless, though Newton's great discovery is sufficient to bring the whole of the movements of the planets and their satellites, whether their simple Keplerian motions or the disturbances produced by their mutual gravitation, the motions of comets, of binary stars, of the tides, or the falling apple, under the domain of a single and simple principle, though it enables one to compare the masses of the sun, the planets and their satellites, and of those binary stars whose parallax has been determined, one thing can never be made known by astronomical research alone, though we may know that twenty-eight suns would be required to make one Sirius; that the sun is equal to 1048 Jupiters, that Jupiter is more than double all the rest of the solar system put together, or that the moon is 1/80 of the earth; no observations of these bodies can ever tell us how many tons of matter go to make up any one of them.

Though we know from first principles of dynamics, by the mere consideration of centrifrugal force, that the whole sun attracts each ton of the earth with a force equal to a weight here of a little more than one pound, and that if it were not for this, every ton of the earth would continue its journey into space in a straight line for ever, and though we know in the same way that the whole earth attracts each ton in the moon with a force equal to the weight of ten ounces and no more, we cannot tell by any astronomical observation whatever, how many tons there are in all.

Newton showed that to complete his law and to put in the numerical constant (the Newtonian Constant of Gravitation) that would convert his proportion into an equality, two methods are available: we may either make observations on the disturbance of the earth's gravitation by the action of isolated parts of it, we may either find the relative attraction of an isolated mountain or the strata above the bottom of a deep mine, or we may make an artificial planet of our own and find the attraction which it exerts.

The Newtonian Constant will be known if we know the force of attraction between two bodies which we can completely measure and weigh. Employing the C.G.S. system of measurement, the Newtonian Constant is equal to the force of attraction in dynes between two balls weighing a gramme each, with their centres one centimetre apart. Of course it may be referred to pounds and inches or tons and yards, but as soon as all the quantities but G in Newton's equation

$$\text{Force} = G\,\frac{\text{Mass} \times \text{Mass}}{\text{Distance}^2}$$

are known, no matter in what units the quantities are measured, G is known. The conversion of its numerical value from one system of measurement to another is of course a mere matter of arithmetic.

Of the first method of finding G, depending on the attraction of a mountain first attempted by Bouguer at the risk of his life in the hurricanes of snow on Chimborazo, of the experiments of Maskelyne, of Airy and of others, I cannot now find time to speak; I can only refer to Poynting's essay on the subject. It is the second method with an artificial planet that I have to describe to-night.

[1] A [illegible] at the R[illegible] J[illegible], by Prof. C. V. [illegible] F.R.S.

[2] [illegible] difficulty of proving this, and not [illegible] that delayed the publication of [illegible]

Now let me give some idea of the minuteness of the effect that has to be measured. Is a wall built true by the aid of a plumb-line vertical, or does it lean outwards? Newton's principle shows that the plumb-bob is attracted by the wall, yet it hangs vertically. The attraction is so small that it cannot be detected in this way. Even the attraction of a whole mountain requires the most refined apparatus to detect it. Do two marbles lying on a level table rush together? According to Newton's principle they attract one another; yet if they were a thousand times smoother than they are, no movement of attraction could be detected.

Leaving matters of common experience, let us go into the physical laboratory where instruments of the highest degree of precision and delicacy (at least so they are called) are found on every table. What precautions are taken to prevent the attractions of the fixed and moving parts from interfering with the result which they are constructed to measure? None. The attractions are so small, that in no apparatus in use for the measurement of electrical, magnetic, thermal, or other constants are they ever thought of, or is any provision necessary to prevent their falsifying the result. Nevertheless, the attractions exist, and if only the means are delicate enough they can be detected and measured. The Rev. John Mitchell was the first to devise a successful method. He was the first to invent the torsion balance with which Coulomb made his famous electrical researches, and which bears Coulomb's name. He devised and he made apparatus for this purpose, but he did not live to make any experiments.

After his death Cavendish remodelled Mitchell's apparatus and performed the famous Cavendish experiment. By means of the apparatus, of which for the second time I show a full-size model in this theatre, Cavendish measured the force of attraction between two balls of lead, one 12 and the other 2 inches in diameter, and with their centres 8·85 inches apart. The same experiment has since been made by Reich, by Baily, and more recently by Cornu and Baille with greatly superior apparatus of one quarter of the size. All these observers actually determined the attraction between masses which could be weighed and measured, and thus found with different degrees of accuracy the value of G.

Let me explain now that this G, the gravitation constant, or as I prefer to call it, for the sake of distinction, the Newtonian Constant of Gravitation, has nothing to do with that other quantity generally written *g*, which represents the attraction at the earth's surface. This is a purely accidental quantity, which depends not only upon G, but also upon the size of the earth, its mean density, the latitude, the height above the sea, and finally upon the configuration and the composition of the neighbouring districts. *g* is eminently of a practical and useful character; it is the delight of the engineer and the practical man; it is not constant, but that he does not mind. It is of the earth, arbitrary, incidental, and vexatious. Prof. Greenhill should spell his name with a little *g*. G, on the other hand, represents that mighty principle under the influence of which every star, planet, and satellite in the universe pursues its allotted course; it may possibly also be the mainspring of chemical action. Unlike any other known physical influence, it is independent of medium, it knows no refraction, it cannot cast a shadow. It is a mysterious power, which no man can explain; of its propagation through space, all men are ignorant. It is in no way dependent on the accidental size or shape of the earth; if the solar system ceased to exist it would remain unchanged. I cannot contemplate this mystery, at which we ignorantly wonder, without thinking of the altar on Mars' hill. When will a St. Paul arise able to declare it unto us? Or is gravitation, like life, a mystery that can never be solved?

Owing to the universal character of the constant G, it seems to me to be descending from the sublime to the ridiculous to describe the object of this experiment as finding the mass of the earth or the mean density of the earth, or, less accurately, the weight of the earth. I could not lecture here under the title that has always been chosen in connection with this investigation. In spite of the courteously expressed desire of your distinguished and energetic secretary, that I should indicate in the title that, to put it vulgarly, I had been weighing the earth, I could not introduce as the object of my work anything so casual as an accidental property of an insignificant planet. To the physicist this would be equivalent to leaving some great international conference to attend to the affairs of a county council, I might even say of a parish council. That is the business of the geologist. The object of these investigations is to find the value of G. The earth has no more to do with the investigation than the table has upon which the apparatus is supported. It does interfere and occasionally, by its attraction, breaks even the quartz fibres that I have used. The investigation could be carried on far more precisely and accurately on the moon, or on a minor planet, such as Juno; but as yet no means are available for getting there.

I shall not have time to-night to describe the work of former investigators, and for this there is little need, since it is all collected in Poynting's Adams prize essay "On the Mean Density of the Earth," published this year. I cannot even find time to explain in more than the merest outline what I have done to develop the apparatus of Cavendish, so that he would hardly recognise in my glorified bottle-jack the balls and lever which have made his name famous. The following table, given by Poynting, however, represents the results of the labours of investigators up to the present time.

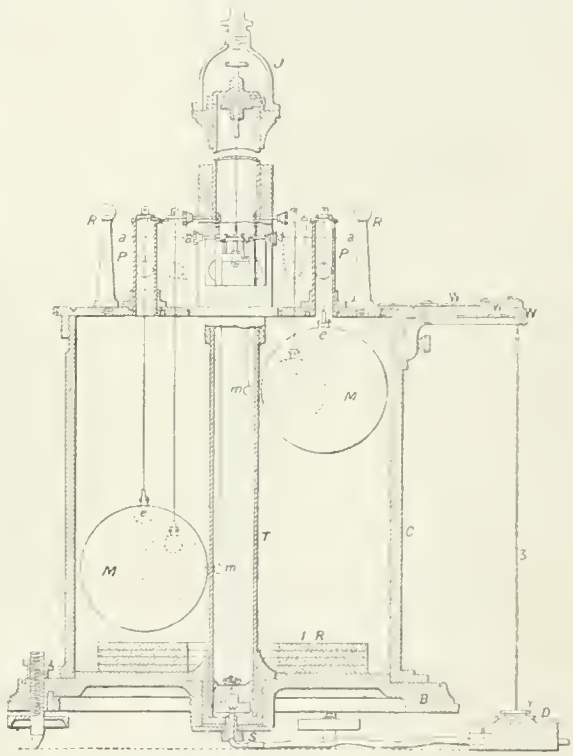
Summary of Results hitherto obtained.

Approximate date	Experimenter	Method	Result
1737–40	Bouguer	Plumb-line and pendulum	Inconclusive
1774–76	Maskelyne and Hutton	Plumb-line	4·5–5
1855	James & Clarke	,,	5·316
1821	Carlini	Mountain pendulum	4·39–4·95
1880	Mendenhall	,,	5·77
1854	Airy	Mine pendulum	6·565
1883	Von Sterneck	,,	5·77
1885	Von Sterneck	,,	About 7
1797–98	Cavendish	Torsion balance	5·448
1837	Reich	,,	5·49
1840–41	Baily	,,	5·674
1852	Reich	,,	5·583
1870	Cornu and Baille	,,	5·56–5·50
1889	Boys	,,	In progress
1879–80	Von Jolly	Common balance	5·692
1878–90	Poynting	,,	5·493 (5·46–5·52)
1884	König, Richarz, and Krigar Menzel	,,	In progress
1886–88	Wilsing	Pendulum balance	5·579
1889	Laska	,,	In progress

In connection with this table I cannot lose the opportunity of quoting Newton's extraordinary prophecy, marvellous in that without any direct knowledge he gave a figure which was nearer the truth than that found by many of the experimenters that came after him. The passage is as follows:—

"Unde cum Terra communis suprema quasi duplo gravior sit quam aqua, et paulo inferius in fodinis quasi triplo vel quadruplo aut etiam quintuplo gravior reperiatur; verisimile est quod copia materiæ totius in Terra quasi quintuplo vel sextuplo major sit quam si tota ex aqua constaret; præsertim cum terram quasi quintuplo densiorem esse quam Jovem jam ante ostensum sit." (Newton's "Principia," 2nd edition, 1714, p. 373, line 10.)

I have placed on the wall the diagram of the apparatus which I showed in action when lecturing here upon quartz fibres five years ago. With this I was able, for the first time, to show to an audience the effect of the very small attraction exerted between a two-inch cylinder of lead and a little one weighing only a gramme or fifteen grains. The apparatus which I have to describe to-night is the same in principle, the main distinction being that it is so designed and constructed that I can tell precisely where every gravitating particle is placed. In the design of this apparatus I have been, as everyone will admit, bold—most would have preferred the word reckless; but knowing the truth of the principles which I had developed, and having faith and confidence in the quartz fibre, I deliberately chose to reduce all the dimensions to an extent which caused the forces, and especially the couples, to be insignificant in comparison with any which had been within the reach of the experimenter hitherto. The whole difficulty of Cavendish, Reich, and Baily had been to measure so minute an effect; instead of increasing this, I diminished it enormously, being satisfied that I should be able to make a proportionately more accurate measure by so doing. Cornu reduced the dimensions to one-quarter; I have reduced the chief one to one-eightieth. Cavendish had a force equal to 1/3650 grain's weight to measure; I have less than a five-millionth. By the use of the long lever, Cavendish had the effect of a force of 1/100 grain's weight on an arm an inch long; I have less than a twelve-millionth of a grain on an arm of that length. His forces were fourteen hundred times as great as mine; his couples or twisting forces were a hundred and twenty thousand times as great. One advantage gained by the use of small apparatus, in which alone the attracting balls can be made large compared with the length of the beam, is the increased sensibility, the greater angle of deflection produced by the attractions when the period of oscillation is the same. This is more especially the case in my apparatus where the two sides are at different levels. But the greatest advantage is in a direction whence it might least be expected. In spite of every endeavour that may be made to keep the air quiet, to exclude draughts, to keep all the apparatus at one temperature in a vault of constant temperature, infinitesimal differences must exist; one side of the apparatus must be hotter than the other, though no thermometer could be made which would detect the difference. In consequence of this difference of temperature the air circulates, and so creates a draught which blows upon the mirror and the suspended balls. Now I have shown that in apparatus geometrically similar these disturbances are likely to be in the proportion of the seventh power of the linear dimensions, while the gravitational couples vary only as the fifth power; the relative disturbances are therefore likely to be in the proportions of the squares of the linear dimensions, so that if we make our apparatus ten times as large, the mirror is likely to be one hundred times as unsteady. In addition to this, the time needed to bring the apparatus to a steady state is far greater with large apparatus. After making the geometrical measures I leave my apparatus, small as it is, three days, if possible, before observing deflections and periods.



By permission of the *Engineer.*]

Fig. 1.

The diagram (Fig. 1) is a vertical section through the apparatus. B and C represent an accurately turned brass box with a lid L, which can be made to turn round insensibly by the action of the wheels W W. The lid carries two tubular pillars, P P, from the tops of which the balls, M M, hang by phosphor-bronze wires, being definitely held in place by geometrical clamps on the heads of the pillars. The lid also carries two supporting pillars, R R. In the centre tube the "beam mirror," N, hangs by means of a quartz fibre from an adjustable torsion head surmounted by a bell jar, and from the ends of the mirror the two gold balls, *m m*, hang by separate quartz fibres. Four rings of india-rubber are placed on the base to prevent destruction of the apparatus in case the balls should drop by any accident. Now it is evident that if the lid is turned from the position in which it is shown, that is, with all four balls in one plane, in which position the attractions do not tend to twist the central torsion fibre at all, then these attractions will produce a couple increasing with the angle up to a certain point (65° in therefore, is such that a great number of measures which are difficult, and can at the best only be made with a second quality degree of accuracy, are of so little consequence that this degree is more than abundant. The final result depends directly upon a few measures which, as I hope to show, can be made with facility and most accurately. These are the horizontal distance from centre to centre of the wires by which the lead balls are suspended, the horizontal distance between the centres of the quartz fibres by which the gold balls are suspended, the angle through which the mirror is deflected, the masses of the lead but not of the gold balls, and the natural time of oscillation of the mirror when the balls are suspended and when a thin cylinder of small moment of inertia, but of the same weight as the balls, is suspended axially in their stead.

Before going more into detail and showing how the operations are carried out so that all the quantities may be known with a sufficient degree of accuracy, it will be convenient to project upon

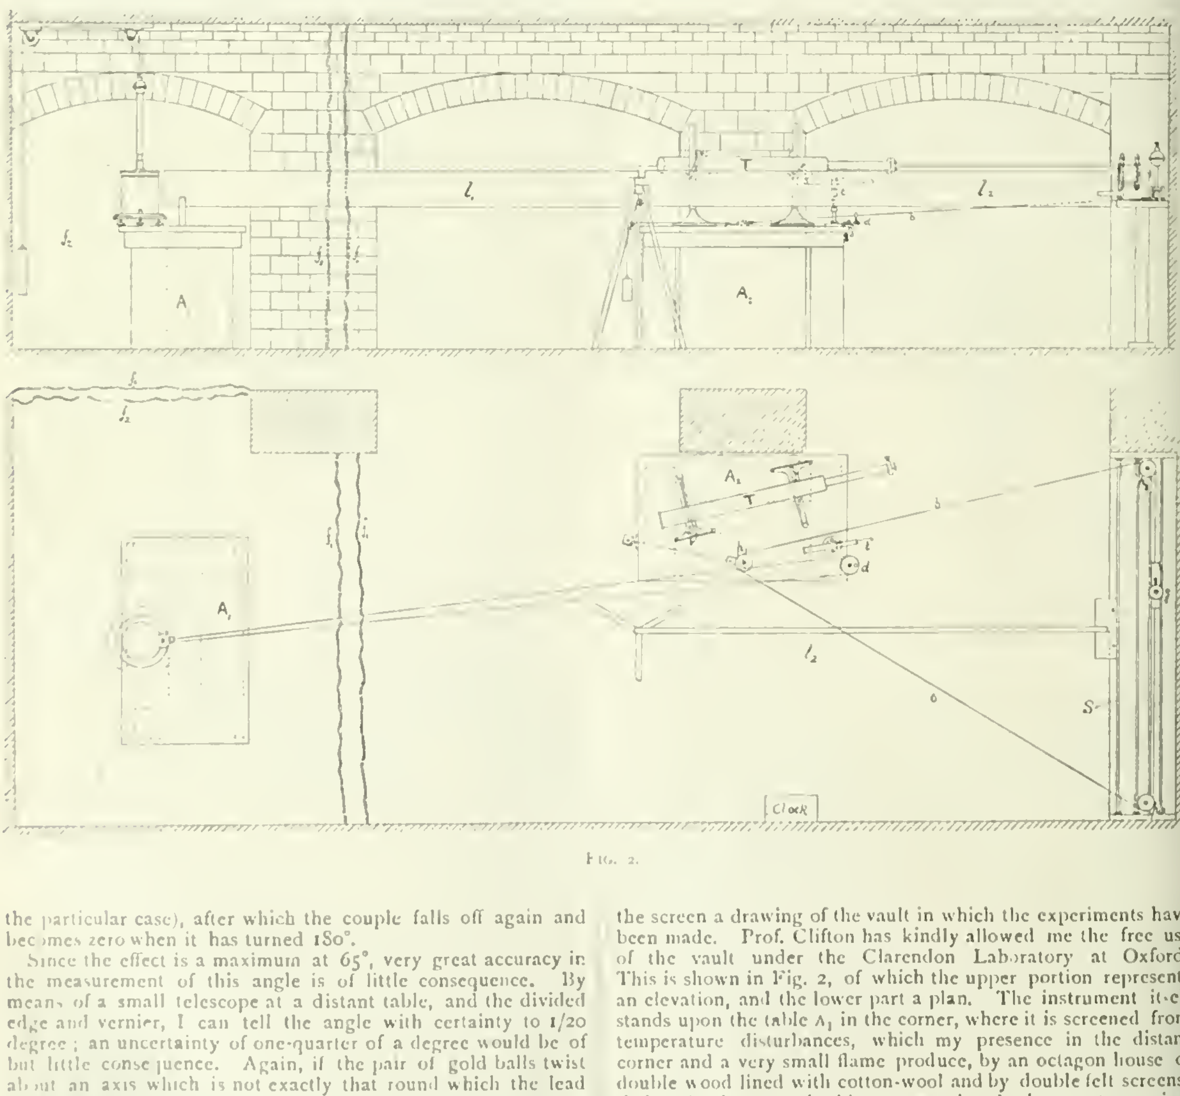


FIG. 2.

the particular case), after which the couple falls off again and becomes zero when it has turned 180°.

Since the effect is a maximum at 65°, very great accuracy in the measurement of this angle is of little consequence. By means of a small telescope at a distant table, and the divided edge and vernier, I can tell the angle with certainty to 1/20 degree; an uncertainty of one-quarter of a degree would be of but little consequence. Again, if the pair of gold balls twist about an axis which is not exactly that round which the lead balls are carried, if there is any small eccentricity of the gold or lead balls, then eccentricity in the common plane removes the gold balls from a position of minimum effect, eccentricity across the plane removes them from a position of maximum effect, and if the levels of the gold balls are not precisely the same as those of the lead balls, again the departure is from a position of maximum effect. All these three eccentricities can be determined with an accuracy of 1/1000 inch. Errors of 1/100 inch would make a barely perceptible effect upon the result. The design, the screen a drawing of the vault in which the experiments have been made. Prof. Clifton has kindly allowed me the free use of the vault under the Clarendon Laboratory at Oxford. This is shown in Fig. 2, of which the upper portion represents an elevation, and the lower part a plan. The instrument itself stands upon the table A_1 in the corner, where it is screened from temperature disturbances, which my presence in the distant corner and a very small flame produce, by an octagon house of double wood lined with cotton-wool and by double felt screens, f_1 f_2. On the second table, A_2, are placed a large astronomical telescope, T, through which the large scale, S, is seen by reflection from the mirror in the apparatus, a small reading telescope, *t*, to read the angle of the lid and vernier, a pulley-wheel, p_1, and a driving-wheel, *d*. The pulley-wheel p_1 keeps the cord *b* which passes round p_2 and p_3, and is attached to the cart, *c*, always tightly stretched, so that the observer at the telescope can always keep a little flame carried by the cart immediately behind the particular division under observation.

The driving wheel d is made with a very large moment of inertia, and the handle is near the axis, so that its motion is necessarily steady. A very light cord passes round this, across the room, and after passing through a hole in the screen passes also round the little wheel D (Fig. 1), and thus serves to drive the train W W, and so carry the lid and balls round almost insensibly. Two hundred and thirty turns of d are required to move the lead balls from the + to the − position. I generally turn the handle 130 times, and then when the mirror is approaching an elongation, turn the handle the remaining 100 times, finally stopping when the lid reading, as observed in the small telescope, is correct. The large scale, S, is 9 feet long, and is divided into 50ths of an inch. There are 4800 divisions.

Two beams, l_1 l_2, are seen in Fig. 2. The upper surfaces of these are straight, and are adjusted by screws until they are truly level. These are used when the true optical distance from the mirror to the scale is being measured. A steel tape, on which I engraved a fine line near each end, rests upon the beams. At one end a slider carrying a microscope is placed so as to see a fine line at the centre of the mirror accurately in focus, while at the other a corresponding slider is placed so that a projecting brass rod rests against the scale. At the same time cross lines engraved upon the plate-glass bases are placed exactly over the lines engraved on the steel tape. When afterwards the microscope is focussed upon the end of the brass rod, the distance between the cross lines, as measured by a scale, is the amount that has to be added to the distance between the engraved lines upon the tape, in order to obtain the distance from the scale to the mirror.

Overhead wheels are shown in Fig. 2, fastened to the roof above the apparatus, and again close to the end wall These serve many purposes, as will appear later. Among others, the middle one of each carries a cord fastened at one end to a crossbar joined at its ends by guys to the pillars R of the lid (Fig. 1), and at the other to heavy balance-weights to counterbalance the balls M M and part of the lid. Thus the friction is greatly reduced, and the tremor set up by rotating the lid is in a corresponding degree slight.

All time observations are made chronographically upon a drum by the Cambridge Scientific Instrument Company. This is placed in the adjoining vault. Two time-markers record with their points less than 1/100 inch apart, one of them marking every second of the clock, with special marks for minutes and half-minutes, and the other every depression of the key at my right hand. The late Prof. Pritchard kindly lent me an astronomical clock for the purpose, to which I fitted time-marking contacts; but into the details of these I must not enter. He also allowed me to make use of one of his assistants to keep me informed of the rate of the clock from time to time.

I have up to the present spoken vaguely of the large lead balls and of the small gold balls, but have given no indication as to how they are made and how I can be sure of the truth of their form and their homogeneity. Mr. Munro, whose capacity for turning accurate spherical work is well known, made for me two moulds of hard cast-iron, which I have on the table. One of these is for a 4¼-inch lead ball, and one for a 2¼-inch lead ball. Each mould is made in two halves, so truly as to shape and size that the thin steel disc that was used as a template would distinctly rattle when in its place, but when a strip of cigarette-paper was inserted on one side it could not be got in at all. The upper half of each of these moulds is provided with a cylindrical steel plunger accurately fitting a central hole in the mould, and with its end turned to the same spherical surface when it is pressed home upon its shoulder. The lower half of each mould has a ¾-inch central cylindrical hole, into which the lug of the brass ball holder exactly fits. There is also a small hole at the side which can be stopped with a brass plug. The balls are made as follows:—The interior of the mould is smoked and then screwed up as tight as possible. It is then heated until a piece of lead upon it begins to melt. The necessary quantity of pure lead melted in an earthen pot is then carefully skimmed and poured in until the cylindrical neck is full. The mould is then made to rest upon a cold iron slab, and a blowpipe is directed upon the upper part so that it cools from below upwards, and not from the surface inwards; more lead is added to keep the neck full. As soon as the lead in the neck solidifies the plunger is inserted, and the whole is placed in a hydraulic press. The plunger is forced down upon its seat, the lead, already free from bubbles and vacuous cavities, is compressed until at last the excess of solid metal flows through the small side hole in the form of wire. The ball is thus made true in form, necessarily homogeneous, which no alloy is likely to be, and definite in size. When cold it can be lifted from the mould, when after cutting off the wire which projects from its equator, it is ready for weighing.

The small gold balls are made by melting the required quantity of pure gold in a hole in a bath brick, and, as in the case of the lead, letting it cool from below upwards, so as to avoid cavities. It is then inserted in a pair of polished hemispherical hardened steel dies, which Mr. Colebrook made for the purpose, and beaten, being turned between each blow, and annealed once or twice until a perfect polished sphere, without a mark upon it, is the result. I make these in pairs of exactly the same weight, and, as in the case of the lead balls, thus obtain truth of form, accuracy of size, and homogeneity all in a very perfect—more than sufficiently perfect—degree. These are each suspended from a quartz fibre of the necessary length, to the other end of which a hook and eye is fastened. Into the very important details of these operations it is impossible, for want of time, for me to enter. The gold balls are ·2 and ·25 inch in diameter, and a

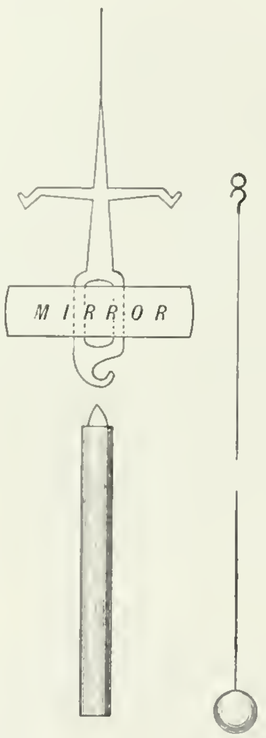

FIG. 3.

pair of gold cylinders were made in a similar tool ·25 inch in diameter, and about the same length.

Perhaps the most important detail in the whole apparatus is the "beam mirror," which is of the form shown in Fig. 3. It is necessary, as far as possible, to reconcile the following incompatible conditions. It should be as light as possible, have as small a moment of inertia as possible, the optical definition should be as perfect as possible, and, almost most important of all, the form should be such that the resistance offered by the viscosity of the air should be reduced to the smallest possible degree. By cutting the middle portion out of an optically perfect round mirror all these conditions are realised in some degree, and the optical definition is actually more perfect in the horizontal direction than that due to the whole disc. This is fastened to a cross-shaped support of gilt copper. The ends of the mirror have vertical grooves of microscopic fineness cut in their thickness, so that the quartz fibre hanging from the cross-arm above may rest definitely in them. The central hook is for the purpose of hanging the "counterweight," *i.e.* a slender silver cylinder of exactly the same weight as the gold balls with their fibres and hooks. By this means the unknown moment of inertia of the mirror may be eliminated with the fibre equally stretched in both cases, a most necessary condition, for I have found that the torsional rigidity is seriously affected by variation in stretching.

Means are provided by which I can effect the transfer of the gold balls from the beam to the side hooks or the reverse, or change their places without opening the window; but these and numerous other important details I must pass over.

Unfortunately accidents are liable to happen, and, as I know by dearly-bought experience, the gold balls may sometimes be precipitated down the central tube. I have recovered them sometimes by an india-rubber tube, let down through the window aperture, sucking at the other end until they closed the open end, when they could be drawn up. Latterly I have made use of a magnetised tuning-fork to pick up a very small fragment of iron tied to a silk line, by means of which I could draw up a diaphragm with anything that might have fallen upon it.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE following list of Royal Scholarships, Medals and Prizes awarded July, 1894, in connection with the Royal College of Science, London, has just been issued:—First Year's Royal Scholarships: Robert Sowter, Arthur Ormiston Allen, Henry Thomas Davidge, John Bousfield Chambers. Second Year's Royal Scholarships: Robert William Forsyth, William Longshaw. Medals and Prizes: "Edward Forbes" Medal and Prize of Books for Biology, George Stephen West; "Murchison" Prize of Books for Geology, John James Green, Francis Chambers Harrison; "Murchison Medal," not awarded; "Tyndall" Prize of Books for Physics, Part I., Robert Sowter; "De la Beche" Medal for Mining, John Ball; "Bessemer" Medal and Prize of Books for Metallurgy, Charles Howard Sidebotham; "Frank Hatton" Prize of Books for Chemistry, John Thomas. Prizes of Books given by the Department of Science and Art: Mechanics, Harold Rigby Cullen; Astronomical Physics, Francis Richard Penn, Robert Sowter; Practical Chemistry, Bouchier Mervyn Cole Marshall; Mining, John Ball; Principles of Agriculture, William Wilson.

THE Council of the City and Guilds of London Institute have conferred the Fellowship of the Institute upon Dr. W. E. Sumpner, who was awarded the Diploma of Associate of the Institute in 1887, and has since, by many original and valuable researches, contributed to the advancement of the electrical industry.

SCIENTIFIC SERIALS.

American Journal of Science, July.—Spiral goniometry in its relation to the measurement of activity, by Carl Barus. One type of the spiral goniometer consists of a "dial" in the form of a circular plate, on one half of which a series of concentric semicircles are traced, and an "index" in the form of another plate, bounded on one side by a semicircle, and on the other by two symmetric confluent spirals, traced so that equal increments of angle correspond to equal radial increments. These two parts are mounted on the same axis in such a manner as to be capable of revolving independently. When they are connected by a spring and made to actuate a dynamometer, the angle between the fundamental diameters of the dial and index can be read off by counting the number of semicircles visible on the revolving disc. These will be apparently drawn out into circles, and can be counted at any speed. This gives a means for measuring the activity of motors. In another form, the index outline is not a spiral but a diameter, and the semicircles are cut off in the outline of a spiral.—On some methods for the determination of water, by S. L. Penfield. This difficult operation may be considerably facilitated by the use of special forms of bulb tubes, which enable the analyst to separate the expelled water from the mineral, and weigh it in a closed tube. Two bulbs are blown half-way along the length of the tube, and kept cool by a strip of wet cloth. The water is driven up into the first of these. After it is all expelled, the glass is fused down upon the substance, and the end containing the substance is pulled off. The water is then weighed in the remaining part of the tube. For cases where the water is only expelled with difficulty, the author uses a kind of charcoal furnace, protecting the glass by a sheet of platinum foil. For entirely decomposing a mineral by fusion with sodium carbonate, the substance is placed in a platinum boat inside the combustion tube, and a sheet of platinum is wrapped round the outside. The tube must be well supported, as it is apt to fuse, but it does not leak even at a full white heat. The method is accurate, and superior to the use of porcelain or platinum. The latter is found at high temperatures to permit of the passage of gases through its substance.—The detection of alkaline perchlorates associated with chlorides, chlorates, and nitrates, by F. A. Gooch and D. Albert Kreider. The chlorates are destroyed by treating with the strongest hydrochloric acid and evaporating to dryness. The nitrates are decomposed by a saturated solution of manganous chloride in the strongest hydrochloric acid, the manganese being then eliminated by sodium carbonate. The perchlorates are then tested for by fusing with anhydrous zinc chloride.

American Meteorological Journal, July.—Changes in the definitions of clouds since Howard, by H. H. Clayton. The author quotes extracts from various authorities to show that there has been a gradual evolution since Howard. Thus a distinction between high and low cirro-stratus and high and low cirro-cumulus has been established, and the lower forms called alto-stratus and alto-cumulus. The stratus has been separated into fog and low sheet clouds, and two distinct forms of rain cloud recognised. He agrees with Hildebrandsson that ten terms, all compounded of Howard's four fundamental types, would fully meet the requirements of practical meteorology.—The newspaper weather maps of the United States, by R. De C. Ward. The history of the publication of these maps is given, together with specimens of those now issued. At present only four daily papers in the United States print weather maps regularly. The *New York Herald* was the first paper to issue them in the United States, and it occasionally prints them now, to illustrate special weather conditions.—Psychrometer studies, by H. A. Hazen. This paper is a criticism of the introduction to the tables recently published by Dr. J. Hann, of Vienna, and has especial reference to the difficulty found in using the wet and dry bulb thermometers when the temperature is near or below the freezing point. Prof. Hazen states that nearly all the difficulty vanishes when the thermometers are well ventilated.—List of cloud photographs and lantern-slides, by R. De C. Ward. A list of typical cloud forms, classified according to the international system, has been prepared, with an explanation of each, for use in lectures. The photographs are chiefly from pictures taken by Riggenbach and Manucci, during various positions and conditions.

Wiedemann's Annalen der Physik und Chemie, No. 8.—On the mechanical effects of waves upon resonators at rest, by Peter Lebedew. The case of electromagnetic waves is the first dealt with. Instruments called magnetic and electric resonators, respectively, were constructed in such a manner that they could be suspended by quartz fibres parallel to the planes of their coils. One of these was arranged so as to resound to the magnetic, the other to the electric components of the waves only. It was found that both resonators behaved in the same way. When "tuned" to a higher pitch, they were attracted by the incident wave system; when tuned lower, they were repelled, the maximum effects occurring when most closely approaching perfect resonance. The phenomena can be explained by supposing that the excitation of electric resonators obeys the laws governing all elastic vibrations, and that the laws of Coulomb and Ampère with respect to the relation between impulse and motion also apply to electric oscillations. The experiments are analogous to attempts to elucidate the molecular forces attending the propagation of light.—On the velocities of sound in air, gases, and vapours for simple tones of different pitches, by James Webster Low. From experiments performed with a Quincke interference tube, it appears that, contrary to the results obtained by Kundt, Regnault, König, and others, for closed tubes, the velocity of sound in air and in carbonic acid is the same for notes of different pitch and intensity when they are propagated in open space.—On the seat of the electric charge in condensers, by A. Kleiner. The experiments were performed chiefly on mica condensers, one coating of which consisted of pure mercury, and the other of tinfoil. The discharges obtained after the coatings had been taken off and replaced were about 5 per cent. less than those from the undisturbed condenser.

When the mica sheet was split in two, approximately equal discharges were obtained from the original condenser and the condensers formed with each of the parts, thus exhibiting the analogy with a magnet when broken into parts.—On the magnetisation of iron cylinders, by O. Grotrian. The parts of an iron cylinder not too short in comparison with its diameter, magnetised by a homogeneous field in the direction of the axis, are very differently magnetised when saturation has not been reached, the outside parts being much more strongly magnetised than the axial ones.

SOCIETIES AND ACADEMIES

LONDON.

Chemical Society, June 21.—Dr. H. E. Armstrong, President, in the chair.—The following papers were read: A specimen of early Scottish iron, by Miss M. D. Dougal.—The interaction of sulphide with sulphate and oxide of lead, by J. B. Hannay. The two equations—$PbS + PbSO_4 = 2Pb + 2SO_2$ and $PbS + 2PbO = 3Pb + SO_2$—given by Percy, to represent the reactions occurring in lead smelting, are insufficient. A much more complex reaction occurs, since metallic lead when formed attacks the remaining sulphate, producing litharge, which in turn reacts with the sulphide; further, some of the sulphide is removed by solution in the metallic lead, whilst some is volatilised as the compound PbS,SO_2.—The mineral waters of Cheltenham, by T. E. Thorpe.—The oxidation of tartaric acid in presence of iron, by H. J. H. Fenton. Tartaric acid is oxidised by certain agents in presence of a trace of ferrous salt with formation of a new crystalline dibasic acid, $C_4H_4O_6, 2H_2O$; it is a powerful reducing agent, and forms crystalline salts.—The supposed relation between the solubility of a gas and the viscosity of its solvent, by T. E. Thorpe and J. W. Rodger. From the results of their own experiments on the viscosity of solutions of gases, the authors are led to modify the conclusions of Winkler respecting the relation between solubility and viscosity.—The specific character of the fermentative functions of yeast cells, by A. J. Brown. Pasteur's view of the cause of the exhibition of the fermentation functions of yeast cells is that it is a starvation phenomenon brought about by lack of free oxygen during the life of the cells in a fermentable liquid. The fermentative power was measured by Pasteur as the ratio of yeast to sugar; the author finds, however, that there is no direct constancy of proportion between the weight of yeast formed and of sugar fermented. Pasteur's experiments are consequently insufficient, and his theory unproven.—Observations on the influence of temperature on the optical activity of organic liquids, by P. Frankland and J. MacGregor. The authors have measured the rotatory powers of methylic and ethylic salts of active glyceric and diacetylglyceric acids at various temperatures; the percentage increase in rotation as the temperature rises is greater for the methylic than for the ethylic salts.—The maximum molecular deviation in the series of the ethereal salts of active diacetylglyceric acid, by P. Frankland and J. MacGregor.—The preparation of sulphonic derivatives of camphor, by F. S. Kipping and W. J. Pope. The sulphonic chlorides and bromides of camphor and its halogen derivatives are best prepared by treating the ammonium salts of the corresponding sulphonic acids with phosphoric chloride.—Dextro-rotatory camphorsulphonic chloride, by F. S. Kipping and W. J. Pope.—On the combination of chlorine with carbon monoxide under the influence of light: preliminary notice, by G. Dyson and A. Harden. There is a well-marked period of photochemical induction in the amount of chemical action occurring when light acts on a moist mixture of equal volumes of carbon monoxide and chlorine.—Solution and pseudo-solution, part ii., by S. E. Linder and H. Picton.—Solution and pseudo-solution, part iii., by H. Picton and S. E. Linder. The continuation of previous work on solutions is described in these two papers.

PARIS.

Academy of Sciences, July 23.—M. Lœwy in the chair.—On the photographs of the moon obtained with the great *coudé* equatorial of the Paris Observatory, by MM. Lœwy and Puiseux. The difficulties met with in taking these lunar photographs are detailed, and an account is given of the methods used in overcoming them. Further, the photographs obtained are discussed and compared with maps and previous photographs.—On a new series of sulphophosphides, the thiohypophosphates, by M. C. Friedel. The iron, aluminium, zinc, copper, lead, silver, mercury, and tin salts are described. The series is viewed as consisting of salts of the general type $P_2S_6M'_4$.—On two menhirs found in Meudon wood, by M. Berthelot. Two previously undescribed sandstone menhirs have their characteristics given in detail.—On the reduction of any differential system whatever to a completely integrable form, by M. Riquier. The conclusions of this memoir are summarised as follows:—"Being given a differential system involving any number of unknown functions and any number of independent variables, simple eliminations, together with differentiations, allow, in general, of putting them into a completely integrable form, of which the order is nearly always superior to one, and approximates to a linear and completely integrable form of the first order."—On the specific inductive capacity of glass, by M. F. Beaulard. The influence of the time of charging has been studied by the ballistic method and k calculated for an instantaneous charge, the author finds $k = 3{\cdot}9$.—On the electrolysis of copper sulphate, by M. A. Chassy. With a neutral saturated solution of copper sulphate at 100° and a current density of a hundredth of an ampère per square centimetre, a bright red deposit of cuprite in forms derived from the cube and octahedron is obtained. By lowering the temperature, diminishing the concentration, or augmenting the current density, varying proportions of metallic copper can be obtained along with the red crystals. In determinations of current by electrolysis of copper sulphate it is necessary, in order to avoid serious error, to acidulate and pass the current through cold dilute solutions.—On manganese steel, by M. H. Le Chatelier. The anomalous results found previously by the author in studying the electric resistance of (13 per cent.) ferromanganese are explained by the formation of two allotropic varieties of the metal. The temperature of transformation is 740°, that temperature at which soft iron passes from the magnetic to the non-magnetic state.—On metaphthalodicyanacetic ether, by M. Locher.—Organo-metallic combinations of borneol, camphor, and monochlor-camphor with aluminium chloride, by M. G. Perier. The compounds having the formulæ

$$(C_{10}H_{18}O)_2Al_2Cl_6,\ (C_{10}H_{16}O)_2Al_2Cl_6, \text{ and } (C_{10}H_{15}ClO)_2Al_2Cl_6$$

have been obtained in crystalline condition. They are very unstable in air, and are readily acted on by water with production of the original constituents.—On a new acid, isocampholic acid, by M. Guerbet.—Action of phosphorus pentachloride on tetrachloroquinone, by M. Et. Barral.—On essence of Pelargonium from Réunion, by MM. Ph. Barbier and L. Bouveault.—On the condensation of formaldehyde with alcohols of the fatty series in presence of hydrochloric acid, by M. C. Favre.—On the existence of hydroxyl in green plants, by M. A. Bach.—On the presence of several distinct kinds of chlorophyll in the same vegetable species, by M. A. Étard.—Researches on the causes of the toxicity of the serum of blood, by MM. Mairet and Bosc. The authors demonstrate the following conclusions:—(1) Blood serum has both toxic and coagulating properties. (2) The coagulating properties are destroyed by heat or by the addition of sodium chloride or sulphate. (3) The symptomatic effects produced by intravenous injections of pure serum are mostly due to the toxic properties of the serum, the coagulating effects making themselves felt only near the limit of the toxic action. (4) The alcoholic extract has no toxic or coagulating properties, these being only shown by the precipitate. (5) By partial precipitation with alcohol, the toxic and coagulating substances may be separated. (6) Both belong to the albumenoids.—On the structure of the membrane of Corti, by MM. P. Coyne and Cannieu.—On the metamorphoses of *Cecidomyia destructor*, Say, and on the puparium or larval envelope before its transformation into a chrysalis, by M. A. Laboulbène.—On the origin of "sphères directrices," by M. Leon Guignard.—The radical tubercles of *Arachis hypogea*, L., by M. Henri Lecomte.—Influence of the distribution of humidity in the soil on the development of chlorosis of the vine on a calcareous soil, by MM. F. Houdaille and M. Mazade.—On a magnetic perturbation, by M. Moureaux.

BERLIN.

Physiological Society, June 8.—Prof. du Bois Reymond, President, in the chair.—Dr. J. Munk gave an account of an experiment made on a dog as to the nutritive value of gelatine. Up to the present it was only known that gelatine alone could not make good the need for proteids, but that a diet of gelatine with some proteid leads to a reduction of proteid metabolised. Dr. Munk had propounded the question, how far can gelatine take the place of proteids? and had carried on an experiment of four days' duration. After the dog had been placed in nitrogenous equilibrium on a diet of meat-meal, rice and fat containing 9½ grms. of nitrogen in the form of proteid, five-sixths of this nitrogen was replaced by nitrogen in the form of gelatine: the animal continued in nitrogenous equilibrium. It appears from this that by the administration of gelatine the nitrogen necessary as proteids can be reduced far below the minimum metabolised in starvation, without any commencing metabolism of tissue nitrogen. Dr. Munk made a further communication on metabolism. It is known that the administration of carbohydrates to dogs leads to a saving of proteids. Recently it has been supposed that this saving is determined by the possibility that the carbohydrates lessen the putrefactive changes which proteids undergo in the intestine, so that they are absorbed unchanged in larger quantities. Since it is known that proteids are absorbed very rapidly from the intestine of dogs, and that the absorption is complete in about six hours, Dr. Munk gave a dog at one time 100 grms. sugar along with his meal of proteid, and at another time the proteid meal in the morning and the 100 grms. sugar later on after an interval of thirteen hours, when presumably there would be little or no proteid in the intestine. In both these experiments he noticed the same saving of proteids. In the first there was additionally a falling off of the ethereal sulphates in the urine, evidencing diminished putrefaction of proteids in the intestine. In the second case, where the sugar was given separately from the proteids, the ethereal sulphates were very slightly lessened in amount, so that here apparently there was no diminution of the putrefactive changes, and still the carbohydrates had saved the proteids. These experiments do not support the view recently put forward.—Prof. König gave an account of his experiments on Dr. Zumft for determining the position of the layers of the retina which are sensitive to light.

June 22.—Prof. du Bois Reymond, President, in the chair.—Dr. Marcuse gave an account of experiments on frogs in studying pancreatic diabetes. After having satisfied himself that extirpation of the pancreas in frogs leads in most cases, at latest after two days, to a distinct diabetes, he investigated the effect on this of total extirpation of the liver. Although the frogs lived from two to five days after the operation, no diabetes was observed in any one case. Notwithstanding the numerous hypotheses as to the influence of the liver and pancreas on the sugar of the blood, it is not as yet possible to offer a satisfactory explanation of the above observations. Prof. Zuntz had recently endeavoured by a lengthy series of experiments to determine whether any one alone of the food-stuffs, proteids, fats, or carbohydrates can be regarded as the source of muscular energy. The experiments were made on a dog, which can be fed and nourished quite well on either proteids or fats or carbohydrates (rice and sugar), and showed that each one of the above three food-stuffs suffices to provide the energy necessary for the work done by the muscles. Comparative experiments made to determine which of the three food-stuffs can be most advantageously employed for supplying this energy, have not as yet led to any decisive result. This important research is to be continued.

Gottingen.

Royal Society of Sciences.—In the *Nachrichten*, No. 2, 1894, the following papers are published:—A. von Koenen: On the age of the mineral veins of the Harz Mountains.—J. Disse: On epithelial buds in the olfactory region of mammalia.—W. Voigt: On media without internal forces, and on a mechanical interpretation of the Maxwell-Hertz equations thereby furnished.—J. Bohls: Notes on the capture and natural history of *Lepidosiren* in Paraguay.—E. Ehlers: On *Lepidosiren paradoxa* (Fitz) and *articulata* (nov. spec.) from Paraguay.—P. Günther: Gauss's researches in the theory of the elliptic functions.—Robert Fricke: An application of the ideal theory to the substitution groups of the automorphous functions.—E. Riecke: The theorem of the thermodynamic potential of a heterogeneous system in equilibrium, with an application to van der Waal's theory and to the law of the boiling-point.—W. THURSDAY, AUGUST 9, 1894.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Wilde's Theory of the Secular-Variation of Terrestrial Magnetism.

IN a recent communication to the Royal Society, contained in the *Proceedings* for March, pp. 210-217, Mr. Henry Wilde, F.R.S., believes that he has cited additional facts in support of his theory of the secular variation of terrestrial magnetism. Wilde first proposed his theory[1] to the Society, June 19, 1890. He had it separately printed, in addition with other papers, in three languages, and the pamphlet was scattered far and wide. It was issued in the form of a reprint from the *Transactions* (though it never appeared in the *Transactions*), and contained such surprisingly good agreements between theory and observations that several eminent men of science, without examining the pamphlet very carefully, and believing that it bore the stamp of the Royal Society, were misled into thinking that Wilde had really achieved some remarkable results.

Having been engaged in the United States Coast and Geodetic Survey as magnetic computer for five years, and being aware of the difficulty in reconciling the secular variation of the magnetic declination for various places on the earth's surface with each other, under the assumption of one period for the whole earth, and that at the same time the orbit described during that period by the north end of a free magnetic needle should be a single closed curve, I undertook to show the fallacy both of Wilde's theory and of the supposed agreement with observations. The result of my investigation was read before the Philosophical Society of Washington, February 27, 1892, and was published in the *American Journal of Science*, vol. xliii., June 1892. The conclusions of that paper were :—

(1) Wilde's theory is physically impossible.

(2) Wilde's mechanism (magnetarium) does not agree in principle with his theory as outlined.

(3) The results from the magnetarium do not represent the facts of terrestrial magnetism.

(4) Wilde's theory is but a modification of Halley's.

In proving (3), I showed that Wilde, in the case of the London results, only got out of his mechanism what he had actually put in. In the case of Cape of Good Hope and St. Helena, such apparently good results were obtained because the law of the secular variation for these two stations, within the period of observation and within the large probable error of the magnetarium results, is not very dissimilar from that for London. So to get a good correspondence for Cape of Good Hope and St. Helena, it was only necessary to turn the crank a few times more. I, moreover, showed from facts stated in the very *Bulletin* of the Coast Survey, which Wilde has cited in his late communication, as giving additional proof of his theory, that in order to satisfy perfectly the three stations, London, Cape of Good Hope, and St. Helena, it would seem that his inner electrodynamic sphere would have to make one complete differential revolution in 960 years (as he has deduced) for the first two stations, but that for St. Helena it would have to move more rapidly and perform a revolution in 780 years. I therefore proposed to Wilde to try to turn out with his magnetarium the secular variation of the magnetic declination for stations which exhibit a vastly different law from that of London, viz. stations in the United States. It is remarkable that although he evidently possesses records of secular-variation stations in the United States, he has thus far made no published attempt to reproduce them with his magnetarium. The point insisted upon was that he should turn out the secular variation at the various stations conjointly, not separately. Is it not strange that he has made no attempt in the four years since he first constructed his magnetarium, to give us the secular variation for other portions of the earth than simply for the three stations given in the first communication, and now in the last one for a station which lies not far from one of these, and so has a similar law of variation? Why does not Wilde read off from his magnetarium the declinations at other stations, *e.g.* Paris, New York City, St. John's, Newfoundland, Peking, &c., when he turns out the secular variation at London?

But I shall now ignore my own paper, with its conclusions, and exhibit the fallacy of Wilde's theory on the basis of the results given in his last communication.

(1) The annual change of the dip at London for the last fifty years has been steadily decreasing, indicating the approach of a minimum. A formula established by myself on the basis of the London dip observations, 1576–1890, which represents the observations many times better than the magnetarium results, predicts this epoch of minimum dip about the middle of the next century.[1] This phase of minimum dip is advancing steadily from the East, and has already set in in Western Russia. The decrease of annual change of dip is borne out by numerous stations in Europe, all indicating the near approach of a minimum dip phase. Now *Wilde's* magnetarium results give a steady *increase* of annual change of dip, in consequence of which his minimum dip for London does not occur until after the year 2200.

(2) On p. 216 of the last communication, Wilde says : "On working the inclination (at St. Helena) backwards on the magnetarium chronologically, it will be seen from the Table VI. that about the year 1747 the dip changed the sign from south to north. As no observations were made on the dip at St. Helena previous to the year 1825, there is no record of this interesting fact, nor has it hitherto been deduced from theory." Unfortunately for Wilde, we have record of observations for this period, which, instead of giving a dip of 0° in 1747, give a dip of 9° to 10° (south end dipping)! To show how poorly his results agree with observation for periods where he does not possess the records himself, I give the following table :—

Date.	Observer.	Observed inclination.	Wilde inclination.	Observation theory.
		°	°	°
1700	Hansteen chart	11·5 S.	3·9 N.	−15·4
1754·3	La Caille	9·00	0·5 S.	− 8·5
1771·4	Ekeberg	13·00	3·5	− 9·5
1775·4	Cook	11·42	4·0	− 7·4
1780	Hansteen chart	10·5	5·1	− 5·4
1825·0	Duperry	14·93	14·7	− 0·2
1840·1	Ross	18·27	18·5	+ 0·2
1842·3	Belcher	17·00	19·0	+ 2·0
1846·8	Smythe	19·39	20·5	+ 1·1
1890·1	U.S.C. & G.S.	29·65	33·8	+ 4·1
,,	,,	31·18	33·8	+ 2·6

Wilde only had the observations 1825–1880, and it will be seen that for this short interval the correspondence between theory and observation is very good.

But before this interval the divergence is so great as to completely vitiate the Wilde magnetarium results. Likewise with 1890, the divergence becomes marked again. The first observation for 1890 was made at Jamestown, the second at Longwood, St. Helena. The first station agrees in locality more closely with preceding observations than the second.[2]

Wilde concludes with a reproduction of the observations of declination and inclination at Ascension Island for the epoch 1834–1890. During this interval the correspondence is very good, but he does not tell us whether he obtained the results separately or conjointly with London, Cape of Good

[1] "That the principal phenomena of terrestrial magnetism, and of the secular changes, could be explained on the assumption of an electrodynamic substance (presumably liquid or gaseous) rotating within the crust of the earth in the plane of the ecliptic, and a little slower than the diurnal rotation." A complete differential revolution of this electrodynamic substance is performed in 960 years, which period, according to Wilde, constitutes the secular-variation period.

[1] *Science*, vol. xx. No. 505.

[2] From a paper, soon to be published, on the secular-variation curves as described, in the course of time, by a freely suspended magnetic needle at various portions of the earth's surface, it would appear as though the inclination at St. Helena never becomes zero as Wilde's theory would demand.

Hope, and St. Helena. But even if the latter were the case, to give convincing proof of the correctness of his theory, he would at the same time have to reproduce the observations at points widely distant from these stations. We would like to ask Wilde to turn out the Ascension declinations and inclinations, say, from 1700-1834. L. A. BAUER.

Friedenau, bei Berlin, July 21.

Time-Gauge of Niagara.

IN the summer of 1890, I had the opportunity of spending some months in Canada, where I devoted what time I had to spare to the later geology of the country.

The time-gauge of the Niagara Falls struck me, and naturally led to further investigation.

We are fairly justified in the assumption, from historical sources in Egypt and elsewhere, that no distinguishable change of climate has occurred for, say, four thousand years. Our first knowledge of Britain, nearly two thousand years ago, would indicate that the climate of the south coast was then, at least in summer, a few degrees higher than now. Restore the conditions, reafforest the country lying north, and we should probably find this state of affairs restored. Four thousand years is a good stretch in the mind to seven thousand, so we may safely assume the "Glacial Epoch" must be put back an indefinite time beyond that.

Now we find, looking at the superficial geology of the lakes, that Erie must be dissociated from the other four. There is every reason to believe it was a river basin draining by the Wabash and Maumee valleys into the Mississippi. Ontario again in pre-glacial times drained by Syracuse into the Atlantic. During the Ice Age these drainage valleys were blocked, as was possibly the present discharge by the St. Lawrence past Montreal. In post-glacial times, on the retiring of the ice, Ontario stood at a much higher level, and probably discharged over the Niagara ridge into Erie.

It is well known that an old river channel exists, passing from above Niagara and tending west of Queenstown to Ontario. It has been assumed that flowing out of Erie the channel divided, one branch flowing west, the other east of Queenstown, and that owing to erosion at the extremity, one (the western) became closed, while the other survived as the Niagara.

If this were the case, there must have been, for a time, two falls over the escarpment near Queenstown, but there is absolutely no evidence of there having been a fall at the extremity of the western branch.

What seems to have happened was that for an indefinite time Ontario discharged westward into Erie, which again drained into the Upper Mississippi. A slight change of level may have occurred, or a local flood have carried away some of the débris closing the Lower St. Lawrence, and Ontario found a way of escape to the east. A rapid erosion of the old valley must have occurred with the result of lowering Erie sufficiently to reverse its outfall, when the river took the lowest channel, and first flowed, as now, over the escarpment.

The time-gauge represents then, not the close of the glaciated period, but the epoch when Ontario returned to its pre-glacial discharge. The intermediate period, when it flowed into Erie, has apparently left only the old western channel as evidence of what may well have been a protracted period

Shanghai, June 22. THOS. W. KINGSMILL.

Late Appearance of the Cuckoo.

ON Friday last, July 27, as I was walking along the Sion Vista in Kew Gardens, towards the river, I heard, far off to my left, the cry of a cuckoo. There was but one cry, and that had not the duplication of the first sound which usually marks his later utterances with us. Clearly though I had heard it, I might almost have doubted the testimony of my ears if I had not, on turning suddenly to the direction from which the sound had come, *seen* the bird rise quickly and fly across the river.

Height of Barometer.

CAN any of your readers refer me to the maximum and minimum *uncorrected* heights of the barometer, which have been hitherto recorded (1) in England, (2) in any part of the world? It would, of course, be necessary to know the height of the place of observation above sea-level in the case of the minimum, at least. KARL PEARSON.

University College, London, August 5.

Magnetisation of Rock Pinnacles.

MR. HILL will be glad to find that systematic observations on the magnetism of rock masses have been taken for the very district he mentions in his letter of July 28.

In vol. x., part 2, of the *Journal* of the Royal Institution of Cornwall, there appears a short paper on "The Magnetism of the Lizard Rocks," by Mr. Thomas Clark. In this he gives not only the results obtained, but his method of procedure. A subsequent paper (printed in vol. xi., part 2, of the *Journal*), on "The Magnetic Rocks of Cornwall," gives the results of his experiments, and is accompanied by a map of the county showing the position of its magnetic rocks. I understand that Mr. Clark is continuing his research in this direction.

If similar observations were taken throughout the whole of the country, especially in the neighbourhood of the coast, doubtless they would yield results of great value to commerce as well as to science. M. M. S.

IF Mr. Hill will refer to *Alpine Journal*, vol. xiii. p. 439, he will find mention of a magnetic peak in the Black Coolins: the mountain bears the name Bidein Druim nan Ramh.

Eccles, August 5. JAMES HEELIS.

THE BRITISH ASSOCIATION.

OXFORD, AUGUST 8.

THE sixty-fourth meeting of the British Association, and the fourth which has been held at Oxford, may now be fairly said to have begun. The reception-room was opened at 2 p.m. on Monday last, and at the moment of the opening of the doors there was an unexampled rush to obtain places in the Sheldonian Theatre for the President's address and the evening lectures. The places in the theatre have been filled with extraordinary quickness, and it is to be feared that late-comers, who have not availed themselves of the offer of the Local Secretaries to engage seats beforehand by letter, will be disappointed in the places which they obtain. This is an unusual occurrence, and demands some explanation. The Sheldonian Theatre is the largest building now standing in Oxford. The old Corn Exchange was larger, and could have comfortably accommodated the audience which assembled to hear Lord Salisbury on Wednesday night. But unfortunately it is no longer existent. It has been pulled down, with the other civic buildings, to make room for larger successors, which are only half completed, and the Local Committee must regret, without being able to remedy, the circumstance that the only available place of meeting is insufficient for the needs of the Association.

Lord Salisbury's address is fully reported in another part of this issue. Many of those who know Lord Salisbury only as a politician and as Minister for Foreign Affairs, will be surprised at the wide range of thought and reading displayed in this address, and more still at the keen critical faculty displayed in his handling of the diverse topics which he passes under review. Possibly the whole of his audience will not entirely agree with his views on current scientific problems, and his concluding remarks on the present position of the Darwinian theory offer almost a repetition of the controversy which made the last meeting at Oxford so famous four-and-thirty years ago. The two other evening addresses are not likely to fall far short in interest of the opening meeting. As is usual, Thursday morning is devoted to the addresses of the Presidents of Sections, and three of these are reported at length in this issue. The addresses at Oxford differ necessarily in one respect from those which are delivered at many other centres at which the Association meets. Oxford has in its relations to science a historical interest, as well as a more present interest in virtue of its being a seat of learning. It will accordingly be found that many of the Sectional Presidents touch upon the history of science as exemplified by Oxford, and enlarge upon its needs as an instrument of culture and education. Oxford indeed, though it is not generally supposed to be a scientific University, has a past which it may look on with pride. Few may remember that Roger Bacon, an early devotee and martyr to science, lived and worked at Oxford, and that this is the sex-centenary of the reputed year of his death. A second period, mentioned by Prof. Dixon in his opening address, is that of Robert Boyle and his colleagues, among whom was for a short time the illustrious Harvey, a band of men who were virtually the founders of the Royal Society.

The proceedings of the Sections derive great interest from the unusual number of communications by eminent foreign men of science. The proceedings of some of the Sections have already been indicated in previous numbers of NATURE; those of others are not even now settled into definite shape. In Section A (Mathematical and Physical Science), besides the joint meetings with Section G, which have already been mentioned, there are, amongst other important papers set down for Thursday, one on "Preliminary Experiments proving the Electrification of Air by the Subtraction of Water from it," by Lord Kelvin and Magnus McLean; another, by Lord Kelvin and Alexander Galt, on "Leyden Jar Discharges through Divided Channels," and a third, by Prof. G. Quincke, on "The Formation of Soap Bubbles by the Contact of Alkaline Oleates with Water." On Saturday Prof. Everett reads on "Some Jointed Frames or Linkages," and Dr. P. H. Schoute on "The Order of the Groups related to the Anallagmatic Displacements of the Regular Bodies in n-dimensional space." On Monday there is a paper by Lord Rayleigh, of which the title is not yet published, and others follow by Prof. H. H. Turner, Prof. Viriamu Jones, Mr. F. H. Newall, and Prof. O. J. Lodge.

In Section D, the Department of Botany, which meets by itself in Magdalen College School, has some very interesting matter. There are important papers by Prof. D. H. Campbell, of the University of California, and Prof. F. O. Bower, on "The Morphology of Vascular Cryptogams"; by Prof. E. Strasburger, on "Chromosomenzahl"; by Dr. Leopold Kny, on "Correlation between Root and Shoot"; by Prof. Green, on "Influence of Light on Diastase," and by Prof. Dukinfield Scott on "The Structure of Fossil Plants and their bearing on Botanical Problems."

The Anthropological Section, of which some account has been given in an earlier number, will devote the greater part of Friday and Monday to discussions on Early Man in Western Europe, in which M. Emile Cartailhac and Comte Goblet d'Alviella will take a leading part; and on Tuesday and Wednesday, various papers on Ethnography will range from North Africa to Australia.

At the soirée in the University Museum, on Thursday evening, there will be a few interesting exhibits, chief among which will be Prof. Henrici's linkage models, exhibitions by the Cambridge Scientific Instrument Company, by Prof. Everett, and demonstrations of anthropometrical methods, by Dr. J. G. Garson.

INAUGURAL ADDRESS BY THE MOST HON. THE MARQUIS OF SALISBURY, K.G., D.C.L., F.R.S., CHANCELLOR OF THE UNIVERSITY OF OXFORD, PRESIDENT.

MY functions are of a more complicated character than usually is assigned to the occupants of this chair. As Chancellor of the University it is my duty to tender to the British Association a hearty welcome, which it is my duty as President of the Association to accept. As President of the Association I convey, most unworthily, the voice of English science, as many worthy and illustrious Presidents have done before me; but in representing the University I represent far more fittingly the learners who are longing to hear the lessons which the first teachers of English science have come as visitors to teach. I am bound to express on behalf of the University our sense of the good feeling towards that body which is the motive of this unusual arrangement. But as far as I am personally concerned, it is attended with some embarrassing results. In presence of the high priests of science I am only a layman, and all the skill of all the chemists the Association contains will not transmute a layman into any more precious kind of metal. Yet it is my hard destiny to have to address on scientific matters probably the most competent scientific audience in the world. If a country gentleman, who was also a colonel of Volunteers, were by any mental aberration on the part of the Commander-in-Chief to be appointed to review an army corps at Aldershot, all military men would doubtless feel a deep compassion for his inevitable fate. I bespeak some spark of that divine emotion when I am attempting to discharge under similar conditions a scarcely less hopeless duty. At least, however, I have the consolation of feeling that I am free from some of the anxieties which have fallen to those who have preceded me as Presidents in this city. The relations of the Association and the University are those of entire sympathy and good will, as becomes common workers in the sacred cause of diffusing enlightenment and knowledge. But we must admit that it was not always so. A curious record of a very different state of feeling came to light last year in the interesting biography of Dr. Pusey, which is the posthumous work of Canon Liddon. In it is related the first visit of the Association to Oxford in 1832. Mr. Keble, at that time a leader of University thought, writes indignantly to his friend to complain that the honorary degree of D.C.L. had been bestowed upon some of the most distinguished members of the Association: "The Oxford Doctors," he says, "have truckled sadly to the spirit of the times in receiving the hodge-podge of philosophers as they did." It is amusing, at this distance of time, to note the names of the hodge-podge of philosophers whose academical distinctions so sorely vexed Mr. Keble's gentle spirit. They were Brown, Brewster, Faraday, and Dalton. When we recollect the lovable and serene character of Keble's nature, and that he was at that particular date probably the man in the University who had the greatest power over other men's minds, we can measure the distance we have traversed since that time; and the rapidity with which the converging paths of these two intellectual luminaries, the University and the Association, have approximated to each other. This sally of Mr. Keble's was no passing or accidental caprice. It represented a deep-seated sentiment in this place of learning, which had its origin in historic causes, and which has only died out in our time. One potent cause of it was that both bodies were teachers of science, but did not then in any degree attach the same meaning to that word. Science with the University for many generations bore a signification different from that which belongs to it in this assembly. It represented the knowledge which alone in the Middle Ages was thought worthy of the name of science. It was the knowledge gained not by external observation, but by mere reflection. The student's microscope was turned inward upon the recesses of his own brain; and when the supply of facts and realities failed, as it very speedily did, the scientific imagination was not wanting to furnish to successive generations an interminable series of conflicting speculations. *That* science—science in our academical sense—had its day of rapid growth, of boundless aspiration, of enthusiastic votaries. It fascinated the rising intellect of the time, and it is said —people were not particular about figures in those days—that its attractions were at one time potent enough to gather round the University thirty thousand students, who for the sake of learning its teaching were willing to endure a life of the severest hardship. Such a state of feeling is now an archæological curiosity. The revolt against Aristotle is now some three centuries old. But the mental sciences which were supposed to rest upon his writings have retained some of their ascendency even till this day, and have only slowly and jealously admitted the rivalry of the growing sciences of observation. The subject is interesting to us, as this undecided state of feeling coloured the experiences of this Association at its last Oxford visit, nearly a generation later, in 1860. The warmth of the encounters which then took place have left a vivid impression on the minds of those who are old enough to have witnessed them. That much energy was on that occasion converted into heat may, I think, be inferred from the mutual distance which the two bodies have since maintained. Whereas the visit of 1832 was succeeded by another visit in fifteen years, and the visit of 1847 was succeeded by another visit in thirteen years, the year 1860 was followed by a long and dreary interval of separation, which has only now, after four-and-thirty years, been terminated. It has required the lapse of a generation to draw the curtain of oblivion over those animated scenes. It was popularly supposed that deep divergences upon questions of religion were the motive force of those high controversies. To some extent that impression was correct. But men do not always discern the motives which are really urging them, and I suspect that in many cases religious apprehensions only masked the resentment of the older learning at the appearance and claims of its younger rival. In any case there is something worthy of note, and something that conveys encouragement, in the difference of the feeling which prevails now and the feeling that was indicated then. Few men are now influenced by the strange idea that questions of religious belief depend on the issues of physical research. Few men, whatever their creed, would now seek their geology in the books of their religion, or, on the other hand, would fancy that the laboratory or the microscope could help them to penetrate the mysteries which hang over the nature and the destiny of the soul of man. And the old learning no longer contests the share in education which is claimed by the new, or is blind to the supreme influence which natural knowledge is exercising in moulding the human mind.

A study of the addresses of my learned predecessors in this office shows me that the main duty which it falls to a President to perform in his introductory address, is to remind you of the salient points in the annals of science since last the Association visited the town in which he is speaking. Most of them have been able to lay before you in all its interesting detail the history of the particular science of which each one of them was the eminent representative. If I were to make any such attempt I should only be telling you with very inadequate knowledge a story which is from time to time told you, as well as it can be told, by men who are competent to deal with it. It will be more suitable to my capacity if I devote the few observations I have to make to a survey not of our science but of our ignorance. We live in a small bright oasis of knowledge surrounded on all sides by a vast unexplored region of impenetrable mystery. From age to age the strenuous labour of successive generations wins a small strip from the desert and pushes forward the boundary of knowledge. Of such triumphs we are justly proud. It is a less attractive task—but yet it has its fascination as well as its uses—to turn our eyes to the undiscovered country which still remains to be won, to some of the stupendous problems of natural study which still defy our investigation. Instead, therefore, of recounting to you what has been done, or trying to forecast the discoveries of the future, I would rather draw your attention to the condition in which we stand towards three or four of the most important physical questions which it has been the effort of the last century to solve.

Of the scientific enigmas which still, at the end of the nineteenth century, defy solution, the nature and origin of what are called the elements is the most notable. It is not, perhaps, easy to give a precise logical reason for the feeling that the existence of our sixty five elements is a strange anomaly and conceals some much simpler state of facts. But the conviction is irresistible. We cannot conceive, on any possible doctrine of cosmogony, how these sixty five elements came into existence. A third of them form the substance of this planet. Another third are useful, but somewhat rare. The remaining third are curiosities scattered haphazard, but very scantily, over the globe, with no other apparent function but to provide occupation for the collector and the chemist. Some of them are so like each other that only a chemist can tell them apart: others differ immeasurably from each other in every conceivable particular. In cohesion, in weight, in conductivity, in melting point, in chemical proclivities they vary in every degree. They seem to have as much relation to each other as the pebbles on a sea beach, or the contents of an ancient lumber room. Whether you believe that Creation was the work of design or of inconscient law, it is equally difficult to imagine how this random collection of dissimilar materials came together. Many have been the attempts to solve this enigma; but up till now they have left it more impenetrable than before. A conviction that here was something to discover lay beneath the persistent belief in the possibility of the transmutation of other metals into gold, which brought the alchemy of the Middle Ages into being. When the immortal discovery of Dalton established that the atoms of each of these elements have a special weight of their own, and that consequently they combine in fixed ponderable proportions from which they never depart, it renewed the hope that some common origin of the elements was in sight. The theory was advanced that all these weights were multiples of the weight of hydrogen—in other words, that each elementary atom was only a greater or a smaller number of hydrogen atoms compacted by some strange machinery into one. The most elaborate analyses, conducted by chemists of the highest eminence—conspicuously by the illustrious Stas—were directed to the question whether there was any trace in fact of the theoretic idea that the atoms of each element consist of so many atoms or even of so many half-atoms of hydrogen. But the reply of the laboratories has always been clear and certain—that there is not in the facts the faintest foundation for such a theory.

Then came the discovery of the spectrum analysis, and men thought that with an instrument of such inconceivable delicacy we should at last find out something as to the nature of the atom. The result has been wholly disappointing. Spectrum analysis in the hands of Dr. Huggins and Mr. Lockyer and others has taught us things of which the world little expected to be told. We have been enabled to measure the speed with which clouds of blazing hydrogen course across the surface of the sun; we have learnt the pace—the fabulous pace—at which the most familiar stars have been for ages approaching to or receding from our planet, without apparently affecting the proportions of the patterns which as far as historical record goes back they have always delineated on the evening sky. We have received some information about the elementary atoms themselves. We have learnt that each sort of atom when heated strikes upon the ether a vibration, or set of vibrations, whose rate is all its own; and that no one atom or combination of atoms in producing its own spectrum encroaches even to the extent of a single line upon the spectrum that is peculiar to its neighbour. We have learnt that the elements which exist in the stars and specially in the sun are mainly those with which we are familiar upon earth. There are a few lines in excess to which we can give no terrestrial name; and there are some still more puzzling gaps in our list. It is a great aggravation of the mystery which besets the question of the elements, that among the lines which are absent from the spectrum of the sun, those of nitrogen and oxygen stand first. Oxygen constitutes the largest portion of the solid and liquid substance of our planet, so far as we know it; and nitrogen is very far the predominant constituent of our atmosphere. If the earth is a detached bit whirled off the mass of the sun, as cosmogonists love to tell us, how comes it that in leaving the sun we cleaned him out so completely of his nitrogen and oxygen that not a trace of these gases remains behind to be discovered even by the sensitive vision of the spectroscope?

All these things the discovery of the spectrum analysis has added to our knowledge; but it has left us as ignorant as ever as to the nature of the capricious differences which separate the atoms from each other, or the cause to which those differences are due.

In the last few years the same enigma has been approached from another point of view by Prof. Mendeléeff. The periodic law which he has discovered reflects on him all the honour that can be earned by ingenious, laborious, and successful research. He has shown that this perplexing list of elements can be divided into families of about seven, speaking very roughly: that those families all resemble each other in this, that as to weight, volume, heat, and laws of combination, the members of each family are ranked among themselves in obedience to the same rule. Each family differs from the others; but each internally is constructed upon the same plan. It was a strange discovery—strangest of all in its manifest defects. For in the plan of his families there were blanks left; places not filled up because the properly constituted elements required according to his theory had not been found to fill them. For the moment their absence seemed a weakness in the Professor's idea, and gave an arbitrary aspect to his scheme. But the weakness was turned into strength when, to the astonishment of the scientific world, three of the elements which were missing made their appearance in answer to his call. He had described beforehand the qualities they ought to have; and gallium, germanium, and scandium, when they were discovered shortly after the publication of his theory, were found to be duly clothed with the qualities he required in each. This remarkable confirmation has left Mendeléeff's periodic law in an unassailable position. But it has rather thickened than dissipated the mystery which hangs over the elements. The discovery of these co-ordinate families dimly points to some identical origin, without suggesting the method of their genesis or the nature of their common parentage. If they were organic beings all our difficulties would be solved by muttering the comfortable word "evolution"—one of those indefinite words from time to time vouchsafed to humanity, which have the gift of alleviating so many perplexities and masking so many gaps in our knowledge. But the families of elementary atoms do not breed; and we cannot therefore ascribe their ordered difference to accidental variations perpetuated by heredity under the influence of natural selection. The rarity of iodine, and the abundance of its sister chlorine, cannot be attributed to the survival of the fittest in the struggle for existence. We cannot account for the minute difference which persistently distinguishes nickel from cobalt, by ascribing it to the recent inheritance by one of them of an advantageous variation from the parent stock.

The upshot is that all these successive triumphs of research, Dalton's, Kirchhoff's, Mendeléeff's, greatly as they have added to our store of knowledge, have gone but little way to solve the problem which the elementary atoms have for centuries presented to mankind. What the atom of each element is, whether it is a movement, or a thing, or a vortex, or a point having inertia, whether there is any limit to its divisibility, and, if so, how that limit is imposed, whether the long list of elements is final, or whether any of them have any common origin, all these questions remain surrounded by a darkness as profound as ever. The dream which lured the alchemists to their tedious labours, and which may be said to have called chemistry into being, has assuredly not been realised, but it has not yet been refuted. The boundary of our knowledge in this direction remains where it was many centuries ago.

The next discussion to which I should look in order to find unsolved riddles which have hitherto defied the scrutiny of science, would be the question of what is called the ether. The ether occupies a highly anomalous position in the world of science. It may be described as a half-discovered entity. I dare not use any less pedantic word than entity to designate it, for it would be a great exaggeration of our knowledge if I were to speak of it as a body or even as a substance. When nearly a century ago Young and Fresnel discovered that the motions of an incandescent particle were conveyed to our eyes by undulation, it followed that between our eyes and the particle there must be something to undulate. In order to furnish that something, the notion of the ether was conceived, and for more than two generations the main, if not the only, function of the word ether has been to furnish a nominative case to the verb "to undulate." Lately, our conception of this entity has received a notable extension. One of the most brilliant of the services which Prof. Maxwell has rendered to science has been the discovery that the figure which expressed the velocity of light, also expressed the multiplier required to change the measure of static or passive electricity into that of dynamic or active electricity. The interpretation reasonably affixed to this discovery is that, as light and the electric impulse move approximately at the same rate through space, it is probable that the undulations which convey them are undulations of the same medium. And as induced electricity penetrates through everything, or nearly everything, it follows that the ether through which its undulations are propagated must pervade all space, whether empty or full, whether occupied by opaque matter or transparent matter, or by no matter at all. The attractive experiments by which the late Prof. Hertz illustrated the electric vibrations of the ether will only be alluded to by me, in order that I may express the regret deeply and generally felt that death should have terminated prematurely the scientific career which had begun with such brilliant promise and such fruitful achievements. But the mystery of the ether, though it has been made more fascinating by these discoveries, remains even more inscrutable than before. Of this all-pervading entity we know absolutely nothing except this one fact, that it can be made to undulate. Whether outside the influence of matter on the motion of its waves, ether has any effect on matter or matter upon it, is absolutely unknown. And even its solitary function of undulating ether performs in an abnormal fashion which has caused infinite perplexity. All fluids that we know transmit any blow they have received by waves which undulate backwards and forwards in the path of their own advance. The ether undulates athwart the path of the wave's advance. The genius of Lord Kelvin has recently discovered what he terms a labile state of equilibrium, in which a fluid that is infinite in its extent may exist, and may undulate in this eccentric fashion without outraging the laws of mathematics. I am no mathematician, and I cannot judge whether this reconciliation of the action of the ether with mechanical law is to be looked upon as a permanent solution of the question, or is only what diplomatists call a *modus vivendi*. In any case it leaves our knowledge of the ether in a very rudimentary condition. It has no known qualities except one, and that quality is in the highest degree anomalous and inscrutable. The extended conception which enables us to recognise ethereal waves in the vibrations of electricity has added infinite attraction to the study of those waves, but it carries its own difficulties with it. It is not easy to fit in the theory of electrical ether waves with the phenomena of positive and negative electricity, and as to the true significance and cause of those counteracting and complementary forces, to which we give the provisional names of negative and positive, we know about as much now as Franklin knew a century and a half ago.

I have selected the elementary atoms and the ether as two instances of the obscurity that still hangs over problems which the highest scientific intellects have been investigating for several generations. A more striking but more obvious instance still is Life—animal and vegetable Life—the action of an unknown force on ordinary matter. What is the mysterious impulse which is able to strike across the ordinary laws of matter, and twist them for a moment from their path? Some people demur to the use of the term "vital force" to designate this impulse. In their view the existence of such a force is negatived by the fact that chemists have been able by cunning substitutions to produce artificially the peculiar compounds which in nature are only found in organisms that are or have been living. These compounds are produced by some living organism in the performance of the ordered series of functions proper to its brief career. To counterfeit them—as has been done in numerous cases—does not enable us to do what the vital force alone can effect—to bring the organism itself into existence, and to cause it to run its appointed course of change. This is the unknown force which continues to defy not only our imitation but our scrutiny. Biology has been exceptionally active and successful during the last half-century. Its triumphs have been brilliant, and they have been rich enough not only in immediate result but in the promise of future advance. Yet they give at present no hope of penetrating the great central mystery. The progress which has been made in the study of microscopic life has been very striking, whether or not the results which are at present inferred from it can be taken as conclusive. Infinitesimal bodies found upon the roots of plants have the proud office of capturing and taming for us the free nitrogen of the air, which, if we are to live at all, we must consume and assimilate, and yet which, without the help of our microscopic ally, we could not draw for any useful purpose from the ocean of nitrogen in which we live. Microscopic bodies are convicted of causing many of the worst diseases to which flesh is heir, and the guilt of many more will probably be brought home to them in due time; and they exercise a scarcely less sinister or less potent influence on our race by the plagues with which they destroy some of the most valuable fruits of husbandry, such as the potato, the mulberry, and the vine. Almost all their power resides in the capacity of propagating their kind with infinite rapidity, and up to this time science has been more skilful in describing their ravages than in devising means to hinder them. It would be ungrateful not to mention two brilliant exceptions to this criticism. The antiseptic surgery which we owe chiefly to Lister; and the inoculation against anthrax, hydrophobia, and perhaps some other diseases, which we owe to Pasteur, must be recorded as splendid victories over the countless legions of our infinitesimal foes. Results like these are the great glory of the scientific workers of the past century. Men may, perhaps, have overrated the progress of nineteenth-century research in opening the secrets of nature; but it is difficult to overrate the brilliant service it has rendered in ministering to the comforts and diminishing the sufferings of mankind.

If we are not able to see far into the causes and origin of life in our own day, it is not probable that we shall deal more successfully with the problem as it arose many million years ago. Yet certainly the most conspicuous event in the scientific annals of the last half-century has been the publication of Mr. Darwin's work on the "Origin of Species," which appeared in 1859. In some respects, in the depth of the impression which it made on scientific thought, and even on the general opinion of the world, its momentous effect can hardly be overstated. But at this distance of time it is possible to see that some of its success has been due to adventitious circumstances. It has had the chance of enlisting among its champions some of the most powerful intellects of our time, and perhaps the still happier fortune of appearing at a moment when it furnished an armoury of weapons to men, who were not scientific, for use in the bitter but transitory polemics of the day. But far the largest part of its accidental advantages was to be found in the remarkable character and qualifications of its author. The equity of judgment, the simple-minded love of truth and the patient devotion to the pursuit of it through years of toil and of other conditions the most unpropitious—these things endeared to numbers of men everything that came from Charles Darwin, apart from its scientific merit or literary charm. And whatever final value may be assigned to his doctrine, nothing can ever detract from the lustre shed upon it by the wealth of his knowledge and the infinite ingenuity of his resource. The intrinsic power of his theory is shown at least in this one respect, that in the department of knowledge with which it is concerned it has effected an entire revolution in the methods of research. Before his time the study of living nature had a tendency to be merely statistical; since his time it has become predominantly historical. The consideration how any organic body came to be what it is occupies a far larger area in any inquiry now than the mere description of its actual condition; but this question was not predominant—it may almost be said to have been ignored—in the Botanical and Zoological study of sixty years ago.

Another lasting and unquestioned effect has resulted from Darwin's work. He has, as a matter of fact, disposed of the doctrine of the immutability of species. It has been mainly associated in recent days with the honoured name of Agassiz, but with him has disappeared the last defender of it who could claim the attention of the world. Few now are found to doubt that animals separated by differences far exceeding those that distinguished what we know as species have yet descended from common ancestors. But there is much less agreement as to the extent to which this common descent can be assumed, or the process by which it has come about. Darwin himself believed that all animals were descended from "at most four or five progenitors"—adding that "there was grandeur in the view that life had been originally breathed by the Creator into a few forms or one." Some of his more devoted followers, like Prof. Haeckel, were prepared to go a step farther and to contemplate a crystal as the probable ancestor of the whole fauna and flora of this planet.

To this extent the Darwinian theory has not effected the conquest of scientific opinion; and still less is there any unanimity in the acceptance of natural selection as the sole or even the main agent of whatever modifications may have led up to the existing forms of life. The deepest obscurity still hangs over the origin of the infinite variety of life. Two of the strongest objections to the Darwinian explanation appear still to retain all their force.

I think Lord Kelvin was the first to point out that the amount of time required by the advocates of the theory for working out the process they had imagined could not be conceded without assuming the existence of a totally different set of natural laws from those with which we are acquainted. His view was not only based on profound mechanical reasoning, but it was so plain that any layman could comprehend it. Setting aside arguments deduced from the resistance of the tides, which may be taken to transcend the lay understanding, his argument from the refrigeration of the earth requires little science to apprehend it. Everybody knows that hot things cool, and that according to their substance they take more or less time in cooling. It is evident from the increase of heat as we descend into the earth, that the earth is cooling, and we know by experiment, within certain wide limits, the rate at which its substances, the matters of which it is constituted, are found to cool. It follows that we can approximately calculate how hot it was so many million years ago. But if at any time it was hotter at the surface by 50° F. than it is now, life would then have been impossible upon the planet, and therefore we can without much difficulty fix a date before which organic life on earth cannot have existed. Basing himself on these considerations Lord Kelvin limited the period of organic life upon the earth to a hundred million years, and Prof. Tait in a still more penurious spirit cut that hundred down to ten. But on the other side of the account stand the claims of the geologists and biologists. They have revelled in the prodigality of the ciphers which they put at the end of the earth's hypothetical life. Long cribbed and cabined within the narrow bounds of the popular chronology, they have exulted wantonly in their new freedom. They have lavished their millions of years with the open hand of a prodigal heir indemnifying himself by present extravagance for the enforced self-denial of his youth. But it cannot be gainsaid that their theories require at least all this elbow-room. If we think of that vast distance over which Darwin conducts us from the jelly-fish lying on the primeval beach to man as we know him now; if we reflect that the prodigious change requisite to transform one into the other is made up of a chain of generations, each advancing by a minute variation from the form of its predecessor, and if we further reflect that these successive changes are so minute that in the course of our historical period—say three thousand years—this progressive variation has not advanced by a single step perceptible to our eyes, in respect to man or the animals and plants with which man is familiar, we shall admit that for a chain of change so vast, of which the smallest link is longer than our recorded history, the biologists are making no extravagant claim when they demand at least many hundred million years for the accomplishment of the stupendous process. Of course, if the mathematicians are right, the biologists cannot have what they demand. If, for the purposes of their theory, organic life must have existed on the globe more than a hundred million years ago, it must, under the temperature then prevailing, have existed in a state of vapour. The jelly-fish would have been dissipated in steam long before he had had a chance of displaying the advantageous variation which was to make him the ancestor of the human race. I see, in the eloquent discourse of one of my most recent and most distinguished predecessors in this chair, Sir Archibald Geikie, that the controversy is still alive. The mathematicians sturdily adhere to their figures, and the biologists are quite sure the mathematicians must have made a mistake. I will not get myself into the line of fire by intervening in such a controversy. But until it is adjusted the laity may be excused for returning a verdict of "not proven" upon the wider issues the Darwinian school has raised.

The other objection is best stated in the words of an illustrious disciple of Darwin, who has recently honoured this city by his presence—I refer to Prof. Weismann. But in referring to him, I cannot but give, in passing, a feeble expression to the universal sorrow with which in this place the news was received that Weismann's distinguished antagonist, Prof. Romanes, had been taken from us in the outset and full promise of a splendid scientific career.

The gravest objection to the doctrine of natural selection was expressed by Weismann in a paper published a few months ago, not as agreeing to the objection, but as resisting it; and therefore his language may be taken as an impartial statement of the difficulty. "We accept natural selection," he says, "not because we are able to demonstrate the process in detail, not even because we can with more or less ease imagine it, but simply because we must—because it is the only possible explanation that we can conceive. We must assume natural selection to be the principle of the explanation of the metamorphoses, because all other apparent principles of explanation fail us, and it is inconceivable that there could yet be another capable of explaining the adaptation of organisms without assuming the help of a principle of design."

There is the difficulty. We cannot demonstrate the process of natural selection in detail; we cannot even, with more or less ease, imagine it. It is purely hypothetical. No man, so far as we know, has ever seen it at work. An accidental variation may have been perpetuated by inheritance, and in the struggle for existence the bearer of it may have replaced, by virtue of the survival of the fittest, his less improved competitors; but as far as we know no man or succession of men have ever observed the whole process in any single case, and certainly no man has recorded the observation. Variation by *artificial* selection, of course, we know very well; but the intervention of the cattle breeder and the pigeon fancier is the essence of artificial selection. It is effected by their action in crossing, by their skill in bringing the right mates together to produce the progeniture they want. But in natural selection who is to supply the breeder's place? Unless the crossing is properly arranged, the new breed will never come into being. What is to secure that the two individuals of opposite sexes in the primeval forest, who have been both accidentally blessed with the same advantageous variation, shall meet, and transmit by inheritance that variation to their successors? Unless this step is made good, the modification will never get a start; and yet there is nothing to insure that step, except pure chance. The law of chances takes the place of the cattle breeder and the pigeon fancier. The biologists do well to ask for an immeasurable expanse of time, if the occasional meetings of advantageously varied couples from age to age are to provide the pedigree of modifications which unite us to our ancestor the jelly-fish. Of course the struggle for existence, and the survival of the fittest, would in the long run secure the predominance of the stronger breed over the weaker. But it would be of no use in setting the improved breed going. There would not be time. No possible variation which is known to our experience, in the short time that elapses in a single life between the moment of maturity and the age of reproduction, could enable the varied individual to clear the field of all competitors, either by slaughtering or starving them out. But unless the struggle for existence took this summary and internecine character, there would be nothing but mere chance to secure that the advantageously varied bridegroom at one end of the wood should meet the bride, who by a happy contingency had been advantageously varied in the same direction at the same time at the other end of the wood. It would be a mere chance if they ever knew of each other's existence—a still more unlikely chance that they should resist on both sides all temptations to a less advantageous alliance. But unless they did so, the new breed would never even begin, let alone the question of its perpetuation after it had begun. I think Prof. Weismann is justified in saying that we cannot, either with more or less ease, imagine the process of natural selection.

It seems strange that a philosopher of Prof. Weismann's penetration should accept as established a hypothetical process the truth of which he admits that he cannot demonstrate in detail, and the operation of which he cannot even imagine. The reason that he gives seems to me instructive of the great danger scientific research is running at the present time—the acceptance of mere conjecture in the name and place of knowledge, in preference to making frankly the admission that no certain knowledge can be attained. "We accept natural selection," he says, "because we must—because it is the only possible explanation that we can conceive." As a politician, I know that argument very well. In political controversy it is sometimes said of a disputed proposal that it "holds the field," that it must be accepted because no possible alternative has been suggested. In politics there is occasionally a certain validity in the argument, for it sometimes happens that some definite course must be taken, even though no course is free from objection. But such a line of reasoning is utterly out of place in science. We are under no obligation to find a theory, if the facts will not provide a sound one. To the riddles which nature propounds to us the profession of ignorance must constantly be our only reasonable answer. The cloud of impenetrable mystery hangs over the development and still more over the origin of life. If we strain our eyes to pierce it, with the foregone conclusion that some solution is and must be attainable, we shall only mistake for discoveries the figments of our own imagination. Prof. Weismann adds another reason for his belief in natural selection, which is certainly characteristic of the time in which we live. "It is inconceivable," he says, "that there should be another principle capable of explaining the adaptation of organisms without assuming the help of a principle of design." The whirligig of time assuredly brings its revenges. Time was, not very long ago, when the belief in creative design was supreme. Even those who were sapping its authority were wont to pay it a formal homage, fearing to shock the public conscience by denying it. Now the revolution is so complete that a great philosopher uses it as a *reductio ad absurdum*, and prefers to believe that which can neither be demonstrated in detail, nor imagined, rather than run the slightest risk of such a heresy.

I quite accept the Professor's dictum that if natural selection is rejected we have no resource but to fall back on the mediate or immediate agency of a principle of design. In Oxford, at least, he will not find that argument is conclusive, nor, I believe, among scientific men in this country generally, however imposing the names of some whom he may claim for that belief. I would rather lean to the conviction that the multiplying difficulties of the mechanical theory are weakening the influence it once had acquired. I prefer to shelter myself in this matter behind the judgment of the greatest living master of natural science among us, Lord Kelvin, and to quote as my own concluding words the striking language with which he closed his address from this chair more than twenty years ago: "I have always felt," he said, "that the hypothesis of natural selection does not contain the true theory of evolution, if evolution there has been in biology. . . . I feel profoundly convinced that the argument of design has been greatly too much lost sight of in recent zoological speculations. Overpoweringly strong proofs of intelligent and benevolent design lie around us, and if ever perplexities, whether metaphysical or scientific, turn us away from them for a time, they come back upon us with irresistible force, showing to us through nature the influence of a free will, and teaching us that all living things depend on one everlasting Creator and Ruler."

SECTION A.

MATHEMATICS AND PHYSICS.

Opening Address by Prof. A. W. Rücker, M.A., F.R.S., President of the Section.

It is impossible for a body of English scientific men to meet in one of our ancient university towns without contrasting the old ideal of the pursuit of learning for its own sake with the modern conception of the organisation of science as part of a pushing business concern.

We are, as a nation, convinced that education is essential to national success. Our modern universities are within earshot of the whirr of the cotton-mill or the roar of Piccadilly. Oxford and Cambridge themselves are not content to be centres of attraction to which scholars gravitate. They have devised schemes by which their influence is directly exerted on every market-town and almost on every village in the country. University extension is but a part of the extraordinary multiplication of the machinery of education which is going on all around us. The British Association, which was once regarded as bringing light into dark places, is now welcomed in every large provincial town by a group of well-known men of science; and we find ready for the meetings of our Sections, not only the chapels and concert-rooms which have so often and so kindly been placed at our disposal, but all the appliances of well-designed lecture-rooms and laboratories.

I do not propose, however, to detain you this morning with a discourse on the spread of scientific education, but you will forgive me if I illustrate its progress by two facts, not perhaps the most striking which could be selected, but especially appropriate to our place of meeting. It is little more than thirty years since the two branches of science with which our Section deals, Mathematics and Physics, have been generally recognised as wide enough to require more than one teacher to cope with them in an educational institution of high pretensions and achievement. In 1860 the authorities of the Owens College, Manchester, debated whether it was desirable to create a Professorship of Natural Philosophy in addition to, and independent of, the Chair of Mathematics. It was thought necessary to obtain external support for the opinions of those who advocated this step. An appeal was made to Profs. De Morgan and Stokes. The former reported that a "course of experimental physics is in itself desirable"; the latter, that "there would be work enough in a large institution for a mathematician and a physicist."

In the end the Chair of Natural Philosophy was established, and the fact that our host of to-day, Prof. Clifton, was its first occupant reminds us how little we have advanced in time and how far in educational development from the days when propositions such as those I have cited were only accepted on the authority of the names of Stokes and De Morgan.

The other fact to which I would refer is that the Clarendon Laboratory, in which the meetings of Section A are to be held, though erected barely a quarter of a century ago, was the first laboratory in this country which was specially built and designed for the study of experimental physics. It has served as a type. Clerk Maxwell visited it while planning the Cavendish Laboratory, and traces of Prof. Clifton's designs can be detected in several of our university colleges.

But though our surroundings remind us of the improvement which has been effected in the equipment of our science, it would not be difficult to indicate weak points which should forthwith be strengthened. On these, in so far as they affect education, I will not dwell—and that for two reasons. In the first place, we meet to-day not as teachers, but as students; and, secondly, I think that whereas we have as a nation awoke—though late in the day—to the importance of education, we are not yet fully awake to the importance of learning. Our attitude in such matters was exactly expressed by one of the most eminent of the witnesses who gave evidence before the "Gresham Commission." In his opinion the advancement of knowledge must in a university in London be secondary to the higher instruction of the youth of London. If this be so—and I will not now dispute it—we shall surely all agree that somewhere or other, in London or out of it, included in our universities or separate from them, there ought to be institutions in which the advancement of knowledge is regarded as of primary and fundamental interest, and not as a mere secondary by-product thrown off in the course of more important operations.

It is not essential that in such an institution research should be the only task. Investigation may be combined with the routine work of an observatory, with teaching, with the care of standards, or with other similar duties. It is, however, essential that, if the advancement of knowledge is seriously regarded as an end worth attaining, it should not be relegated to a secondary place.

Time and opportunity must be found for investigation, as time and opportunity are found for other tasks. It is not enough to refer to research in a prospectus and then to leave it to be accomplished at odd times and in spare moments not claimed by more urgent demands. Those to whom the future of the higher learning in England is dear must plan and scheme to promote the life-long studies of men, as in the last quarter of a century they have struggled, with marked success, to promote the preparatory studies of boys and girls. That the assignment of a secondary position to research is the more popular view, and that the necessity for encouraging it has as yet hardly been grasped by many of those who control our modern educational movements is, I fear, too true. It is therefore a matter for congratulation that within the last year Oxford has established a research degree, and has thus taken an important step towards gathering within her fold workers of mature years who are able and willing, not merely to gain knowledge, but to add to it.

We may also note, with pleasure and gratitude, that the stream of private munificence has recently been in part directed to the advancement of learning. Sir Henry Thompson has generously offered a sum of £5000 to provide a large photographic telescope for the National Observatory at Greenwich. The new instrument is to be of 26 inches aperture and 22 feet 6 inches focal length, or exactly double the linear dimensions of that which has been previously employed. Mr. Ludwig Mond, too, has added to his noble gifts to science by the new research laboratories which he is about to establish in connection with the Royal Institution. Albemarle Street is thronged with memories of great discoveries. The researches of Lord Rayleigh and the remarkable results of Prof. Dewar's studies of matter at low temperatures are maintaining the great reputation which the Royal Institution has gained in the past, and all English physicists will rejoice that prospects of new and extended usefulness are opening before it.

Another hopeful, though very embarrassing fact is that the growth in the number of scientific workers makes it increasingly difficult to find the funds which are necessary for the publication of their work. Up to the present the author of a paper has had to submit it to criticism, but, when it has been approved by competent judges, it has been published without ado and without expense to himself. This is as it should be. It is right that due care should be exercised to prune away all unnecessary matter, to reduce as far as may be the necessary cost. It will, however, be a great misfortune if judgment as to what curtailment is necessary is in future passed, not with the object of removing what is really superfluous, but in obedience to the iron rule of poverty. Apart from all other disadvantages, such a course would add to the barriers which are dividing the students of different sciences. A few lines and a rough diagram may suffice to show to experts what has been attempted and what achieved, but there is no paper so difficult to master as that which assumes that the reader starts from the point of vantage which months or years of study have enabled the author to attain. Undue pruning will not make the tree of knowledge more fruitful, and will certainly make it harder to climb.

Connected also with the vast increase of scientific literature is a growing necessity for the publication of volumes of abstracts, in which the main results of recent investigations are presented in a concentrated form. English chemists have long been supplied with these by the Chemical Society. The Physical Society, though far less wealthy than its elder sister, has determined to undertake a similar task. We are compelled to begin cautiously, but in January next the first number of a monthly pamphlet will be issued containing abstracts of all the papers which appear in the principal foreign journals of Physics. In this venture the Society will incur grave responsibilities, and I avail myself of this opportunity to appeal to all British physicists to support us in a work, the scope of which will be rapidly extended if our first efforts succeed.

From this brief glance at what has been or is about to be done to promote the study of Physics, I must now turn to the discussion of narrower but more definite problems, and I presume that I shall be most likely to deserve your attention if I select a subject in which I am myself especially interested.

During the last ten years my friend Dr. Thorpe and I have been engaged upon a minute magnetic survey of the United Kingdom. The main conclusions at which we have arrived are about to be published, and I do not propose to recount them now. It is, however, impossible to give so long a time to a single research without having one's attention drawn to a number of points which require further investigation, and I shall perhaps be making the best use of this opportunity if I bring to your notice some matters in the practical and theoretical study of terrestrial magnetism which deserve a fuller consideration than has yet been given to them.

In the first place, then, there is little doubt that the instruments at present used for measuring Declination and Horizontal Force are affected with errors far greater than the error of observation.

We employed four magnetometers by Elliott Brothers, which were frequently compared with the standard instrument at Kew. These measurements proved that the instrumental differences which affect the accuracy of the declination and horizontal force measurements are from five to ten times as great as the error of a single field observation. The dip circle which two generations ago was so untrustworthy is, in our experience, the most satisfactory of the absolute instruments.

In most cases these comparisons extended over several days, but the Astronomer Royal has described in his recent report observations made at Greenwich for two years and a half with two horizontal force instruments. These differ between themselves, and the discrepancy is of the same order of magnitude as those we have detected.

If such differences exist between instruments of the Kew pattern, it is probable that they will be still greater when the magnetometers under investigation are of different types.

This point has been investigated by Dr. Van Rijckevorsel, who five years ago visited Kew, Parc St. Maur, Wilhelmshaven, and Utrecht, and, using his own instruments at each place, compared the values of the magnetic elements determined by himself with those deduced from the self-registering apparatus of the observatory.

The discrepancies between the so-called standards, which were thus brought to light, were quite startling, and prove the necessity for an investigation as to their causes.

Magneticians had long been aware that the instruments used by travellers should be compared at the beginning and end of a journey with those at some fixed observatory, to make sure that the comparatively rough usage to which they are subjected has not affected their indications. But Dr. Van Rijckevorsel's expedition first drew general attention to the fact that there are serious differences between the standard observatory instruments themselves.

The importance of a careful comparison between them was at once recognised. The Magnetic Sub-Committee of the International Meteorological Conference, held at Munich in the autumn of 1891, resolved that it is "necessary that the instruments employed for absolute measurements at the different observatories should be compared with each other and the results published." As far as I am aware nothing has been done to give effect to this resolution, but the necessity for such an international comparison is urgent. The last few years have been a period of unexampled activity in the conduct of local magnetic surveys. To cite instances from the north-west of Europe only, observations have recently been made on a more or less extended scale in the United Kingdom, France, Holland, North Germany, and Denmark.

It will be absurd if these surveys cannot be collated and welded into a homogeneous whole, because we are in doubt whether the indications of our standard instruments for the measurement of declination and dip differ by five or six minutes of arc.

If, however, an official international comparison of the magnetic standards in use in different countries is instituted it is probable that only one observatory in each country will take part in it.

It may fairly be left to each nation to determine for itself the relations between the results of measurements made in its own institutions. Apart, therefore, from all other reasons, we in England would only be able to make the best use of an international comparison if we had beforehand set our own house in order, and were able at once to extend the results of experiments made at Kew or Greenwich to Stonyhurst, Valentia, and Falmouth.

This we are not at the present moment in a position to do. As far as I know nobody has ever carried a magnetometer backwards and forwards between Kew and Greenwich to test the concordance of the published results. During the recent survey single or double sets of observations have been made at Stonyhurst, Falmouth, and Valentia, with instruments which have been compared with Kew, but these measurements, though amply sufficient for the purposes of our research, were not numerous enough to serve as a firm basis for determining the discrepancies between the various standards, so that the exact relations between these important sets of apparatus are still unknown.

The first point, therefore, to which I wish to draw the attention of the Section is the necessity for a full primary comparison between the standard magnetic instruments in use at our different observatories.

But, if this were satisfactorily accomplished, the question would arise as to whether it should be repeated at regular intervals. We have at present only a presumption in favour of the view that the standards which we know are discordant are nevertheless constant. A single instance may suffice to show how necessary it may be—at all events in the case of outlying and isolated observatories—to put this belief to the test.

In the most recent account of the work of the observatory of the Bombay Government at Colába, the dips are discussed for the period of twenty years between 1872 and 1892. During this interval the adjustment of the agate plates upon which the dip needle rolls has thrice been modified. In 1877 the plates were renewed. In 1881 and 1887 the dip circle was taken to pieces and rebuilt. In the intervals the dip as determined by several needles, but always with this circle, remained approximately constant, but after each overhauling it suddenly altered, increasing by 12′ on the first occasion, by 23′ on the second, and by 20′ on the third. Mr. Chambers states that he "can give no satisfactory account of this behaviour of the instrument," but suggests that "the needle gradually hollows out a depression in the agate plates on which it rolls, and that this characteristic of the dip circle" has not before been discovered owing to the reluctance of magnetic observers to interfere with the adjustments of instruments which are apparently working well.

I do not think that this explanation will suffice. Dr. Thorpe and I employed a new dip circle in the earliest part of our survey work, which has remained in accord with Kew for ten years. During that time the dip has been measured some 700 times with it. This corresponds, I believe, to more than the amount of work done with the circle at Colába in six years, which in turn is longer than some of the intervals in which the Colába instruments gave results erroneous to the extent of 20′. I feel, therefore, quite sure that the difficulties which have been experienced at Bombay are not due to any "characteristic [defect] of the dip circle." But, whatever the cause may have been, surely the lesson is that, if such things can happen in so well-known an institution, it is desirable that we should take the moderate pains required to assure ourselves whether smaller —but, possibly, not unimportant—errors are gradually affecting the results at any of our observatories.

This brings me to my next point, namely, that if we are to draw conclusions from the minor differences between measurements of secular or diurnal change made in the observatories, it is not only necessary that we should know whether the instruments are strictly comparable and constant, but the observations must be reduced by precisely the same methods.

In 1886 the late Mr. Whipple drew the attention of the British Association to the fact that there was a systematic difference between the diurnal ranges of declination at Greenwich and Kew. His results were based on the three years 1870–72. In 1890 two of my students, Messrs. Robson and S. W. J. Smith, extended the comparison to three more recent years (1883–6–7), and obtained results in complete accord with those of Mr. Whipple.

It is well known that the average daily oscillation of the magnet is affected by the magnetic weather. Sabine showed that magnetic storms do not merely buffet the needle now in this direction and now in that—they affect its average behaviour, so that the mean swing east and west is different according as we deduce it only from days of magnetic calm or include those of storm.

Mr. Whipple reduced the Kew observations by two methods,[1] one of which depended on the calmest days only, while the other included those which were moderately disturbed. Neither agreed exactly with the method in use at Greenwich, but the difference between the results deduced from them was so small when compared with the difference between either and that obtained at Greenwich, that it seemed possible that the diurnal variations, even at these closely neighbouring places, might differ appreciably. The question whether this is so has now been answered. In 1890, at the resquest of the Kew Committee, the Astronomer Royal undertook to select early in each year five quiet days in each of the preceding twelve months. It was also agreed that, whether they adopted other methods or not, the chief English magnetic observatories should determine the diurnal variations from these days alone. The Greenwich[2] and Kew observations for 1890 have therefore been worked up in exactly the same way, with the result that the discrepancy, which had persisted for twenty years, has entirely disappeared, and that the two diurnal ranges at the two observatories are in as close accord as could be expected.

If, therefore, we may judge from a single year, the cause of the difference lay in the choice of days. Greenwich will in future give us two diurnal variations, one obtained from the most quiet days only, the other from all days except those of violent storm, and in these we shall have most valuable data for studying the mean effect of disturbances on the diurnal variation.

To this satisfactory conclusion I have only one suggestion to add. The Astronomer Royal and M. Mascart now publish for the same stormy days the photographic traces by which the history of a magnetic storm is mapped. Is it possible for Greenwich and Paris also to agree in their choice of calm days for the calculation of the diurnal variation, so that a precise similarity of method may obtain not only between the English observatories, but between England and France?

The importance of co-operation between institutions engaged on the same tasks having been illustrated, I am glad to be able to announce that another step is about to be taken in the same direction. For some years, in spite, I believe, of great financial difficulties, the Cornwall Royal Polytechnic Society has maintained a magnetic observatory at Falmouth. The results of the observations have hitherto been printed in the Journal of

[1] Sabine's and Wild's.

[2] The Greenwich observations for subsequent years have not yet been published.

the Society only, but the Royal Society has now consented to publish them in the *Proceedings*. Before long, therefore, the Kew and Falmouth records, which are already worked up in the same way, will be given to the world side by side. Is it too much to hope that this may be the first step towards the production of a British Magnetic Year Book, in which observations whose chief interest lies in their comparison, may be so published as to be easily compared?

We owe to private enterprise another advance of the same kind. The managers of the new journal *Science Progress* have made arrangements with the Kew Committee for the yearly publication of a table showing the mean annual values of the magnetic elements as determined at the various magnetic observatories of the world. It will therefore in future be possible to get a general idea of the rate of secular change in different localities without searching through a number of reports in different languages, which can only be consulted in the rooms of the few societies or institutions to which they are annually sent. The present state of our knowledge of the secular change in the magnetic elements affords indeed very strong support to the arguments I have already adduced in favour of a comparison between the instruments of our magnetic observatories.

The whole question of the cause of this phenomenon has entered on a new stage. It has long been recognised that the earth is not a simple magnet, but that there are in each hemisphere one pole or point at which the dip needle is vertical, and two foci of maximum intensity. A comparison of earlier with later magnetic observations led to the conclusion that one or both of the foci in each hemisphere is in motion, and that to this motion—however caused—the secular change in the values of the magnetic element is due. Thus the late Prof. Balfour Stewart, writing in 1883, says, "While there is no well-established evidence to show that either the pole of verticity or the centre of force to the North of America has perceptibly changed its place, there is on the other hand very strong evidence to show that we have a change of place on the part of the Siberian focus."[1] The facts in favour of this conclusion are there discussed. The arguments are based, not on the results of any actual observations near to the focus in question, but on the behaviour of the magnet at points far distant from it in Europe and Asia. The westerly march of the declination needle, which lasted in England up to 1818, and the easterly movement which has since replaced it, are connected with a supposed easterly motion of the Siberian focus, which, it is added, "there is some reason to believe . . . . has recently been reversed." In opposition, therefore, to the idea of the rotation of a magnetic focus round the geographical poles which the earlier magneticians adopted, Stewart seems to have regarded the motion of the Siberian focus as oscillatory.

A very different aspect is put upon the matter by a comparison of the magnetic maps of the world prepared by Sabine and Creak for the epochs 1840 and 1880 respectively. Captain Creak, having undertaken to report on the magnetic observations made during the voyage of the *Challenger*, supplemented them with the unrivalled wealth of recorded facts at the disposal of the Hydrographic Department of the Admiralty. He was thus able, by a comparison with Sabine's map, to trace the general course of the secular changes all over the world for forty years. The negative results may be shortly stated. There is no evidence of any motion either of magnetic pole or focus. The positive conclusions are still more curious. There are certain lines on the surface of the earth towards which in the interval under consideration the north pole of the needle was attracted. From each side the compass veered or backed towards them. Above them the north pole of dip needle moved steadily down.

There are other lines from which, as tested by compass and dip circle, a north pole was in like manner repelled. The two principal points of increasing attraction are in China and near Cape Horn; the chief points of growing repulsion are in the North of Canada and the Gulf of Guinea.

I am sure that my friend Captain Creak would be the first to urge that we should not generalise too hastily from this mode of presenting the facts, but there can be no doubt that they cannot be explained by any simple theory of a rotating or oscillating pair of poles. *Prima facie* they suggest that the secular change is due not so much to changes at the principal magnetic points, as to the waxing and waning of the forces apparently exerted by secondary lines or points of attraction or repulsion.

All down the west coast of America, close—be it noted—to one of the great lines of volcanic activity, north hemisphere magnetism has since 1840 been growing in relative importance. Near Cape Horn a weak embryonic pole is developing of the same kind as the well-known pole at the other end of the continent near Hudson's Bay. Along a line which joins Newfoundland to the Cape of Good Hope, precisely the reverse effects have been experienced; while in the Gulf of Guinea a south hemisphere pole is growing within the tropics. Of course I do not suggest that these secondary systems can ever determine the principal phenomena of terrestrial magnetism, or reverse the magnetic states of the hemispheres in which they occur. These are no doubt fixed by the rotation of the earth. I do, however, wish to emphasise the fact that they show that either secular change is due to the conjoint action of local causes, or that if some single agent such as a current system within the earth, or a change of magnetic conditions outside it, be the primary cause, the effects of this cause are modified and complicated by local peculiarities.

Mr. Henry Wilde has succeeded in representing with approximate accuracy the secular change at many points on the surface of the earth by placing two systems of currents within a globe, and imparting to the axis of one of them a motion of rotation about the polar axis of the earth. But he has had to supplement this comparatively simple arrangement by local features. He has coated the seas with thin sheet iron. The ratio between the two currents which serves to depict the secular change near the meridian of Greenwich fails in the West Indies. Thus this ingenious attempt to imitate the secular change by a simple rotation of the magnetic pole supports the view that local peculiarities play a powerful part in modifying the action of a simple first cause, if such exist. I need hardly say that I think the proper attitude of mind on this difficult subject is that of suspended judgment, but there is no doubt that recent investigation has, at all events, definitely raised the question how far secular change is either due to, or modified by, special magnetic features of different parts of the earth.

It is possible that light may be thrown upon this point by observations on a smaller scale. Assuming for the moment that the difference in the secular changes on opposite sides of the Atlantic is due to a difference of local causes, it is conceivable that similar causes, though less powerful and acting through smaller ranges, might produce similar though less obvious differences between places only a few miles apart. For testing this Greenwich and Kew are in many respects most favourably situated. Nowhere else are two first-class observatories so near together. Differences in the methods of publishing the results have made it somewhat difficult to compare them, but the late Mr. Whipple furnished me with figures for several years which made comparison easy. Without entering into details it may be sufficient to say that the declination needles at the two places do not from year to year run parallel courses. Between 1880–82 Kew outstripped its rival, between 1885 and 1889 it lost, so that the gain was rather more than compensated. The difference of the declination of the two places appears to increase and diminish through a range of five minutes of arc.

This evidence can be supplemented by other equally significant examples. No fact connected with terrestrial magnetism is more certain than that at present the rate of secular change of declination in this part of Europe increases as we go north. This is shown by a comparison of our survey with those of our predecessors fifty and thirty years ago, by M. Moureaux's results in France, and by Captain Creak's collation of previous observations. Yet, in spite of this, Stonyhurst, which is some 200 miles north of Greenwich and Kew, and should therefore outrun them, sometimes lags behind and then makes up for lost time by prodigious bounds. Between 1882 and 1886 the total secular change of declination at Stonyhurst was about 3'·5 less than that at Greenwich and Kew, whereas in the two years 1890–1892 it reached at Stonyhurst the enormous amount of 28', just doubling the corresponding alteration registered in the same time at Kew. If these fluctuations are caused by the instruments or methods of reduction, my argument in favour of frequent comparisons and uniform treatment would be much strengthened, but, apart from the inherent improbability of such large differences being due to the methods of observation,

[1] *Encyclopædia Britannica*, 9th edition. Art. "Meteorology—Terrestrial Magnetism."

the probability of their physical reality is increased by the work of the magnetic survey.

The large number of observations at our disposal has enabled us to calculate the secular change in a new way, by taking the means of observations made about five years apart at numerous though not identical stations scattered over districts about 150 miles square. The result thus obtained should be free from mere local variations, but as calculated for the south-east of England for the five years 1886-91 it differs by nearly 5 from the change actually observed at Kew.

We have also determined the secular change at twenty-five stations by double sets of observations made as nearly as possible on the same spot at intervals of several years. The results must be interpreted with caution. In districts such as Scotland, where strong local disturbances are frequent, a change of a few yards in the position of the observer might introduce errors far larger than the fluctuations of secular change. But when all such changes are eliminated, when all allowance is made for the possible inaccuracy of field observations, there are outstanding variations which can hardly be due to anything but a real difference in the rate of change of the magnetic elements.

A single example will suffice. St. Leonards and Tunbridge Wells are about thirty miles apart. Both are situated on the Hastings Sand formation, and on good non-magnetic observing ground. At them, as at the stations immediately around them —Lewes, Eastbourne, Appledore, Etchingham, Heathfield, and Maidstone—the local disturbing forces are very small. All these places lie within a district about forty miles square, at no point of which has the magnet been found to deviate by 5′ from the true magnetic meridian. No region could be more favourably situated for the determination of the secular change, yet according to our observations the alteration in the declination at St. Leonards in six years was practically equal to that at Tunbridge Wells in five. It is difficult to assign so great a variation to an accumulation of errors, and this is only one amongst several instances of the same kind which might be quoted.

We find, then, when we consider the earth as a whole, grave reason to question the old idea of a secular change caused by a magnetic pole or focus pursuing an orderly orbit around the geographical axis of the earth, or oscillating in some regular period in its neighbourhood. It would, of course, be absurd to admit the possibility of change in the tropics and to deny that possibility in the arctic circle, but the new facts lead us to look upon the earth not as magnetically inert, but as itself—at the equator as well as at the pole—producing or profoundly modifying the influences which give rise to secular change. And then, when we push our inquiry further, accumulating experience tells the same tale. The earth seems as it were alive with magnetic forces, be they due to electric currents or to variations in the state of magnetised matter. We need not now consider the sudden jerks which disturb the diurnal sweep of the magnet, which are simultaneous at places far apart, and probably originate in causes outside our globe. But the slower secular change, of which the small part that has been observed has taken centuries to accomplish, is apparently also interfered with by some slower agency the action of which is confined within narrow limits of space. Between Kew, Greenwich, and Stonyhurst, between St. Leonards and Tunbridge Wells, and I may add between Mablethorpe and Lincoln, Enniskillen and Sligo, Charleville and Bantry, the measured differences of secular variation are so large as to suggest that we are dealing not with an unruffled tide of change, which, unaltered by its passage over continent or ocean, sweeps slowly round the earth, but with a current fed by local springs or impeded by local obstacles, furrowed on the surface by billows and eddies, from which the magnetician, if he will but study them, may learn much as to the position and meaning of the deeps and the shallows below. But if this is the view which the facts I have quoted suggest, much remains to be done before it can be finally accepted; and in the first place—to come back to the point from which I started—we want, for some years at all events, a systematic and repeated comparison of the standard instruments in use at the different observatories. That they are not in accord is certain; whether the relations between them are constant or variable is doubtful. If constant, the suggestions I have outlined are probably correct; if variable, then the whole or part of the apparent fluctuations of secular change may be nothing more than the irregular shiftings of inconstant standards.

I cannot myself believe that this is the true explanation, but in any case it is important that the doubt should be set at rest, and that if the apparent fluctuations of secular change are not merely instrumental, the inquiry as to their cause should be undertaken in good earnest.

The question is interesting from another point of view. It is now fully established that even where the surface soil is non-magnetic, and even where geologists have every reason to believe that it lies upon non-magnetic strata of great thickness, there are clearly-defined lines and centres towards which the north-seeking pole of a magnet is attracted, or from which it is repelled. To the magnetic surveyor fluctuations in secular change would appear as variations in the positions of these lines, or as changes in the forces in play in their neighbourhood.

Greenwich and Kew are both under the influence of a widespread local disturbance which culminates near Reading. At both places the needle is deviated to the west of the normal magnetic meridian, and if the westerly declination diminishes sometimes faster and sometimes more slowly at one observatory than at the other, this must be, or, at all events, would in the first instance appear to be, due to local changes in the regional disturbing forces. The questions of the nature of the irregularities of secular change and of the causes of local disturbances are therefore intermingled; and information gained on these points may in turn be useful in solving the more difficult problem of world-wide secular variations.

Two causes of regional and local disturbances have been suggested, viz. earth currents, and the presence of visible or concealed magnetic rocks. The two theories are not mutually exclusive. Both causes of the observed effects may, and probably do, coexist. I have, however, elsewhere explained my reasons for believing that the presence of magnetic matter, magnetised by induction in the earth's field, is the principal cause of the existence of the magnetic ridge-lines and foci of attraction which for so many years we have been carefully tracing. I will only now mention what appears to me to be the final and conclusive argument, which, since it was first enunciated, has been strengthened by the results of our more recent work. We find that every great mass of basic rock, by which the needle is affected at considerable distances, attracts the north-seeking pole. Captain Creak some years ago showed that the same statement is true of those islands in the northern hemisphere which disturb the lines of equal declination, while islands in the southern hemisphere repel the north pole and attract the south. In other words, these disturbances are immediately explained if we suppose that they are due to magnetic matter magnetised by induction. The theory of earth currents would, on the other hand, require that round the masses of visible basalt, and round the island investigated by Captain Creak, currents, or eddies in currents, should circulate in directions which are always the same in the same hemisphere, and always opposed on opposite sides of the equator. For this supposition no satisfactory explanation is forthcoming, and, therefore, with all reserve and a full consciousness that in such matters hypothesis differs but little from speculation, it appears to me that the theory that induced magnetism is the main cause of the disturbance has the greater weight of evidence in its favour.

If this be granted, it is evident that the positions of the main lines and centres of attraction would be approximately constant, and, so far as it is possible to form an opinion, these conditions seem to be satisfied. There has certainly been no noticeable change in the chief loci of attraction in the five years which have elapsed between the epochs of our two surveys. Mr. Welsh's observations made in Scotland in 1857-8 fit in well with our own. Such evidence is not, however, inconsistent with minor changes, and it is certain that as the directions and magnitude of the inducing forces alter, the disturbing induced forces must alter also. But this change would be slow, and as the horizontal force is in these latitudes comparatively weak, the change in the disturbing forces would also be small, unless the vertical force altered greatly. It is at all events impossible to attribute to this cause oscillations which occupy at most eight or ten years. It is possible to suggest other changes in the state of the concealed magnetic matter—alterations of pressure, temperature, and the like—to which the oscillations of secular change might be due, but probably there will be a general consensus of opinion that if the slowly changing terms in the disturbance function are due to magnetic matter, the more rapid fluctuations of a few years' period are more likely to be connected with earth currents. It becomes, therefore, a matter of interest to disentangle the two constituents of local disturbances; and there is one question to which I think an answer might be obtained without a greater expenditure than the importance of the investigation warrants. Are the local variations in secular change waves which move from place to place, or are they stationary fluctuations, each of which is confined to a limited area beyond which it never travels? Thus, if the annual decrease in the declination is at one time more rapid at Greenwich than at Kew, and five years afterwards more rapid at Kew than at Greenwich, has the maximum of rapidity passed in the interval through all intervening places, or has there been a dividing line of no change which has separated two districts which have perhaps been the scenes of independent variations? The answer to this question is, I take it, outside the range of our knowledge now, but if the declination could be determined several times annually at each of a limited number of stations in the neighbourhood of London, to this inquiry, at all events, a definite answer would soon be furnished.

There are two other lines of investigation which I hope will be taken up sooner or later, for one of which it is doubtful whether the United Kingdom is the best site, while the other is of uncertain issue.

If, however, it be granted that the principal cause of local and regional magnetic disturbances is the magnetisation by the earth's field of magnetic matter concealed below its surface, the question as to the nature of this material still remains to be solved. Is it virgin iron or pure magnetite, or is it merely a magnetic rock of the same nature and properties as the basalts which are found in Skye and Mull? There is, of course, no *à priori* reason why all these different materials should not be active, some in one place and some in another.

As regards the United Kingdom I have, both in a paper on the Permeability of Magnetic Rocks and in the description of the recent survey, made calculations which tend to prove that, if we suppose that the temperature of the interior of the earth is, at a depth of twelve miles, such as to deprive matter of its magnetic properties, and if we further make the unfavourable assumption that down to that limit the susceptibility is constant, the forces which are observed on the surface are of the same order of magnitude as those which could be produced by large masses of ordinary basalt or gabbro. It would not, however, be wise to generalise this result, and to assume that in all places regional disturbances are due to basic rocks alone.

We know that local effects are produced by iron ore, for the Swedish miners seek for iron with the aid of the magnet, and in some other cases magnetic disturbances of considerable range are so intense as to suggest that material of very high magnetic permeability must be present.

If the concealed magnetic matter were iron, and if it were present in large quantity, it is evident that the results of experiments with the magnetometer and dip circle might be supplemented by observations made with the plumb-line or pendulum. In such a case the region of magnetic disturbance would also be a region of abnormal gravitational attraction. An account of a suggested connection between anomalies of these two kinds occurring in the same district has lately been published by Dr. Fritsche.[1]

Observations made about thirty years ago by a former director of the Astronomical Observatory in Moscow led to the conclusion that throughout two large districts to the north and south of that city the plumb-line is deviated in opposite directions. The deflections from the vertical are very considerable, and indicate a relative defect in the attraction exerted by the rocks in the neighbourhood of Moscow itself, and the suggestion has been made that there is either a huge cavity—a bubble in the earth crust—under the town, or that the matter beneath it is less dense than that which underlies the surface strata on either side at a distance of ten or twelve miles.

As long ago as 1853, Captain Meyen made magnetic observations in order to determine whether the same district is also the seat of any magnetic irregularity. His stations were hardly [illegible]tly numerous to lead to decisive results, but the magnetic [illegible] have recently been measured by Dr. Fritsche at thirty-one [illegible] within fifty miles of Moscow. The experiments were all made [illegible] seven days, so that no correction for secular change [illegible]. They indicate a locus of magnetic attraction running through Moscow itself. South of the town the disturbance again changes in direction so as to show either that repulsive forces are in play, or that there is another magnetic ridge line still further to the south. Dr. Fritsche thinks that these observations explain the gravitational anomalies without recourse to the somewhat forced hypothesis of a vast subterranean cave. He assumes that there is a concealed mass of iron, which approaches near to the surface at Moscow, and also along two loci to the south and north of the city. He attributes the magnetic irregularities to the attraction of the central iron hill, the deflections of the plumb-line to the flanking masses. It is perhaps not inconceivable that such results might follow in a special case, but without the support of calculation it certainly appears that the magnetic experiments point to the existence of the principal attracting mass under the town. This is in fact the arrangement shown in the figure with which Dr. Fritsche illustrates his hypothesis. If this is so, the theory would *prima facie* seem to require that the bob of a plumb-line should be attracted towards and not—as is actually the case—away from the centre of the magnetic disturbance. On the whole, then, though the coexistence of large magnetic and gravitational disturbances in the same place is suggestive, I do not think that they have as yet been proved to be different effects of the same hidden mass of magnetic matter.

In a few weeks an International Geodetic Conference will meet at Innsbruck, at which the Royal Society will be represented. It is, I believe, intended to extend the detailed investigation of the relations between the nature of the earth's crust and the gravitational and magnetic forces to which it gives rise. We may therefore hope that soecial attention will before long be given to localities where both may combine to give information as to facts outside the range of the ordinary methods of geology.

The second phenomenon on which more light is desirable, is the permanent magnetisation of magnetic rocks. It is known that fragments of these are strongly but irregularly magnetised, but that the effect of very large masses at a distance appears to be due to induced rather than to permanent magnetism. There are three questions to which I should like an answer. Are underground masses of magnetite ever permanently magnetised? Are large areas of surface masses, say a few hundred square yards in extent, ever permanently and approximately uniformly magnetised in the same sense? Is there any relation between the geological age and the direction of the permanent magnetism of magnetic rocks?

Inquiries such as these can only be taken up by individual workers, but I venture to think that the comparison of the observatory instruments and the fluctuations of secular change outside the observatories could best be investigated under the auspices of a great scientific society. The co-operation of the authorities of the observatories will no doubt be secured, but it is most important that the comparison should in all cases be made with one set of instruments, and by the same methods. Whether the British Association, which for so long managed a magnetic observatory, may think that it could usefully inaugurate the work, it would be improper for me in a presidential address to forecast. Who does it is of less importance than that it should be done, and I cannot but hope that the arguments and instances which I have to-day adduced may help to bring about not only the doing of the work, but the doing of it quickly.

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. H. B. DIXON, M.A., F.R.S., PRESIDENT OF THE SECTION.

"An Oxford School of Chemists."

IT has been said, and no doubt with truth, that few Presidents of Sections start writing an address without referring to that of their predecessor who held office on the last occasion when the Association met in the same city. By such reference each new President gains the advantage of many points of perspective and contrast; for in the interval a generation of workers has passed away, and the last new thing of the old meeting is the ancient instance of to-day. In the present case I turned to the Report of 1860 with a lively hope of drawing inspiration from it, for my predecessor at the last Oxford meeting was no less a master of experiment and expression than the late Prof. Brodie. Judge of my disappointment when I found that Brodie had written no address at all. Whether that great man, knowing there were better things to do here than listen to addresses, had the courage to make an innovation he thought desirable in itself, or whether, as others say, he was but obeying the etiquette of the Oxford professoriate—the fact remains the assembled chemists went away unaddressed, and the natural spring of inspiration for the address of 1894 is found dry at its source. Of course you will say, "Why do you not follow such a good example?" I wish I had the courage. As it is, I can but urge the vacuum of 1860 as some excuse for the emptiness of the address I now present—compelled to do so partly by the force of fashion and the demands of the assistant general secretary, and (shall I add?) partly by the gratification of holding forth, with a little brief authority, in my old academic home, endeared to me personally by so many happy memories, and hallowed in the minds of chemists by the traditions of such great achievements in the science we pursue.

I say *traditions* advisedly, for the chemical achievements spoken of were largely forgotten, or put on one side as guesses and half-truths. No chemist here will need reminding that I refer to *the first school of scientific chemistry*, the school founded two centuries and a half ago by Robert Boyle with his disciples Hooke and Mayow—a group whom I will venture to call "the Oxford school of chemists." And now that chemists are met together once more in Oxford it seemed to me not inappropriate for us to consider what this school of chemists accomplished, and wherein it failed, what led to the sudden growth and what to the decline of chemical investigation here, and what lessons for modern Oxford may be read in the history of that rise and fall.

The intellectual awakening which followed the re-discovery of the ancient world of literature gave rise to the scientific interrogation of nature. In Italy first, and then in France, England, and in Germany, the diffusion of classical learning broke down the ancient barriers of restraint, and developed a spirit of free inquiry. It was not so much that ignorance had to be dispelled, but that the right of search had to be established. Here and there during the middle ages some man of genius had arisen—learned beyond all his contemporaries, intrepid in the pursuit of truth—only to be crushed by a political and mental despotism. The name of Roger Bacon arises at once in our thoughts, who from his Oxford cell sent forth that great appeal for experimental science that nearly converted a Pope of Rome and won three centuries for intellectual freedom. But his labour bore no fruit. I know no better index to the dominant sentiment of the time than the following words from a papal rescript reproving the members of an Italian university for scientific presumption: "They must be content with the landmarks of science already fixed by their fathers, and have due fear of the curse pronounced against him who removeth his neighbour's landmark." Under such conditions no wonder philosophy was at a standstill. "The same knots were tied and untied; the same clouds were formed and dissipated."[1] The cramped philosophy of the middle ages had in alchemy a fitting colleague—with its mysticism, its sordid ideals, its trickery, and its arrogance. The revival of learning was thus an emancipation of the mind, and in the new freedom the sciences of mechanics, physics, and chemistry arose. The first necessity for progress was enlightenment, the second was experiment; in the year that Francis Bacon died Robert Boyle was born.

The common pursuit of experimental inquiry and the need for constant criticism and discussion among its followers led to the foundation of scientific societies. Such societies, which have greatly influenced the progress of knowledge, sprang up in Florence and Padua, in Paris and Oxford—wherever, among bodies of learned men, some were found in sympathy with natural philosophy. Among these associations the Philosophical Society of Oxford has played no unimportant part, and, however much Oxford may have undervalued its work, for one thing all chemists are grateful, and Oxford herself may feel proud—that here, under her influence, first grew up the idea that chemistry was no mere drudge of medicine, or genii of the alchemist, but a science to be studied purely for itself.

The origin of this Oxford Society has been well told by Dr. Wallis, one of its founders:—

"About the year 1645, while I lived in London (at a time when, by our civil wars, academic studies were much interrupted at both Universities), besides the conversation of eminent divines, I had the opportunity of being acquainted with divers worthy persons inquisitive into natural philosophy, and particularly of what hath been called experimental philosophy. We did by agreements meet weekly in London to treat and discourse of such affairs; of which number were Dr. John Wilkins, Dr. Jonathan Goddard, Dr. Ent, Dr. Merret, Mr. Samuel Foster, then Professor of Astronomy in Gresham College, and Mr. Theodore Haak, and many others.

"These meetings we held sometimes at Dr. Goddard's lodgings, on occasion of his keeping an operator at his house for grinding glasses for telescopes and microscopes; sometimes at a convenient place in Cheapside, and sometimes at Gresham College. Our business was (precluding matters of theology and State affairs) to discourse and consider of philosophical inquiries . . . . About the year 1648, some of our company being removed to Oxford (first Dr. Wilkins, then I, and soon after Dr Goddard), our company divided. Those in London continued to meet there as before, and those of us at Oxford, with Dr. Seth Ward (since Bishop of Salisbury), Dr. Ralph Bathurst, President of Trinity College, Dr. Petty, Dr. Willis (an eminent physician in Oxford), and divers others, continued such meetings in Oxford, and brought those studies into fashion there, meeting first at Dr. Petty's lodgings (in an apothecarie's house), because of the convenience of inspecting drugs, and, after his removal, at the lodgings of Dr. Wilkins, then Warden of Wadham College, and, after his removal, at the lodgings of the Honourable Mr. Robert Boyle, then resident for divers years in Oxford."

Robert Boyle, the youngest child of the great Earl of Cork, was born at Lismore in 1626. His mother died when he was a child. Always delicate, he was sent at twelve years of age with a tutor to the Continent; he remained abroad for six years. He studied chiefly at Geneva and at Florence, where he read the works of Galileo. Returning to England, in 1644, he busied himself with chemistry at Stalbridge, a manor in Dorsetshire left him by his father. On his visits to London he became one of the members of the "Invisible College," the germ of the Royal Society. "Vulcan has so bewitched me," he writes at the age of twenty-three, "as to make me fancy my laboratory a kind of elysium."

Drawn to Oxford in 1654, Boyle spent here the most active years of his life in experimental research. Of Boyle's scientific writings much has been said in extravagant praise and much in ridicule. Boerhaave wrote: "To him we owe the secrets of fire, air, water, animals, vegetables, and fossils." This phrase is not more grotesque than that of a recent writer, who says, "Boyle's name is identified with no great discovery.' Dr. Johnson has very justly remarked, in a number of the *Rambler*: "It is well known how much of our philosophy is derived from Boyle's discoveries, yet very few have read the details of his experiments. His name is indeed reverenced, but his works are neglected." It is, indeed, rather hard to read through one of Boyle's papers, even in the abridged form. Though clear, they are discursive. The writer cannot rid himself entirely of the essences and qualities of the alchemists; and it is only when we compare these records with the works of Van Helmont, his immediate predecessor, that we recognise the enormous advance that has been made by Boyle. I must pass over his physical work on the elasticity of the air. It must suffice to say that he established by most careful experiment the law which is known by his name—that the volume of a given mass of air varies inversely as the pressure upon it. He determined the density of the air, and pointed out that bodies altered in weight according to the varying buoyancy of the atmosphere. One of his most important chemical papers—certainly the one most frequently cited—is "The Sceptical Chemist," published anonymously in 1661. I will attempt the briefest account of it. The opening words of the dialogue strike the keynote of the whole:—

"Notwithstanding the subtle reasonings of the Peripatetics and the pretty experiments of the Chymists, I am so diffident as to think that, if neither can produce more cogent arguments than are usually given, a man may reasonably doubt as to the number of those material ingredients of mixed bodies which some call elements and others principles." He proceeds, through the mouth of one of the supposed disputants, to attack the doctrine of the three elements, the *tria prima* of the alchemists—sulphur, mercury, and salt. "There are some bodies," he says, "from which it has not yet been made to appear that any degree of fire can separate either salt, or

[1] Whewell, "Hist. of Ind. Sci."

sulphur, or mercury, much less all the three. Gold is the most obvious instance. It may be heated for months in a furnace without losing weight or altering in character, and yet one of its supposed constituents is volatile and another combustible. Neither can water or solvents separate any of the three principles from gold; the metal may be *added to*, and so brought into solution and into crystalline compounds, but the gold particles are present all the time; and the metal may be reduced to the same weight of yellow, ponderous, malleable substance it was before its mixture." He points out the confusion which earlier chemists had made between calcination in the open air and distillation in retorts; he shows that in compounds, *e.g.* copper nitrate, the particles retain their nature, although disguised, in the combination, for the nitric acid may be separated by heat, the copper by precipitation. But the sceptical chemist, though pouring ridicule on the *tria prima*, could not but admit the power of water to produce organic substances. He quotes Van Helmont's famous experiment of growing a shoot of willow in baked earth moistened with distilled water, and he repeats the experiment in various forms. Ignorant of the existence of carbonic acid in the air (discovered a century later by Black), he is driven to conclude that the plant is fashioned out of the pure water. But he rejects the doctrine—as old as Thales and as modern as Van Helmont—that water is the foundation of all things. M. de Rochas had published a remarkable experiment on water. By artificial heat, by graduations of coagulations and congelations, he had turned it into earth which produced animals, vegetables, and minerals. The minerals began to grow and increase, and were composed of much salt, little sulphur, and less mercury; the animals moved and ate, and were composed of much sulphur, little mercury, and less salt. "I have some suspicions," says Boyle, "concerning this strange relation; though as for the generation of living creatures, both vegetable and sensitive, it need not seem incredible, since we find that our common water, which is often impregnated with a variety of seeds, long kept in a quiet place, will putrefy, and then, too, produce moss and little worms according to the nature of the seeds that were lurking in it."

I will give two short quotations from the "Sceptical Chemist," which show the author at his best and his worst. In the first he is discussing the nature of chemical combination between elementary particles: "There are clusters wherein the particles stick not so close together, but they may meet with corpuscles of another denomination, disposed to be more closely united with some of them than they were among themselves; and in such case two corpuscles thus combining, losing that shape, size, or motion upon whose account they exhibited such a determinate quality, each of them really ceases to be a corpuscle of the same denomination as it was before; and from the coalition of these there may result a new body, as really one as either of the corpuscles before they were confounded. . . . If you dissolve minium in good spirit of vinegar and crystallise the solution, you shall not only have a saccharine salt exceedingly different from both its ingredients, but the union is so strict that the spirit of vinegar seems to be destroyed . . . for there is no sourness at all, but an admirable sweetness to be tasted in the concretion." In this passage we can distinctly see the germ of the modern theory of chemical affinity uniting atoms into chemical compounds. In the second quotation Boyle is arguing that fire is not only an analyser of mixtures, but compounds the ingredients of bodies after a new manner; mercury, for instance, may be turned into a liquid, from which the mercury cannot be reduced again, and consequently is more than a "disguise" of it. "Two friends of mine," he says, "both of them persons of unsuspected credit, have solemnly assured me that after many trials they made to reduce mercury into water, they once, by several cohobations, reduced a pound of quicksilver into almost a pound of water, and this without the addition of any substance, but only by urging the mercury with a fire skilfully managed. Hence it appears that by means of fire we may obtain from a mixed body what did not pre-exist therein." Boyle has sometimes been charged with credulity, and chemists who know how mercury has a way of disappearing without leaving even its weight of water behind will smile to hear that the persons of unsuspected credit responsible for this experiment were "the one a physician, the other a distinguished mathematician."

Boyle's writings contain the record of numerous important chemical observations, *e.g.* the synthesis of nitre, and the preparation of nitric acid by the distillation of nitre with oil of vitriol. He discovered several of the delicate tests we still use, *e.g.* solution of ammonia as a test for copper, silver nitrate as a test for chlorides, gallic acid as a test for iron. But I wish especially to refer to the work done by Boyle on the air and its relation to combustion. The air, according to him, was composed of three different kinds of particles: (1) exhalations from water and animals; (2) a very subtle emanation from the earth's magnetism, which produces the sensation of light; and (3) a fluid compressible and dilatable, having weight, and able to refract light. It is this third portion of air which plays an active part in many chemical operations. Like Van Helmont, Boyle recognised differences in gases, but did not distinguish them as being something different in kind from air. He prepared hydrogen by the action of hydrochloric and sulphuric acids on iron, but his chief concern was to show that the new gas was compressible and was dilatable by heat; in other words, that it was really *air*. His observations are worth quoting; they contain, I believe, the first undoubted description of hydrogen, and the first method devised for collecting and examining freshly prepared gases.

"Having provided a saline spirit . . . exceedingly sharp and piercing, we put into a vial a convenient quantity of filings of steel, purposely filed from a piece of good steel. This metalline powder being moistened with the menstruum was afterwards drenched with more, whereupon the mixture grew very hot, and belched up copious and stinking fumes. . . . Whencesoever this stinking smoak proceeded, so inflammable was it, that upon the approach of a lighted candle it would readily enough take fire, and burn with a blewish and somewhat greenish flame at the mouth of the viol; and that, though with little light, yet with more strength than one would easily suspect."[1]

And again: "We took a clear glass vial, capable of containing three ounces of water, with a long cylindrical neck; this we filled with oil of vitriol, and fair water, of each a like quantity, and casting in six small iron nails we stopped the mouth of the glass, and speedily inverting it, we put the neck of it into a wide-mouthed glass with more of the same liquor in it. . . . And soon after we perceived the bubbles, produced by the action of the menstruum upon the metal, ascending in swarms; by degrees they depressed the liquor till, at length, the substance contained in these bubbles possessed the whole cavity of the vial. And for three or four days and nights together the cavity of the glass was possessed by the air, since by its spring it was able for so long a time to hinder the liquor from regaining its former place. Just before we took the vial out of the other glass, upon the application of the warm hand to the convex part of the glass, the imprisoned substance readily dilated itself like air, and broke through the liquor in several succeeding bubbles."

The importance of this experiment will be evident when we consider that Van Helmont had declared that gases could be made artificially in many ways, but could not be caught and held in vessels.[2]

Armed with the air-pump which he had so greatly improved, Boyle in 1660 began many experiments on combustion, which he afterwards published under the title "New Experiments touching the Relation betwixt Flame and Air." In these researches he shows that sulphur will not burn when the air is removed. The sulphur was lowered on to a hot iron plate in a receiver made vacuous by the pump; it smoked, but did not ignite. On allowing a little air to enter "divers little flashes could be seen": these were extinguished on sucking out the air again. A candle flame and a hydrogen flame under a receiver were gradually extinguished when the air was pumped away. On the other hand, on dropping gunpowder on to a hot iron plate *in vacuo* there appeared "a broad blue flame like that of brimstone, which lasted so very long we could not but wonder at it"; and fulminating gold detonated *in vacuo* when heated by a burning glass, or when dropped on heated iron. Gunpowder also he found to burn under water. He is driven to the conclusion "that flame may exist without air." But it may be supposed that air is mechanically enclosed in the crystals of nitre—"in its very formation the corpuscles may intercept store of little aereal particles. . . . According to this surmise,

[1] "On the Difficulty of preserving Flame without Air," 1672.

[2] "Gas, vasis incoercible, foras in aerem prorumpit." (*Ortus Medicinæ*. The epithet "sylvestre" was applied by Van Helmont to all artificially prepared gases. He meant by it "untameable" and "non-condensible"—"quod in corpus cogi non potest visibile."

though our mixture burns under water, yet it does not burn without air, being supplied with enough to serve the turn by the numerous eruptions of the aereal particles of the dissipated nitre." However, he "removes this suspicion" by obtaining nitre crystallised *in vacuo*. He then suggests the possibility of the nitre supplying "vehemently agitated vapours" which are no true air, but being exceedingly rarefied by the fire "emulate air." Boyle never grasped the true function of air in combustion. From his later experiments on the calcination of metals he drew the same conclusion that we find in the "Sceptical Chemist," namely, that igneous particles combine with other corpuscles to form new bodies. And yet he saw there was a real connection between air and fire. In his tract on Artificial Phosphori, Boyle showed that a piece of phosphorus sealed up in a glass vessel gradually lost its light. "It seems," he wrote, "that the air included with the phosphorus either had some vital substance preyed upon thereby, or else was tamed by the fumes of the phosphorus and rendered at length unfit to continue the particular flame of our noctiluca."

The genius of Robert Hooke was in sharp contrast with that of Boyle. Quick, restless, imaginative, he sprang from discovery to discovery. With extraordinary acuteness and powers of invention, he lacked the steady purpose of Boyle, the calm judgment and completeness of Newton—his two great scientific contemporaries. It might be said of Hooke, as was said of a great poet, he touched nothing he did not strike fire from; and some would add that his touch had the same effect on persons as on things. We can hardly name a discovery of this age which Hooke had not in part anticipated and claimed as his own. Like a prospector in a newly discovered mining district, he hurried from spot to spot, pegging in his claims and promising to return to work out the ore. And what rich lodes he struck! The particular claim we are concerned with here is the discovery of the relation between air and flame. In 1665 Hooke published in the "Micrographia" a description of flame and the phenomena of combution which in my judgment has never been surpassed. How far he was indebted to Boyle will appear directly.

Born in 1635, Hooke spent five years at Westminster School, then under Dr. Busby, and proceeded to Christ Church in 1653. At school and college it is related of him that he devoted his time to designing flying machines. These mechanical inventions attracted the notice of Dr. Wilkins, Warden of Wadham, and a leading member of the Philosophical Society. This led to his introduction to Dr. Willis, to whom he became assistant in chemistry and natural philosophy. Willis recommended him to Boyle, whose assistant he became. His first work in Boyle's laboratory was the construction of the improved air-pump. In 1662 Boyle obtained for him the position of curator of experiments in the London Society, soon to be known as the Royal Society. Hooke was thus Boyle's assistant when those experiments on combustion I have described were being carried on. Among other experiments made by Boyle were some on the distillation of wood in retorts.

"Having sometimes distilled such woods as box, whilst our *caput mortuum* [*i.e.* the residue] remained in the retort it continued black like charcoal, though the retort were kept red hot in a vehement fire; but as soon as ever it was brought out of that vessel into the open air the burning coals would degenerate or fall asunder into pure white ashes."[1] Hooke saw the experiment and a new light flashed on him. "From the experiment of charring coals," he writes "(whereby we see that, notwithstanding the great heat, the solid parts of the wood remain, whilst they are preserved from the free access of the air, undissipated) we may learn that which has not been published or hinted, nay, not such much as thought of by any; and that in short is this:—

"That the air is the universal dissolvent of all sulphurous [*i.e.* combustible] bodies. . . .

"That this action of dissolution produces a very great heat, and that which we call fire.

"That this action is performed with so great a violence, and does so rapidly agitate the smallest parts of the combustible matter, that it produces in the diaphanous medium of the air the action, or pulse of *Light*.

"That this dissolution is made by a substance inherent and mixed with the air, that is like, if not the very same with, that which is mixed in saltpetre.

"That the dissolving parts of the air are but few . . . whereas saltpetre is a menstruum . . . that abounds more with these dissolvent particles.

"It seems reasonable to think that there is no such thing as an element of fire, . . . but that that shining transient body which we call flame is nothing else but a mixture of air and volatile parts of combustible bodies, which are acting upon one another whilst they ascend; which action . . . does further rarifie those parts that are acting or are very near them, whereby they, growing very much lighter than the heavy parts of that *menstruum* they are more remote, are thereby protruded and driven upwards."

Hooke quotes no other experiments in support of his theory of flame. He states that he has made many; he has, however, only time "to hint an hypothesis," which, if he is permitted opportunity, he will "prosecute, improve, and publish." Some years later he returned to his subject of flame in his tract called "Lampas," published in 1677. "The flame, as I formerly proved, being nothing but the parts of the oyl rarified and raised by heat into the form of a vapour or smoak, the free air that encompasseth this vapour keepeth it into a cylindrical form, and by its dissolving property preyeth upon those parts of it that are outwards, . . . producing the light which we observe; but those parts which rise from the wick which are in the middle are not turned to shining flame till they rise towards the top of the cone, where the free air can reach and so dissolve them. With the help of a piece of glass anyone will plainly perceive that all the middle of the cone of flame neither shines nor burns, but only the outward superficies thereof that is contiguous to the free and unsatiated air."

What is practically the same theory of flame was worked out experimentally by John Mayow, Fellow of All Souls: this was published a few years after the "Micrographia."

But Mayow went further, and distinctly showed the dual nature of the air. One constituent of air, the nitre air, is concerned in respiration and combustion; the other will neither support flame nor animal life. The ideas, the names, proposed by Hooke and Mayow are so exactly similar that it is impossible to imagine that the work was done independently. The two were working at the same time at Oxford, and Mayow, having been an undergraduate at Wadham under Dr. Wilkins, became the pupil of Willis. Yet Mayow nowhere mentions Hooke's name. A writer in the "Dictionary of National Biography"[1] has shrewdly observed that Hooke has brought no charge of plagiarism against Mayow, and even proposed him for the Royal Society four years after the publication of the "Five Tracts." Knowing what we do of Hooke's jealousy, it seems exceedingly unlikely that Mayow was merely working out Hooke's ideas. It seems to me probable that Hooke and Mayow worked together under Boyle between 1660 and 1662; that in Boyle's laboratory they saw and assisted in the experiments which led them jointly to their theory; that Hooke, busy with other work in London, published the hypothesis in 1665 without further verification: and that Mayow in Oxford systematically worked through the experiments on which he based his conclusions.

Let me briefly show what the experiments were on which Mayow relied. Combustible bodies will not burn in the vacuous receiver of Boyle's air-pump; they will burn *in vacuo* or under water when mixed with nitre. There is, therefore, something common to air and to nitre which causes combustion. The fiery particles in air and in nitre both form oil of vitriol by their union with sulphur; they both form iron vitriol by their union with pyrites. Rust of iron is produced both by the air and by acid of nitre; the acids of sugar and honey are formed, and wine is soured in the same way. The nitre-air (spiritus nitro-aereus), the supporter of combustion and the acid producer, is therefore the same chemical substance whether it exist in the gaseous form in air or is condensed in saltpetre.

Mayow heated a weighed quantity of antimony by means of a burning glass, and found it increased in weight during the calcination;[2] the calcined antimony, he adds, has the same properties as the body prepared by heating antimony with nitric acid; it is impossible to conceive, he says, whence the increase in weight arises except by the fixation of the particles of nitre-air during the heating.

The nitre-air does not make up the whole of the air, but only its more active and subtle part, for a candle under a glass will

[1] "The Sceptical Chemist."

[1] Mr. P. J. Hartog.

[2] This experiment seems to have been first described by Poppius, *Basilica Antimonii*, 1625.

cease to burn while there is still plenty of air left. The experiment by which Mayow shows this is so important that I will quote his words:—

"Let a lighted candle be so placed in water that the burning wick shall rise about six fingers' breadth above the water; then let a glass vessel of sufficient height be inverted over the candle. Care must be taken that the surface of the water within the glass shall be equal in height to that without, which may be done by including one leg of a bent syphon within the vessel while the other opens outside. The object of the syphon is that the air, enclosed by the vessel and compressed by its immersion into the water, may escape through the hollow syphon. When the air ceases to issue, the syphon is immediately withdrawn, so that no air can afterwards get into the glass. In a short time you will see the water gradually rising into the vessel while the candle still burns."

In other experiments he burnt camphor and sulphur supported on a shelf in the inverted vessel. The water rose, he says, because, owing to the disappearance of the fire-air, the air left could not resist the pressure of the atmosphere outside. When the combustibles were extinguished it was impossible to kindle them again by means of the sun's rays concentrated on them by a burning glass. The residual air was no more able to support combustion than the vacuum of Boyle's engine. Again, the respiration of animals in the closed space was shown to diminish the air, and to render it incapable of supporting combustion; the fire-air was as necessary for life as for flame. The larger portion of the air was something entirely different from fire-air, and incapable of supporting life or combustion. I believe this to be the first definite statement founded on experiment that the air is composed of two distinct gases.

I have given the fundamental facts in chemistry we owe to Mayow: the limits of his work are sufficiently obvious. He detected the existence of what we call oxygen gas in the air, and demonstrated some of its most remarkable properties. He did not isolate the gas, or show what became of it in combustion; he did not always distinguish between the gas itself and the heat produced by its action. But the advance he made was extraordinary—not so much in the conclusions he drew as in the experiments and arguments he founded them on. Compare him for a moment with another writer who had previously expressed similar views concerning the calcination of metals. Jean Rey, of Perigourd, a witty and shrewd physician, published in 1630 a series of essays attributing the increase in weight of metals on calcination to the fixation of the air. "When asked," he writes, "why tin and lead increase in weight on calcination, I reply and gloriously maintain that this increase comes from the air, which is thickened and made heavy and adhesive by the long and continued heat of the furnace. This air mingles with the calx and attaches itself to the smallest particles." The reply is good, but the reasons that gloriously maintain it are not altogether conclusive. I can only give two of them: (1) *The air has weight.*—This is shown by the increase in velocity of heavy bodies falling to the earth, because as the body approaches the earth it subtends a wider angle from the centre of the earth, and receives more shocks from the particles of air. Again, although the air appears to weigh nothing on the balance, this is because we weigh it in the air; it loses its weight, just as water weighs nothing in water. Fire has weight too, and should we ever find ourselves in a region where fire is the predominant element, we shall be able to prove the statement in the same way. (2) *Fire can thicken and make air heavy.*—Stand a cannon upright and put a red-hot ball into it. You must admit that the air in the gun is so small in quantity that it will be heated to the same temperature as the ball. Nevertheless you can hold your hand in the mouth of the gun at first, but in a short time you cannot do so. Not that the air has got hotter, it is cooling all the time; it is because the air is thickened. Now if you drop a piece of wool into the mouth, it will not descend, and if you push it in, it will come up again, proving the air is heavier. Lastly, the air is seen to tremble over the mouth of the gun, and objects seen through it are blurred. This is due to the thickening, it cannot be due to a motion of the air; "for I see," he says, "a lady's beauty quite distinctly through the air she flutters with her fan."

From what has been stated it will be clear that the Oxford school of Chemistry was a *school of research*. Boyle gave no instruction in the ordinary sense; and, indeed, had no official connection with the University. But that he thought instruction in chemistry should be given in the University is obvious from the fact that he brought over a chemist from Strasburg, and set him up as a lecturer with rooms next his own and the use of his laboratory. Of these lectures we find a quaint account in Anthony Wood's diary:—

"An. Dom. 1663.

"Began a course of chemistry under the noted chemist and rosicrucian, Peter Sthael, of Strasburg, brought to Oxon. by the hon. Mr. Rob. Boyle, an. 1659. He took to him scholars in the house of John Cross next on the w. side to University Colle The club consisted of 10 at least, whereof Francis Turner of New Coll. was one, Ben Woodroff of Ch. Ch. another, and John Lock of the same house, afterwards a noted writer. This John Lock was a man of turbulent spirit, clamorous and never contented. The club wrote and took notes from the mouth of their master, who sat at the upper end of the table, but the said J. Lock scorned to do it; so that while every man besides were writing, he would be prating and troublesome. After the beginning of the year 1663 Mr. Sthael removed his elaboratory to a draper's house, called John Bowell, afterwards mayor of the city, situate in the parish of All Saints. He built his elaboratory in an old hall in the back, for the house itself had been an ancient hostle; therein A. W. and his fellows were instructed. The chemical club concluded, A. W. paid Mr. Sthael 30 shill: having paid 30 shill: beforehand. A. W. got some knowledge and experience, but his mind still hung after antiquities and musick."

In spite of Boyle's private position, his blameless life, his devoutness, and his charity, his work aroused bitter animosity in Oxford. He was attacked in the University pulpit, in public orations, in private squibs; his theories were described as destructive of religion, his experiments as undermining the University. But what chiefly drew the indignation of his opponents was that he, a gentleman by birth and fortune, should concern himself with low mechanical arts. Against these attacks Boyle replied with irresistible logic. His vindication of the nobility of scientific work constitutes one of his greatest claims on our gratitude.

Boyle left Oxford in 1668. Mayow died in 1679. In 1683 Anthony Wood informs us that "the Oxford elaboratory was quite finished"; but the impulse given to the study of Chemistry in Oxford gradually died out. I do not know the history of the Chair of Chemistry in Oxford (if there was one) in the eighteenth century. Richard Frewin, of Christ Church, is described as Professor of Chemistry in 1708. He does not seem to have taken himself too seriously in this capacity. Uffenbach, who visited Oxford in 1710, says he found the stoves in fair condition, but everything else in the laboratory in dirt and disorder. Frewin himself was elected Camden Professor of Ancient History in 1727. He seems to have thrown himself into his new work with greater ardour; for Hearne relates that, on his election, he at once bought one hundred pounds' worth of books in chronology and history to fit himself for his duties. For a companion picture to this we may glance at the appointment in 1764 of Richard Watson (afterwards Bishop of Llandaff) to the Chair of Chemistry at Cambridge, which had been founded in 1702. Dr. Watson, we are told, knew nothing at all of chemistry: had never read a syllable nor seen a single experiment on the subject. On his election he sent to Paris for an "operator," and set to work in his laboratory. In fourteen months he began to lecture to a large audience.

But Watson at Cambridge was succeeded by Wollaston. We had to wait till Brodie for a successor to Boyle.

II.

We have seen what a vigorous effort Chemistry made to plant itself in Oxford in the seventeenth century. If the soil had been prepared the roots must have struck deep. But the University paid little heed, and after a few years of prodigal growth the plant withered and died out. It would seem that the positions are reversed at the present day. The University spends large sums for supervision and appliances; the young plants are brought here and nurtured at great expense, but the fair blossoms produce little fruit. Even our best friends admit that the results are somewhat disappointing. If these are the facts—and I speak as one who shares the responsibility for the present condition of chemistry here—it is the duty of those concerned to speak out; and I can conceive no more fitting opportunity than the present for pointing out some of the causes that appear to hinder our growth. Let no one think I wish to disparage the University. I should be the last person to do so. I owe to my old college the opportunity, the help, and the example which made me a chemist, and gave me an interest in life. I only wish to see more general the advantages it was my luck to meet with in Christ Church.

Chemistry in modern Oxford is accorded a place side by side with older studies. No one can complain that scholarships are not offered broadcast, that money has not been freely given for laboratories; and yet I think the student does not feel around him the atmosphere in which an experimental science should be cultivated. We see Chemistry endowed and extended, we do not see it respected by the bulk of students and of learned men. In my undergraduate days a rhyme was current here (I think it was coined in Cambridge—the Parnassus of parodies) expressing views which were undoubtedly held concerning the claims of chemistry as a subject for a degree. One verse ran—it was from the Lamentation of a would-be Bachelor—

> "I thought to pass some time before, but here, alas, I am,
> Having managed to be plucked in every classical exam.
> I cannot get up Plato, so my reverend tutor thinks
> I had better take up Chemistry, which is commonly called 'Stinks.'"

I do not quarrel with the versifier (except as a poet), I do not even quarrel with the reverend tutor, whose opinion of us is obviously small, because I do not think myself that Chemistry as it is taught is a very good subject for a degree. Still less is it a subject which we should allow to monopolise the schoolboys' time. While holding strongly that the elements of Physics and Chemistry form a necessary part of a liberal education, I believe we have made two mistakes with regard to the teaching of science. We have by our science scholarships encouraged too early specialisation at school; we have overburdened our undergraduates here with a multitude of facts they cannot retain. A boy specialises for two years at school; he learns a prodigious array of facts from the latest text-book, and also acquires some skill in the art of quickly reproducing what he has learnt. He wins a science scholarship. We then tell him he must go back to, or begin, the study of the classical languages we look on as essential for our degrees. By a certain time he must reach a certain (rather low) standard, or his scholarship lapses. He learns that it is advisable to get assistance from those who have made a special study of preparing candidates for pass examinations. He crams; or he goes to a crammer and is crammed. Let us suppose, as is usually the case, that the obstacle is Greek. I will not deny that the standard of Greek demanded may imply some important discipline at school, and some real culture of the mind, provided the instruction given is on wholesome lines and forms part of a liberal course. Got up in a hurry as it too often is, solely with the object of passing, it means time and effort wasted and worse than wasted. It is of no value in itself, for it is forgotten in less time than it took to acquire; and it gives the student the first pernicious taste of that superficiality and false knowledge it should be our special aim to remove. Is it not desirable that scholarships should be the reward of progress and ability *in the general subjects of school education* among which the elements of science should have a place? The brightest and most persevering boys would come to the University, and there make choice of the special course they wished to pursue.

My second complaint is that we teach too many facts. They are not all important. After three or four years' steady accumulation our men go into the schools walking dictionaries of chemistry. Parents not unnaturally think that their sons, after four years of college training, should be fit to take responsible places wherever chemists are in demand. But manufacturers, as a rule, do not care for University graduates. I cannot blame them. We cannot guarantee that the men we send out with honours in Chemistry can attack a new problem, can work out new processes, can prepare new dyes. German manufacturers, on the other hand, *prefer* a University graduate, for they have in *their* degree a guarantee that the student has successfully attacked some unknown problem, and added to the store of knowledge.

The influence of science on the nation's industry has been recognised and insisted on by those who can make their voices heard. The country has at length awakened to the fact that something is wanting, and cries out for Technical Instruction. It is not afraid of spending money: indeed, many well-meaning bodies are spending—and in some cases I fear, wasting—money with a prodigal hand. And what, after all, is the great need? Speaking for the subject I know best, I say unhesitatingly that we want scientific chemists who can and will make discoveries; we want men trained, not only in what has been done, but taught how to set about winning new knowledge. The Universities, I urge, should teach the art of research. This is what is wanted, and this, as all experience shows, is what the Universities can do better than anyone else. And no exorbitant amount of time need be demanded for this purpose. If the student has learnt the elements of science at school, three years at most should suffice for the preliminary degree course. The graduate, armed with the necessary manipulative skill, would then start research work under proper guidance as the second and more valuable portion of his University training. And here the new research degree (by whatever name it may be called) may give us most valuable help. I hope that serious work will be demanded for it, and that the research course will become the recognised avenue to science fellowships and lectureships in the University. Two years would show what the man had in him. In that time either he would have proved himself no chemist, or he would have made some useful advance in our knowledge, and would have secured a testimonial of fitness such as no examination could confer. Five years in all—the minimum time now laid down for a medical qualification—would surely be not too much to ask for the chemist's training.

No extra expense need be incurred to carry out this plan. Some of the college scholarships at present offered on entrance might be reserved for research studentships on graduation. These studentships should be the reward of the successful undergraduate career. On this point, which I have urged for many years, I am glad to find myself in entire agreement with the President of the Chemical Society. At Owens College our most successful endowment in chemistry has been the Dalton Scholarship, awarded for a research done in the College laboratories. In the Victoria University we have lately founded scholarships for the encouragement of research, which are awarded on the results of the final examination in the several Honours Schools. The winners are entitled to hold their scholarships at any university at home or abroad where they can continue their special studies.

I plead, then, for greater encouragement of chemical research in Oxford. Make it part of the normal course of training for everyone who wishes to be a chemist in fact as well as in name. Consider, not only the country's need, but the value of research itself as a mental training, as stimulating and strengthening the activities, as creating that sense of devotion and discipleship which becomes the tradition of every great school of learning.

Lastly, let us own that we ourselves—the teachers here—have been perhaps too critical, too much afraid of making mistakes, forgetting that the witty American's remark—that he who never makes mistakes never makes anything—has a far wider application in science than in politics. Only by practice and drill can we learn to collect our strength and swing it with precision into acts. Without that training, no matter how much faculty of seeing a man has "the step from knowing to doing" is rarely taken. There is nothing, I believe, in Oxford antagonistic to our cause. The genius of the place has not declared against scientific research; and if it be a true saying that men here imbibe a liberal education from the very air breathed by Locke and Berkeley, surely we also may draw scientific inspiration from this air, not only breathed, but first explained by Boyle and Hooke and Mayow.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY L. FLETCHER, M.A., F.R.S., F.G.S., PRESIDENT OF THE SECTION.

WITH an anxious desire to conform to the traditions of the past, I have sought in the Reports of the Association for guidance in my present difficulty; and have remarked that it is customary for a president, on first taking the chair, to express a deep sense of unworthiness for the position to which he has been called. My first duty, then, seemed a simple and obvious one; till I further remarked, to my dismay, that the more distinguished the president the more humble have been the terms in which such expression has been made. Hence I feel that it may appear to you presumptuous on my part if I myself make any apology at all, and it would doubtless imply a claim to the highest distinction if I were to make that humble apology which would be most appropriate to the circumstances of the case.

Instead, however, of dispensing with the apology altogether—that might be too radical an innovation to be introduced this year—I propose, with your sanction, to make a lesser change, and merely to defer the apology from the first to the last day of our session. I may reasonably hope to be able, at that later stage, to make clear to you, by simple reference to your own experience during the meeting, that any apology I may feel it to be then my duty to make is of no merely formal character, but one which is worthy of your serious consideration.

I would ask that in the meantime your continuous sympathy be extended to one who now finds himself in a position he would have been the last to seek, and whose ordinary duties in life involve speechless communion with inanimate nature rather than oral address to an assembly of fellow-workers.

This matter of apologetic precedent being thus disposed of to our common satisfaction, I should have preferred to have brought the delay of the normal business of the Section to an immediate end by calling upon the author of the first paper to now address you. Such, indeed, was the ordinary course of procedure in the earlier, and perhaps presidentially happier, years of the Association; but the occasion of taking the chair having been once seized upon, in absence of mind, by a mathematical president for the delivery of an address, it has come about that each president now feels it his bounden duty, not merely to give an address, but to make the address at least as long and at least as elaborate as any which has preceded it.

We shall all agree that a presidential address, if there is to be any at all, should be elaborately short and elaborately simple; it should deal, not with technical details such as are only intelligible, even to the president himself, after much study, but with general principles such as can be immediately grasped by every member of an audience; an opening address which is so long that it can be only partly read, and is written to be studied afterwards in the Reports of the Association, may more appropriately be issued as an ordinary memoir. I make this remark to safeguard the interests of future audiences, for the example of technicality which I am now about to set is one which I cannot recommend my successors to follow.

As for subject, an account of the progress of scientific work is always interesting and instructive, and immediately suggests itself as the natural basis of a presidential address. But seeing that, so lately as in February last, the geologists have had the advantage of an address from the retiring president of their Society, Mr. Hudleston, which has been virtually exhaustive in its survey and criticism of the British geological work of the last seven years, the time has scarcely yet arrived when a continuation of that review by the president of this Section can be of service to the members of the Association.

For this and other still more weighty reasons which I need not directly mention, I feel myself debarred from undertaking any review of recent geological progress, and shall therefore ask you to allow me to confine myself, in the remarks it is my duty to make, to a science which, though it is not purely geological and in the Reports of the Association has long been associated with another science, chemistry, is yet very closely related to the science of our own Section, Geology.

I trust that the members of the Section of Chemistry and Mineralogy are now so closely engaged in another place that they will fail to discover, or at any rate to resent, the technical trespass on their own domain: as for yourselves, you will perhaps be more ready to pardon the temporary excursion from the domain of pure geology if I remind you that the fathers of the Geological Society defined their sole object to be "the investigation of the mineral structure of the earth"; and I may add, if further defence be desired, that in the first half of this century the relationship of mineralogy and geology was so intimate that it was possible for a Section of the British Museum to be officially designated "the Department of Mineralogy, including Geology."

I was the more impelled to choose this subject for our consideration to-day when I reflected that pure mineralogy has been hitherto almost completely out of sight, and therefore probably out of mind, at the meetings of the Association. It is true that at the first meeting, held sixty-three years ago, Dr. Whewell, then the Professor of Mineralogy at Cambridge, was invited to draw up a report on the state of knowledge of the science, and that his report was submitted and printed in the following year. But in the course of the sixty-three years during which the Association has flourished, it has chanced that a mineralogist has on only one occasion, that of 1862, been seated in a presidential chair; and since at that time presidential addresses had not yet come to be regarded as necessary to the existence of the Sections, Prof. Miller refrained from inflicting a mineralogical dissertation on an audience which, he had reason to presume, would consist entirely, or almost entirely, of chemists. Perhaps you might be tempted to think that the want of prominence of the mineralogists at our previous meetings has been due to a becoming sense of modesty resulting from the study of that science: this would be a mistake. The fact is that a mineralogical memoir, dealing largely with numerical quantities and involving great variety of experiment and technicality, may be read and studied, but should never be heard; like the mathematician, the mineralogist despairs of making clear to an audience, especially a mixed one, the bearing of any researches which have been made in his subject. But now that sixty-two years have elapsed since the issue of Prof. Whewell's Report, the time has perhaps at length arrived when it is advisable, notwithstanding the difficulties surrounding an oral treatment of mineralogy, to attempt to give to the Association a faint idea of the present position of the study of the subject. And if most of my hearers find that the remarks are too technical to be in any great part intelligible, let them console themselves with the reflection that, if the future at all resembles the past, only Shalum and Hilpa can have to endure again that particular kind of *mauvais quart d'heure* which is to precede the geological feast of to-day.

The Systems of Crystallisation.—At the time of the publication of Prof. Whewell's report it had already been established by the researches of Romé de l'Isle, Haüy, Mohs, and Weiss that the position of any single face of any crystal can be exactly defined by means of two sets of quantities: firstly, three lines or axes, of which the lengths and mutual inclinations are characteristic of the substance itself; secondly, three whole numbers or indices, rarely rising higher in magnitude than the number 6: further an empirical arrangement of crystals into systems had been based by Mohs and Weiss on the relative lengths and inclinations of the axes. And a long series of observations of the optical characters of crystals had revealed to Brewster the fact that the boundaries of the classes of optically isotropic, uniaxal and biaxal crystals form part of the boundaries of the empirical systems. But whereas only three optical classes of crystals had been recognised, it was certain that there were at least four geometrical systems, and it was a matter of controversy as to whether the independence of two others should not be regarded as geometrically established.

The first important discovery following the issue of Whewell's Report was one which proved that the two doubted systems are natural ones. It was found by Herschel and Neumann that the biaxal crystals are not optically similar, as had hitherto been supposed, but are of three kinds. In crystals of one kind—for example, barytes—the two lines bisecting the angle of the optic axes internally and externally, and a third line perpendicular to both, are constant in direction in the crystal whatever the colour of the light; in a second kind—for instance, selenite—only one of these lines is constant when the colour varies; in a third kind—for instance, borax—none of the three lines has any constancy of direction. And these three kinds of biaxal crystal correspond exactly in their facial development to the three systems of crystallisation of which the independence had already been asserted by some crystallographers on geometrical grounds. From this time the arrangement of crystals into the six systems has been regarded as a natural one; and the optical method based on the figures seen in plates when examined in convergent polarised light has been in constant use, and is an invaluable aid in the determination of the system of crystallisation.

Crystallographic Notation.—For a simple method of expressing the relative positions of crystal faces by a symbol, crystallographers are infinitely indebted to the late Prof. Miller, of Cambridge. The symbols introduced by Mohs, Weiss, Lévy, Naumann, and the modification of the latter suggested by Dana, though interesting, are not to be compared for legibility, pronounceability, or utility in calculation, with the simple symbol which is associated with the name of Prof. Miller. Though the symbol was not invented by him, he was the one who, so to say, gave it life. He discovered and made known its many advantages; and in his treatise published in 1839—a treatise which is a masterpiece of mathematical terseness and simple elegance—he gave the methods of crystallographic calculation which render the advantages of the symbol particularly manifest. It may be here remarked that in that treatise the rationality of the anharmonic ratios of any four tautozonal planes of a crystal was first made known, and the property was largely used in the simplification of the methods of calculation: the fact that the fraction was of the knd which had been already termed an anharmonic ratio, however, had escaped the atteation of the author.

But the change of a method of notation, like a change in the system of weights and measures, involves such serious practical difficulties that many years passed away before the Millerian symbol received abroad the consideration which it deserved. Now, at last, no continental text-book of mineralogy fails to introduce the Millerian indices, even if the symbols of Lévy or of Naumann are given in addition; and it is evident that within a few more years the mineralogist will be completely relieved from the tiresome necessity of translating each crystalline symbol into another form to make it intelligible to him, and the student will be able to make a more advantageous use of the time which has been hitherto devoted to acquiring a mastery over a second and unnecessary form of crystallographic notation. For this result credit is largely due to Prof. Groth, of Munich, whose adoption of the Millerian symbol in the *Zeitschrift für Krystallographie* has done much to bring home its advantages to the foreign worker. It is to be hoped that Prof. Groth will earn the further gratitude of students by encouraging the adoption of the true Millerian symbol in the still outstanding case of the Rhombohedral System.

Rationality of Indices and the Law of Zones.—It may here be pointed out that, although the importance of zones for the simplification of crystallographic calculation had been recognised by Weiss, it was only later that Neumann proved that the fact that all possible crystal faces can be derived by means of the intersection of zones is a necessary consequence of the rationality of the indices; that, indeed, the law of zones is mathematically identical with the law of rationality. To the same able physicist and mathematician we owe the development of the method of stereographic projection now in common use by crystallographers for the representation of the poles of crystal faces.

Symmetry.—We have said that the recognition of six systems of crystallisation was a result of consideration of the lengths and mutual inclinations of certain lines called axes. Now, it had long ago been remarked that any one face of a crystal is accompanied by certain others similarly related to the geometrically similar parts of what may be regarded as a fundamental figure: such a group of concurrent faces is called a simple form. It came to be recognised, too, that all the faces of such a form can be geometrically derived from any one of them by repetition, according to certain laws of symmetry, and that the same laws of symmetry are binding for every simple form or combination of forms exhibited by crystals of the same substance. Hence it came to be perceived, though very slowly, that the essential differences of the systems of crystallisation are not mere differences of lengths and mutual inclinations of lines of reference, but are really differences of symmetry. Ever since his appointment to the professorship of Mineralogy in this University, now thirty-eight years ago, Mr. Maskelyne has been persistent in directing attention to the importance of symmetry, and such importance now receives universal recognition.

Thirty-two Types of Symmetry in Crystals.—But in each system of crystallisation it becomes necessary to recognise both completely and partially symmetrical types. In the latter, the symmetry is in abeyance relative to various planes or lines which in other crystals of the same system are active as planes or axes of symmetry. But this abeyance of symmetry is itself found to be subject to a law, for all planes or axes of symmetry which are geometrically similar are either simultaneously active or simultaneously in abeyance. By means of this law relating to partial symmetry, it has been inferred that altogether thirty-two types of symmetry are possible in the six crystalline systems.

The possible existence of these thirty-two types of symmetry of crystals is thus an induction from observation: the question naturally arises as to why only these thirty-two exist, or are inferred by analogy to be possible. Axes of symmetry are observed, round which faces of crystals are symmetrically repeated by twos or threes or fours or sixes; why is it that in crystals no axis of symmetry is ever met with round which the faces are symmetrically repeated by fives or sevens? A few words as to how this most important problem has been attacked and solved may be of interest.

We know that the characters of a crystal relative to any line in it vary with the direction of the line, but are the same for all lines parallel to each other. Such a property will result, if we imagine with Bravais that in a crystal elementary particles are arranged at equal distances from each other along every line, and are similarly arranged in all those lines which are parallel to each other; the distances separating particles being, however, in general different for lines which are inclined to each other. Such an arrangement of particles is termed parallelepipedal: space may be imagined to be completely filled with equal and similarly disposed parallelepipeds, and an elementary particle to be placed at every corner or quoin of each. Further, each particle is regarded, not as being spherical, but as having different characters on its different side; and the particles must be similarly orientated—that is, have similarly sides in similar positions.

Now, it will be seen on an examination of a model or figure that with such an arrangement any plane containing three particles will contain an infinite number, all arranged at the corners of parallelograms. Further, any such plane will clearly have whole numbers for the indices which fix its position, for along any line the distance between two particles is by hypothesis a whole multiple of the common distance between any two adjacent ones in the same line. Thus the first great crystallographic law—the law of the rationality of the indices—is an immediate consequence.

In the next place, it was found that the possible modes of symmetry of arrangement of the particles of such a system depend on the form of the paralleliped, and that any possible arrangement of the particles must present a symmetry which is identical with one or other of the six completely symmetrical types already referred to. Aod calculation shows that any other mode of grouping—a repetition by fives or sevens, for example—round an axis of symmetry, would involve the presence of planes having irrational indices; and this according to the first law is impossible.

The abeyance of symmetry, however, met with in the partially symmetrical types required the aid of an auxiliary hypothesis—namely, that the abeyance of symmetry belongs to the particle itself, and not to the arrangement of the particles.

But the parallelepipedal arrangement imagined by Bravais is unnecessarily special. Our actual observations of physical characters relate not to single lines of particles, but to groups of parallel lines of particles: the identity of character observed in parallel directions is thus not necessarily due to actual identity of each line with its neighbour, but may be due to statistical equality, an equality of averages. If, for example, a plane were divided into regular hexagons, and a particle were placed at each corner of each of these figures, the physical properties of the system of particles would be the same along all lines parallel to each other as far as experiment could decide, and yet the arrangement of the particles in the plane, though possibly crystalline, is not that of a Bravais system. In any straight line passing along the sides of a series of the hexagons, the particles will not be equidistant from each other: they are in equidistant pairs, and the two nearest particles of adjacent pairs are twice as far from each other as the particles of the same pair.

Sohncke accordingly suggested a more general definition than that of Bravais for the regularity of the arrangement, a definition which had been proposed some years before by Wiener—namely, that the grouping relative to any one particle is identical with that relative to any other. This definition admits of the possibility of the hexagonal arrangement just mentioned; further, it allows of the orientation of the particles themselves being different in adjacent lines. Following a mathematical process which had been already employed by Jordan, Sohncke deduced all the possible modes of grouping consistent with the new definition, and for a time was under the impression that the types of symmetry found by him to be mathematically possible are exactly identical with those already referred to; and this without introducing the auxiliary hypothesis relative to partial symmetry of the elementary particles of merosymmetrical crystals, except in cases of hemimorphism. It was, however, pointed out by Wulff, who has himself made valuable contributions to the subject, that though no unknown crystallographic type belongs to such a regular arrangement, one type of symmetry, that presented by dioptase, is missing; and it seems that, in this case at least, the merosymmetry can only be accounted for by the merosymmetry of the particle, or something equivalent to it, if the definition of regularity suggested by Sohncke is to be accepted. It was recognised by Sohncke that each of his point-systems can be regarded as a composite Bravais system, one of the latter being repeated in various positions corresponding with the symmetry of the parallelepiped itself.

More recently, Schonflies has made a more general hypothesis still—namely, that in each substance, whether its crystals be completely or partially symmetrical in facial development, the particles are not of a single kind, but of two kinds, related to each other in form in much the same way as a right-hand glove and a left-hand glove. With this hypothesis he finds that all the thirty-two known types are accounted for without any specialisation of the characters of the particle, and that no other type of symmetry is mathematically possible.

It now only remained to discover that Prof. Hessel had already arrived at the thirty-two types of crystallographic symmetry by mathematical reasoning more than sixty years ago; his work, being far in advance of his time, appears to have attracted no attention, and the memoir remained unnoticed till more than half a century after its publication.

Starting from Sohncke's definition of a regular point-system, and proceeding, though independently, by a method which closely resembles that of the regular partitioning of space by Schonflies, Mr. William Barlow has given in a paper just issued a general definition applicable to all homogeneous structures whatever, and has shown that every such homogeneous structure falls into one or other of thirty-two types of symmetry, coinciding exactly with the thirty-two types of crystal-symmetry. He points out that each of those homogeneous structures which possess planes of symmetry or centres of symmetry does so by reason of its having an additional property beyond mere homogeneity, namely, that if we disregard mere orientation, it is identical with its own image in a mirror. Mr. Barlow further discovers that every one of the Sohnckian point-systems can be geometrically constructed by finite repetition of some one of a certain ten of them.

Lord Kelvin, who, with characteristic versatility, has lately enlightened us with his researches on Molecular Tactics, has quite recently attacked another problem of the same group, and has sought to discover the most general form of cell which shall be such that each cell encloses a single point of a Bravais system, while all the cells resemble the parallelepipeds, of which we have already spoken, in being equal, similar, similarly orientated, and in completely filling up space. He finds that in the general case the cell can have at most fourteen walls, which may be themselves either plane or curved, and may meet in edges either plane or curved. Having regard, however, to the limited time at our disposal, we may hesitate before following Lord Kelvin into his curious and many-walled cells.

The deduction of the thirty-two types of symmetry by mathematical reasoning was also made independently by both Gadolin and Viktor von Lang thirty years ago from the law of rationality of indices; while Fedorow points out that the method of deduction recorded in the recent German treatise of Schonflies is remarkably similar to the one independently published by himself in Russia. Both Curie and Minnigerode have also lately given comparatively brief solutions of the problem.

Nor must I omit to mention to you the elaborate memoir dealing with the symmetry of parallelepipedal point-systems which was written by the late Prof. Henry Stephen Smith, whose too early death this University has so much reason to deplore. To the outer world he was perhaps best known as one of the most perfect mathematicians of the age, but those who had the good fortune to find themselves among his pupils will always treasure up in their memory rather the kindly courtesy, the warm sympathy of the man, than the genius, however transcendent, of the mathematician.

To sum up this part of the subject—it is now established that a definition of the regularity of a point system can be so framed that thirty-two, and only thirty-two, types of symmetry are mathematically possible in a regular system, and that these are identical with the types of symmetry that have been actually observed in crystals, or are inferred by analogy to be crystallographically possible.

It remains for subsequent investigators to determine what the points of the system really correspond to in the crystal; according to Schonflies, the physicist and the chemist can be allowed in each crystal absolute control within a definite elementary region of space, and the crystallographer is only entitled to demand that the features of this region are repeated throughout space according to one or other of the thirty-two types of symmetry already referred to; or, what appears to be the same thing, the crystallographer requires mere homegeneity of structure.

Simplicity of Indices.—We have seen that the planes containing points of a regular point-system have rational indices. But there still remains unaccounted for the remarkable fact that the indices of the natural limiting faces, and also of the cleavage-planes of a crystal are not merely whole numbers, but are in general extremely simple whole numbers. Bravais and his followers have sought to account for this by the hypothesis that both the natural limiting planes and the cleavage-planes are those planes of a point-system which are most densely sprinkled with points of the system. Curie and Liveing, independently of each other, have been led to the same result from considerations relative to capillary constants. Sohncke, however, pointing out that there are many cases—for instance, calcite—where an excellent cleavage-plane is rarely a limiting plane, suggests that his generalised point-system is more satisfactory than a Bravais system in that not only the density of the sprinkling must be had regard to, but also the tangential cohesion of the particles in the plane, and that in his system these may be independent of each other; while Wulff remarks that Sohncke's arrangement is identical with that of Bravais for the anorthic system, where the same objection holds, and he denies the legitimacy of the reasoning by which the hypothesis of a relation between the density of the sprinkling of points on a plane and the likelihood of the natural occurrence of the plane as a limiting face is supported.

Complexity of Indices.—Doubtless, however, crystal faces are observed of which the symbols involve indices far exceeding 6 in magnitude—so complex, in fact, that one is tempted to doubt the rigidity of the experimental proof that indices are necessarily rational. Often, though the numbers are high, their ratios differ by only small amounts from simple ones. A most patient and detailed study of such faces was made for danburite by the late Dr. Max Schuster of Vienna, and the results were brought by him some years ago to the notice of this Section. From careful examination of similar faces in the case of quartz, Molengraaf has been led to conclude that it is extremely probable that such faces are of secondary origin and have been the result of etching; they would in such case correspond, not to original limiting planes, but to directions in which the crystal yields most readily to solvent or decomposing influences.

Optical Characters.—Passing from the purely geometrical characters of crystals to the optical, we may in the first place remark that the relationship between crystalline form and circular polarisation discovered by Herschel in the case of quartz, has been generalised since the issue of Whewell's Report. We now know that many crystallised substances belonging to different systems give circular polarisation, and that all of them are merosymmetrical in facial development or structure; further, they belong to types of symmetry which have a common feature, though this is only a necessary, not a sufficient, condition.

The importance of the discovery of the dispersions of the mean lines has already been referred to.

We may recall attention to the fact noticed by Reusch that when cleavage-plates of biaxal mica are crossed in pairs and the pairs are piled one upon another in similar positions, the optical figure yielded by the combination approaches nearer and nearer to that of a uniaxal crystal the thinner the plates and the more numerous the pairs: in the same way, by means of triplets of plates, each plate being turned through one-third of a complete revolution from the position of the preceding one, it is found possible to closely imitate the optical figure of a right-handed or a left-handed circularly polarising crystal.

And it has been observed that repeated combinations of differently orientated parts actually occur in crystals. Large crystals of potassium ferrocyanide, for example, are really composite, and the different parts are differently orientated: on the one hand, a thick slice may give an optical figure which is uniaxal; on the other hand, a thin slice shows two optic axes inclined to each other at a considerable angle.

It has been suggested that the circular polarisation of quartz and other crystals is due to a spiral molecular arrangement orresponding to that of the mica-triplets as arranged by Reusch. ;uch a spiral arrangement is shown by the points of the corre-ponding Sohnckian system.

Optical Anomalies.—As already mentioned, we owe to 3rewster the establishment of the relation between the optical ·ehaviour of crystals and the systems of crystallisation. But in he course of his long research Brewster met with numerous ·uzzling exceptions, and to the investigation of the origin f their peculiar optical behaviour he devoted much study; ıbsequent workers have concurred in expressing their admira-on of the accuracy of his observations and descriptions, more specially when regard is had to the extreme simplicity of the pparatus available in those early days.

It was recognised by Brewster that some of these optical nomalies are due to a condition of strain, of the crystal as in ıe case of the diamond. But in other minerals, as analcime nd apophyllite, the hypothesis of strain was not entertained by im: he regarded the crystals as being truly composite and not imple; and, recognising optically different kinds of apophyllite, ent so far as to give to one of them the specific name of tesse-te by reason of its distinctive characters. Biot, on the other and, sought to account for this kind of optical behaviour in nother way, by the hypothesis of lamellar polarisation: a rystal of alum, for example; he held to be built up of thin ıminæ arranged parallel to the octahedral planes, and imagined ıat light which had traversed such a crystal is polarised by its assage through the aggregation of laminæ in the same way as y passage through a pile of glass plates. But in the latter case ıere is a frequent passage of the light from air to glass and lass to air, whereas in the case of alum there is no evidence of ıe existence of atmospheric intervals. Frankenheim sought to vercome this difficulty by the further hypothesis that the ıccessive layers of a composite posassium- and ammonium-lum are of different chemical composition, but such a differ-ıce of material would be insufficient for the desired object by ·ason of the nearness to each other of the refractive indices of lums of different composition. Still it is a remarkable fact that either a pure potassium-alum nor a pure ammonium-alum ıows any depolarisation-effects at all; these belong only to ıe alums of mixed composition, and yet there is no visible ifference in the physical structure of the crystals of simple and omposite material.

An epoch was made in the history of the so-called optical nomalies by the publication in 1876 of an elaborate memoir by rof. Ernest Mallard of Paris, whose death last month eprived Mineralogy of its greatest philosopher. To make the osition more clear, we may take as a definite illustration the ıineral boracite. In development of faces and magnitude of ngles the crystals of this mineral are, as far as measurement ith the goniometer can decide, precisely cubic in their sym-ıetry. But an apparently simple crystal of boracite, when xamined in polarised light, behaves exactly like a regularly omposite body. If the crystal be a rhombic dodecahedron in xternal development, all the twelve pyramids which can be ırmed by drawing lines from the centre to the angular points re found to be exactly similar to each other in everything but rientation; and, further, each of them has the optical haracters of a biaxal crystal, the optic bisectrix of each indi-idual pyramid being perpendicular to the corresponding base, nd thus having a different direction for each of the six pairs of arallel faces of the dodecahedron. Hence Mallard inferred ıat boracite belongs really, not to the cubic, but to the ortho-ıombic system, and that its crystallographic elements are so early those of a cubic crystal that the molecular structure is in able equilibrium, not only when different molecules have their milar lines parallel, but also when only approximately similar nes have the same orientation: further, the cubic symmetry of ıe external form was regarded by him as a consequence of the pproximation of the crystallographic elements to those of a ıbic crystal and of the variety of orientation of the constituent ıoleculcs. Variety of orientation of constituent molecules is, ı fact, already recognised in the case of ordinary interpenetrant vins. The variation of optical character in different crystals f the same substance or different parts of the same crystal was ıen explained as being due to the variation in the number of ıolecules belonging to each mode of orientation.

According to another view, it was contended that a crystal f boracite is really cubic and simple, but that, like unannealed lass, it is in a state of strain related to the external form. It as replied that the optical characters of such unannealed glass are changed with the change of strain which follows the fracture of the specimen, while those of boracite are unaltered when the crystal is broken. To this it was rejoined that a once compressed gum retains its depolarising character unchanged on fracture of the specimen, and that the same permanence may very well be a character of some strained crystallised bodies.

The controversy, however, passed to a fresh stage when it was discovered that boracite becomes optically isotropic when sufficiently heated, and resumes an optically composite character on cooling. Mallard showed that the temperature at which the change takes place is a definite one, 265° C., and that a definite amount of heat is absorbed or given out during the change of condition.

It is now agreed that boracite is really dimorphous; that above 265° it is cubic in symmetry, below 265° orthorhombic: the only remaining point of controversy as regards boracite seems to be whether the external form owes its cubic symmetry to the crystallisation having taken place at a temperature higher than 265°, and therefore when the structure itself was truly cubic—or at a temperature below 265°, in which case the cubic character of the form would be ascribed to the fact that the orthorhombic constituent particles are so nearly cubic in their dimensions that at any temperature they may by variety of orientation combine to form a structure having practically cubic symmetry, and naturally limiting itself by faces corresponding to such a symmetry.

In exactly the same way leucite and tridymite become re-spectively optically isotropic and uniaxal when sufficiently heated, and the optical characters then correspond exactly to the symmetry of the external form.

Three years ago Dr. Brauns prepared a most useful summary of the ninety-four memoirs which had up to that time been con-tributed relative to the much-discussed subject of the optical anomalies of crystals, and added many new experimental results which had been obtained by himself. He concludes that the original view of Mallard—namely, that an optically anomalous structure consists merely of differently orientated particles of the same kind and of symmetry approximating to a higher type—is only applicable to a very limited number of crystals, such as those of prehnite; that dimorphism is the true cause in others, boracite being an example; that in the remaining minerals the cause is strain, which in some of them is due to foreign enclosures, as in the case of the diamond, and in others is due to a molecular action between isomorphous substances, as in the mixed alums and the garnets.

Planes of Gliding.—One of the most startling of crystallo-graphic discoveries was one made by Reusch, who found that if a crystal of calcite is compressed in a certain way each particle springs into a new but definite position, exactly as if the crystal had undergone a simple shear and the particles at the same time had each described a semi-somersault: a simpler method of producing the same result was discovered afterwards by Baumhauer. If only part of the calcite crystal is sheared, the two parts of the structure itself are related to each other in the same way as the two parts of a twin growth; but in general the external form is different from that of a twin, since after the shearing of the material few of the faces retain their former crystallographic signification. The property has since been shown by Bauer, Liebisch, and more especially Mugge, to be a very general one; and doubtless the so-called twin lamellæ met with in rock-constituents have in many cases resulted from pressure during earth-movements long subsequent to the epoch of formation of the crystals. Similar lamellæ have been pro-duced artifically in anhydrite and some kinds of felspar by ex-posure of the crystals to a high temperature.

Piezo-electricity.—The most remarkable addition to our knowledge of the relation of minerals and electricity has been the recent discovery of the electrification produced by strain (piezo-electricity). It has been shown by J. and P. Curie that if a quartz-plate, with faces cut parallel to the axis and silvered to make them conductive, be strained in a certain direction, the two faces either become oppositely electrified or show no signs of electrification at all, according as the faces of the plate are cut to be perpendicular to the prism-faces, or to pass through the prism edges. Lord Kelvin says that this result is explicable by electric eolotropy of the molecule and by nothing else, a character which he had suggested for the molecule thirty-four years ago: experiments confirmatory of this hypothesis of the permanent electrification of the molecule were made some time ago by Riecke.

Pyro-electricity.—The development of opposite electricities at different parts of a crystal during changing temperature (pyro-electricity) has long been known in the case of tourmaline. We owe to Hankel a long series of investigations of this kind relative to boracite, topaz, and various other minerals, but it seems to be now established that most of the electrifications observed by means of his method are really piezo-electric, and are due to strains caused by inequality of temperature in different parts of the cooling crystal. A model has been lately made by Lord Kelvin which gives a perfect mechanical representation of the elasticity, the piezo-electricity, and also the pyro-electricity of a crystal.

Electrical Methods.—A delightfully simple method of investigating the difference of electrical condition of the parts of a cooling crystal and of making the distribution of electricity visible to the eye has been invented by Kundt. Mixed particles of red minium and (yellow) sulphur are oppositely electrified by their passage through the meshes of a small sieve; falling on the cooling crystal, each particle adheres to the oppositely electrified region, and the electrical condition of the latter is thus immediately indicated by the colour of the adherent powder. Mr. Miers remarks that this method is practically useful as a means of discrimination even when the crystals are extremely minute.

Other Physical Characters.—Of other physical characters much studied since the issue of Whewell's Report, I may recall to you more especially the dilatation of crystals on change of temperature, in which the observations of Mitscherlich have been extended by Fizeau and Beckenkamp; the forms of the isothermal surfaces of crystals, as determined by Sénarmont, and afterwards by Röntgen; the magnetic induction treated of by Faraday, Lord Kelvin, Plucker, and Tyndall; the hardness of crystals for different directions lying in the same faces, by Grailich, Pekárek, and Exner; the elasticity of crystals, investigated by Neumann, Lord Kelvin, Voigt, Baumgarten, and Koch; the distortion of crystals in an electro-magnetic field, by Kundt, Röntgen, and MM. Curie.

Chemical Relations.—In the short time I can reasonably ask you to allow me it is clearly impossible to enter upon any discussion of the increase of our knowledge of the chemical relations of minerals, and to treat of the much-investigated subjects isomorphism, polymorphism, and morphotropy, nor can I attempt to give you any idea of the advance which has been made towards a natural classification: nor must I mention the experiments which have been made relative to the growth of crystals, the etching of their faces, or their directions of easiest solution.

As regards systematic mineralogy an immense amount of progress has been made. The condition of affairs in 1832 was described by Whewell as follows:—"We have very few minerals of which the chemical constitution is not liable to some dispute; scarcely a single species of which the rules and limits are known, or in which two different analyses taken at random might not lead to different formulæ; and no system of classification which has obtained general acceptation or is maintained, even by its proposer, to be free from gross anomalies." An idea of the extent of the improvement will be best obtained from a comparison of the first edition of Dana's Treatise, published in 1837, and that treasury of information, the sixth edition, which appeared in 1892. The names of Miller and Descloizeaux are to be honourably mentioned in connection with this detailed work on species. In the interval of time under consideration the number of well-established species has been more than doubled, and the rate at which new species are discovered shows as yet no sign of diminution. In particular, I may remind you of the work which has been done in the correlation of the members of large groups, like the felspars, amphiboles, pyroxenes, scapolites, micas, tourmalines, and garnets. A paper just published by Penfield relative to topaz furnishes an excellent illustration of the important results which are still to be arrived at from a careful study of a common mineral. It has long been known that the mutual inclination of the optic axes of topaz is very different in different specimens, and it has been suspected that the variation might depend on the percentage of fluorine. Prof. Penfield has carefully determined, not only the fluorine, but also the water yielded in the course of analysis of specimens from different localities, and finds that the analytical results are best explained by the hypothesis of an isomorphous replacement of fluorine by hydroxyl; further, he discovers that the magnitude of the angle between the optic axes is a function of the amount of that replacement.

The successes achieved in the artificial formation of minerals, the advances made in the methods of discrimination of minerals by the blowpipe and micro-chemical reactions, the increase in our knowledge of the modes of alteration of minerals, of their association, of their modes of occurrence, must all be left undiscussed.

Instruments.—I may add a word relative to the instrumental appliances which have been placed at the service of the mineralogist since the issue of Whewell's Report. As regards goniometers, the provision of two mechanical circular movements in perpendicular planes for the easier adjustment of a crystal-edge parallel to the axis of the instrument, first suggested by Viktor von Lang when assistant at the British Museum, has proved a great convenience and is now in general use. The employment of a collimator with interchangeable signals, of a telescope with interchangeable eyepieces, and the provision of lenses and diaphragms for obtaining images from faces so small as to be invisible to the unassisted eye, would seem to have brought the reflective goniometer, the invention of our distinguished countryman Dr. Wollaston, to a degree of perfection where further improvement is scarcely to be looked for; though two crystallographers, Fedorow and Goldschmidt, have recently constructed instruments with an additional telescope and entirely different arrangements. It may be worthy of remark that, though reflective goniometers are generally made for use with very small specimens, one was constructed for the British Museum some years ago by which it is possible to measure the angles of a valuable crystal without removal of the specimen from a matrix of several pounds' weight.

The polariscope for use with convergent light, the stauroscope, the employment of polarised light with the microscope, the adaptation of the microscope for the observation of the interference-figures yielded by extremely minute crystals, the spectroscope in the investigation of selective absorption, have all proved of great service in the advancement of our knowledge of the characters of minerals.

Worthy of special mention is that recent addition to our resources, the total reflectometer, an instrument by which it is possible to determine with wonderful accuracy the refractive index or indices from observation of the reflected light. The process was long ago suggested by Wollaston: but it is only within the last few years that forms of instrument have been devised by Kohlrausch, Soret, Liebisch, Pulfrich, and Abbe, which make the method as precise in its results as that which depends on refraction by a prism. In its more refined forms the total reflectometer has been used to test the accuracy of the form of Fresnel's wave-surface: in the convenient, though less precise, form devised by Bertrand, the instrument is useful in the discrimination of the species of minerals.

For the measurement of the optic axal angle, when the angle is so large that the rays corresponding to the optic axes are totally reflected at the surface of the plate and do not emerge into air from the crystal, Prof. W. G. Adams made the valuable suggestion that the crystal-plate should be interposed between two hemispheres of glass; several instruments on this principle have been constructed abroad, and have only been imperfectly satisfactory, but one lately made in this country for the British Museum, under the superintendence of my excellent colleague Mr. Miers, proves to be most efficient for the intended purpose. Mr. Tutton's apparatus for supplying monochromatic light of any desired wave-length is a noteworthy addition to the instrumental resources of the mineralogist. The meldometer of Joly for the more accurate determination of the fusing point of minerals should also be recalled to you.

In this slight sketch it has been possible to make only the barest mention of some of the more important results which have been arrived at since the issue of Whewell's Report. You will doubtless think that it must have been possible in the year 1832 to look forward enthusiastically to the progress which was about to be made. But though Professor Whewell was himself confident that valuable discoveries would reward the mineralogical worker, he was sadly depressed, and, I think I may venture to say, with good reason, by the neglect of mineralogical study in this country. His own words are: "This decided check in the progress of the science has, I think, without question, damped the interest with which Mineralogy, as a branch of Natural Philosophy, has been looked upon in Eng land. Indeed, this feeling appears to have gone so far that all the general questions of the science excite with us scarcely any interest whatever. But a more forward and hopeful spirit appears to have prevailed for some time in other countries, especially Sweden, Germany, and more recently France." Those are the words of despair. I may add that in the same year he resigned his professorship of Mineralogy, and directed his vast energy to the advancement of other subjects.

Now, I think, that a country like our own, which aims at taking and maintaining a high place in the scale of civilisation, ought in some way or other to secure that in every important branch of learning there is a group of men in the country who will make it the main purpose of their lives to render themselves familiar with all that has been and is being discovered in the subject, will do whatever is possible to fill up the gaps in the science, and, last but not least, will make the more important results accessible to other workers for whom so complete and original a survey is impracticable.

No one will doubt that Mineralogy should be such an important branch of learning. Minerals existed before man was thrust upon the scene; they will possibly continue to exist long after he himself has passed away; at least as persistent as himself, they will have an interest for every age.

The continental nations have not only long recognised the importance of mineralogical study, but have acted accordingly. The difference between action and inaction will be most clearly grasped if we compare the position of Mineralogy in Germany with that in this country.

In Freiberg, the centre of a mining district in Saxony, an institute was opened in the year 1766 for the scientific training of those students whose interest was in minerals, and the lectures on Mineralogy given there by Prof. Werner became a prominent feature; of the many pupils of this remarkable man, Von Buch Breithaupt, Haidinger, Humboldt, Mohs, Naumann, and Weiss may be especially mentioned as having afterwards distinguished themselves by their scientific work. Of other Germans, who have likewise gone to their rest after much labour given to the advancement of Mineralogy and Crystallography, we may especially recall Beer, Bischof, Blum, Credner, Hessel, Klaproth, Kobell, Lasaulx, Mitscherlich, Neumann, Pfaff, Plattner, Plücker, Quenstedt, Vom Rath, Reusch, Gustav Rose, Heinrich Rose, Sadebeck, Scheerer, Sartorius von Waltershausen, Websky, and Wöhler. Of the many Germans who are now contributing to our knowledge of minerals it is an invidious task to make a selection, but we may mention Arzruni, Bauer, Beckenkamp, Bücking, Cathrein, Cohen, Goldschmidt, Groth, Haushofer, Hintze, Hirschwald, Klein, Klockmann, Knop, Laspeyres, Lehmann, Liebisch, Lüdecke, Mügge, Osann, Rosenbusch, Sandberger, Streng, Voigt, Weisbach, and Zirkel: most of them are University Professors of Mineralogy; all of them hold important positions as teachers of the subject. Further, the laboratories and instruments available for the teaching of practical work are in many cases, notably at Strassburg, Munich, Göttingen, and Berlin, of an elaborate character.

So much for Germany; let us now look at home. In the Universities of England, Wales, Scotland, and Ireland there is a grand total of—two Professorships of Mineralogy, one of them at Cambridge, the other, and younger one, at Oxford. Further, the stipends are nearly as low as they can be made; in the former case, according to the University Calendar, the stipend paid from the University Chest to the present holder of the office amounts to 300*l*. a year; in the more ancient but less extravagant University of Oxford, the Calendar states that the present professor receives, subject to previous deduction of income-tax, the annual sum of 100*l*., and the necessary instruments and many of the specimens have presumably been provided from his private resources; in case of residence he is to be allowed another 150*l*. a year for the luxuries which University life involves. And these are the only teaching appointments in his own subject that a successful investigator of minerals can look forward to being a candidate for! The result is that all those students who intend to earn their own living, all those who feel anxious to undertake professorial work, conclude that, however much they may be interested in the investigation of the characters of minerals, they will do well to follow the example of Prof. Whewell and turn to other branches of science in which there is a more hopeful prospect of their studies meeting with practical recognition.

It cannot be expected that advanced Mineralogy will ever be able to command the attention of more than a limited number of students, seeing that its successful pursuit requires a preliminary knowledge of at least three other sciences—mathematics, physics, and chemistry—sciences which must be assigned a fundamental importance in any scheme of education; if geology can be added, so much the better. Only few students can find time in their undergraduate days to acquire a competent knowledge of the preliminary sciences and to proceed afterwards to the study of Mineralogy. But the comparatively flourishing condition of the science in Germany, France, and other countries indicates that this is not a sufficient reason for refraining from giving proper facilities and encouragement to those who wish to enter upon its study. Some years ago the University of Cambridge took a step in the right direction, and introduced Mineralogy into their examinational system in such a way that the students of Physics, Chemistry, and Geology could give time to the acquisition of a knowledge of Crystallography and Mineralogy, and obtain credit for that knowledge in the examination for a degree.

It is clear that if in the future there is to be an honourable rivalry between this and other countries in the advancement of the knowledge of minerals, each of our Universities should be enabled in some way or other to found Professorships of Mineralogy, and be prevailed upon to follow the example of Cambridge in encouraging the students of Physics, Chemistry, and Geology to acquire a knowledge of Crystallography and Mineralogy before their education is regarded as complete. Even where a student has no intention of devoting himself to advanced mineralogical study, an elementary knowledge of Crystallography and Mineralogy will be extremely useful in giving him a better grasp of his own special subject.

And if, perchance, any of you are anxious to reduce the amount of those unmentionable duties of which we have heard so much of late, and feel that you can best do this by the endowment of Professorships of Mineralogy in our Universities, I would advise you not to do what has been so long practicable at this Association, couple Mineralogy with any other science—that would be an unwise economy. Each of the sciences is now so vast in its extent that no professor can be thoroughly master of what has been done, and is now being done, by other workers, in more than one of them. I remember that in my younger days it was held by some at Oxford that the Professor of Mineralogy, a so-called subordinate subject, should continue to be paid on a lower scale than his brother professors, and that he should obtain a living wage by adding a college tutorship or a lectureship in some other subject to his professorial duties. It is not by the prospect of such appointments that you can expect the most capable men to be attracted to the study of minerals. The practical effect of such an arrangement would only be that a college lecturer would give formal teaching in Mineralogy while devoting his real energy to another subject in which the pupils are more numerous.

It only remains to thank you for the way in which you have listened to a technical address relative to a science for the study of which very few facilities have been offered to you in our own country. Not often does the mineralogist present himself before an audience; he sees only too clearly that

> The applause of listening senates to command,
> To read his history in a nation's eyes,
> His lot forbids;

but I shall not have broken the long silence in vain if I have made clear to you that, though the Science of Mineralogy is itself making great progress, we have hitherto given too little encouragement to its study in our own Universities, and lag far behind both Germany and France in the recognition of its importance.

NOTES.

WE notice with much regret that Dr. C. R. Alder Wright died on July 25, at the early age of forty-nine. He was elected a Fellow of the Royal Society in 1881.

DR. M. FILHOL has been appointed to the chair of Comparative Anatomy in the Paris Muséum d'Histoire Naturelle, in succession to the late Prof. Pouchet.

ACCORDING to a telegram from Prjevalsk (formerly Karakol), a monument to the Russian traveller Prjevalsky has been unveiled there. The monument is built very picturesquely on the slope of the mountains, facing Lake Issyk-kul.

IT is reported that Prof. Brugsch, the eminent Egyptologist, is seriously ill.

MR. CHARLES E. CASSAL, Public Analyst for Kensington and St. George's, Hanover Square, has been elected honorary president (of Section VII. Food) of the forthcoming International Congress of Hygiene and Demography at Budapest.

NEWS of the Wellman Arctic expedition has been received which fortunately confirms the hope, which we expressed when the report of the disaster was received, that the exploring party of the expedition had escaped the initial danger. The *Malygen*, a Norwegian fishing vessel, arrived at Tromsö from Spitzbergen, on August 2, with the captain and three of the crew of the *Ragnvald Jarl* on board. They report that Mr. Wellman landed on May 24, at Walden Island (80° 37′ N.), in the north of Spitzbergen, with 13 men, all in good health, 40 dogs, and provisions for 110 days. Four days later the *Ragnvald Jarl* was crushed in the ice and sank, only part of the stores and equipment being saved. A message was despatched to Mr. Wellman, who was overtaken at Marten's Island, and immediately returned with several members of his party, and after helping to build a house on Walden Island for the shipwrecked crew, set out finally on May 31 for his northern journey. He was heard from on June 17, when Mr. Winship left the advanced party, who were waiting six miles east of Platen Island for open water to form, as the ice was impassable. All were well at that time. This news shows that Mr. Wellman found the conditions of ice-travel harder than he had expected, and since he had spent so much of the best time of the year in travelling so short a distance, there seems little hope that he could have made a great journey northward before the general southward movement of the ice set in, and compelled his retreat to Danes Island. Baron Nordenskjold telegraphs to the Royal Geographical Society, strongly urging the importance of sending out a supply of provisions, and arranging for the return of the expedition to Europe, should it succeed in regaining Spitzbergen.

THE great Constantine medal of the Russian Geographical Society has been awarded this year to Prof. A. N. Veselovsky, for his thirty-five years' work in the domain of both Russian and West European ancient literature and folk-lore; and the Count Lutke medal to W. E. Fuss, for his many years' investigations of chronometers. It is known that since the splendid researches of Struve into the influence of temperature upon the errors of chronometers, these errors can easily be eliminated; but that changes of moisture still continued to remain a considerable cause of errors, the more so as its action was found to be different on different instruments. In the course of his researches, Fuss made the important discovery that the rate of some chronometers is not modified at all by that cause, and he was able to determine a means of rendering the instruments quite insensible to the influence of moisture. Consequently, all devices which are in use in the navies of Western Europe for isolating the chronometers from the surrounding moisture on board ship, have been abandoned in Russia; and the chronometer determinations are nevertheless quite free from this source of error, as may be seen from the many researches of Fuss, printed in the "Hydrographical Memoirs," published at St. Petersburg. The great gold medals of the different sections of the Geographical Society have been awarded, by the section of Ethnography to M. Karskiy, for researches among the Byelo-russians; in Statistics, to a collective work of twenty-two explorers, on the economic conditions of the peasants in the governments of Irkutsk and Yeniseisk; and to Prof. Fortunatoff, for various works, of which his inquiry into the productivity of rye crops in European Russia is the most remarkable. The great silver medal bearing Prjevalsky's name has been awarded to K. N. Rossikoff, for his explorations of the glaciers and physical geography of Caucasus. Small gold medals have been awarded to B. I. Sreznewski, for meteorological work; D. Z. Trofimenko, for cartographic work in Mezen; and to P. S. Popoff, for translations of Chinese manuscripts relative to Mongolia. Several silver and bronze medals have been distributed for various works of less importance.

WE have received from the Imperial Russian Geographical Society a pamphlet by Admiral S. Makaroff, setting forth the desirability of an international agreement with regard to the publication of the materials contained in the meteorological log-books of ships in all parts of the world. Admiral Makaroff has paid some attention to this subject, and as the author of a volume containing the results of observations made during a voyage of exploration round the world, in the Russian frigate *Vitiaz*, in 1886–89, his opinion carries considerable weight. He proposes that original observations should be published by each country in a tabular form, or at least for a period of two years, viz. from January 1, 1882, to January 1, 1884, thus embracing the time during which observations were made by the international Polar expeditions. In the report of a committee appointed to consider certain questions relating to the Meteorological Department of the Board of Trade, and presented to Parliament in 1866, of which Mr. Francis Galton was a member, it was recommended that the results of marine observations should be published on one uniform plan, in the form of tables, for months and seasons. The main difference between these two proposals is that Admiral Makaroff asks for original observations, pointing out that mean data give no exact idea of the daily changes which occur in the condition of the atmosphere. At a conference on maritime meteorology, held in London in 1874, it was also recommended to publish deductions in the form of tables, in addition to charts. Thus while general opinion favours a tabular, as one form of publication of marine meteorological data, experience of over forty years, since the Maritime Conference held at Brussels, shows that each country is disposed to publish its observations in the form suited to its own requirements, Russia, only, having published a small number of meteorological logs *in extenso*; so that the prospect of any international agreement binding all countries to adopt any special form of publication, however desirable it may be, seems very remote.

THE Midland Union of Natural History and Scientific Societies held their seventeenth annual meeting at Ellesmere, Shropshire, on Friday and Saturday last. The Council met at the Town Hall on Friday afternoon, under the presidency of Mr. W. H. Wilkinson, and eleven delegates from the various societies were present. It was decided that the papers competing for the Darwin medal should be published within the area of the Union, in place of the *Midland Naturalist*, now defunct. The annual meeting was subsequently held in the Museum, when Mr. Brownlow R. C. Tower was elected president for the ensuing year, Mr. Egbert de Hamel was re-elected treasurer, and Prof. Hillhouse (Mason College, Birmingham) and Mr. T. V. Hodgson (of Harborne) were elected secretaries.

PROF. W. C. MACKENZIE, of the Tewfikieh College of Agriculture, Ghizeh, sends us some further particulars with regard to the nitrate-bearing clays of Egypt, described in these columns in May last (vol. l. p. 61). It appears that Messrs. Floyer and Sickenberger have sent in a preliminary report, in which they state that the supply seems to be almost inexhaustible. They consider it to be a "foliated marl, greenish and sometimes reddish, with veins of white gypsum, and incrustations or small crystals of chloride of sodium, and some sulphate of sodium. Its taste is salty and slightly bitter, from the latter

Its primary stratum has a depth of from 50 metres (Floyer and Seckenberger) to 100 metres (Zittel), and is horizontally bedded between the Lower Londinian, a hard white limestone of the Lower Eocene, and the Suessonian, a yellowish or greyish limestone between the Lower Eocene and the Upper Cretaceous formations." Prof. Mackenzie says that the substance is hard and stony in the deeper regions, and disintegrated near the surface. The compositions of the samples obtained, however, do not give any further information as to the possibility of extracting the nitrate with any hope of commercial success. Fifteen samples were sent to Prof. Mackenzie, and they contained quantities of nitrate varying from 1 per cent. to 17·5 per cent. The average of all would be equal to about 5 per cent. but whether this represents the composition of the mass, is open to question. We understand that a lot of forty tons has been taken to Cairo for extraction, and this will give a better idea as to the possibility of success than can be obtained from the analyses of small samples taken at random from the surface.

WE recently referred to the important studies of M. Marcel Bertrand on the geological structure of the Western Alps. A full account of them, with maps and sections, has now been published in the *Bull. Soc. Géol. France.* The author also describes the lustrous schists of that area, and concludes that they are a "flysch" facies of Triassic age.

IN a somewhat crude paper, entitled "Migration and the Food Quest, a Study in the Peopling of America," contributed to the *American Anthropologist* for July, Mr. Otis Tufton Mason, starting with the simple generalisation that the desire to appease hunger and thirst in the easiest way determines migration, seeks evidence for the primitive peopling of America from the islands of the Indian Ocean. The theory in its main features is probably sound enough, but there are so few facts bearing on the application of the theory to the peopling of America, that the specific question is not much advanced.

DR. F. PLEHN, the German Government medical officer in the Cameroons, has made a special study of the beliefs and customs of the Dualla negroes with respect to illness and death, and he has a paper on the subject in the last number of Danckelmann's *Mittheilungen aus den Deutschen Schutzgebieten.* He finds that, contrary to the custom of most primitive tribes, the magician and medical man have separate functions amongst the Dualla. The magician lives in the bush, only coming to the villages when his services are required, and his duties are practically confined to the discovery of thieves and of people who have used magic in order to produce illness or death. The doctor may be a man or a woman, and the office is usually hereditary, although sometimes a student is initiated on payment of a handsome fee. They have some knowledge of the use of plant products as medicine, but are practically ignorant of surgery.

IN the form of a lecture delivered at the Marine Biological Laboratory of Wood's Holl, Massachusetts, Prof. J. M. Macfarlane describes some very interesting observations on the irrito-contractility of plants. He maintains that, in the animal as in the vegetable kingdom, we have to do with a true contractile tissue. In the higher plants this tissue is made up of cells, each consisting of an irrito-contractile protoplasmic sac enclosing a quantity of sap, each cell being joined to neighbouring cells by protoplasmic processes which pass through minute pores in the common cellulose membrane. Irrito-contractility may be started by stimuli of a mechanical, chemical, thermal, luminous, or electrical nature. The seat of this contractility is unquestionably the vacuolated protoplasm, and not the cell-wall, as held by some observers. The degree of contraction of an organ is proportional to the relative molecular activity of the protoplasm, and to the strength or continuity of the stimulus. Prof. Macfarlane has already shown that in the leaves of *Dionæa* contractility can only be excited by two successive stimuli separated by an interval of time; and he now illustrates his conclusions by the phenomena presented by the closure of the leaves in a number of different plants.

THE Report of the Director of the Aquarium of the U.S. Fish Commission at the Chicago Exhibition (*Bull. U.S. Fish Com.* for 1893, pp. 143-190) is well worthy of perusal by those who are concerned in the management of large aquaria, or who take any general interest in such affairs. It is the record of an ambitious enterprise, fraught with many inherent difficulties; and the frank statement which Prof. S. A. Forbes has given, both of the failures and the successes which attended the efforts of his staff, should be of considerable service in other and future undertakings of a similar kind. The marine aquaria had a capacity of 40,000 galls., and, although the necessary supply of sea-water and marine animals had to be obtained at a distance of nearly a thousand miles, this part of the exhibition gave the greatest satisfaction. The fresh-water aquaria, paradoxically enough, were much more difficult to maintain in good condition, owing to the ravages wrought among the fishes by that well-known fungous pest *Saprolegnia,* the germs of which were found to be abundant in the water supply from Lake Michigan. The precipitation of nocuous matter from the water by the ingenious use of an alum tank, followed by careful filtration, was the principal means by which the disease was kept in check; but the least derangement of the filtering apparatus was immediately followed by a fresh outbreak of the plague. Another equally troublesome pest made its appearance during the hot weather in the form of an Infusorian parasite (*Ichthyophthirius* of Fouquet), which attacked and inflamed the skins of the less hardy fishes, and led to a great mortality. "Young cat-fish died like sheep with the murrain." Special observations on these two unbidden guests are given as appendices to the Director's Report. It may be mentioned, in passing, that Prof. Forbes speaks strongly in favour of the employment of shallow open pools or basins, freely exposed to sun and air, instead of the traditional deep narrow tanks with sides of glass.

A RECENT number of the *British Medical Journal* says "that a large collection of indigenous medicinal plants and drugs, fibres, and cereals has already been made in the Imperial Institute from India and the East. A great many of the Indian drugs have enjoyed a reputation in tropical diseases for the last 2000 years. They are, however, employed in the crude state, generally in combination with metallic and mineral compounds, and do not therefore indicate their individual value as medicines. They have, with a few exceptions, undergone no chemical analysis or pharmacological experimentation, and such researches have not yet been taken up either by Government or by private individuals in India, neither are there facilities or expert knowledge easily procurable for such researches. To submit them to experts in London for proper investigation would be very costly under the circumstances. The establishment of a chemical and pharmacological laboratory in connection with the Imperial Institute, under a committee of experts, would be a valuable addition. There are few institutions of the kind where any original researches can be made in London; it will therefore be a very desirable and useful institution for the promotion of science. It may in addition be expected to help towards the discovery of important medicines and products of great dietetic and commercial value. The benefits which would accrue from the institution would be greatly appreciated both by English and Indian contributors to the funds of the Imperial Institute; and it would tend to bring together scientific men from all classes and races of men in the British Empire." It is remarked with regret that though such a project as this has been contemplated by the authorities in charge of the Institute, little more progress has been made in the matter. We cordially agree with our contemporary in thinking the matter important enough to engage the attention of the committee of the Institute, and would urge that the necessary steps for its consideration be taken at the earliest possible date.

DR. J. W. VAN BEBBER, of the Deutsche Seewarte, has examined the daily synoptic weather charts for the North Atlantic Ocean and adjacent continents, issued in connection with the Danish Meteorological Institute, for four years ending November 1887, and has published some useful results obtained from them in the *Annalen der Hydrographie* for June. The tables show the frequency of the occurrence of barometric depressions in the North Atlantic for areas of 10° of longitude and 5° of latitude, and charts give further information graphically. These low pressure areas exhibit an increase of frequency from high northern to middle latitudes, and then a decrease towards low latitudes, so that below the 30th parallel the minima occur very rarely. In the meridianal direction, the barometric minima are most frequent on the eastern coast of North America, and originate less frequently over the ocean. The mean height of the barometer in the areas of low pressure exhibits several peculiarities in different seasons. In spring, the depth of the barometric minima over the whole area is relatively small; to the south of Iceland the barometer frequently falls considerably below twenty-nine inches. In summer the mean height of the barometer, especially on the ocean, is higher than in spring, the lowest readings being generally between Iceland and Greenland, while in autumn and winter the readings over the ocean are considerably lower than in the other seasons. The lowest readings are again found to the south of Iceland, where the mean minima in winter fall below 28·5 inches. With regard to barometric maxima, or areas of high pressure, their movement is mostly towards east and south-east. The regularity of their paths is shown by the charts to be much greater than is usually supposed. The behaviour of stationary maxima is very interesting; there is in all seasons a great frequency of stationary maxima over the ocean between 20° and 40° W. long. and 25° and 40° N. lat. There is also another maximum of frequency in spring and summer between Greenland and Spitzbergen. These stationary maxima exert an important influence over the weather of the British Islands, and the discussion of synoptic charts, such as now undertaken by Dr. van Bebber, is one of the most likely means of improving our knowledge of weather phenomena.

AN account of the performance of the new continuous-record seismometrograph of the Collegio Romano, during 1893 and 1894, was communicated to the Accademia dei Lincei at a recent meeting by Dr. G. Agamennone. The registration was mechanical, and not, as in some modern instruments, photographic. The pendulum for the two horizontal components was 6m. long, and carried a bob weighing 75 kgr. Records were obtained at Rome of the three earthquakes of Zante in 1893, and also of the shocks felt in Samothrace, Aleppo, Servia, and Nikolaiev. On November 5, 1893, the instruments, both at the Collegio Romano and the Rocca di Papa Observatory, registered the violent earthquake proceeding from Turkestan and Northern India. But the most interesting record, reproduced in the author's paper, is that of the Japanese earthquake of March 22, 1894. The disturbances registered at Rome lasted nearly an hour, and showed three main series of shocks, with intervals of comparative quiet between. Towards the close of the earthquake the individual wave-lines became distinctly visible, each wave taking about seventeen seconds to pass. Taking the velocity of propagation of these earth tremors as 2500 metres per second, this would give some 40 km. for the wave-length of this disturbance. These slow undulations began to appear at 11h. 58m., whereas from the beginning of the earthquake at 11h. 37m. 20s. till then the period had been much shorter, and the individual traces overlapped. What is of special importance in this record is the enormous distance—nearly one earth-quadrant—across which the disturbance was propagated.

AT the last meeting of the Société Helvétique des Sciences Naturelles at Lausanne, M. Raoul Pictet gave some particulars concerning cold-burns experienced by himself and his assistants during his investigations of the lowest temperatures attainable. He distinguishes two degrees of burns. In the case of the first, the skin is reddened, and turns blue on the following day. The area of the spot is nearly doubled during the following days, and it is not generally healed till about five or six weeks afterwards. It is accompanied by a very painful itching on the affected spot and the surrounding tissues. When the burning is more serious, produced by a longer contact with the cold body, or by contact rendered perfect by alcohol, ether, or liquid air, a burn of the second degree is experienced. The skin is rapidly detached, and all the parts reached by the cold behave like foreign bodies. A long and stubborn suppuration sets in, which does not seem to accelerate the reconstitution of the tissues. The wounds are always malignant, and scar very slowly and in a manner altogether different from burns produced by fire. When on one occasion M. Pictet had suffered a severe burn on the hand, due to a drop of liquid air, he seriously scorched the same hand accidentally. The scorched portion was healed in ten or twelve days, whereas six months afterwards the wound produced by the cold burn was still open. In order to try the effect of radiation in dry cold air, M. Pictet held his bare arm up to the elbow in a refrigerating vessel maintained at − 105° without touching the metallic walls. He felt over the whole skin and throughout the muscles a sensation which had a distinct character, and could not be described by words. The sensation is not disagreeable at first, but gradually becomes decidedly so, and appears to have its seat in the central bone or the periosteum. After three or four minutes the skin is rather blue, and the pain becomes intense and more deep-seated. On withdrawing the arm from the refrigerator at the end of ten minutes a strong reaction is experienced, accompanied by superficial inflammation of the skin. This reaction resembles that which takes place after handling snow for some time with bare arms, except that it is more intense.

WHETHER electromagnetic waves are capable of producing mechanical effects on the conductors forming resonators, is a question which has been investigated by different observers, the results obtained being entirely discordant. The current number of *Wiedemann's Annalen* contains a paper, by Herr Lebedew, on the subject, in which he describes a new form of apparatus which he has employed, and with which he finds that these waves can exert mechanical effects on suspended resonators. The electric waves were set up by means of a Lecher wire system twenty-eight metres long; the waves in this system, which damp out with such great rapidity, being used to induce others in a suitably placed vibrator. The magnetic vibrator consists of a piece of zinc, 20 cm. by 65 cm., bent double, so that the distance between the opposite ends, which form the plates of a condenser, could be adjusted, and thus the wave-length of the vibrations produced be varied between 320 cm. and 380 cm. The magnetic resonator consists of a coil of four turns of fine silver wire, with its axis horizontal, and having terminals connected to two electr meter needles, the relative position of which could be adjusted, and thus the "pitch" of the resonator altered. The resonator for showing the effect of the electric component consisted of a coil of fine silver wire with its axis vertical, the two ends being connected to two cylindrical quadrants. In each case the wires, &c., were fixed to a light glass rod, and the whole was suspended by a fine quartz fibre. The author finds that both types of instrument behave in the same manner, and that the effect increases as the pitch of the resonator approaches unison with the vibrator, suddenly changing sign when this point is passed. Thus, when the resonators were tuned higher than the vibrators, they were attracted, while when they were turned lower, they were repelled. The effects of slow changes of potential and electrostatic charges produced thereby did not affect the instruments, since the author found that when the knobs of the induction coil were so far separated that no spark passed, and therefore no electrical oscillations were set up, the resonators were unaffected.

An interesting contribution to the subject of electrical oscillations and electrical resonance is made in a paper by Mr. John Trowbridge in the current number of the *Philosophical Magazine*. Being desirous of investigating the conditions under which the formulæ given by Kelvin, Stefan, and others for the time of oscillation hold, and considering that method first employed by Spottiswoode of exciting a Ruhmkorff coil, by means of an alternating current dynamo, was a much more powerful method of exciting oscillations than the ordinary method of charging Leyden jars by means of an electrical machine, or working an induction coil by a primary battery, the author has designed a form of apparatus in which he employs an alternator capable of giving a current of from 15 to 25 ampères with a potential difference of 120 volts, together with a suitable transformer to obtain the necessary difference of potential. He, in general, employs one primary circuit between two entirely separate and disconnected secondary circuits, so arranged that the images of the sparks in the three spark-gaps, after reflection in a rotating mirror, could be formed side by side on the same photographic plate. The most striking results obtained by the author are that a unidirectional spark (non-oscillatory) always excites an oscillatory discharge in a secondary circuit if the self-induction, capacity and resistance of this circuit permit an oscillatory movement. In every case the first effect of the exciting unidirectional primary spark is to make the secondary circuit act as if there were no capacity in its circuit, a thread-like spark resulting, which is exactly like that produced when all the capacity in the secondary circuit is removed. After a short interval of time the electricity rushes into the condensers, and begins to oscillate, the strength of the oscillations rising, after one or two vibrations, to a maximum, and then decreasing; the rate of oscillation finally assuming a steady state, and being expressed by the formula $t = 2\pi\sqrt{LC}$. If a unidirectional primary spark excites oscillations in neighbouring circuits which are slightly out of tune, the phenomenon of electrical beats or interferences can be produced in these circuits, and is very clearly shown on the photographs of the sparks. If the primary spark ceases to be unidirectional, and becomes oscillatory, these oscillations will tend to compel those of the secondary to follow them, and if they are not sufficiently powerful to do this they beat with the secondary oscillations. When all capacity is removed from the secondary circuits they oscillate in tune with the primary circuit. The author has been led to suspect that there is a change in the period of electrical oscillations when an iron wire is substituted for a copper one of the same geometrical form, and is at present engaged in investigating this point.

The forty-first report of the Department of Science and Art, and the Directory (revised to June 1894), have been issued.

Messrs. Dulau and Co., have issued a catalogue of works they have for sale, on astronomy, terrestrial magnetism, and meteorology.

We have received from the publishers (Messrs. Bliss, Sands, and Foster) the latest volume of their very pretty series, entitled "The Country Month by Month." The number treats of "The Plant-World in August," and "Wild Life" in the pleasant month upon which we have just entered. The series should be a favourite one with lovers of nature, the style of writing in it being bright and chatty, and the general get-up very tasteful.

A report, just received from Mr. Joseph Baxendell, showing the results of observations made in connection with the meteorological department of the Corporation of Southport during 1893, does credit to municipal meteorology. The report includes tables showing the results of routine observations, and also various notes relating to the instruments used and methods employed.

Mr. J. D. Potter has sent us "Twelve Charts of the Tidal Streams of the North Sea and its Coasts," which he has recently published for Mr. F. Howard Collins. The two thousand arrows which are to be found upon the charts represent the direction of the tidal streams of the North Sea and its surrounding coasts at all hours of the tide upon any day of the year. The time of high water at Dover supplies the key. The charts are reduced from the one published by order of the Lords Commissioners of the Admiralty, and numbered 2339.

The first number of *Contributions from the Zoological Laboratory of the University of Pennsylvania* has been received. It contains three articles, as follows, and is illustrated by four plates:—"The Correlations of the Volumes and Surfaces of Organisms," by Dr. J. A. Ryder; "The Growth of *Euglena viridis* when constrained principally to two Dimensions of Space," by Dr. J. A. Ryder; "Descriptions of three new Polychæta from the New Jersey Coast," by J. P. Moore. The new serial is issued through the Pennsylvania Press, Philadelphia.

Yet another magazine professing to be devoted to science has appeared—*The New Science Review: a Miscellany of Modern Thought and Discovery*. The latest arrival, which will be published quarterly, hails from America, but has an office in Henrietta Street, Covent Garden. Some of the articles in the first number seem to us scarcely to fall under the head of science, but this lapse into other realms may be due to the fact that the magazine aims at originality. Among the articles somewhat more closely allied to science than those we have hinted at, may be mentioned—"The Mystery of the Ice-age and its Solution," by Major-General Drayson; "The Problem of the Pole," by C. Morris; and "Nikola Tesla and his Works," by Lieut. F. J. Patten; while Prof. A. Heilpin contributes "Current Scientific Discussion."

Both physical and natural science are fairly represented in the current number of *Science Progress*. Dr. D. H. Scott surveys recent work on the morphology of tissues in the higher plants; St. George Mivart makes some critical remarks on the theories of epigenesis and evolution; and Prof. E. Waymouth Reid describes electromotive phenomena in glands. The arrangement of the molecules in a crystal, forms the subject of an interesting article by Mr. H. A. Miers; and a useful paper on atomic weights is contributed by Mr. Alexander Scott. In the July number of the journal the titles of chemical papers which appeared in May were enumerated. A similar list for June is given in the current issue, and an editorial note informs us that the list will be continued in each number.

THE First Biennial Report, for the years 1892 and 1893, of the Maryland State Weather Service, which was organised on May 1, 1891, has been published. As in other States, the observers are voluntary, and the Weather Bureau supplies instruments, &c. The present report is intended to give a general view of the climate, so far as conclusions can be drawn from data yet obtainable; it also contains a general summary of the physical features of Maryland, and of the different types of soil, each of which is specially adapted to the cultivation of certain classes of plants. The Director of the service, W. B. Clark, points out that the climate is generally what is known as continental, but is greatly modified in the eastern part of the State by the ocean. The average mean temperature of January is 32°·8, and of July 75°·8, a mean range of 43°, but the differences in certain localities are very considerable. Rainfall is fairly equally distributed throughout the year, the maximum occurring in the spring; the mean annual fall is 42·4 inches. Snow never fails completely, even with warmest winters.

THE *Reports of the Director of the Michigan Mining School* for 1890–1892 have just been distributed, and tell of much good work having been accomplished at this popular institution during the years under review. In the report for 1891–92 mention is made of a number of changes which were to come into effect in 1893, one being the lengthening of the course from three to four years, and the raising the age for admittance into the regular course to twenty years, unless the intending student shall have completed a regular course in some good high school or academy. The need of some kind of endowment is pointed out, the school being at present entirely dependent upon legislative aid. The report also calls attention to the necessity for the erection of an additional building on grounds belonging to the school. This building would be used for machine shops, testing and electrical laboratories, the mining engineering laboratories, &c. A metallurgical laboratory is much needed, but cannot at present be proceeded with for want of funds. The work in each department has developed so much that an increased expenditure all round is deemed necessary.

DIAZOMETHANE, $H_2C\begin{smallmatrix}N\\ \\ N\end{smallmatrix}$, has been isolated by Prof. von Pechmann, of Munich, and a preliminary communication concerning it is contributed to the current *Berichte*. This interesting substance is a yellow gas at the ordinary temperature, which condenses when cooled to a yellow liquid. It appears to be odourless, but is extremely poisonous, so much so that Dr. Pechmann finds it very difficult to work with in the gaseous state, owing to its violent action upon the respiratory organs. The principal properties of the substance have therefore been studied with its solution in ether. It is obtained by the action of alkalies under special conditions upon any of the nitrosamines of the type NR . Ac . NO, where R represents an alkyl radical such as methyl, ethyl or benzyl, and Ac stands for acetyl, benzyl, or the radicals $CONH_2$ and $COOC_2H_5$. The yield of the gas is at least fifty per cent. of the theoretical when nitrosomethylbenzamide or nitrosomethylurethane are employed. The reaction appears to be a very simple one, represented by the following equation:—

$$CH_3N\begin{smallmatrix}\diagup NO\\ \diagdown Ac\end{smallmatrix} + NaOH = CH_2N_2 + H_2O + AcONa.$$

The new substance behaves in a characteristic manner towards dilute acids. The yellow solution in ether is instantly decolourised upon the addition of the acid at the ordinary temperature, nitrogen being evolved. Water acts in a similar manner and almost as vigorously as when acidified. It is much more stable, however, towards alcohol. Iodine decomposes diazomethane with formation of methylene iodide CH_2I_2 and evolution of nitrogen. The reaction may be carried out volumetrically if the iodine is likewise employed dissolved in ether, the completion being indicated by a sudden decolourisation of the liquid; the nitrogen can readily be measured by means of the nitrometer, over mercury. Diazomethane reacts with silver nitrate and Fehling's solution in a similar manner to the diazoacetic ether described by Curtius. Mercuric oxide is reduced in the cold. Cork is bleached and eventually destroyed by the gas, so that the ethereal solution cannot be preserved in vessels closed with cork stoppers. The best proof of its composition and constitution is considered by Prof. Pechmann to be afforded by its reaction with the methyl ether of fumaric acid. The yellow ethereal solution of diazomethane is instantly decolourised upon admixture with the fumaric methyl ether; the substance produced is a direct addition product which has been obtained in crystals, and which upon boiling with dilute hydrochloric acid evolves carbon dioxide and yields crystals of hydrazine hydrochloride. Moreover, the silver salt of this compound is stable, and has been analysed. In concluding his preliminary notice, Prof. Pechmann states that he has likewise isolated diazoethane in a similar manner, employing, of course, an ethyl instead of a methyl nitrosamine. Further particulars of these compounds will doubtless be awaited with considerable interest.

THE additions to the Zoological Society's Gardens during the past week include a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, presented by Mrs. Keirnander; a Blotched Genet (*Genetta tigrina*) from Lamoo, East Africa, presented by Miss M. Clode; a Grey Ichneumon (*Herpestes griseus*) from India, presented by Miss Sullivan; a Four-horned Sheep (*Ovis aries*, var.) presented by Mr. Frank C. Strick; a Blackcap (*Sylvia atricapilla*) British, presented by Captain John Richardson; a Smooth Snake (*Coronella lævis*) British, presented by Mr. John Gray; a Common Viper (*Vipera berus*) from Scotland, presented by Mr. J. Anderson; a Red and Blue Macaw (*Ara macao*) from South America, deposited.

OUR ASTRONOMICAL COLUMN.

THE MAGNESIUM SPECTRUM AS A CRITERION OF STELLAR TEMPERATURE.—The variations undergone by the spectrum of magnesium when the element is subjected to different temperatures were studied some years ago, and their use in estimating the comparative temperatures of celestial bodies have been pointed out. Prof. J. E. Keeler contributes a note on the matter to the *Astronomische Nachrichten*, No. 3245, his remarks referring especially to some observations recently published by Prof. Scheiner on the behaviour, under different temperatures, of the lines at λ 4482 and λ 4352. The former line is strong and broad in the spectrum of magnesium, when luminosity is produced by means of the electric spark with Leyden jar in the circuit, but it does not appear in the arc spectrum; on the other hand, the line at λ 4352 is strong in the arc spectrum, but faint in the spark spectrum. Similar differences of relative intensity are found to exist in stellar spectra, and Prof. Scheiner is not alone in thinking that they afford a means of estimating the approximate temperatures of the absorptive atmospheres of celestial bodies exhibiting them. In connection with this subject, Prof. Keeler comments upon the absence of the magnesium triplet *b* from the spectrum of Rigel, while the line at λ 4482 is conspicuous. He suggests that the star is at too high a temperature for the production of the *b* group, and uses the relative strength of the group in different spectra as a criterion of stellar temperature. It is pointed out that Kayser and Runge have shown that the group is characteristic of a molecular structure which cannot exist at a very high temperature, whereas the lines at λ 4482 and λ 4352 do not represent the same molecular state. These considerations lead to the conclusion that the aspect of the *b* lines in stellar spectra may be used as an index to the temperature in the same way as the two lines selected by Prof. Scheiner. And since the *b* group is absent from the spectra of Rigel and certain other stars, it is thought that these bodies must be at a temperature higher than that of the most powerful electric spark, for, were they at this temperature, laboratory observations indicate that the group should be well visible in their spectra.

THE AUGUST SWARM OF METEORS.—Many have already begun to observe, during the past few evenings, some of the forerunners of the August swarm of meteors which at this time are visible in very considerable numbers. Although, at its best, this swarm does not offer such beautiful displays as those which occur when the earth meets with the densest part of the November swarm, yet, on account of their uniform distribution and moderate density along their orbit, the shower is always fairly bright and distinct. Unlike the November meteors, the Perseids always herald their approach a few days beforehand by an increasing number of outliers as the maximum approaches; on the 10th this is reached, and from that time a decrease in their number rapidly diminishes. Another peculiarity of this swarm is that the average intensity year by year does not exhibit such wide variations as those shown by the Leonids, which attain a maximum every $33\frac{1}{4}$ years. By plotting the paths of the observed meteors on a globe or star chart, the radiant point so found should be approximately 45° R.A. and 57° Declination for the 10th. Close observation every evening will reveal a daily movement of the radiant point eastward among the stars, as shown in the following ephemeris, taken from Mr. Denning's table in the "Companion to the Observatory." The dates before the 10th are given for the sake of those who have commenced their observations early, and would like to compare their observed radiant points with those calculated :—

Date.	Radiant. α.	δ.	Date.	Radiant. α.	δ.
	°	°		°	°
July 19	19	+51	Aug. 2	36	+55
,, 21	22	52	,, 4	38	56

,, 31	34	55	,, 14	50	58
			,, 16	53	58

The comet with which these Perseids are supposed to be connected, is that which appeared in 1862, and was discovered by Mr. Swift, of Rochester, New York, on July 15. The orbit, after a calculation made by the late Dr. Oppolzer, of Vienna, was found to be elliptic, and the periodic time 120 years. Schiaparelli it was, however, that drew attention to the similarity between the meteoritic and cometary orbits. The next appearance of the comet does not take place before another half-century.

INSTITUTION OF MECHANICAL ENGINEERS.

THE annual summer meeting of the Institution of Mechanical Engineers was held last week in Manchester, under the presidency of Prof. A. B. W. Kennedy, the President of the Institution. The meeting commenced on Tuesday, the 31st ult., and concluded on the Friday following. There were but two sittings for the reading and discussion of papers. The following is a list of the papers on the agenda :—

(1) "Description of the New Electric Lighting Works, Manchester," by Dr. John Hopkinson, F.R.S.

(2) "Electric Welding," by Benjamin Alfred Dobson.

(3) "Description of Twin Screw-Propellers with Adjustable Immersion, fitted on Canal Boats," by Henry Barcroft, of Newry.

(4) "Description of the Manchester Main Drainage Works," by Wm. Thomas Olive, Resident Engineer.

(5) "The Manufacture of Standard Screws for Machine-made Watches," by Charles J. Hewitt, of Prescot.

(6) "Drilling Machines for Cylindrical Boiler Shells," by Samuel Dixon, of Manchester.

The last two papers were adjourned until the next meeting in London. Dr. Hopkinson's paper was a short one, the scope of which is sufficiently indicated by the title. Outlined particulars were given of the new installation at Manchester. There were, however, no special features which require notice in the present instance. The discussion which followed chiefly turned on the use of jockey pulleys. It is interesting to notice, however, the progress that has been made in electric lighting since the author read his first paper on the subject before the Institution, now fifteen years ago. Since that time this department of practical science has undergone an extraordinary development. The only electric lights then were arc lights, the first incandescent lights in a practical form being made about a year later. To-day there are millions of incandescent lights in use. The machine the author used for experimenting upon in 1879 was at that time considered a fairly large one and highly economical; it required six horse-power to drive it. Now many machines have been working for a considerable time, requiring over 1000 horse-power to drive them. The commercial efficiency of the machine then was about 50 per cent., but now machines are produced having commercial efficiencies of 94 per cent.

Mr. Dobson's paper on electric welding was one of practical interest, although the system of welding by electricity is one that is now well known. The author, has, however, adopted this method of joining metal for some time in the extensive works of his firm at Bolton. Practical every-day working for nearly three years of the process of welding by electric force enabled him to give certain indications and appreciations of the method considered as a practical workshop operation. During the period mentioned his firm has had two machines in operation, worked from the same generating dynamo, and engaged upon different classes of work. The one is specially arranged for joining bar iron and steel, and the other, which is a smaller machine, is used for work of a more delicate nature, such as brazing and piecing clean-finished work, where the fire-heat would have destroyed the quality of the work on the adjacent material. Great difficulties were experienced at first in regard to the requisite mechanical power, it being found that this power had been much understated. The author, having about 35 indicated horse-power to spare on a certain engine, and understanding that 30 horse-power would be the utmost required to piece a 2-inch round bar, determined to drive the dynamo from that engine. This practical test showed that instead of 30 horse-power as much as 80 horse-power seemed to be wanted for the larger sizes. A portable engine capable of working up to 100 indicated horse-power with 80 lbs. pressure was supplied and placed at a distance of about 45 yards from the welding machine. Even with this engine it was found that when piecing the larger diameters—as yet nothing over $2\frac{1}{4}$ inches has been pieced—if the work was to be done in reasonable time, the speed of the engine was greatly checked. A Thomson-Houston welding dynamo was used by the author's firm. Its speed is 1000 revolutions per minute, and it gives at full load a current of 200 ampères at 300 volts with 100 alternations per second. Transformers are used. The author gave full particulars of the work done and tests made. The question of cost had not been alluded to in detail by the author, who admitted, however, that the payment of royalty, the cost of horse-power, and the depreciation, which on electrical apparatus is heavy, together brought the cost considerably over the net cost of the ordinary smith's hearth work; the payment in wages, &c., being considerably less. The loss in weight of iron is about one-twentieth. On straightforward welds the total cost is between ten and fifteen per cent. more than the ordinary smith's work; but in the case of delicate work and difficult operations, the cost is about one-third of that of the smith's work. The real advantage of the apparatus, as at present arranged, is not so much an economy as a method of securing an absolutely reliable result, and occasionally saving considerable expenditure by its adaptability.

In the discussion which followed the reading of this paper, no important points were brought forward.

Mr. Barcroft in his paper described an arrangement by which steam power could be applied to ordinary canal boats. Although doubtless the application was suitable for the position it had to fill, the machinery possessed neither scientific nor engineering interest, except of a very limited order.

Mr. Olive's paper on the Manchester Main Drainage Works was a useful description of an ordinary installation of this nature. The Manchester works have but recently been put up, and are indeed hardly yet in full working order.

ON THE NEWTONIAN CONSTANT OF GRAVITATION.[1]

II.

I HAVE already stated that two measurements, viz. the horizontal distances between the axes of the wires which support the lead balls, and of the fibres which support the gold balls,

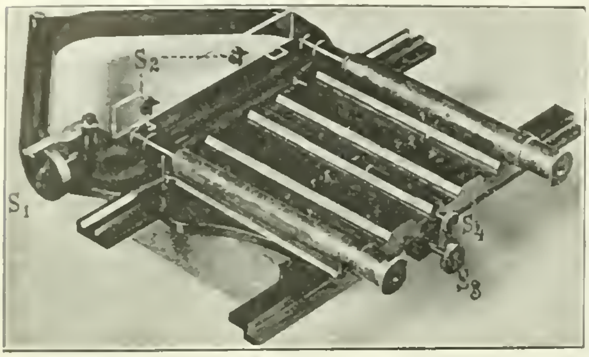

Fig. 4.

must be made with the highest degree of accuracy attainable, for on these the result directly depends. In order to accomplish this, I had to design a special instrument, an optical compass, which is illustrated in Fig. 4. This is an arrangement pair of traversing slides, each carrying a microscope in one or other of three grooves. The two traversing slides are drawn together by a spring, and can be separated by a screw cone, forming a very delicate fine adjustment. This is operated by the screw-head S_4; S_3 is a focussing screw giving a fine adjustment to the focussing slide. S_2 S_2 are two parallelising screws, the purpose of which is to bring the microscopically-divided glass scale into focus at each end simultaneously. S_1 is a micrometer screw-head, which is employed to push the scale bodily to the right by measured amounts. The two microscopes are focussed upon, say, the right sides of the wires, the focussing slide is then withdrawn, leaving them relatively unchanged, and the microscopic scale is then put in its place. The distance from wire to wire is thus transferred directly to the scale, and the fractional part of any one division of 1/100 inch is all that has to be referred to and measured by the screw. Every slide in this apparatus is geometrically arranged, so that the movements are all perfectly free, unconstrained, and without shake. In measuring the distance between the fibres, which must be done while they are freely suspended, so that a force of a millionth of the weight of a grain will give them a considerable motion, means have to be provided to exclude draught, which yet must not interfere with the apparent distances of the fibres. No microscope cover-glass is any use for this purpose. It is sure to be prismatic, and when inserted between the microscope and an object, it will certainly cause it to shift its apparent position. A piece of clear mica is perfect in this respect, no movement, even with a high power, being visible. I mention this, as it well illustrates the sort of trap that is ever set for the experimentalist. If I had not been aware of this, and had used, as would be natural, a window

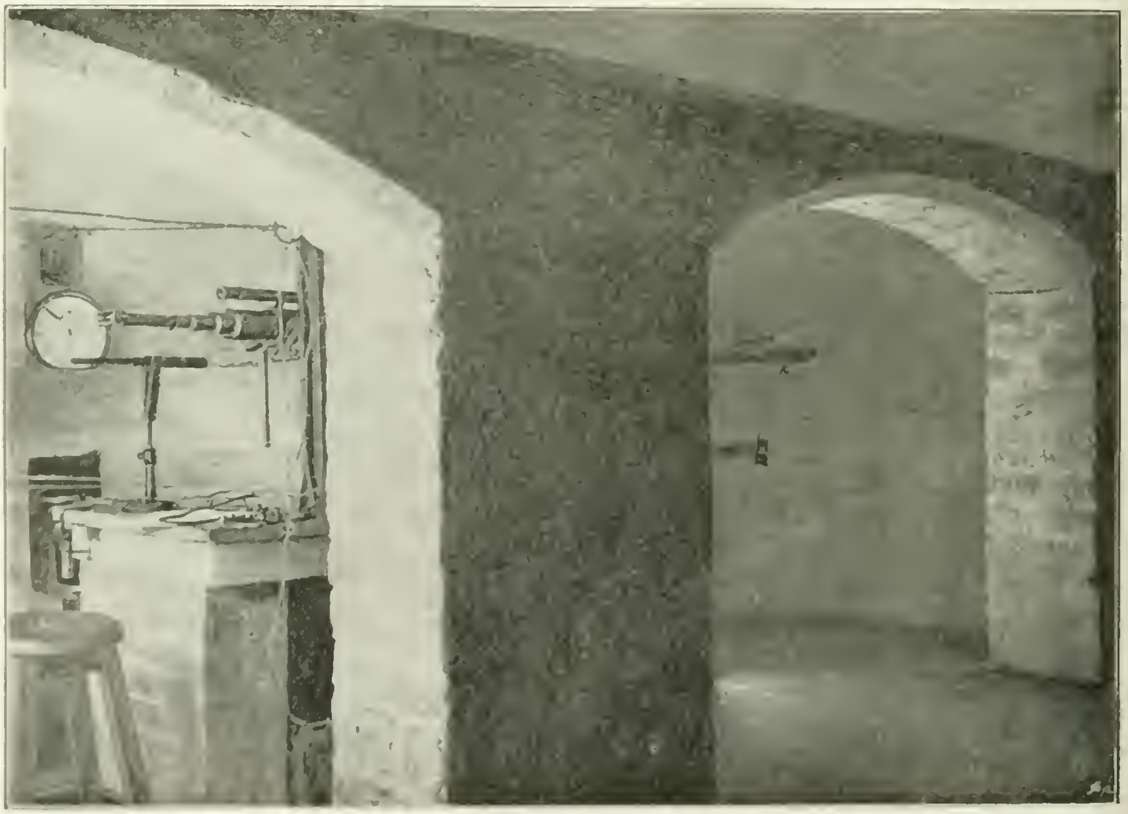

Fig. 5.

which rests upon the lid of the apparatus on the circular V-groove seen in Fig. 1, so that it can rotate without shake. Upon the lower framing rests the focussing slide, and on this a of microscope cover-glass, then each fibre would have appeared as definitely in its place as before, but the place would have been wrong, perhaps by 1/1000 inch, and thus a consistent error affecting all the experiments alike would have been introduced,

[1] Continued from p. 3?4.

and no multiplication of observations or taking of means would have eliminated it. It is on this account that it is so important in experimental work to vary the conditions in every way, so as to discover unsuspected consistent errors.

The microscope scale was made by Zeiss, and is a most perfect example of scale construction. In order to test the accuracy and find the errors of the scale, I took advantage of my visit to Cardiff, for the meeting of the British Association, to compare it with a series of Whitworth standard bars on Prof. Viriamu Jones's very perfect Whitworth measuring machine. For this class of work sunshine or dust give great trouble, but I was fortunate in having splendid weather for my purpose, as visitors will probably remember. It rained without ceasing during the two days that I was making these measurements.

Having now very imperfectly described the apparatus and the place in which I have carried out my experiments, I will next show a series of photographs, which I took by magnesium

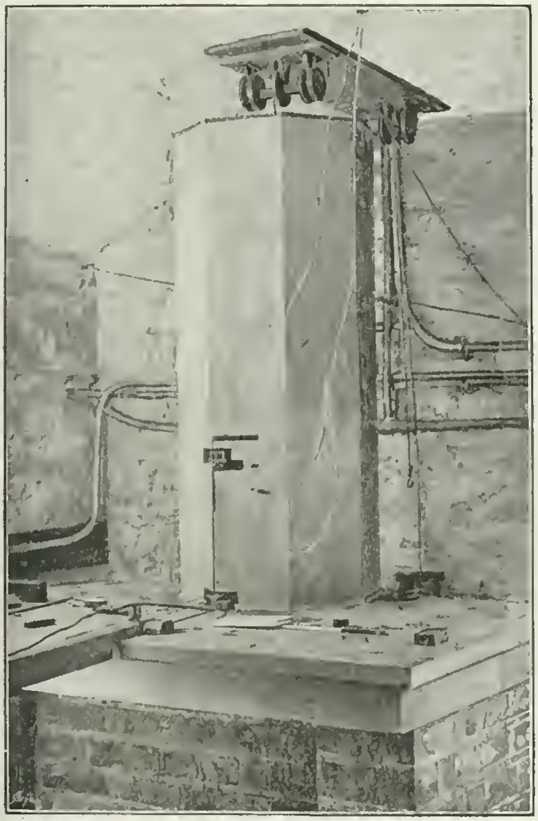

FIG. 6.

light, to give a better idea of the appearance of the apparatus and its surroundings. Fig. 5 is a view of the vault showing the clock, the eye end of the big telescope, and the little telescope. In the distant corner is seen the felt screen with a long slit, through which the scale and telescope can be seen from the mirror of the instrument. This, of course, is on the table behind the screen. Fig. 6 is a view of the corner itself, with the screen drawn back. The octagon protecting house, which surrounds the apparatus, is seen in position. Here again a slit is cut large enough to allow the scale and telescope to be seen from the mirror. Fig. 7 is a view of the instrument with the two halves of the octagon house separated. Here a further system of screens consisting of concentric brass tubes may be seen, but the lower one, which surrounds the window, has been removed and placed upon the table. The driving gear is also seen in this photograph, and a tube coming from the screw under the instrument which holds the central tube, which tube is also seen in Fig. 1. This tube enables me to control the motion of the mirror from the telescope without approaching the corner in which the apparatus is set up. This is done as follows: the back window at the level of the mirror is made of metal, with a hole in it in which is screwed a metal tube lightly filled with cotton wool. This is not central, but opposite one end of the mirror. The tube on the table does not fit the screw, but is merely bent up and enters it loosely. By gently drawing air from the end of the tube at the telescope a very feeble draught is produced in the apparatus, for nearly all the required air is supplied by leakage round the pipe near the screw, very little entering through the window pipe, in consequence of the resistance offered by the cotton wool. In this way, if the mirror is

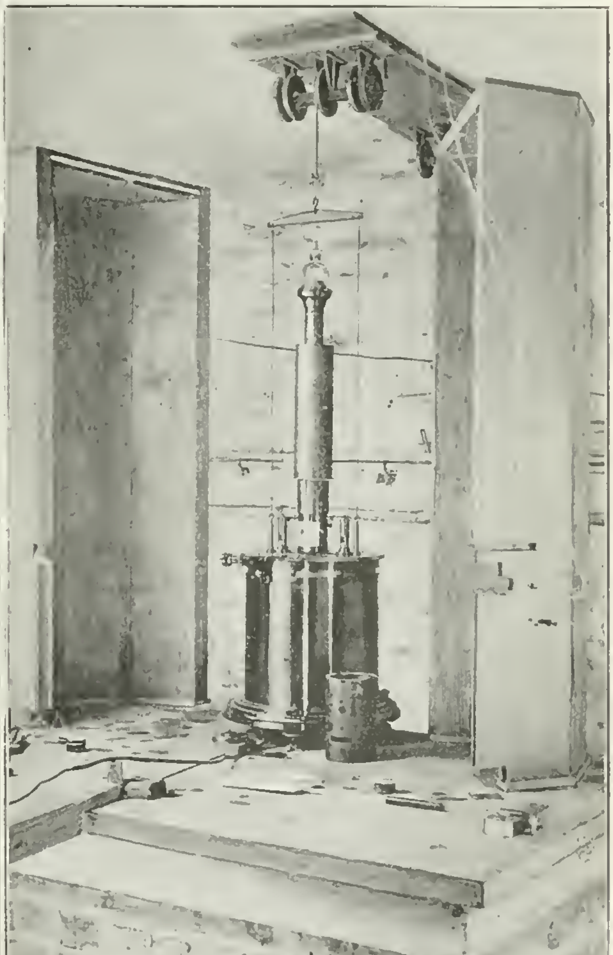

FIG. 7.

moving it may be gently brought to rest without impact, or it may be given a swing of any desired amplitude. So perfectly does this work, that the mirror may be steadied very quickly so as to move through less than a scale division, an amount which corresponds to six or seven seconds of arc, or to a force of less than one thousand millionth of the weight of a grain.

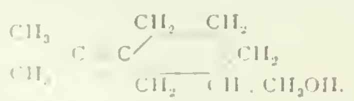
The operations for any complete experiment are fourteen in number. I do not intend to go through these seriatim, as time will not allow me to do so. It is sufficient now to say that the first eight are necessary to get the instrument and scale relatively fixed and adjusted, the vertical measures made, and generally all ready for operation 9, in which the optical compass is employed. This is a most important one, for not only are the horizontal measures made, on which so much depends, but in addition the plane of the wires and fibres are made identical, the corresponding scale reading is found, and any eccentricities are measured and may be corrected.

(*To be continued.*)

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, July 30.—M. Lœwy in the chair.—Conditions necessary for the production and the perception of murmurings in tubes through which air-currents pass, by M. A. Chauveau.—On certain of the later geological and climatic phases in Barbary, by M. A. Pomel. The quaternary period was marked in Barbary by (1) a rainy phase with formation of alluvial deposits, followed by (2) a dry period characterised by the formation of travertinous crusts, and (3) the partial submergence and reappearance of the coast districts with the production of a narrow band of marine beds and a moderately humid climate, which has since deteriorated to the present condition of excessive dryness.—Report on M. Bigourdan's memoir "On the micrometric measurement of small angular celestial distances, and on a method of perfecting this kind of measurement," by MM. Lœwy, Tisserand, and Wolf. The method used by the author for the measurement of micrometric angular distances consists in the use of glass points in place of the micrometer threads, so that the image is never blotted out by superposition. It allows of much easier work, and is at least as accurate as any method previously employed.—On the theory of differential quadratic formulæ, by M. Wladimir de Tannenberg.—On the integration of certain systems of equations with derived partials of the first order involving several unknown functions, by M. Riquier.—On the absorption of light in isotropic and crystallised media, by M. G. Moreau.—A contribution to the study of the structure of steel, by M. F. Osmond. With moderately hard steel, containing 0·45 per cent. of carbon and 0·35 per cent. of manganese, the structure was found to vary gradually in samples all originally heated to 825° C. and quenched in water at 15° C. after cooling to 720°, 690°, 670°, 650°, and 640° respectively. Hardening from 640 left the structure almost the same as slow cooling. With hard steel, containing 1·24 per cent. carbon, the variation is more rapid; the temperature of maximum hardening lies very near to that of no hardening. The structure, as studied by polished surfaces, in steel of moderate hardness gives information concerning (1) the maximum temperature of heating, (2) the temperature from which it has been hardened, and (3) the rate of cooling.—A refractometer with a chamber capable of being heated, and its application to measurements with fatty substances, by M. Fery.—On the constitution of rhodinol from essence of Pelargonium, by MM. Ph. Barbier and L. Bouveault. Rhodinol is demonstrated to be a primary alcohol, $C_{10}H_{18}O$, containing one ethylenic grouping; it is a cyclic compound, and its rotatory power and that of its derivatives prove the presence of an asymmetric carbon atom. The consideration of the foregoing, together with the ease with which on oxidation it yields acetone and α-methyladipic acid, leads to the provisional formula:



—Action of thionyl chloride on some inorganic acids and organic compounds, by M. Ch. Moureu. With mineral acids $SOCl_2$ gives the corresponding chlorhydrins; with aldoximes it yields nitriles by dehydration; with oxalic and formic acids it behaves just like sulphuric acid. In each case equal volumes of hydrogen chloride and sulphur dioxide are liberated.—On the stability of aqueous solutions of mercuric chloride, by M. E. Burcker.—The oxidation of beer worts, by M. P. Petit.—The mechanism of the influence of toxic substances acting by means of secondary causes in the production of infection, by MM. Charrin and Duclert. The conclusion is drawn that poisons aid infection by an antiphagocytary action allowing the more rapid multiplication of the disease microbe without increasing the virulence of its virus.—On some new laws of pupillary contraction, by M. Ch. Henry.—Is the use of the Auer burner capable of causing partial poisoning? By M. N. Grehant. The author quotes experimental results from which he draws the conclusion that the Auer burner in use does not cause poisoning by the trace of carbon monoxide produced.—On the transformation of "Paguriens" into anomourous crabs of the sub-family of the Lithodinæ, by M. E. L. Bouvier.—On the venomous gland of the "Myriapodes Chilopodes," by M. O. Duboscq.—Branchiæ in *Physa lamellata*, by M. Paul Pelsener.—On the Hongkong plague, by M. Yersin. A specific bacillus is found in great numbers in the bubon, but not in the blood.

THURSDAY, AUGUST 16, 1894.

THE BRITISH ASSOCIATION.

OXFORD, AUGUST 15.

THE meeting which is now ending is in many ways a memorable one. To those who are engaged chiefly in the serious work of the Sections it will be memorable because of the unusual fulness of the sectional meetings and the exceptionally high standard of the communications which have been brought before them. To the popular mind the great feature of the meeting is the Presidential address. Apart from the accessory advantages derived from the eminence of the speaker, his position as Chancellor of the University, his command of the English language, his oratorical powers, and the unusual splendour of the University ceremonial, the address must be considered as one of the most remarkable that has been given from the Presidential chair for many years past. Its effects are likely to be considerable, because, unlike the majority of scientific addresses, it was thoroughly comprehended by the whole audience, and was written in such clear, vigorous, and easy English that there is no educated person who cannot understand every word of it. Whether the effect will be for good or for evil, time will show. Lord Salisbury passed in review the weaknesses of all branches of science, but his exposure of the incompleteness of the ethereal and atomic theories are not likely to prejudice the general belief in them. These are impersonal questions which the average layman is content to leave in the hands of specialists. It is otherwise with Evolution, which came in for a large share of criticism, much of which, it must be said, was criticism of a somewhat unfair kind. Evolution and the Darwinian hypothesis have been accepted of late by the people in a somewhat reluctant and hesitating fashion; there has been no great champion of the opposite view, and the "lay" mind has been overwhelmed with masses of technical argument until it has relapsed into sullen acquiescence. For the first time for some years past a voice has spoken from a seat of authority, and has raised the hope that the bondage under which unwilling minds were lying may be broken, that the doctrine of Evolution may be overthrown, and that of design resuscitated in place of it. One has only to read the articles which have appeared in all the leading newspapers to understand how real this hope is, and how gladly a large number of educated people would undo the labours which were begun by Treviranus and Lamarck, carried on to success by Charles Darwin and by Wallace, and elaborated by Huxley, Haeckel, Weismann, and many others. The biologist knows well the answer to most of Lord Salisbury's criticisms, and can show that most of them have often been raised before, and have been completely answered. They were partly answered by Prof. Huxley in the admirable speech in which he seconded the vote of thanks, and it is to be hoped that he has not said his last word in response to the challenge thrown down. A perusal of the newspaper articles of last week betrays a weakness in the armour of scientific debate, a weakness from which Prof. Huxley alone, or almost alone, is exempt. Since the "Origin of Species" was first published, much has been spoken and written on the subject, and an enormous mass of evidence has been accumulated, much of which is of the nature of verification, and carries, or should carry, as much weight in support of the theory of descent with modification as did the discovery of new elements in support of the theory of Mendeléef. But the subject is a large and intricate one, and the writings of many of the staunchest adherents of Evolution have failed to influence those who are not professed biologists because they have been couched in such technical, and, at times, in such uncouth language that they could not possibly be understood except by those who have had a long training in the special subject. Lord Salisbury has taught us that a skilled debater and a master of epigram may, by a sudden and brilliant attack, make a breach of some considerable extent in what we have come to consider as an almost impregnable stronghold. That the breach will be rapidly repaired, there can be no doubt, and in repairing it biologists will feel the advantage of having to improve the range and penetration of their weapons of offence and defence. It is not enough that a scientific truth should be the possession of a privileged few; those who value the truth should try to spread it and make it common intellectual property, and this can only be done when they realise that simplicity of language, a correct style, and a good arrangement are essential to its propagation. It is unnecessary to remind readers of NATURE that the questions in dispute among biologists are not as to whether evolution has taken place, but as to the manner in which it has taken place; that the selection of favourable variations is not denied, but that the operations of natural selection are still imperfectly understood, and that arguments drawn from artificial selection, if they are applicable at all, are applicable only to a very limited extent. Nobody supposes that the methods of artificial selection, the mating of the favourably varying bridegroom with the favourably varying bride, find their exact parallel in nature. The argument from artificial selection was originally brought in to prove that under certain conditions species were capable of transformation, and the different conditions under which transformation may be effected, and the extent of transformation under known conditions, are now the most promising subjects of biological study. This fact was very well exemplified in the discussion which followed Prof. D'Arcy Thompson's paper "On some Difficulties of Darwinism," on Monday last. It might appear that the debating of such a question in Section D was proof of the truth of Lord Salisbury's contention, that there is a reaction against Darwinism; but it is to be observed that none of the eminent authorities who took part in the debate doubted the fact of progressive modification; the question at issue was whether the direct effect of external conditions is or is not a factor of importance in causing and perpetuating variations. The sum and substance of Lord Salisbury's address was that science is not infallible, and still far from having attained an exact knowledge even of fundamental problems. This science knows very well, and the proceedings of Sections show how very much is still to be learnt.

It is impossible to review the work of each Section in detail, but it may be said that never in recent years has so much matter of novel or remarkable character been communicated in every department of Science. Section A has been particularly active. When it has not been occupied in holding joint discussions with Section G, on Flight and on Integrators, or with Section I, on the Theory of Vision, it has divided itself into three departments—two for Physics, and one for pure Mathematics—and in each the number and the quality of the communications have been of the highest order, one of the most remarkable being that of Prof. G. Quincke, on the formation of soap-bubbles by the contact of alkaline oleates with water.

But, so far as the scientific importance of the communications made to the present meeting is concerned, it is conceded on all hands that a verbal and really an informal announcement made by Lord Rayleigh to Section B, on Monday, on behalf of himself and Prof. Ramsay, takes the first place. It is known that Lord Rayleigh has been for many years engaged upon the determination of the densities of various gases. We have learnt that he found in the case of nitrogen different densities amounting to about one half per cent. according as the gas was obtained from chemical compounds and the so-called nitrogen of the atmosphere. This and other points have recently occupied the attention of both Lord Rayleigh and Prof. Ramsay, and they have succeeded in isolating from this so-called atmospheric nitrogen, and by two distinct processes, a second inert ingredient denser than true nitrogen. The first method employed was that used by Cavendish in his demonstration of the composition of nitric acid. Air mixed with oxygen is submitted to electric sparks in presence of alkali until no further contraction takes place. The excess of oxygen is then absorbed by pyrogallol. That the residual gas is not nitrogen is inferred from the manner of preparation, and from the appearance of its spectrum. A second method giving much larger quantities of the new gas depends upon the removal of nitrogen from deoxygenated air by passing it over heated magnesium. When this process was allowed to continue, the density gradually rose to 14·88, 16·1, and finally to 19·09. At this stage the absorption appeared to have reached its limit, indicating that the new gas amounts to about 1 per cent. of the nitrogen of the atmosphere. When the gas thus prepared was sparked with oxygen there was little or no contraction. Lord Rayleigh and Prof. Ramsay have already found that no liquefaction occurs when the gas is compressed at atmospheric temperatures.

Sir Henry Roscoe said that the communication was one of the greatest possible interest and importance, and the Section as well as the distinguished authors were greatly to be congratulated on the announcement of the discovery of what would in all probability turn out to be a new elementary body existing in the atmosphere. The discovery appeared to him to be of special significance, as being one brought about by the application of exact quantitative experiment to the elucidation of the problem of the chemical constitution of our planet.

There were many other communications of a most interesting nature, including a discussion on the action of moisture in promoting chemical changes, a problem which has occupied the attention of several Oxford chemists of late years. Mr. Miers read a paper of great interest to crystallographers in Section C, and Mr. Culverwell's criticism of Croll's views on the Ice Age excited much interest.

It was thought by many that the division of Section D into two very distinct departments of Zoology and Botany, and into a third and completely separate department of Physiology, might weaken the proceedings of each; but the fear has proved to be entirely groundless, for there has been almost a superfluity of interesting material, and the attendance in each Section or department has been as good as was usually the case in the undivided Section. One is glad to note, however, that the division is permissive, and that the three subjects may reunite under the common denomination of Biology in any meetings at which such a galaxy of talent as has been brought together on this occasion is not to be expected. Section E (Geography) has had one of the most successful years in its experience, and has been attended daily by large audiences, which were very well accommodated in the great North Writing School. Economic Science has been hardly less successful, and G and H have at various times been densely crowded, the accommodation in the Anatomical Department having proved sometimes to be altogether inadequate for the large audiences which assembled to hear Mr. Arthur Evans, Prof. Macalister, M. Emile Cartailhac, and Dr. Louis Robinson.

A further feature of the Oxford meeting may be mentioned. Several of the colleges dispensed a magnificent hospitality, and the reunions of foreign and English men of science in Magdalen and Merton will long be remembered by those who were fortunate enough to take a part in them. New College was not behindhand, since it entertained the Sectional Secretaries during their stay in Oxford; whilst Brasenose, Merton, Corpus Christi, Lincoln, Jesus, and Balliol vied with one another in hospitable efforts. Pembroke College was prepared to have done as much, but its intentions were frustrated by a sad event which happened just before the meeting. During the month of August Oxford is usually depleted (most of the University residents are away on their holidays), but for this occasion many returned and showed that the old traditions of University hospitality have not been forgotten since the Universities Acts came into force. The sixty-fourth meeting has altogether been a magnificent one, and well worthy of the town in which it was held.

The following is a synopsis of grants appropriated to scientific purposes by the General Committee:—

	£
Electrical Standards	25
Photographs of Meteorological Phenomena	10
Earth Tremors	75
Abstracts of Physical Papers	100
Reduction of Magnetic Observations made at Falmouth Observatory	50
Comparison of Magnetic Standards	25
Calculation of certain Integrals	15
Meteorological Observations on Ben Nevis	50
Uniformity of Size of Pages of Transactions, &c.	5
Wave-length Tables of the Spectra of the Elements	10
Action of Light upon Dyed Colours	5
Formation of Haloids from Pure Materials	20
Isomeric Naphthalene Derivatives	30
Electrolytic Quantitative Analysis	40
Erratic Blocks	10
Palæozoic Phyllopoda	5
Photographs of Geological Interest (renewed)	10
Shell-bearing Deposits at Clava, &c.	10
Eurypterids of the Pentland Hills	3
New Sections of Stonesfield Slate	50
Exploration of Calf Hole Cave	10
Investigation of a Coral Reef by Boring and Sounding	10
Nature and Probable Age of High-level Flint-drifts	10
Examination of the Locality where the Cetiosaurus in the Oxford Museum was found	20
Table at the Zoological Station, Naples	100
Table at the Biological Laboratory, Plymouth (renewed)	20
Zoology, Botany, and Geology of the Irish Sea (partly renewed)	40
Zoology and Botany of the West India Islands	50
Index of Genera and Species of Animals	50
Climatology of Tropical Africa	5
Exploration of Hadramout	50
Calibration and Comparison of Measuring Instruments	50
Anthropometric Measurements in Schools	5
Lake Village at Glastonbury	30
Exploration of a Kitchen-midden at Hastings	10
Ethnographical Survey	30
Physiological Applications of the Phonograph	25
Corresponding Societies	30
Mathematical Tables (unexpended balance)	
	£1093

SECTION D.

BIOLOGY.

Opening Address by Prof. I. Bayley Balfour, M.A., M.D., F.R.S., President of the Section.

The prospect of visiting Oxford to-day has, I am sure, been to all of us a pleasant one, and we who are specially interested in biology have looked forward to our meeting at this time with the distinguished members of the Oxford Biological School. But as we gather here there will, I think, be present to the minds of all of us a thought of one member of that school, whom we had hoped to meet, who is recently gone from it in the prime of his intellectual life. By the death of George John Romanes biological science is bereft of one of its foremost expositors, Oxford is deprived too soon of one whose mental power was yet in its zenith, and each one of us who knew him cannot but feel a deep sense of personal loss; and we shall in our meeting here sadly miss the man brimming with a geniality which robbed differences of their difficulty and charmed away bitterness from those controversies in which he revelled. This is not the occasion upon which to dwell on his character, his merits, or his work. We must all, I think, have appreciated the graceful accuracy with which these were sketched in the pages of Nature by one of his colleagues; but under the shadow, as we are here, of his recent death, I believe I give utterance to feelings every one of you would wish expressed in paying this passing tribute to his memory from the chair of the Section of the Association devoted to the subject of his life-work.

I cannot open the business of the Section without referring to the fact that its organisation appears to be variable, like the objects of its study. It has changed its constitution more than any other Section of the Association, under influences partly from within in the strength of its elements, partly from without in the local circumstances of its meetings. At its origin it was the Section of botany, zoology, anatomy, and physiology; in the following year anatomy and physiology became a new Section, E, only after some years to merge again in the original one. Then a partition was tried—a physiology department and an anthropology department were formed within Section D; but the Montreal meeting saw anthropology as Section H of the Association, and physiology again an integral portion of Section D. This year, as you are aware, physiology—I must be careful to say animal physiology—has again become a definite Section—I. Whether or no the habit thus acquired through the environment of Oxford will be so permanent as to be transmitted and appear at future meetings of the Association is a problem upon which I refrain from speculating; my reason for mentioning this matter at all is to point out that, as in previous devolutions of subjects from Section D, animal physiology is the only physiology which is concerned. It was part of the original proposal that plant physiology should form a portion of the province of Section I. To this the botanical members of Section D are unable to assent. We all readily admit that the development within recent years of our knowledge of plant-life is entirely in the direction of bringing to light fundamental similarities between the vital processes in plants and in animals. To no one do we owe more in this sphere of investigation than to two of the distinguished botanists from Germany whom we are glad to welcome at this meeting—Profs. Pfeffer and Strasburger. And we fully reciprocate the desire for mutual comment and criticism implied in the suggestion of combination. But allowing these as grounds for the conjoint treatment of the physiology of plants and animals in one section, what we botanists feel is that we are a compact body of workers in a science the boundaries of which it is at present not difficult to define, and that to divorce physiology from morphology and other branches of botany would tend to loosen our cohesion, would be to go against the current of our progress, and would take all the vitality from our discussions. To have papers on plant physiology dealt with in Section I, whilst those on other botanical subjects were dealt with in Section D, would be not merely an extremely inconvenient arrangement, from causes inherent in the subjects themselves, but would strike at that fraternity and spirit of camaraderie amongst those treading the same path of science, the promotion of which is the chief, if not the only, function the British Association now fulfils. At the outset, therefore, of our meetings, I wish to make it known that papers and discussions on all botanical subjects will take place in Section D.

And now I pass to the special topic upon which I am to address you. In selecting it I have followed the lead of those of my predecessors in this chair who have used the opportunity to discuss a practical subject. Forestry, about which I purpose to speak, is a branch of applied science to which, in this country, but little attention has been given by any class of the community. By scientific men it has been practically ignored. Yet it is a division of Rural Economy which ought to be the basis of a large national industry.

There are no intrinsic circumstances in the country to prevent our growing trees as a profitable crop for timber as well as our neighbours. On the contrary, Great Britain is specially well adapted for tree-growing. We have woodlands of fine trees, grown after traditional rule-of-thumb methods, abundant in many districts. The beauty of an English landscape lies in its trees and its pastures. Nowhere in the world, probably, are to be found finer specimens of tree-growth. As arboriculturists we are unrivalled. But the growing of trees for effect and in plantations is a very different matter from their cultivation on scientific principles, for the purpose of yielding profitable crops. This is sylviculture. The guiding lines of the two methods of culture are by no means the same—nay, they may be opposed; and it is the sylvicultural aspect of the science of forestry which has hitherto been neglected in this country. The recognition of this is no new thing. But within recent years it has attracted considerable public attention, as the importance of wood cultivation in our national life has been more realised; and although various proposals have been put forward, and some little effort made for the purpose of remedying the admittedly unsatisfactory state of forestry practice, there has been so far no great result. I attribute this in great measure to the apathy of scientific men, especially botanists, and I am convinced that until they devote attention to forestry the great issues involved in it will not be rightly appreciated in the country.

It is not the first time the subject has been before this Section. I find that in 1885, at the Aberdeen meeting, a committee was appointed by it to consider "whether the condition of our forests and woodlands might not be improved by the establishment of a forest-school." The good intention of the promoters was not fulfilled, however. The committee did not meet.

In the first instance, let me briefly refer to the national economic features of forests as they affect us.

There are two aspects from which forests are of importance to a country—firstly, as a source of timber and fuel; secondly, on account of their hygienic and climatic influences.

With regard to the latter, it is a popular notion that trees exercise considerable influence upon atmospheric conditions, but it is only within recent years, and as the result of long experimental research in Switzerland, France, Austria, Germany, and other areas where forestry is practised at a high level of excellence, and also in the United States, that any sufficient data have been forthcoming to form a basis of scientific conclusion upon so important a matter. Although many points are still far from clear, the evidence goes to show that the direct influence of tree-growth upon climate is no mere superstition. Stated in the most general terms, it is proved that forests improve the soil drainage, and thereby modify miasmatic conditions; whilst, like all green plants, trees exercise, through the process of carbon-assimilation, a purifying effect upon the air, the existence of the increased quantity of ozone often claimed for the vicinity of forests is not yet established; by opposing obstacles to air currents, forests prevent the dissemination of dust particles with their contingent germs; they reduce the extremes of temperature of the air; they increase the relative humidity of the air and the precipitation in rainfall, and they protect and control the waterflow from the soil.

To us these effects do not appeal with the same force that they do in continental areas. Our insular and geographical position renders us in a measure independent of them. The data for these continental results, it must be remembered, are derived from large forest areas such as do not exist here. For this country I know of no experimental evidence on the subject. As, however, the effects of forest influence are felt mainly in local modifications of climatic conditions, we are not justified in regarding the conclusions that have been reached as inapplicable to Britain. No little interest attaches, therefore, to a statement based upon these continental observations to which Dr. Nisbet has recently done well to call attention—that, "where the rainfall is over forty inches it is undesirable to increase the forest area." The significance of this dictum, if it be established, to Britain, dependent so largely upon her agriculture, is evident. Wet years, unfavourable to farm crops, are, under existing conditions, more numerous than favourable dry ones, and any extensive tree-planting in agricultural areas might therefore prove disastrous. But I may here emphasise the point that, whilst for the growing of specimen trees we may agree with Evelyn when he says, "If I were to make choice of the place or the tree, it should be such as grows in the best cow-pasture, or upland meadow, where the mould is rich and sweet," yet the harvest which scientific sylviculture reaps comes from land unsuited to agriculture, which would otherwise lie barren and waste, and therefore schemes for the afforestation of such areas in non-agricultural districts need not be prejudiced by the prospect of an increased local rainfall. At the same time we must not fail to learn the obvious lesson that afforestation is not, as some suppose, a simple matter of employment of labour, but that it involves the consideration of weighty scientific problems.

Forests, as a source of fuel, have not the direct importance to this country, rich as it is in coal-supply, that they have in States less favoured, but their economic importance to us as a source of timber needs no comment. There are no means available through which to estimate the annual output of timber from our plantations, but indirectly we can gauge the insufficiency of our woodlands to supply the timber necessities of the country by reference to the returns showing the amount and value of forest produce annually imported. This has been steadily increasing until in 1893 its value exceeded eighteen million pounds. Of course a considerable proportion of the materials thus imported could not in any circumstances be produced in Britain. But, after allowing a liberal discount for these, there remains a large bill which we pay for produce, no small portion of which could be furnished at home. No one would suggest that in the limited and densely populated area of Great Britain timber-trees of kinds suiting our climate could be grown sufficient to supply all our demands; that would be impossible. But few would venture to deny that we could do very much better for ourselves than we do, and that our labour payments abroad might be materially reduced. It is admitted that well-grown home timber is, of its kind, equal to, if not superior in quality to, that which is imported; it is surely, then, legitimate to expect that a large supply of well-grown timber would enable us to hold the market to a much larger extent than is presently the case, and that we might be very much less dependent than we are upon the surplus timber of other nations.

The importance of this to the country is increased by the consideration of the continued appreciation of timber. There is abundant evidence forthcoming to indicate that the present rate of timber consumption of the world is in excess of the present reproduction in the forests of the great timber supplying countries, and with the persistence of existing conditions we would appear to be within measurable distance of timber famine. Experience, too, teaches that we may expect not a diminution but rather an increase in consumption. No doubt as civilisation advances the discoveries of science will, as they have done in the past, enable us to substitute in many ways for the naturally produced wood other substances prepared by manufacture; but this saving in some directions has been, and will probably continue to be, counterbalanced by greater utilisation in others—witness, for example, the enormous development within recent years of the wood-pulp industry abroad, and consider the prospect opened up by the manufacture of wood silk which is now being begun in Britain.

That the possibility of forest exhaustion is no chimera should be evident to anyone conversant with current timber literature. Taking North Europe, for instance:—In Norway, "raw timber is yearly becoming more expensive and more difficult to obtain." To Sweden, "pitch pine long beams are taken from America, suitable ones of sufficient size and quality being unobtainable now in Sweden." In Scandinavia, the virgin forests, "excepting such as are specially reserved by the Government in the districts where mills are situated, are almost exhausted." In Russia, the Riga "supply of oak is exhausted." These sentences, culled within the past few weeks from trade journals, show that this is a more pertinent question than some would suppose. In Sweden, which, it is remarkable, is actually importing logs from America, the situation is regarded as so serious that proposals are on foot for the imposition of a tax upon exported timber for the purpose of raising a fund for replanting denuded areas. But it is not only in North European countries that there are signs of the giving out of timber forests. As they fail the demand upon Canadian and American stocks increases, and when we look at these Canada "shows signs of beginning to find it hard to continue her voluminous exports to Europe, and at the same time send sufficient supplies to the United States." But the most striking evidence is that furnished by the chief of the United States department of forestry, in his official report for the year 1892, in which he says: "While there are still enormous quantities of virgin timber standing, the supply is not inexhaustible. Even were we to assume on every acre a stand of 10,000 feet B.M. of saw timber—a most extravagant average—we would, with our present consumption, have hardly one hundred years of supply in sight, the time it takes to grow a tree to a satisfactory log size. Certain kinds of supplies are beginning to give out. Even the white pine resources, which a few years ago seemed so great that to attempt an accurate estimate of them was deemed too difficult an undertaking, have, since then, become reduced to such small proportions that the end of the whole supply in both Canada and the United States is now plainly in view."

It must be owned that there are those who do not regard the suggestion of forest exhaustion as a serious one. They argue that the prophecy is no new one, and yet we are none the worse off than we have been; that failing supply from one source it has always been possible to tap another, and so it will probably continue; and then the period when exhaustion is likely to take place is so far off, there is ample time for the growth of new forests to replace those being cut. No doubt there is time. But this is just the kernel of the whole forestry question. With proper conservancy of forest areas, the application of scientific principles to the recuperation of areas recklessly denuded, and the afforestation of barren and waste lands, timber sufficient to meet a greater demand than is now made could be produced. This is the aim of scientific forestry, and it is to secure this that those who have given attention to the subject are working, conceiving it to be a duty of this generation to hand down to its successors a heritage no less valuable than that which it received.

With an acreage of wooded land amounting to only 4 per cent. of their total area, Great Britain and Ireland possess a smaller proportion so covered than any other European country. Denmark comes near with only about 5 per cent., in France the percentage rises to 15, in Norway and Germany to 25, in Austria-Hungary to 30, whilst in Sweden the amount is over 40 per cent. The United States is estimated to have about 25 per cent. These figures do not, however, give a fair basis of comparison of the amount of timber area in Great Britain with other countries, inasmuch as in the continental lands the bulk of the woodlands is true forest, whilst a large part of the area included in the British return is merely pleasure ground, and another large portion is only plantation; of real forest the area is extremely limited. It is not surprising, then, that we are not able to furnish ourselves with an adequate supply of timber. But although there is so little land under wood, there are thousands of acres unsuited for any other crop, and these for reasons I have already indicated, it is desirable to have planted. How to have this accomplished, and how to secure that woodlands already existing shall be tended so as to produce a maximum result, giving a profitable return, are the problems we wish to see solved.

It will conduce to appreciation of the question if I briefly discuss the causes which have been active in developing the present condition of woodlands in Britain, and in bringing about the disparity between it and other countries in respect of woodland area.

State ownership of continental forests will probably occur to most people as the reason for the difference in area just pointed out. This is true with, however, some qualification. In consequence of the circumstances of their situation continental States have been compelled to recognise the national economic importance of forests. This they have done, not so much by the creation of State ownership in vast forests as by the organisation of a State department of forestry and a State system of forestry education. It is altogether a mistake to suppose, as is often the case, that the whole or even a large part of the forests on the continent belong to the respective States. The amount of State-owned forest is surprisingly small. Fernow gives it in Germany as about 33 per cent. of the whole forest area; in Scandinavia 15 to 20 per cent., in France some 10 per cent., in Switzerland 4 per cent., whilst in Italy it is not 2 per cent. The bulk of the forest is in the hands of private owners or corporate bodies, subject, though apparently not always, to some control or limitation by the State. But the example of the States in the management of their own woods, their readiness to give advice through their officials, and the education which is carefully provided for those concerned in forestry work, have resulted in those privately-owned forests being as well managed as those of the State. It is important to make clear this distinction, because it shows that a State system of conservancy and supervision of forestry is quite compatible with large private ownership in forests, and that efficient sylviculture upon a large scale is not inseparable from State ownership.

But someone may say, "We, too, have State forests!" Yes, but it is almost absurd to mention them in the same sentence with those of the continent for any part they play at present in connection with forestry in Britain. The nine thousand acres at Windsor are mainly covered with specimen trees. Of the twenty-five thousand acres in the Forest of Dean, a portion is supposed to be cultivated for a profitable crop, but appears to result in an annual deficit. The New Forest, with its sixty-three thousand acres of soil-area, affords us one of the most interesting object-lessons, showing the triumph of sentiment over common-sense, that the country affords. Its history is well enough known, and I need only remind you that Parliament has decreed the major part of it to persist as a barren waste, whilst in the remainder, which is covered with trees, the practice of forestry is prohibited, so that slowly the whole is going to wreck and ruin. This illustrates the value to us of State forests! In the days of the "wooden walls" the dockyards obtained valuable timber from them, but now their large area is, one may say, of no State service whatever as forest, if one excepts a small portion of Windsor Forest recently attached for instruction purposes to Coopers Hill College. There can be no question that if the State had set an example of scientific forestry in even a portion of these areas, the practice of sylviculture now throughout the country would have been very different.

I need not dwell on the fact that the conditions of land tenure in the country have exercised an important influence upon the extent of wood-planting in the country; and they must always do so. "The oak scorns to grow except on free land" is a saw that sums up pithily the relationship between land-laws and woodlands in England. Copyholders could hardly be expected to plant much timber when the lord of the manor claimed the crop; and I believe it is possible in some counties to trace the boundaries of copyholds by the entire absence of trees on one side of a line and the luxuriant growth on the opposite side. The intricacies of entail and the fact that life-renters had themselves to bear the expense of planting, except where necessary for shelter, without prospect of seeing a return for the outlay, must have operated prejudicially to an increase in woodlands. Happily since 1882 in England, and by an Act of last year for Scotland, the last-mentioned restriction upon tree-planting is removed.

Nor shall I pause over the question of game, which has been at once the origin and the destruction of forests in Britain. Not that it is an unimportant element. But the instinctive love of sport in the British race is proof against all argument of utility, and the needs of sport will always be a barrier, as they have been in the past, to the planting of large areas well adapted for timber-growing. It cannot well be otherwise. Landowners can hardly be expected to forego large and immediate game-rents for what appear the long-delayed, even though possibly greater, profits of timber cultivation. In this case the inevitable must be accepted. Nevertheless, there are large areas, the game-rent of which is infinitesimal for their acreage, which might be planted.

The most potent factors in bringing about the present condition of our woodlands are probably to be looked for in the nature of the crop itself and in the want of appreciation of its character manifested by landowners; in a word, in a want of knowledge of the principles of scientific forestry. Forestry is handicapped as compared with agriculture by the fact that the crop cannot be reaped within the year. The owner who plants and incurs the initial expense of stock, fencing, and perhaps draining, may after some years secure intermediate return from thinnings, but it will rarely happen that he reaps the final yield at maturity of the crop he has sown; it will fall to his successor. It is this planting for posterity that makes demands upon the landowner to which he is unequal. Hence it comes about that woodlands, beyond what may be requisite in the way of cover plantation and for shelter, are often regarded as expensive luxuries, and, in the time of high agricultural values, landowners have even grubbed out trees to make way for annual crops yielding an immediate return. But scientific tree-growing for profit does not consist in the covering of soil-area indiscriminately with trees, without definite system and relation of its part one to the other. Just as the farmer has to plan his rotations on a definite system with reference to his total acreage, so in properly managed timber-growing must areas be arranged in such a way that some part of the forest will be yielding annually its final return of mature crop, and cleared areas will by a natural process of regeneration replenish themselves without recourse to the expensive operation of planting being necessary. Scientifically worked a forest area of suitable land, of which there is such abundance in Britain, should be capable of yielding an annual net revenue as regular as that obtainable by any other form of soil cultivation.

It is nevertheless frequently urged as a reason for not growing timber that wood will not pay in Britain. A landowner will tell you he has acres of land which do not return him more than half-a-crown, and if it would pay better he would be glad to put them under timber, but he does not believe it would; and he will point to rates on woodlands which must be paid although no crop is being reaped. He will demonstrate that there is no market for home timber, which seldom fetches its value, and that there is a prejudice against it which increases the difficulty of any attempt to compete with the foreigner.

There is some reason in the latter part of this contention. The wood-grower in Britain has I think just cause for complaint when he finds his produce not only handicapped by preferential transport rates to foreign timber, as has been the case in the past, but that it is also disparaged by exclusion from, or admission only under conditions to, competition with foreign timber by the terms of building specifications. It is said to be the common practice of architects and others to bar home timber in this way, and the Government itself has not been guiltless in the matter. The Post Office form of tender a couple of years ago for telegraph poles entirely cut out native produce from competition, and the conditions of contract framed by the Board of Agriculture under the Land Improvements Act were until recently almost prohibitive to home timber. These latter are now modified, but whether or not the Post Office still boycotts home produce I cannot say.

However it is come about—and there are no doubt various effective causes—this undervaluing of home-grown timber is quite unreasonable, and the slur cast upon it is undeserved, so far as its quality is concerned. At the same time, there is ground for saying that the difficulties, occasioned in this and other ways, of disposing of home timber at renumerative prices are due to causes not altogether beyond the control of landowners who grow timber.

It is generally admitted that with a more regular and certain supply, as well as a larger amount in different districts, home timber would have a better chance of holding its own in the market. This is just what scientific forestry would bring about. Given a systematic cultivation of forest on scientific principles of rotation, and the conditions are prepared for a steady output of timber by annual cut, as well as for a supply of raw material for utilisation in the manufacture of the many subsidiary products derivable from forest growth. If landowners would only provide such supplies, they would alter altogether, and to their own advantage, the conditions under which they dispose of so much of their home wood. The timber merchant who now travels hither and thither over the country picking up small lots where they may occur for transport to his, probably distant, mills, at a cost which eats a big hole in the value of the trees to the landowner, would find it worth his while—and for that matter, it would be worth while for the landowner himself—to erect in the vicinity of the forest, mills for the purpose of converting and preparing the timber, and to put up machinery for the extraction of useful products from the waste wood. In such conditions a steady market could be created in which the advantage would lie altogether on the side of the home-grown article, and materials, the débris of the forest, now thrown aside as useless, would be turned to account to the greater benefit of the landowner. Encouragement, too, would be given to the establishment of local industries dependent upon forest growth, through which fresh outlets for forest produce would be provided.

The amount of profit returnable from timber cultivation must of course vary with the circumstances of the area in each case, but in comparing values it must always be borne in mind that timber land is land which can yield no agricultural rent. The official statistics relating to continental State forests show us the result of forestry on a large scale, and it is interesting to note how, under what we must believe to be an equally efficient system of forestry management, the net revenue from the several areas differs greatly. Thus from its two million acres of forest area Bavaria draws a little over five shillings per acre per annum; Wurtemburg, with nearly half a million acres, gets a return of about eleven shillings; and Saxony, with a somewhat less area, receives over seventeen shillings per acre per annum. For this country we have no such figures. Our State forests result in a loss. It is unfortunate, too, that no returns are available from private forests and woodlands, either in Britain or abroad. Estimates of possible profits in this country we have abundantly, but solid figures of expenditure and receipt in relation to timber growing there are none. By the favour of Mr. Munro-Ferguson, M.P., who, as a landowner, exhibits a most enlightened spirit in regard to forestry, I am, however, able to cite the case of a pine and larch wood at Novar, in Ross-shire, twenty-four acres in extent, which was clean cut in 1883, and gives instructive figures. After sixty-one years' growth on land similar to that which in the neighbourhood yields a grazing rent of from one to two shillings per acre, it is found to have yielded a net sum equal to a revenue to the landlord during the whole period of its growth of over nine shillings per acre per annum, or an increased value of quite seven shillings per acre per annum. Although it refers to only a single wood of limited extent, this return shows how profitable waste land may become under timber. No doubt from the estates of other of our landlords who own extensive woodlands, where, if there is not the highest scientific forestry, there is certainly good wood management, results of an equally instructive kind could be obtained—many would be better; and it is much to be desired in the interest of forestry that they should be made known as an object-lesson to those who doubt the profit of tree-growing.

But in the return I quote from there is another interesting point which I must not fail to note. During the period of growth of the wood, the outlay upon labour in connection with it amounted to a sum equal to an expenditure of over thirty-one shillings per acre per annum. That is to say, this sum was distributed in wages to the people of the neighbourhood. This exhibits the benefits brought in the train of forestry, which are no less important to the community at large than is the profit of the crop to the landowner. The scientific treatment of woodlands and cultivation of forests for profit on a proper scale involve the employment of a considerable amount of labour, much of it at a time when there is little else doing in country districts, not only in the actual tending of the forest area, but in the manipulation and subsequent preparation of the timber, and in the manufacture of the numerous by-products obtainable from it. In these days of congestion in cities the importance of the development of such an industry which can provide occupation in the country, and thus may aid in restraining migration to the towns, has not escaped notice, and it cannot be too often or too greatly emphasised.

The influences, to which we have just given attention, that have prevailed in bringing about the present limited area of woodland in Britain are, it will be seen, not wholly irremovable, nor are the obstacles to betterment insurmountable. And the question we have now to discuss is—How are these to be counteracted and overcome? By what means is it possible to bring forestry in Britain more in line with that of other nations? At the outset I would say that if forestry is to be established on a sound commercial basis, the only one on which it should rest, if we are to have a national home-timber industry, it can only be when the issues involved are more fully realised than they are nowadays. As in agricultural practice failure can only be obviated by the application of scientific methods in farm cultivation, so is it with forestry. To become a profitable industry it must be practised as an applied science, and not as an empirical routine.

We live beyond the days when it would be possible to apply the autocratic remedy for want of woodlands introduced in Scotland by the Jacobean statute, which compelled the landlords not only to plant wood and forest and make hedges, but also enjoined them under penalties to see that each of the tenants planted one tree for every marke of land. Nor, indeed, can much be said of the success of the compulsion. And I do not imagine anything could be gained nowadays by the method adopted in Scotland in the middle of last century by the "Select Society," as it was called, of offering a premium to farmers who planted the most trees within a specified time. That such processes were deemed necessary is interesting as showing how old standing has been the recognition of the want of sufficient woodland area in the country. At the present time there are those who would reverse, as it were, the process of the old statute, and who look to the acquisition by the State of large areas of waste land, and their afforestation by it, for the solution of this forestry question. It is, no doubt, a wise policy which encourages private enterprise to deal with the details of industries, and only invokes State aid as a directive and controlling force when its need can be clearly shown. That there is need for State aid in the case of forestry I do not deny, but it is not required to the extent just mentioned.

I unhesitatingly say that the State ought to treat the forest areas now in its possession in a reasonable and scientific manner, instead of leaving them as objects for the finger of scientific scorn. They might be made, in part at least, models of the best forestry practice. It is no use to dispute with the sentiment and taste which have prevailed in making the New Forest what it now is, and it is hopeless to expect an unanimous verdict as to the destiny of State woods and upon the method of treatment to which they should be subject. We have had recently, in the lively discussion regarding the management of Epping Forest, an illustration of how large is the number of people who have views upon the subject of the management of woodlands, and how the majority of them, if they had their way, would, through ignorance, defeat the very object they desire to accomplish. We must be prepared in any proposal for utilisation of State forests to incur the opposition of those who regard all scientific handling of woods as vandalism, although I do not know that forestry in itself involves a want of recognition of the beautiful, or dulls the feelings which a sylvan landscape invokes in the minds of those in touch with nature. It is allowed there are areas in our State forests sacred by many memories, possessing a grandeur and picturesqueness with which no hand, whether of forester or landscapist, would venture to meddle. But, on the other hand, there are tracts which without damage to the natural beauty, and without depriving in any sensible degree the people of their privileges of recreation they prize so much, might be and should be dealt with as forest cultivated on scientific principles. These might serve as instruction areas, showing all that is best for the information of foresters. The creation of some such experimental teaching stations in State forests is one of the essentials for forestry in Britain. I would go further and say that the area of State ownership should be increased to the extent of the establishment of forest stations, of an acreage sufficient to allow of a satisfactory rotation, in other parts of the country as centres of instruction. There have been, as you are aware, proposals for the afforestation of some of the three million and more acres of waste land in the Highlands of Scotland capable of growing timber, and we await with some interest the report of the Deer Forest Commission, which has taken evidence on the subject. If, as has been suggested may be possible, afforestation is attempted through any system of State-aided planting, an opportunity would be afforded for securing what would be of so much advantage to the country. Beyond this system of model experimental stations, the State ownership of forest in Britain does not seem to me to be necessary in the cause of forestry.

Replying recently to Sir John Lubbock in the House of Commons, the President of the Board of Agriculture, after recounting what his Board is now doing for forestry in Britain, added: "I shall always be glad to receive and to consider any suggestion for the increase of sound technical knowledge on this subject." Well, now, I have a suggestion to make. In a practical science like forestry "an increase of sound technical knowledge" can only be possible when facilities for practical instruction are provided. I would, therefore, ask the President to consider what I have just said with regard to State forest experimental areas. These cannot, of course, be created by a stroke of the pen, but the initiative for their formation would naturally come from the Board of Agriculture. It is possible that, with betterment in forestry practice, landowners might be found who would be willing to devote portions of their land for the purposes of instruction, following for forestry the noble example of Sir John Lawes in his work for agriculture; and everyone interested in forestry must hope this may be so. But when the State has already in its hands the means through which a large national industry can be fostered, it is surely incumbent on it to utilise them for the purpose. And mark you, in asking for this, one does not make a large demand upon the Treasury. The whole could be done at no ultimate cost, for the profits from the areas could unquestionably more than repay any outlay incurred upon them.

The true solution of the forestry question in Britain is to be found in the diffusion of accurate knowledge of forest science. The landowner has to be convinced that through scientific forestry a sound and profitable investment for his capital is to be found in woodlands; the factor or land agent must be instructed in the scientific principles of tree-growing for profit to enable him to secure a steady income to the landowner from his invested capital; and the working forester has to be taught methods of cultivation based upon science, by which his faith in traditional practice, when it is, as is so often the case, unscientific, may be dispelled. It is through education alone that we can arrive at improved forestry.

This was recognised by the Select Committee upon Forestry of the House of Commons in its report in 1887, which performed a very valuable service by its exposure of the prevalent ignorance of scientific forestry and of well-known facts of tree-cultivation amongst those professedly engaged in its practice and study—an ignorance the continued existence of which manifests itself in some of the writings in current periodicals. The remedy it suggested of a State Forest Board, including representatives of science and of bodies interested in forestry, charged with the superintendence of the formation of forest schools and the preparation of forest literature, was superseded by the later institution of the Board of Agriculture, in which were absorbed such functions in regard to forestry as the Government of the day accepted. We are so accustomed to anomalies in our administrative system that the discovery of an additional one hardly surprises us. Yet it is difficult to understand why it is that a Board which deals with subjects so essentially based on science as does the Board of Agriculture should not have on its staff scientific men representative of the fields of science within its purview. But I do not know that either agriculture or forestry is so represented. It seems odd that this Board should be dependent for scientific advice upon outsiders, and now that it proposes to undertake the responsibility of the publication of a journal which, I take it, will be a means for the circulation of accurate information upon scientific questions, I do not see how its functions can be adequately performed without scientific help from within. No one of us would expect to see, either to-day or to-morrow, in this country a Board of Agriculture with an organisation like that of the similar department in the United States, which excites our admiration by the excellence of the practical information it circulates. But there is a wide interval between the completeness of the American department and the incompleteness of ours; and if I may make another suggestion to the President of the Board of Agriculture, I would ask him to consider whether it would not strengthen the Board in the discharge of its rapidly growing functions if it had competent scientific advisers upon its staff. Such a man for forestry would, I believe, do much for "the increase of sound technical knowledge" in Britain, and promote to no little extent its interests.

Since 1887 we have made some advances along the lines of improved literature and of teaching pointed out by the Select Committee as those by which reform could be accomplished.

If one looks at the literature available up to a recent period to anyone desirous of learning something about forestry, one need feel little surprise at the ignorance which prevailed. It was alike meagre in amount and deficient in quality, consisting chiefly of the records of empirical practice of men who had had no scientific training. It is satisfactory to note that these are now being replaced by works having some pretension to scientific method and accuracy. From Coopers Hill there is issuing, more slowly than could be wished, Prof. Schlich's excellent "Manual of Forestry," and from his colleague Prof. Fisher we may, I believe, soon expect an important forestry book. You all know Prof. Marshall Ward's lucid little books on timber and plant-diseases, and we are promised immediately, under his editorship, a translation of Hartig's "Diseases of Trees," by Prof. Somerville. A most valuable and interesting contribution to forestry literature is the book by Dr. Nisbet, recently issued from the Clarendon Press, containing the lectures he delivered in the University of Oxford during the past year; and to his marvellous energy we shall owe the new edition of "Brown's Forester," which is shortly to appear, and an English version of Hartig's "Text-Book" for foresters. All this activity shows an increasing interest in forestry, but it is only the beginning of a movement to make up for the preceding dearth. Botanists are greatly indebted to the Delegates of the Clarendon Press—and it is fitting I should here acknowledge the obligation—for the splendid series of standard foreign works on botany they have brought within the reach of English-speaking students, and which have done so much for the progress of botany in Britain. If we have now got beyond the stage of dependence in pure botany, we are far from it in scientific forestry, and I would hope that the Clarendon Press will add to its botanical series some of the standard foreign forestry books, and thus aid in the dissemination of the knowledge so essential to progress in the subject.

I must not omit to refer here to the excellent opportunity that is afforded for the circulation of scientific information by the new journal of the Board of Agriculture, of which intimation has recently been made, and it is to be hoped that forestry will find a place in it side by side with agriculture.

The attention paid to the teaching and study of forestry by continental States, their many schools and copious literature of forestry, make it remarkable that, apart altogether from the economic side, forestry as a subject of study and investigation has not been long ago introduced in some of our teaching centres. I think the Sibthorpian Chair of Rural Economy of the University of Oxford was for long the only one through which forestry was recognised as within the sphere of University education. So far the limited tenure of this chair, in its new dress, has been held by agriculturists—in their line the most distinguished men; but I should like to think that one may look forward to a time when forestry shall have its turn, if by that time it has not come about that it is otherwise provided for.

It was, however, only the necessities of India which, at a comparatively recent date, led to the first starting of forestry teaching in Britain, and then only at the cost of India, and for those destined to serve there as foresters. Coopers Hill College, the outcome of these, with its excellent equipment—including now, I believe, a slice of Windsor Forest for purposes of practical work—possesses the elements of a successful forestry school, and it has within recent years opened its doors to outsiders who may wish to learn forestry. But, so far as I am aware, it does not draw the young landowners of the country as it should do. Possibly the expense of the special education, which equals that of the universities without offering the advantages in other directions they afford, may be deterrent; but I am inclined to think that if the authorities made the fact better known that men other than foresters for India are admitted to the college, more would avail themselves of the opportunity.

Beyond this and some slight notice of forestry at agricultural colleges, there have been no facilities for forestry-teaching in Britain until within the last half-dozen years. I leave out of reckoning mere examining boards. Can we wonder, then, that there is a general want of intelligent appreciation of scientific forestry? Even now all that has resulted from the agitation in favour of more attention being given to this subject is—a lectureship on forestry in the University of Edinburgh, supported partly by the Board of Agriculture and partly by an endowment from subscriptions among landowners and others (and, I may mention here, forestry is now included as an optional subject in the university curriculum for an agricultural degree); a chair, or part of one, in the Royal College of Science at Newcastle, founded conjointly by the Board of Agriculture and the County Council; a course of instruction in science for practical foresters in the Royal Botanic Garden at Edinburgh, maintained by the Board of Agriculture; and a lecture course on forestry in the Glasgow and West of Scotland Technical Institute, similarly provided for. I must not omit to mention, too, the beginning, just made, by the Surveyors' Institute of the formation of a forestry museum in London, which should have an important educative influence. Little though it is, I think there is occasion for congratulation that even so much has been done to provide instruction, and I would have you note that in this education the different classes concerned with forestry are all recognised. Valuable as the teaching so being given is, it must have an effect in showing the need there is for more. In one way the teaching of all these bodies is incomplete, and must be imperfect, inasmuch as they have not the means for practical forestry work. Until this is provided, as I have indicated already, the teaching of forestry cannot be thoroughly carried out.

But, after all, what has been done in the way of supplying our wants in the way of teaching is nothing to what is required if forestry is to be adequately taught in Britain. Dr. Nisbet, who in his book already mentioned, has had the last say on this question, boldly states the requirements at six forestry chairs in universities, and four schools of practical sylviculture in the vicinity of forests. I do not think he puts the needs one whit too high. I should be even disposed to add to them, because I note he has omitted to take into account the claim of Wales, whence there has recently been a request for the establishment of forestry teaching.

But there are two questions strictly pertinent to this demand, which need answering if the proposals are to be brought within the sphere of practicability—firstly, whence are the funds to be obtained for this organisation; and, secondly, where are we to get the teachers?

Dr. Nisbet puts his hand in the Treasury pocket for the money—some five thousand pounds per annum—required by his scheme. I do not think many of us will be so sanguine as to expect the whole financial aid could be directly obtained in this way. But it may be, I think, of significance in regard to this to consider the sources from which money has been forthcoming for what has already been done. The Government, through the Board of Agriculture, has given most, the remainder has come from the County Councils and from private contributions.

There is no reason to suppose that the Board of Agriculture will be less willing in the future than it has been to aid in the establishing of forestry teaching in suitable centres; but its support from the limited funds—eight thousand pounds—at its disposal for educational purposes, is always given as a grant in aid, and is contingent upon evidence of local effort towards the end desired, which we must therefore look to in the first instance.

It is of no use to speculate upon the prospects of private munificence providing equipment in any centre. We may hope for it, but I do not think times are such as to lead us to expect large pecuniary aid from landowners. After vigorous effort amongst them, extending over some years, to secure an endowment for a chair of forestry in Edinburgh, a sum a little over two thousand pounds is all that has been raised.

But forestry is one of those subjects to the teaching of which we may be more sanguine of support from County Councils. It will always be a matter of regret to scientific men, and those interested in the industrial progress of the country, that the grand opportunity furnished by the fund dealt with under the Local Taxation Act (1890) was not taken more advantage of by the Government of the day. Distributed, even in part, through representative educational institutions, it could have provided equipment for technical education of the highest kind beyond our dreams. Thrown at the heads of the County Councils, before these bodies had had time to settle to their prescribed work, there has been, in the opinion of those well qualified to judge, no little waste. You could not create all at once the machinery requisite for the most efficacious expenditure of half a million of money on technical teaching. Much of the work done by these bodies is admirable. It is indeed surprising in the whole circumstances how efficiently technical instruction has been carried out, and no doubt it will improve. But it had a most extravagant start. It is difficult to trace, in the general returns of the technical education undertaken by the County Councils, the details of their work, and I have not been able to discover how far forestry has been treated as a subject of instruction. It has not, I think, been often included. But the example of Northumberland and Durham in respect of the Newcastle chair is one that gives encouragement for thinking that if the due importance of forestry to the community were made clear, County Councils, in districts favourable for forestry and its concomitant industries, might come forward with some of the financial support needed for the provision of the educational equipment.

It appears to me that whilst we must obtain from the Government the institution of sylvicultural areas for practical instruction, our best chance of success in acquiring the necessary endowment for the rest of the teaching lies in the line of combination between the Board of Agriculture and the County Councils, with, it may be, aid from private benefactors. But if we were to draw financial support from County Councils, or from private sources, we must as a first step towards this make known, more thoroughly than it is, the nature of the national interests involved. We must disabuse landowners, land agents, and practical foresters of the notion that forestry consists in the random sticking in of trees, which anyone, no matter how unskilled, may accomplish. We must bring home to the people's minds that in science is to be found the only sure guide to proper timber-growing, and that scientifically managed forests are alike a profit to the producer, a benefit to the community of the region in which they are reared, and a source of national wealth. Once we have got so far as to create this opinion, the funds for as extended a scheme of forestry education as may be necessary will, I venture to think, be forthcoming.

There is still the other question to answer—Whence are the teachers to come? This is, I think, fundamental. For, given a competent teacher, he will soon find opportunity for teaching. If to-morrow the whole or even a half of the chairs suggested by Dr. Nisbet as essential were founded, how should we meet the demand for men to fill them? We might, of course, draw upon the Indian Forest Service, but I do not know where you would find teachers in Britain. But if there is no prospect of such immediate requirement of teachers, that does not make the fact of their deficiency of any less moment. There is surely something wrong when men capable of giving scientific instruction in so important a practical subject are so scarce.

This is how it touches us botanists, and upon our shoulders I am disposed to throw the blame for the present outlook. We do not seem to have realised, except in relation to medicine, that modern botany has an outlet. Perhaps it has been the influence of medicine that has engendered this. We find chemists and physicists devoting their science to the furtherance of practical aims. Zoologists have applied theirs to the elucidation of problems bearing on the fishery industry, and we see in that monument to the ability and energy of Prof. Ray Lankester, the marine biological laboratory at Plymouth, an experimental station which, while it contributes to the nation's prosperity, serves at the same time as a home of pure research. But where is the practical outcome of modern botany? I must not overlook such brilliant work as that of Marshall Ward, full of purpose, and significant as it is to many large industries, nor that of Oliver in its bearings on horticulture. But it does seem to me that the general trend of botanical work in Britain is not utilitarian. Perhaps as good an illustration as could be given of the slight practical importance attached by the lay mind nowadays to botany is the fact that the Scottish Universities Commissioners have made it—though I must add it is bracketed with zoology—optional with mathematics for the degree in agriculture!

It is matter of history that its utilitarian side gave the first impetus to the scientific study of botany. The plant-world, as the source of products of economic value and drugs, attracted attention, and out of this grew, by natural development, the systematic study of plants. The whole teaching of botany was at the first, and continued for long to be, systematic and economic, and it was from this point of view that, the herbalist having become the physician, botany became so essential a branch of medical study. It is noteworthy that as an early practical outcome of the study came the establishment of botanic gardens, which, at their institution, were essentially what we would now style experimental stations, and contributed materially to the introduction and distribution of medicinal and economic plants, and to the trial of their products. If they are now in many instances simply appendages of teaching establishments, or mere pleasure-grounds, we at least in Britain are fortunate in possessing an unrivalled institution in the Royal Gardens at Kew, which still maintains, and under its present able Director has enormously developed, the old tradition of botanic gardens as a centre in our vast empire, through which botany renders scientific service to our national progress.

In Britain, consequent perhaps on our colonial and over-sea possessions, the systematic side of botany continued predominant long after morphological and physiological work had absorbed the attention of the majority of workers and made progress on the continent. Not that we were wanting in a share of such works, only it was overshadowed by the prevalent taxonomy, which in the hands of many no longer bore that relation to its useful applications which had in the first instance given it birth, and had become little more than a dry system of nomenclature.

The reaction of a quarter of a century ago, which we owe to the direct teaching of Sachs and De Bary and the influence of Darwin, many of us can remember; in it some who are here to-day had a share. Seldom I think is a revolution in method and ideas of teaching and study so rapidly brought about as it was in this instance. The morphological and physiological aspect of the subject infused a vitality into the botanical work which it much needed. The biological features of the plant-world replaced technical diagnosis and description as the aim of teachers and workers in this field of science. No weightier illustration of the timeliness of this change could be found than in the attitude of medicine. But a few years ago he would have been rash who would predict that botany would for long continue to be recognised as a part of university training essential to medical students. Its utility as ancillary to materia medica had lost point through the removal of pharmacy from the functions of the physician. But what do we see now? Not the exclusion of botany from the university curriculum of medical study, but the recognition to such an extent of the fundamental character of the problems of plant-life, that it is now introduced into the requirements of the colleges.

But if the old taxonomic teaching was stifled by its nomenclature, there is, it seems to me, a similar element of danger in our modern teaching, lest it be strangled by its terminology. The same causes are operative as of old. The same tendency to narrowing of the field of vision, which eventuates in mistaking the name for the thing, is apparent. With the ousting of taxonomy, and as the laboratory replaced the garden and museum, the compound microscope succeeded the hand-lens, and for the paraphernalia of the systematist came the stains, reagents, and apparatus of microscopical and experimental work as the equipment necessary for the study of plants, the inwards rather than the outwards of plants have come to form the bulk of the subject matter of our teaching, and we are concerned now more with the stone and mortar than with the general architecture and plan of the fabric; we are inclined to elaborate the minute details of a part at the expense of its relation to the whole organism, and discuss the technique of a function more in the light of an illustration of certain chemical and physical changes than as a vital phenomenon of importance to the plant and its surroundings. This mechanical attitude is quite a natural growth. It is a consequence of specialisation, and it is reflected in our research. But it must be counteracted if botany is in the future to be aught else than an academic study, as it was of old an elegant accomplishment. It has come about very much because of that want of recognition by botanists, to which I have already referred, of the natural outlets of their study—of their failure so far to see the lines through which the subject touches the national life. Modern botany has not yet found in this country its full application. It has not yet rendered the State service as it ought, and as was done by the taxonomic teaching it supplanted.

It is from this point of view that I wish to point out to you to-day that through forestry—and although I have particularly dealt with this branch of Rural Economy, what I say is equally true of horticulture and agriculture—modern botanical study should find a sphere of application by which it may contribute to our national well-being, and which would have a directive influence upon its teaching, taking it out of the groove in which it tends to run. What we botanists need to do in this connection is to teach and to study our subject from a wider platform than that of the mere details of individual form, and to encourage our pupils to study plant-life not merely in water-cultures in the laboratory, but in the broader aspects exhibited in the competitive field of nature.

If forestry is ever to thrive in Britain, botanists must lay the foundation for it in this way. We cannot expect to make our pupils foresters, nor can they yet get the practical instruction they require in Britain. In this we must depend yet a while on continental schools; the stream of continental migration, which needs no longer to flow in morphological and physiological channels, must now turn in the direction of forest schools. But we can so mould their studies and give bias to their work as will put them on the track of this practical subject. If we had only a few men so trained as competent foresters, and capable of teaching forestry, there would be an efficient corps with which to carry on the crusade against ignorance and indifference, the overcoming of which will be the prelude to the organisation of forestry schools and scientific sylviculture in Britain. The influence of the individual counts for much in a case like this. The advent of a capable man started forestry teaching in Scotland, which years of talk had not succeeded in doing. And so it will be elsewhere

I have endeavoured, thus briefly, to sketch the position, the needs, and the prospects of forestry in Britain. Its vast importance as a national question must sooner or later be recognised. It is a subject of growing interest. Its elements are complex, and it touches large social problems; but the whole question ultimately resolves itself into one of the application of science. To botanists we must look in the first instance for the propagation of the scientific knowledge upon which this large industry must rest. They must be the apostles of forestry. And forestry in turn will react upon their treatment of botany. Botany cannot thrive in a purely introspective atmosphere It can only live by keeping in touch with the national life, and the path by which it may at the present time best do this is that offered by forestry.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY CAPTAIN W. J. L. WHARTON, R.N., F.R.S., PRESIDENT OF THE SECTION.

YOU will not be surprised if, having called upon an hydrographer to preside over this Section, he takes for the subject of his review the Sea. Less apparently interesting, by reason of the uniformity of its surface, than the land which raises itself above the level of the waters, and with which the term geography is more generally associated, the ocean has, nevertheless, received much attention of later years. In Great Britain, especially, which has so long rested its position among the nations upon the wealth which our merchant fleets bring to its shores, and upon the facilities which the sea affords for communication with our numerous possessions all over the globe, investigation into the mysteries, whether of its ever moving surface or of its more hidden depths, has been particularly fascinating. I purpose, therefore, to attempt a brief survey of our present knowledge of its physical condition.

The very bulk of the ocean, as compared with that of the visible land, gives it an importance which is possessed by no other feature on the surface of our planet. Mr. John Murray, after a laborious computation, has shown that its cubical extent is probably about fourteen times that of the dry land. This statement appeals strongly to the imagination, and forms, perhaps, the most powerful argument in favour of the view, steadily gaining ground, that the great oceans have in the main existed in the form in which we now see them since the constituents of the earth settled down into their present condition.

When it is considered that the whole of the dry land would only fill up one-third of the Atlantic Ocean, the enormous disproportion of the two great divisions of land and sea becomes very apparent.

The most obvious phenomenon of the ocean is the constant horizontal movement of its surface waters, which in many parts take well-defined directions. These great ocean currents have now been studied for many years, and our knowledge of them is approaching a point beyond which it is doubtful whether we shall ever much advance, except in small details. For though, while indisputably the waters continually move in each great area in generally the same direction, the velocities vary, the limits of the different streams and drifts vary, mainly from the ever-varying force and direction of the winds.

After long hesitation and much argument, I think it may be now safely held that the prime motor of the surface currents is the wind. Not, by any means, the wind that may blow, and even persistently blow, over the portion of water that is moving, more or less rapidly, in any direction, but the great winds which blow generally from the same general quarter over vast areas. These, combined with deflection from the land, settle the main surface circulation.

I do not know if any of my hearers may have seen a very remarkable model, devised by Mr. Clayden, in which water disposed over an area shaped like the Atlantic, and sprinkled over with lycopodium dust to make movement apparent, was subjected to air impelled from various nozzles, representing the mean directions of the permanent winds. It dispelled the last doubt I held on the subject, as not only were the main currents reproduced, but the smaller effects and peculiarities of the Atlantic drifts were produced with surprising accuracy.

There is a small current, long shown on our charts, but which I had always regarded with suspicion. I refer to the stream which, after travelling from the Arctic Ocean southward along the east coast of Greenland, turns sharply round Cape Farewell to the northward into Davis Straits, where it again doubles sharply on itself to the southward. This is exhibited, in the model, in all its details, and is evidently caused by the pressure of the water forced by the mimic Gulf Stream into the Arctic region, where it has no escape except by this route, and is pressed against the land, round which it turns as soon as it can. This is, no doubt, the explanation of the real current.

The very remarkable winter equatorial current, which runs in a narrow belt eastwards, just north of the main stream travelling west, was also reproduced with extraordinary fidelity.

The winds, however, that are ordinarily considered permanent vary greatly, while in the monsoon areas the reversal of the currents caused by the opposite winds exercise a great influence on the movements of the water far beyond their own limits, and anything like a prediction of the precise direction and rate of an oceanic stream can never be expected.

The main facts, however, of the great currents can be most certainly and simply explained in this manner.

The trade winds are the prime motors. They cause a surface drift of no great velocity over large areas in the same general direction as that in which they blow. These drifts after meeting and combining their forces eventually impinge on the land.

They are diverted and concentrated and increase in speed. They either pour through passages between islands, as into the Caribbean Sea, are pressed up by the land, and escape by the only outlets possible—as, for example, the Strait of Florida, and form a great ocean current like the Gulf Stream—or, as in the case of the Agulhas current and the powerful stream which runs north along the Zanzibar coast, they are simply pressed up against and diverted by the land, and run along it with increased rapidity.

These rapid currents are eventually apparently lost in the oceans, but they in their turn originate movements of a slower character, which on again passing over shallow water or on meeting land develop once more into well-defined currents.

We find an analogous state of things on the western side of the Pacific, where the Japan current is produced in a similar manner.

The fact that on all western shores of the great oceans towards which the trade winds blow we find the strongest currents running along the coast, is almost enough of itself to prove the connection between them.

The westerly winds that prevail in higher northern and southern latitudes are next in order in producing great currents. From the shape of the land they in some cases take up and continue the circulation commenced by the trade winds; in others they themselves originate great movements of the water.

Compared to the great circulation from this source the effect of differences of temperature or of specific gravity is insignificant, though no doubt they play their part, especially in causing slow under-circulation, and in a greater degree the vertical mixing of the lower waters.

No drop of the ocean, even at its greatest depth, is ever for one moment at rest.

Dealing with minor points, the American officers of the Coast and Geodetic Survey have found after long and patient investigation that the velocity of the Gulf Stream in its initial and most marked part, the Strait of Florida, is greatly affected by the tide, varying as much as one-half its maximum rate during the twenty-four hours.

These American investigations are of greatest interest. They have extended over the whole area of the Caribbean Sea and its approaches, the Gulf of Mexico, and the Gulf Stream proper and its vicinity. In no other part of the ocean has observation of this detailed character been carried out, and they throw a great light on oceanic circulation. The *Blake*, the vessel specially fitted for the purpose, has during the several years in which she was employed on this work anchored in over 2000 fathoms water, or a depth of considerably more than two miles; a feat which would a short time ago have been deemed impossible.

One great point that has come out very strongly is the continual variation in the strength and direction of the currents, and the varying depths to which the surface current extend.

Eastward of the chain of the Windward Islands the general depth of the surface movement may be said to be about 100 fathoms, below which tidal influence is very distinct.

There is also a very plain backward flow of water, at depths which vary, caused by the submarine ridge which connects the Windward Chain of the West Indian Islands. These observations also generally support what I have already mentioned; that the velocity of a current depends on the strength of winds, possibly thousands of miles distant, which have given the original impetus to the water, and this, combined with tidal action when the current approaches or runs along a coast, will always cause uncertainty on the resultant velocity.

Dealing for yet another moment with the Gulf Stream, there are two points which have not been much dwelt upon, but which have a great effect on its power of bringing the modifying influence of its warm water as far as our shores.

The first is the prevention of its spreading, as it leaves the Strait of Florida, by the pressure of the portion of the equatorial current which, unable to get through the passages betweeen the Windward Islands, is diverted to the north of the Bahamas, and bears down on the eastward side of the Gulf Stream proper, compressing it between itself and the cold water flowing southward along the American coast, and at the same time adding to its forces and maintaining its high temperature.

The second is that by the time the Gulf Stream has lost its velocity as a current, in about the vicinity of the Bank of Newfoundland, it has arrived in the region of the westerly winds, that is of winds whose average direction is from west; whose influence, causing a surface drift somewhat comparable to that of the trade winds, bears the water onward to the British Islands and Norway. Without tnese prevailing westerly winds the warm water of the Gulf Stream would never reach these shores.

The depth to which the surface currents extend in other parts is little known. Direct observations on under-currents have been rare.

In the first place, it is not an easy observation to make. Apparatus has generally to be improvised. This has usually consisted of some form of flat surface lowered to the required depth, and suspended in the water by a buoy, which presents to the resistance of the upper stratum a very much smaller area than that of the surface below.

More perfect machines have been devised, notably, that used by the Americans in their West Indian experiments.

These, however, are delicate, and require so much care and experience in working, and so much time is wanted for such observations, that under the pressure of the more urgent requirements on surface movements in the interests of navigation very little has been done.

The *Challenger* made some observations on the depth of the equatorial current in mid-Atlantic, but they were not very conclusive for lack of suitable appliances. They, however, tended to show that below 100 fathoms there was but little current.

It has been calculated theoretically that winds blowing steadily in one direction with the ordinary force of the trade winds would in 100,000 years by friction between the particles put the whole of a mass of water 2000 fathoms deep, not otherwise influenced, into motion in that direction; but the direction and force of the trade winds are ever changing, and the actual strong currents of the ocean are not in the trade wind areas, but are the result of these drifts meeting one another and being compressed by the conformation of the land. We cannot, therefore, expect this theoretical effect to be realised.

One instance of the underrunning of one current by another is brought very plainly to our notice in the North Atlantic, to the east of the Great Banks of Newfoundland, where the icebergs borne by the Arctic current from Baffin Bay pursue their course to the southward across the Gulf Stream running eastward.

These great masses of ice, floating with seven-eighths of their volume under the surface, draw so much water that they are all but wholly influenced by the under-current. A large berg will have its bottom as much as six or seven hundred feet below the surface. The only reason that these bergs continue their journey southward is the action of the cold under current.

It was my good fortune to be ordered in 1872 to undertake a series of experiments of the currents and under-currents of the Dardanelles and Bosporus. They proved most interesting.

It was well known that a surface stream is almost continuously passing out of the Black Sea through the Bosporus into the Sea of Marmara, and again through the Dardanelles into the Mediterranean. Certain physicists, of whom Dr. W. Carpenter was one, were, however, of opinion that a return current would be found under the surface running in the opposite direction, and this I was enabled to demonstrate.

Though from the imperfection of our apparatus, which we had to devise on the spot, we were unable to exactly proportionate the quantities of water moving in the two directions, we found, whenever the surface current was rushing south-westward through these straits, that for a certain distance, from the bottom upwards, the water was in rapid motion in the opposite direction. It was an astonishing sight to behold the buoys which supported a wooden framework of 36 square feet area, lowered to depths from 100 to 240 feet tearing up the straits against a strong surface current of as much as three and four miles an hour. It was as perfect an ocular demonstration of a counter under-current as could be wished, and the Turks, who watched our proceedings with much suspicion, were strongly of opinion that the devil had a hand in it, and only the exhibition of the Sultan's firman saved us from interruption. In the investigation of these currents we found, as usual, that the wind was the most potent agent. Though the surface water from the Black Sea is almost fresh, and the bottom water of the heavy Mediterranean density of 1·027, it was found that when calm had prevailed the surface current slackened, and at times became nil, whilst the under-current responded by a similar slackening.

The ordinary condition of wind in the regions of the Black Sea and Sea of Marmara is that of a prevalent north-east wind. This causes a heaping up of the water on the south-west shores of those seas, precisely where the straits open, and the surface water therefore rapidly escapes.

These straits no doubt present abnormal characters, but, so far as surface currents are concerned, the long series of observations then made convinced me of the inadequacy of differences of specific gravity, which were here at a maximum, to cause any perceptible horizontal flow of water.

I have said that we were unable to define by direct observation the exact position of the dividing line between the opposing currents, but the rapid change in the specific gravity at a certain depth, which varied on different days, gave a strong indication that the currents changed at this point.

A Russian officer, Captain Makaroff, afterwards made similar experiments in the Bosporus, but with more perfect appliances, and he found that at the point where the specific gravity changed the currents also changed.

I have been anxious to obtain similar observations at the Straits of Babel Mandeb, the southern outlet of the Red Sea, where somewhat similar conditions prevail. Here the winds are governed by the monsoons. For half the year the wind blows from the north down the whole length of the sea, causing a surface flow outwards into the Gulf of Aden, and a general lowering of the whole level of the sea of about two feet. For the other half of the year the wind at the southern end of the sea is strong from the south-east, causing a surface set into the Red Sea, over which the general level of the water rises, while the northerly wind continues to blow throughout the northern half.

At either of these times I think it is highly probable that there is an under-current in the opposite direction to that at the surface, but unfortunately the sea disturbance is great and observations are very difficult.

Observations were, however, made by Captain W. U. Moore in H.M.S. *Penguin* in 1890, but at a time when the change of monsoon was taking place.

The result was peculiar, for it appeared that at a depth of about 360 feet the movement of the water was tidal, while the surface water was moving slowly in one direction—a result generally similar to that obtained by the Americans in the West Indies—but the direction of the tidal flow was directly opposite to what might have been expected, viz. the water ran in while the tide fell, and *vice versâ*.

More observations are, however, needed here before any certain conclusions can be formed.

The depth of the ocean is the next great feature which demands attention.

On this our knowledge is steadily, though slowly, increasing. The whole of it has been gained during the last fifty years.

Commenced by Sir James Ross, whose means were very small, but who nevertheless demonstrated that the so-called unfathomable ocean was certainly fathomable everywhere, the sounding of the ocean has continuously proceeded. The needs of submarine cables have constantly demanded knowledge in this particular, and the different cable companies have had a large share in ascertaining the facts.

Expeditions, whose main object has been to obtain soundings, have been sent out, Great Britain and the United States taking the first place; but most maritime nations have aided.

In the immediate past the additions have mainly been from the soundings which H.M. surveying ships continually take whenever on passage from one place to another, from the work of our cable companies, and from United States vessels.

We have, as a result, a very fair general knowledge of the prevailing depths in the Atlantic, but of the Indian and Pacific Oceans it is very fragmentary. We have enough to give us a general idea, but our requirements increase as years roll on. It is a vast task, and, it may be safely said, will never be completed; for we shall never be satisfied until we know the variations of level under the water as well as we know those on the dry land.

It is hopeless to do more than to briefly sketch the amount of our knowledge.

First, as to the greatest depths known. It is very remarkable, and from a geological point of view significant, that the very deepest parts of the ocean are not in or near their centres, but in all cases are very near land.

One hundred and ten miles outside the Kurile Islands, which stretch from the northern point of Japan to the north-east, the deepest sounding has been obtained of 4655 fathoms, or 27,930 feet. This appears to be in a deep depression, which runs parallel to the Kurile Islands and Japan; but its extent is unknown, and may be very large.

Seventy miles north of Porto Rico, in the West Indies, is the next deepest cast known, viz. 4561 fathoms, or 27,366 feet; not far inferior to the Pacific depth, but here the deep area must be comparatively small, as shallower soundings have been made at distances sixty miles north and east of it.

A similar depression has been sounded during the last few years west of the great range of the Andes, at a distance of fifty miles from the coast of Peru, where the greatest depth is 4175 fathoms.

Other isolated depths of over 4000 fathoms have been sounded in the Pacific. One between the Tonga or Friendly Islands of 4500 fathoms, one of 4478 fathoms near the Ladrones, and another of 4428 fathoms near Pylstaart Island, all in the Western Pacific. They all require further investigation to determine their extent.

With these few exceptions, the depth of the oceans, so far as yet known, nowhere comes up to 4000 fathoms, or four sea miles; but there can be little doubt that other similar hollows are yet to be found.

The sea with the greatest mean depth appears to be the vast Pacific, which covers 67 millions of the 188 millions of square miles composing the earth's surface.

Of these 188 millions, 137 millions are sea, so that the Pacific comprises just one-half of the water of the globe, and more than one-third of its whole area.

The Northern Pacific has been estimated by Mr. John Murray to have a mean depth of over 2500 fathoms, while the Southern Pacific is credited with a little under 2400 fathoms. These figures are based on a number of soundings which cannot be designated otherwise than very sparse.

To give an idea of what remains to be done, I will mention that in the eastern part of the Central Pacific there is an area of 10,500,000 square miles in which there are only seven soundings, whilst in a long strip crossing the whole North Pacific, which has an area of 2,800,000 square miles, there is no sounding at all. Nevertheless, while the approximate mean depth I am mentioning may be considerably altered as knowledge increases, we know enough to say that the Pacific is generally deeper than the other oceans. The immensity, both in bulk and area, of this great mass of water, is difficult to realise; but it may assist us when we realise that the whole of the land on the globe above water level, if shovelled into the Pacific, would only fill one-seventh of it.

The Indian Ocean, with an area of 25,000,000 square miles, has a mean depth, according to Mr. Murray, of a little over

2000 fathoms. This also is estimated from a very insufficient number of soundings.

The Atlantic, by far the best sounded ocean, has an area of 31,000,000 square miles, with a mean depth of about 2200 fathoms.

The temperature of this huge mass of water is an interesting point.

The temperature of the surface is most important to us, as it is largely on it that the climates of the different parts of the world depend. This is comparatively easy to ascertain. We know so much about it that we are not likely to improve on it for many years. We are quite able to understand why countries in the same latitude differ so widely in their respective mean temperatures; why fogs prevail in certain localities more than others; and how it comes about that others are subject to tempestuous storms.

On the latter point nothing has come out plainer from recent discussion than the fact that areas where great differences of surface temperature of the sea prevail are those in which storms are generated.

It is a matter of observation that in the region south of Nova Scotia and Newfoundland many of the storms which travel over the Atlantic to this country have their rise.

An examination of surface temperature shows that in this region the variations are excessive, not only from the juxtaposition of the warm water of the Gulf Stream and the cold water of the Arctic current flowing southward inside of it, but in the Gulf Stream itself, which is composed of streaks of warm and colder water, between which differences of as much as 20° F. exist.

The same conditions exist south of the Cape of Good Hope, another well-known birthplace of storms. Here the Agulhas current of about 70° F. diverted by the land pours into the mass of water to the southward, colder by some 25°, and the meeting-place is well known as most tempestuous.

South-east of the Rio de la Plata is another stormy area, and here we find the same abnormal variations in surface temperature.

Yet another is found off the north-east coast of Japan with the same conditions.

These differences are brought about by the mingling of water carried either by the flowing of a powerful current turned by the land into a mass of water of different temperature, as is the case off the Cape of Good Hope, or by the uprising of lower strata of cooler water through a shallow surface stream, as appears to be the case in the Gulf Stream.

A remarkable point recently brought to light by the researches of Mr. John Murray in Scotch lochs is the effect of wind on the surface temperature. It has been observed that wind driving off a shore drifts the surface water before it. This water is replaced by the readiest means, that is to say, by water from below the surface rising to take its place. As the lower strata are in all cases cooler than the surface a lowering of the temperature results, and we find, in fact, that near all sea shores off which a steady wind blows the water is cooler than further to seaward.

This has an important bearing on coral growth, and explains why on all western coasts of the great continents off which the trade winds blow we find an almost absolute dearth of coral, while on the eastern coasts, on which warm currents impinge, reefs abound, the coral animal flourishing only in water above a certain temperature.

Observations of the temperature of the strata of water between the surface and bottom have been of late years obtained in many parts. Compared with the area of the oceans they are but few, but our knowledge steadily increases every year.

The subject of the vertical distribution of temperature has not yet been thoroughly investigated in the light of the whole of the information which we now possess, but Dr. Alex. Buchan has been for some time devoting his spare time to the task, and it is a heavy labour, for the data obtained here and there over the world by different ships of all maritime nations are very difficult to collect and to appraise, but I understand that before long we shall have the result, which will prove very interesting, in the last volume of the *Challenger* series.

It will readily be understood that observations on temperatures at great depths require great care. In the first place the thermometers must be most carefully manufactured. They must be subjected to rigorous tests, and they must be carefully handled during the operation. All observations are not of the same value, and the discussion, therefore, presents considerable difficulty and demands much discretion.

In the meantime we can state certain known facts.

We have learnt that the depth of the warm surface water is small.

In the equatorial current between Africa and South America, where the surface is of a temperature of 78°, at 100 fathoms it is only 55°, a difference of 23°, and a temperature of 40° is reached at 400 fathoms. In this region, so far as knowledge goes, the fall in temperature as we descend is most rapid, but generally speaking the same variations prevail everywhere.

In the tropical Pacific the temperature falls 32° from the surface, where it stands at 82°, to a depth of 200 fathoms, 40° being reached at from 500 to 600 fathoms below the surface.

Below the general depth of from 400 to 600 fathoms, the temperature decreases very slowly, but there is considerable variation in the absolute amount of it when we get to great depths in different parts of the ocean.

One of the most interesting facts that has been recognised is that in enclosed hollows of the ocean the bottom temperature is apparently much less than that of the stratum of water at a corresponding depth in the waters outside the submarine ridge that forms the enclosing walls, separating them from deeper areas beyond, and is, in all cases that have been observed, equal to that on the ridge. From this fact we are enabled to supplement our imperfect knowledge of depths, because if in a certain part of an ocean we find that the temperature at great depths is higher than we know exists at similar depths in waters apparently connected, we can feel certain that there is a submarine ridge which cuts off the bottom waters from moving along, and that the depth on this ridge is that at which is found the corresponding temperature in the outer waters. As a corollary we also assume that the movement of water at great depths is confined to an almost imperceptible movement, for if there was a motion that we could term, in the ordinary acceptation of the word, a current, it would infallibly surmount a ridge and pour over the other side, carrying its lower temperature with it.

A notable instance is the bottom temperature of the North Atlantic. This is nowhere below 35° F., although the depths are very great. But in the South Atlantic at a depth of only 2800 fathoms the bottom temperature is but a little above 32° F., and we are therefore convinced that somewhere between Africa and South America, though soundings do not yet show it, there must be a ridge at a depth of about 2000 fathoms.

We also come to the same conclusion with regard to the eastern and western portions of the South Atlantic, where similar differences prevail.

Again, the few temperatures that have been obtained in the eastern South Pacific show a considerable difference from those in the South Atlantic, and we are compelled to assume a ridge from the Falkland Islands to the Antarctic continent.

It is interesting that the investigation into the translation of the great seismic wave caused by the eruption of Krakatoa in 1883 led to a similar and entirely independent conclusion. The wave caused by the explosion in the Straits of Sunda reached Cape Horn, where by good chance a French meteorological expedition had erected an automatic tide gauge, but instead of one series of waves being marked on the paper there were two. A little consideration showed that the South Pole having directly interposed between Sunda Straits and Cape Horn, the waves diverted by the land about the pole would arrive from both sides.

One wave, however, made its appearance seven hours before the other.

Study showed that the earliest wave coincided in time with a wave travelling on the Pacific side of the pole, with a velocity due to the known depth, while the later wave must have been retarded in its journey *via* the South Atlantic. The only possible explanation is that the wave had been impeded by comparatively shallow water.

The evidence from bottom temperature was then unknown, and thus does one branch of investigation aid another.

In the Western Pacific the water is colder, a few bottom temperatures of a little over 33° F. having been found in the deep trough east of the Tonga Islands; but the North Pacific, though the deeper ocean—of enormous area and volume—is apparently again cut off by a submarine ridge. The north-western part of the Indian Ocean is for similar reasons assumed to be divided from the main body, the shallower water probably running from the Seychelles to the Maldive Islands.

Mr. Buchanan has pointed out why some parts of oceans, deep and vast though they be, are when cut off from communication with others warmer at the bottom.

Water can only sink through lower layers when it is the heavier, and though a warm surface current becomes from evaporation denser, its heat makes it specifically lighter than the strata below.

It is only when such a current parts gradually with its heat, as in travelling from tropical to temperate regions, that it sinks and slowly but surely carries its temperature with it, modifying the extreme natural cold of the bottom layers.

In the North Atlantic and Pacific we have such a condition. The great currents of the Gulf Stream and Japan current as they flow to the north sink, and in the course of ages have succeeded in raising the bottom temperature three or four degrees.

In the southern seas this influence is not at work, and, directly connected with the more open water round the South Pole, there is nothing to carry to the abysmal depths any heat to raise them from their normal low temperatures, due to the absence of any heating influence.

The ice masses round the South Pole have probably little or no effect on bottom temperature, as the fresher, though colder, water will not sink; and, as a matter of fact, warmer water is found at a few hundred fathoms than at the surface.

The lowest temperature ever obtained was by Sir John Ross in the Arctic Ocean in Davis Straits at a depth of 680 fathoms, when he recorded a reading of 25° F. This probably requires confirmation, as thermometers of those days were somewhat imperfect.

In the great oceans the greatest cold is found on the western side of the South Atlantic, where the thermometer stands at 32°·3 F., but temperatures of 29° F. have been obtained of recent years east of the Færoe Islands, north of the ridge which cuts off the deeper waters of the Arctic from the Atlantic.

Though scarcely within the limits of my subject, which is the sea itself, I must say a few words on the sea floor.

The researches carried on in the *Challenger* revealed that while for a certain distance from the continents the bottom is composed of terrestrial detritus, everywhere in deep water it is mainly composed of the skeletons or remains of skeletons of the minute animals that have lived in the water.

In comparatively small depths we find remains of many shells. As the depth increases to 500 fathoms or so we get mainly the calcareous shells of the globigerinæ which may be said to form by far the greater part of the oceanic floor.

In deeper water still, where pressure, combined with the action of the carbonic acid, has dissolved all calcareous matter, we find an impalpable mud with skeletons of the silicious radiolaria of countless forms of the greatest beauty and complexity. Deeper still, *i.e.* in water of—speaking generally—over 3000 fathoms, we find a reddish-coloured clayey mud, in which the only traces of recognisable organic remains are teeth of sharks and cetacea, many belonging to extinct species.

What the depths of these deposits may be is a subject of speculation. It may be that some day, as mechanical appliances are improved, we shall find means of boring, but up to the present no such operation has been attempted.

On the specific gravity of the water of the sea I can say but little except that it varies considerably.

It is not yet known for certainty how far the specific gravities observed at various points and depths remain appreciably constant.

In localities where evaporation is great, and other influences do not interfere, it is evident that the specific gravity of the surface will be high; a consideration which observations confirm, but there are many complications which require more observation before they can be resolved.

In some few places repeated observations permit deductions, but taking the sea as a whole we are yet very ignorant of the facts bearing on this point.

The waves which for ever disturb the surface of the sea demand much study.

The greatest of these, and the most regular, is the tidal wave. On this many powerful intellects have been brought to bear, but it still presents many unsolved anomalies.

Lord Kelvin and Prof. Darwin have demonstrated that the tidal movement is made up of many waves depending upon different functions of the moon and sun, some being semi-diurnal, some diurnal. The time of transit over the meridian, the declination of both bodies, create great variations; the changing distance and position of the moon and the position of her node, also have great effect, while the ever-varying direction and force of the winds, and the different pressure of the atmosphere play their part, and sometimes a very large part, on what is somewhat loosely known as the meteorological tide.

The amplitude of the oscillation of the water depending upon each of the astronomical functions varying for every point on the earth, the effect is that, each having a different period, the resulting mean movement of the water has most astonishing variations.

In some places there is but one apparent tide in the day; in others this phenomenon only occurs at particular periods of each lunation, while in the majority of cases it is the movements of each alternate tide only that appear to have much to do with one another.

Though after long observation made of the times and ranges of tides at any one spot, they can now be predicted with great accuracy, for that particular place, the meteorological tide excepted, by the method of harmonic analysis, perfected by Prof. G. Darwin, no one can yet say what the tide will be at any spot where observations have not been made.

Observations all over the world have now shown that there is no part where the tidal movement is so regular and simple as around the British Islands. This is more remarkable when it is found that the tides on the other side of the Atlantic—at Nova Scotia, for instance—are very complicated.

The minor tides, which in most parts of the world, when combined in one direction, amount to a very considerable fraction of the principal lunar and solar tides, and consequently greatly increase or diminish their effects, are in Great Britain so insignificant that their influence is trifling; but why this should be, I have never yet found anyone to explain.

Nevertheless there are many very curious points about our tides which are plainly caused by interference, or, in other words, by the meeting of two tidal waves arriving from opposite directions, or from the rebound of the tidal waves from other coasts.

This effect, also, it has been so far found impossible to predict without observation. On our southern coasts, for instance; in the western part the tide rises about 15 feet, but as it travels eastward the range becomes less and less until, about Poole, it reaches a minimum of 6 feet. Farther east again it increases to Hastings, where the range is 24 feet. Yet farther east it again gradually diminishes. This is due to the reflection from the French coast, which brings another wave which either superposes itself upon, or reduces the effect of, the main tide advancing up the English Channel; but the details of such reflection are so complex that no one could forecast them without more knowledge than we possess.

There can be little doubt that to this cause, reflection, is mainly due the variations in the amount of mean range of tide which are found on many coasts at different parts; and as these reflected waves may arrive from great distances, and be many in number, we may cease to wonder at the extraordinary differences in range of tide which prevail, though it will be understood that this is wholly separate from the varying heights of each successive tide, or of the tide at different parts of each lunation, or at different times of the year, which depend upon the astronomical influences.

The actual height of the tide in deep water is small, but on passing into shallow water when approaching a shore, and especially when rolling up a gulf of more or less funnel shape, it becomes increased by the retardation caused by friction, and by compression laterally, and hence the height of the tide on a coast affected by other causes is greater than in the open sea.

The oceanic tide wave is supposed to be from 2 to 3 feet in height, but as this has been assumed from observations made at small oceanic islands, where, although the magnifying influences mentioned are at a minimum, they still exist, we wait for precise information until some means of actually measuring the tide in deep water is devised.

The waves due to wind, though not so far-reaching in their effects as the majestic march of the tide wave, are phenomena which are more apparent to the traveller on the ocean.

The deep sea in a heavy gale presents, perhaps, the most impressive manifestation of the powers of nature which man can behold, and doubtless many of us have experienced feelings that may vary from awe and wonder to sheer delight, according to the temperament of each individual, at for the first time finding himself face to face with this magnificent sight, though I rather fear that discomfort is the prevailing feeling that many carry away.

The height to which storm waves may rise has never been very satisfactorily determined. Apart from the difficulty of the task and the small number of people who will address themselves to it when they have the chance, it is but rarely that any individual sees really abnormal waves, even though he may be at sea all his life.

Different heights for what are called maximum waves have been recorded, and they vary from 40 to 90 feet from crest to hollow.

All we can say is that the most probable figure is about 50 or 60 feet.

These great storm waves travel very far. In some cases they convey a warning, as their velocity always far exceeds that at which the storm is travelling. In others they intimate that a gale of which no more is seen has occurred somewhere—it may be many miles distant.

When they have travelled beyond the limits of the wind which raised them, they lose the steepness of slope which characterises them when under its influence, and become an undulation which is scarcely noticed when in deep water.

On approaching shallow water, however, they are again apparent, and the "rollers" that occur unperiodically at various places in latitudes where gales never occur would seem to be caused by such waves, originating in areas many thousands of miles distant. Such appears to be the origin of the well-known rollers at Ascension and St. Helena, where the rocky and exposed nature of the landing has caused this phenomenon to be especially noticed.

Other rollers are, however, undoubtedly due to earthquakes or volcanic eruptions occurring in the bed of the sea.

Many of the great and sudden waves which have caused devastation and great loss of life on the shores of western South America are referable to this cause.

Observations to enable the focus of such a disturbance to be traced have generally been lacking, but it is probable that where the wave has been large the point of origin has not been far distant.

In one notable instance the conditions were reversed. The point of origin was known, and the distance to which the resulting wave travelled could be fairly satisfactorily traced.

This was the great eruption in the Straits of Sunda, in August 1883, which locally resulted in the disappearance of the major part of the island of Krakatoa, and the loss of nearly 40,000 lives, on the neighbouring shores of Java and Sumatra, by the huge wave which devastated them.

The records of automatic tide gauges and the observations of individuals enabled the waves emanating from this disturbance to be followed to great distances. These waves were of great length, the crests arriving at intervals of about an hour, and moving with a velocity of about 350 miles an hour, were about that distance apart.

The waves recorded at Cape Horn were apparently undoubtedly due to the eruption, and travelled distances of 7500 miles and 7800 miles in their course on either side of the south polar land.

They were only five inches in height above mean level of the sea, while the waves recorded at places on the southern part of Africa, at a distance of about 5000 miles from the scene of the eruption, were from one to two feet high, the original long waves being of an unknown height, but probably did not exceed ten or fifteen feet.

No other such opportunity of testing the distances to which great waves may travel has ever occurred, and as such a catastrophe as gave rise to them could scarcely be repeated without similar loss of life, it may be hoped we shall not live to see another, interesting though the discussion of the numerous phenomena were.

The movement of the particles of water due to the tide wave extends to the bottom of the deepest water, and doubtless plays an important part in keeping up a constant motion in the abysses, but the depth to which the action of the surface waves originating in wind reach is still but little known by observation.

If, however, we study the contour of the bottom off the shores of land exposed to the full influence of the great oceans, we are struck by the very general rapid increase of slope after a depth of about 80 to 100 fathoms (500 to 600 feet) has been reached.

It appears very probable that this is connected with the depth to which wave action may extend, the fine particles brought down by rivers or washed from the land by the attrition of the breakers being distributed and gradually moved down the slope.

When we examine banks in the open sea we find, however, that there are a great many with a general depth of from 30 to 40 fathoms, and the question arises whether this may not be the general limit of the power of oceanic waves to cut down the mass acted upon when it is fairly friable.

The question has an interesting bearing on the subject of the ever-debated origin of coral atolls, for this is the general depth of many large lagoons; and granted that the sea can cut down land to this depth, we have at once an approach to the solution of the problem of the formation of bases of a suitable depth and material upon which the coral animal can commence operations.

This question also awaits more light, and I merely offer this remark as a suggestion.

It is, however, somewhat remarkable that in recent cases of volcanic islands piled up by submarine eruptions, they have all been more or less rapidly washed away, and are in process of further diminution under the surface.

Observations on the mean level of the sea show that it constantly varies, in some places more than others.

This subject has not yet been worked out.

In some localities it is plainly due to wind, as in the Red Sea, where the summer level is some two feet below that of winter, owing to the fact that in summer the wind blows down the whole length of the sea, and drives the water out.

In many places, as in the great estuary of the Rio de la Plata, the level is constantly varying with the direction of the winds, and the fluctuation due to this cause is greatly in excess of the tidal action.

In others the cause is not so clear.

At Sydney, New South Wales, Mr. Russell found that during eleven years the level was constantly falling at about an inch a year, but by the last accounts received it was again stationary.

The variations in the pressure of the atmosphere play an important part in changes of sea level.

A difference of one inch in the barometer has been shown to be followed by a difference of a foot in the mean level of the sea, and in parts of the world where the mean height of the barometer varies much with the seasons, and the tidal range is small, this effect is very marked.

Of any secular change in the level of the sea little is known. This can only be measured by comparison with the land, and it is a question which is the more unstable, the land or the water—probably the land, as it has been shown that the mass of the land is so trifling, compared with that of the ocean, that it would take a great deal to alter the general mean level of the latter.

All the points connected with the sea that I have had the honour of bringing before you form part of the daily observation of the marine surveyor when he has the chance, but I cannot refrain from also mentioning other duties, which are indeed in the present state of our knowledge and of the practical requirements of navigation the principal points to which he has to pay attention, as it may explain why our knowledge on so many interesting details still remains very imperfect.

Working as we do in the interests of the vast marine of Great Britain, the paramount necessity of good navigational charts requires that the production of such charts should be our principal aim.

It is difficult for a landsman and difficult even for a sailor who has never done such work to realise the time that is necessary to make a really complete marine survey. The most important part, the ascertainment of the depth, is done, so to speak, in the dark—that is to say, it is by touch and not by sight that we have to find the different elevations and depressions of the bottom of the sea.

In making a map of the land, an isolated rock or hill stands up like a beacon above the surrounding land, and is at once localised and marked, but a similar object under the sea can only be found by patient and long-continued sounding, and may very easily be missed.

When it is considered that marine surveying has only been seriously undertaken for about 100 years, with a very limited number of vessels, we shall, I think, understand how in the vast area of the waters, taking only those bordering the shores, many unsuspected dangers are yearly discovered.

Very, very few coasts have been minutely surveyed, and setting aside for a moment the great changes that take place off shores where sandbanks prevail, I should be sorry to say that even on our own coasts charts are perfect.

Yearly around Great Britain previously unknown rocks come to light, and if this is the case at home, what are we to think of the condition of charts of less known localities!

Our main efforts, therefore, are directed to the improvement of charts for safe navigation, and the time that can be spared to the elucidation of purely scientific problems is limited.

Nevertheless, the daily work of the surveyor is so intimately connected with these scientific problems that year by year, slowly but surely, we add to the accumulation of our knowledge of the sea.

SECTION G.

MECHANICAL SCIENCE.

OPENING ADDRESS BY PROF. A. B. W. KENNEDY, LL.D., F.R.S., M.INST.C.E., PRESIDENT OF THE SECTION.

The Critical Side of Mechanical Training.

WHILE there is no place in the kingdom more suitable for a meeting of the British Association than Oxford, and certainly no place in which it is more delightful for the members to meet, it is yet to be admitted that there are few places which have much less in common with the special work of Section G. Nominally devoted to "Mechanical Science," the Section has for many years specially dealt with those branches of applied mechanical science which constitute the business of the engineer—to quote the well-known words of the Royal Charter, "the art of directing the great sources of power in nature for the use and convenience of man." The association of this ancient and learned city with boilers and chimneys, with the noise and racket of ordinary mechanical work, seems an incongruity. Even the harmless necessary railway-station is kept as far away as possible, and the very river flows with a quiet dignity which seems to shut out the thought of anything more mechanical than the most ancient and futile of water-wheels.

Naturally enough these considerations did not tend to make more easy the choice of a subject for this address, and I have come very near to agreement with a recent critic in the opinion that presidential addresses are, in fact, almost immoral in the nature of things and fit only to be abolished. Finally I decided upon taking up my present subject, as being one in which the academic rather than the technical side of our work comes to the front, while at the same time it does not lead me out of lines in which I have been able, in past years, to work myself. It is now twenty years since I first took any active part in the scientific training of engineers, and five since I ceased to do so. I have often wished that I may have been at all as successful in teaching others at University College as I was, at the same time, in teaching myself. And since I have ceased to teach I seem to have been spending my time in finding out how much better I could now do it than was possible when I was actually engaged in it. This may be pure imagination on my part; there is nothing more easy, as we all know, than to suppose that we know best how to do the things that other people do, and not the things we have to do ourselves. Indeed, I understand that this is the recognised attitude of the really superior critic. If, however, in anything which I have to say, it should seem that I am finding fault with what is now being done, I may at least point out that most of all I am finding fault with myself for not having done right when I had the opportunity—an opportunity which can now never recur. Indeed, instead of the decorous and unobtrusive heading which I have given to this address, I might have indicated its general lines almost as truly if I had entitled it "The Regrets of an Emeritus Professor"—a name which, on a suitable binding, might even have secured it a sale at the railway bookstalls.

I know well—too well—that in the present congested state of the engineering profession there are many of us who do not like to bear the word "training" mentioned at all. It seems to mean merely the preparation of more lads to struggle for a share of work that is even now insufficient to go round. There is no doubt much to be said for this point of view. But against it one must remember that all other professions are equally full, and that, after all, lads must do something. The fault is surely that there are too many lads! If our population is really to go on increasing as rapidly as at present—the benefits of which Sections D, E, and F might have a joint meeting to discuss, if not to discover—it is inevitable that demands should come for more and more complete professional preparation. The man of exceptional parts will come to the front under any conditions, training or no training, in the future as in the past. But for ordinary men—that is for 99 per cent. of us—it is essential that no advantage should be given to a rival in the fierce competition of life, and for them therefore it is of an importance hardly to be exaggerated to obtain the most complete and perfect training possible. At the same time, and on purely general grounds, it can hardly be denied that to raise the standard of our profession is indirectly to confer a benefit on the whole community. I hope, therefore, that in making certain suggestions about the training of engineers, it will not be thought that I am desirous of increasing their number, which is really an end as far as possible from my own wishes. Whether the number increases or stands still or falls off, it is of importance from every point of view that those who come forward should be as well prepared as possible. And even the most conservative of us are compelled to recognise that the standard required in engineers' offices now is enormously higher than it was thirty years ago. This may truly be either the cause or the effects of improved training, but in either case it has made the training itself a necessity.

The particular aspect of mechanical training of which I wish to speak is its critical side. I do not know how a man should be trained to be an inventor. I would not tell anyone if I did! To be a creator in mechanical matters—which, however, is a quite different thing,—is a faculty given only to a very few, and with them it is "born, not made." Many of us, however, without being either inventors or creators, have sufficient natural aptitude or inclination towards things mechanical to form a basis for the trainer or educator to work on, with some hope that he may be of service. About the sciences which should be taught to such men, or the methods of teaching them, about the extent and nature of their experience in shops or on works, I do not intend to speak. I shall confine myself to one aspect of the training only, an aspect which is perhaps not always sufficiently clearly kept in view—the aspect which I have just called the critical side of mechanical training.

An engineer is a man who is continually being called upon to make up his mind. It may be only as to the size of a bolt; it may be as to the type of a Forth Bridge; it may be as to the method of lighting a city; or only as to the details of a fire-grate. But, whatever it is, once it is settled it is decided irrevocably—it is translated into steel and iron and copper, and cannot be revoked by an Act passed in another session. The time given him in which to decide may be a day, or a month, or a year, but in any and every case (so far as my own experience goes) it is about one-tenth part of the time which he would like to have. It is only in rare cases that the decision is obvious—most often there are more courses open than even the most facile politician ever dreamt of. The matters are too complex to be dealt with mathematically or even physically; even if they were not, there are few engineers who would have the special capacity to handle them. Moreover, their solutions are seldom "unique." From this point of view, the whole use of college training, of workshop practice, of practical experience, is to provide the engineer later on with the means of critically examining each question as it comes up, of reviewing systematically the *pros* and *cons* of each method of dealing with it, of coming finally, rapidly and positively to some defensible decision, which may then be irrevocably carried out.

In the case of a problem in pure mathematics or physics, where only one right solution can exist, that solution is arrived at by the help of a thorough knowledge of the science in question—there is little room for the critical faculty except as to method—the result is either right or wrong. With our work, on the other hand, solutions of all problems except the very simplest—in other words, decisions on all points which present themselves—can be arrived at only by a process of criticism applied to the problems, to their statement, to their condition, to all their many possible solutions. The development of the necessary critical faculty should be one of the chief aims of every teacher and every student.

A scientific training cannot make a man an engineer. Perhaps it is impossible for anything to make a man an engineer unless he has grown that way from the beginning! But a scientific training may make him, or at least give him the possibility of making himself, a critic.

In the vigorous attempts which have been made to specialise the education of engineers very early, I am afraid that the idea of teaching *subjects* is sometimes too prominent, to the neglect of matters less obviously useful. It is, of course, one thing to know a subject from the examination point of view, and quite another to be able to think about it, and still another to be able to write about it. In particular, I have often regretted to find how little attention has been given to a matter which perhaps may be called literary rather than scientific, but which is all-important in criticism, I mean to the power of expression. It is not easy to overrate the importance to the engineer, as to other folk, of the power of saying clearly what he means, and of saying just what he means. I do not mean only of doing this for its own sake, but because if a man cannot say or write clearly what he means it is improbable that he can *think* clearly By the power of expression I do not mean, of course, the mere power of speaking fluently in public, a thing which appears physically impossible to some people; I mean rather the power of expression in writing, which carries with it clearness and consecutiveness of thought. It is difficult to know how this matter can be taught, but at least it can be insisted upon probably to a much greater extent than is commonly the case. A man requires to see clearly not only the exact thing which he wants to say, but the whole environment of that thing as it appears to him. Not only this, but he must see the whole environment of the same thing as it appears to the persons for whom he is writing, or to whom he is speaking. He has to see what they know about the matter, what they think, and what they think they know, and if he wishes to be really understood has got to do much more than merely write the thing he means. He has carefully to unwrite, if I may use the expression, the various things that other people will be certain to think that he means. For after all the great majority of people are very careless listeners and readers, and it is not for the small minority who are really exact in these matters that one has to write. Moreover, it is a great help to clearness of thought and expression to keep before one always an ideal audience of people who will certainly misunderstand every single sentence about which any misunderstanding is in any way possible, and some others as well.

In attempting to think out or to discuss any question, whether it be technical or non-technical—in fact as long only as it is non-political—the first necessity is probably a knowledge of the question itself; and not only this, but also a proper understanding of its whole environment. This knowledge must be of such a kind as to distinguish what parts of it are important, what parts of it are unimportant, what parts can be described in two sentences, and what others may require as many paragraphs; what parts affect the result but little, however large they seem; and which ones must be considered vital, although their very existence is difficult to discover. The faculty which enables a man to handle his knowledge in this fashion may be summed up in the single expression, "sense of proportion." Moreover, the knowledge, to be of real value, must be as totally free from prejudices and prepossessions as in the most rigorous branch of pure science, and as thoroughly imbued with a healthy spirit of scepticism.

One is accustomed to think of engineering work as mainly constructive. But after all it is quite as much critical. In almost every department of mechanical work there are half a dozen ways of solving any particular problem. In some fashion or other the engineer must be able to judge between these various methods, methods which are often very much alike, but each of which may possess certain particular advantages and certain particular drawbacks. The arithmetical criticism which merely counts the advantages and the drawbacks, and puts an equal number of the one against an equal number of the other, is common enough, but obviously useless. The very first necessity to the critic is that he should have what I have just called the sense of proportion, a sense which will enable him to distinguish mere academical objections from serious practical difficulties, which shall enable him to balance twenty advantages which can be enumerated on paper by one serious drawback which will exist in fact, which will enable him in fact to place molehills of experience against mountains of talk. It is perhaps a doubtful point how far this sense of proportion can be taught at all. No doubt it can only be built up upon some natural basis. I am sure that in engineering we all know men whose judgment as to whether it was advisable to take a particular course we would accept implicitly, because we know that it is based on large general criticism, in spite of the most elaborate and specious arguments against it set down on paper.

Any third-year student—not to go still further back—can criticise perfectly along certain very narrow lines, just as anyone can learn the rules of harmony and can write something in accordance with them which purports to be music. But after all the music may be music only in name, and the criticism may not be worth the paper it is written upon, however formal it may appear to be, unless the writer is thoroughly imbued with a sense of the proportionate value of the different points which he makes. To take the commonest possible case, I dare say we have all of us heard certain methods, mechanical, chemical, or other, stigmatised as totally wrong and absolutely useless because they contain certain easily provable errors I am sure, too, that most of us could give illustrations of cases in which this has has been said with the very greatest dogmatism when the errors of the impugned method are not one-tenth part as great as the equally unavoidable errors of observation in the most perfect method.

Probably the best special education in proportion which a man can have is a course of quantitative experimental work. I say *quantitative* with emphasis, as meaning something much more than mere qualitative work. Here, I think, comes in the usefulness of the engineering laboratory. We require that the training should be not only in absolute measurement, but in relative measurement, the latter being quite as important as the former. Many kinds of measurements stand more or less upon a level as a training of the faculties of observation in themselves, but no single kind of measurement is sufficient as a training in proportion. A year spent in calibrating thermometers or galvanometers might make an exceedingly accurate observer in a perticular line, but it would not give the observer a knowledge of what even constituted accuracy in other directions; for accuracy is a relative and not an absolute term. In most engineering matters the conditions are, unfortunately, of a most complex kind; so complex that our problems are incapable of any solution sufficiently exact to satisfy the mathematician or physicist. The temptation to treat these problems as the mathematician treats those with which he deals—namely, to alter the assumed conditions in order to get an exact solution—is a very strong one. I am afraid it is most strong often in those engineers who are the best mathematicians. It is a temptation, however, steadily to be resisted. We must assume our conditions to be what they actually are, and not what we should like them to be; and if we cannot obtain an exact solution of our problem with its actual conditions, so much the worse for us, not so much the worse for the conditions. Our first duty is generally to find out the conditions; if they are disadvantageous (in fact I mean, and not merely in the problem) to alter them if they can be altered, but not to ignore them because they are inconvenient. We have then to find out the extent to which the known conditions permit any exactness of solution at all, and, finally, we have to keep this in view as a measurement of the highest accuracy which is attainable. To work out certain branches of the problem with such minuteness as to give us apparently very much greater accuracy than this is not only useless, but is apt to be positively misleading, as giving an impression of an accuracy which has no real existence.

The relative value of accuracy in different sets of observations is in itself a matter in which a sense of proportion is wanted, and often very badly wanted. Where one has to measure half a dozen things of which two are very easily measured and the remaining four are only measurable with great difficulty, it is only human nature that we should spend our energies on getting extremely accurate results with the first two and roughly do our best with the others. It is very difficult under such circumstances to remember that the accuracy of the whole is not the accuracy of the best part of our work, but of the worst.

The extraordinary effect of a want of sense of proportion is nowhere better shown than in the absurd statements which are constantly made as to technical matters in public prospectuses, and the still more absurd statements made in those very numerous documents of a similar kind of which some of us see a great many, but which do not finally emerge into public view. Fortunes are apparently to be made by inventions which, although doubtless ingenious, yet only concern one way of doing a thing which could be done equally well in half a dozen other ways. Every one is expected to run after a piece of apparatus which is to save 50 per cent. of something, the total cost of that something, however, being so very small that nobody cares to save in it at all. I need hardly mention the all too common case where a contemplated saving of 10 per cent in the cost of a material works out yearly to an amount much more than equal to the whole cost of the original article.

I believe that experimental work in an engineering laboratory can educate this critical sense of proportion very admirably in a number of ways. In the first place, it directs quantitative work into very varied channels, and not along one particular line. Secondly, it compels the observer to combine a number of measurements in such a way that the relative importance of accuracy in each can be seen. In the case of an engine trial, for instance, the combined results are affected by the accuracy of measurements of the dimensions of the machine, by the apparatus and methods used for measuring the water, by the indicator, and by its springs, by the speed counter, by the thermometers, and so on. An error of 1 per cent. in counting the revolutions is just as important as an error of 1 per cent. in measuring the water, or in measuring the mean pressure. I am afraid that one could point to a good many cases in which this has been more or less forgotten. Then, by making a series of measurements all in absolute quantities, the relative importance of each quantity to the desired total result can be seen. Thus it will be found that changes in certain quantities affect the total result to a very small extent, while changes in others affect it very largely, so that not only is the accuracy with which different quantities can be determined very different, but also the same degree of accuracy is of very different importance according to the particular quantity to which it refers. Once it is found that a final result is exceedingly little affected by a particular set of changes, it ceases to be of importance to measure or observe those changes in any extremely minute way, and of course the reverse holds equally good. Finally, and this perhaps is the most important matter of all, measurements in such a laboratory are made to a great extent under the complicated conditions under which the actual final result has to be obtained in practical work. They are not made under the conditions which insure the greatest individual accuracy of each result.

It will be seen that throughout, but particularly in the two last points which I have mentioned, the work of an engineering laboratory is in intention and in essence different from that of a physical laboratory. The aim of the latter is to make its problems as simple as possible, to eliminate all disturbing elements or influences, and to obtain finally a result which possesses the highest degree of absolute accuracy. In most physical investigations the result aimed at is one in which practically absolute accuracy is attainable, although attainable only if infinite pains be taken to get it. It is the business of the physicist to control and modify his conditions, and to use only those which permit of the desired degree of accuracy being reached. In such investigations it sometimes becomes almost immoral to think of one condition as less important than another. Every disturbing condition must be either eliminated or completely allowed for. That method of making the experiment is the best which ensures the greatest possible accuracy in every part of the result. The business of the engineer, on the other hand, is to deal with physical problems under conditions which he can only very partially control, and the conditions are a part of his problem. He does not, for instance, experiment with a steam engine so made that it can work with a Carnot cycle. It is in the nature of the case that he must experiment with a much less perfect machine. In burning fuel he does not use apparatus especially made to absorb the whole heat of combustion, but in the nature of the case has to investigate the behaviour of apparatus in which a very large part of that heat is unavoidably wasted. So one might go on through an immense number of instances. Perhaps the whole matter may best be summed up by saying that in a physical laboratory the conditions of each experiment are under the control of the experimenter, and are subservient to the experiment itself. In an engineering laboratory the conditions form part of the experiment. However much more difficult or complicated they render it, they still unavoidably form part of it—an experiment under any other conditions, or with those conditions removed, would *ipso facto* be irrelevant.

A critical training in matters mechanical is, however, only too similar to the celebrated training of the Mississippi pilot which so nearly broke the heart of Mr. Mark Twain. Whenever the whole matter seems to be completely mastered from one point of view, it is only to find, with a little more experience, that from another point of view everything looks different, and the whole critique has to be started afresh. Machines cannot be finally criticised—that is to say, they cannot be pronounced good or bad—simply from results measurable in a laboratory. One wishes to use steam plant, for instance, by which as little coal shall be burnt as possible. But clearly it would be worth while to waste a certain amount of coal if a less economical machine would allow a larger saving in the cost of repairs. Or it might be worth while to use a machine in which a certain amount of extra power was obviously employed, if only by means of such a machine the cost of attendance could be measurably reduced. In fact, what may be summed up in the phrase the "worth-whileness" of economies, is in itself a matter upon which a whole paper might be written. Unfortunately, the latter points which I have mentioned are just such as cannot easily be measured in laboratory work, or, indeed, in any other way whatever, except by actually using the apparatus in question. All that can be said is that a careful training in the critical measurement of comparatively simple points fits a man more than anything else to gauge accurately the importance of such other matters as I have mentioned. No doubt there are many men in whom the critical faculty is insufficiently developed to allow them ever to be of use in these matters, but to those who are intellectually capable of the "higher criticism" it must be, I think, of inestimable benefit to have had a systematic training in the lower.

Is there, then, any general standpoint from which mechanical criticism can be directed? Certain points are obvious, but probably the whole matter cannot easily be generalised. A city has to be supplied with water; there are three requisites: that the water should be of proper quality, of sufficient quantity, and that it should be brought in at a reasonable cost. But in such a case the first two are so enormously more important than the third, that the ideal is comparatively simple (of course, this is quite a different thing from being simply reached). A city has to be supplied with electric light: the essential conditions are similar. But in this case there are so many qualities which are equally proper, and there are so many different ways of bringing it in in sufficient quantity, that the third point—namely, the cost—becomes especially important. A factory has to be driven by steam power: the amount of power that is wanted can be produced by so many different types of engine and boiler—all capable of approximately equal economy, and all claiming equal freedom from breakdowns—that the choice is a peculiarly difficult one from the critical point of view.

It seems almost impossible that a criticism on any one basis could meet all the three cases which I have supposed unless that basis were that the thing supplied should be the absolutely fittest, having regard to all the conditions of each case and the relative importance of each condition. Possibly in all cases we could get at some generalisation which would show us which was the absolutely fittest, if only the necessary data were in any way complete, which they very seldom are. Perhaps in one sentence we may say that that scheme, or system, or machine, will be the absolutely best in any particular case which will the longest survive and maintain its place in its particular environment. I cannot doubt that this development of Darwinian ideas in the world of the inorganic is a legitimate one. Of course the problem would be comparatively easy in each particular case if only the environment would stand still. It would even be comparatively easy if we knew how the environment was going to alter, but this we are unable to do. We only know that it certainly *will* change and will go on changing, and that therefore the things which we make now have not got to survive in the conditions in which we make them, but have got to survive through some new sets of conditions of which we know nothing. I do not think the difficulty is in any way met by the popular method of guessing at what will be wanted fifty years hence, which generally means simply guessing at something very big. It is of no use making our ships or our engines of a type which we choose to imagine will be that of fifty years hence. If we do they will be of no use to-day, and for that very reason they will not even be in existence, useful or other, at the end of the fifty years. Sufficiently sad illustrations of this will occur to everyone in very different directions. I hope I shall not be considered churlish in saying that I do not think that the men who have worked on this principle have really been far seeing, or have really brought us much forward. They have been men often of genius, often of great personal fascination, always of immense imagination. But they have proceeded by methods essentially opposed to anything like the gradual evolution which must occur in technical as it does in natural matters, and in too many cases the results of their labours have not even been giants, but only monsters.

As to what causes one thing to survive rather than another we can only speak very generally. Mere survival may come about by the accident of a peculiarly tough constitution. A few engines built in the time of James Watt are still to be found at work in our own day, but can no more be taken as the fittest type than some solitary megatherium would be who, having outlived all his contemporaries, was able in after ages to look down upon his pigmy and short-lived successors. Mere length of life in such a case may be a mere accident, and is not itself a proof of fitness. We have it thrown at us every now and then that our engines nowadays do not last like the old ones, as if the mere existence of a very old machine were a proof of its virtues. It is certainly a proof of the excellence of its construction—or, as one may say, of its constitution—and perhaps also of the very small amount of work it has done in proportion to its life and its dimensions.

It is sometimes, I am afraid, rather humiliating to have to remember that, to a very great extent, the question of the fittest, so far as it affects us, is a financial one. In manufacturing processes efficiency and economy tend to survival because they lead to decreased cost of production. In structures or other large permanent works those types tend to perpetuate themselves which require the least material—that is, in which the material used is disposed to the best advantage—and in which the outlay on labour is also smallest, assuming, of course, equal fitness in other respects. There is, no doubt, at present a tendency to dispute this altogether, and to treat all reductions in cost of labour as disadvantageous, unless, indeed, the labour be very highly skilled, in which case its remuneration must necessarily be brought down for the sake of equality! I imagine this tendency will last exactly as long as the faithful can get some other people to pay the increased cost, and will thereafter determine itself somewhat suddenly. It can no more stand in the way of natural progress in engineering matters than could the somewhat similar outcry against the introduction of machinery into manufactures two generations ago. It would be as wise to paint a generation of cats green, in the hope of compelling natural selection to work along new lines.

I think we may fairly assume, therefore, that efficiency and economy are both legitimate criteria as to ultimate fitness, and will remain so. Moreover, they are both matters in which measurements can be made, and as to which judgment can be guided by such measurements. But there are other characteristics, not directly measurable, by which we can in some degree form an opinion as to the ultimate fitness of things or processes.

One set of considerations which has great critical importance is summed up in the word *simplicity*. This does not mean fewness of parts. Reuleaux showed long ago that with machines there was in every case a practical minimum number of parts, any reduction below which was accompanied by serious practical drawbacks. Nor is real simplicity incompatible with considerable apparent complexity. The purpose of machines is becoming continually more complex, and simplicity must not be looked at as absolute, but only in its relation to a particular purpose. There are many very complex-looking pieces of apparatus in existence which work actually so directly along each of their many branch lines as to be in reality simple. I believe it almost always happens that the first attempt to carry out by a machine a new purpose is a very complicated one. It is only by the closest possible examination of the problem, the getting at its very essence, that the machine can be simplified, and this is a late and not an early stage of design. If a mechanical problem is really only soluble by exceedingly complicated apparatus, it generally becomes a question whether the solution is worth having. There is no impossibility in making a machine that will do anything. But the very simplest possible form of apparatus which would wash our hands for us in a suitable manner is probably so very complicated that for many years to come at least that operation will be performed by manual labour.

Very closely allied to simplicity is what I may call directness. In nearly all mechanical processes certain transformations are unavoidable. In many mechanical processes, as I have recently had occasion to mention, a very large number of transformations is at present practically unavoidable. I myself cannot help thinking that probably one of the most distinct signs of fitness is a reduced number of transformations, the bringing of the final and the initial stages as close together as possible, and cutting out altogether the apparently worthless middle processes. But any generalisation of this kind must be very cautiously handled; these apparently useless processes are no doubt in certain cases as indispensable as is the much abused middle-man in matters economic.

In a critical view of any case where similar results are aimed at by hand-work and by mechanical means, it is important to recognise that the similarity of result should very seldom become identity. In the first machine to do anything mechanically which has before been done by hand, the error is often made of trying to imitate the hand-work rigorously. The first sewing machines were, I believe, made to stitch in the same way as a seamstress. It was not until a form of stitch suitable for a machine, although unsuitable for hand, was devised that the sewing machine proved successful as a practical matter. In another but analogous line too you may remember that the first railway carriages were practically stage coaches put upon trucks, from which the present carriages have only very slowly been evolved.

The critic has also to remember that very often the attainment of some very unimportant point, or point of which the importance has been greatly exaggerated, is made the reason mechanically for very great complication. The question of proportion comes in here again, and it has to be considered in any particular case whether the academically perfect machine, which is also extremely complicated, is not inferior to the *almost* equally good machine which has been constructed in a practicable shape,—it almost always is so.

I have endeavoured in my remarks to indicate what appears to me to be the attitude of the engineer towards a very large portion of the work which comes into his hands. In order to deal with the work it is necessary for him first of all to have a certain definite knowledge of "things," that is to say, both of the various subjects which form part of the curricula of all technical schools, and of the further matters which form as it were his professional alphabet. These last he learns not from books or lectures as a student, but by example and attempt, as does an artist. Of this part of his training I have said nothing; it has been perhaps sufficiently talked about of late years, and there is little to say which I could have made interesting to a general gathering like this. I cannot leave it altogether, however, without dealing with one matter. Exceptional men are all-round mathematicians or physicists, still more exceptional men are both; but for ordinary folk the study of one side of mathematics or of a single branch of physics is the work of a lifetime. The engineer is bound to know his own profession, by hypothesis, and it is in itself no small matter. Yet in addition he must know some mathematics, some physics, some chemistry, even also some geology, if he is to take any high rank in it. It is, therefore, surely in the very nature of things impossible that he should be a great mathematician or a great physicist, or should devote as much study to those most fascinating sciences as if they themselves were the work of his life. Therefore I beseech my friends of Section A to do what they can to modify their natural attitude of superiority—even of contempt—towards us, especially when we are students. The young engineer—I speak as a member of the great majority of the ordinary kind—would probably never have chosen his profession if he had had special aptitude for mathematical work. Having chosen it, he has to look at mathematics simply as a tool, a means to an end, not an end in itself. I cannot myself see that this point of view is one disrespectful to the parent of all the sciences, and I am confirmed by the knowledge that one or two of the greatest mathematicians in the country are of the same opinion and have the courage to act on it—with infinitely beneficial results to the young men they have to deal with. But I know that to mathematicians in general—the physicists are not so bad—the very name of engineering student is odious, indicating only a man who wilfully refuses to make mathematics his "first subject," and who therefore deserves neither consideration nor quarter, to whom it is privilege sufficient that he should be allowed to pick up such crumbs as he can digest from a table prepared for his betters. I humbly protest that we deserve better treatment. It is no doubt a great misfortune to us that we cannot afford to spend our training-time preparing for examinations, and that we have been compelled to choose for our future a career in which mathematics plays only a secondary part. It is our further misfortune that we have to solve twenty real live problems, each demanding a real live answer, for every single one which otherwise we would have worked out on paper. Perhaps it is also our misfortune—or it may be only our thickheadedness—to believe that in consequence of this we are quite able to judge for ourselves what units it is most convenient for us to work in, what nomenclature satisfies our requirements, and that we are as capable of getting our "*g*'s" in their right places as even some of our distinguished critics. But this is the end of the nineteenth century; philanthropy fills our breasts. May not our misfortunes call out some pity and not alone contempt? In spite of solemn warnings which I have lately received in the press against the monstrous idea that a presidential address should contain any individual opinions, I venture to repeat here what I had lately an opportunity of saying before a Royal Commission, that in cases where a University or University College takes in hand the preparation of engineers (and I hope that such cases will grow in number) they should provide for them special training in mathematics, and probably also in physics, distinct from the general training in these subjects most suitable for Degrees. I say this with the full knowledge that I may be accused of wishing to degrade the purity of scientific work, and, at the same time, with the full knowledge that I have no such wish. On the contrary, this special training is the only means by which the rank and file of us will ever know any mathematics at all. And I can say from my own knowledge that, if only we can be made what I may call mathematically articulate beings, we shall be able to repay the kindness by placing before the man of pure science problem after problem of transcendent difficulty, of immense interest, and having no single drawback whatever except that its solution may really be "useful"; and, after all, this need not be brought too prominently under his notice.

This digression has turned out a long one. I have only further to say that my main object in this address has been to indicate, as well as I could, the general attitude which the engineer must of necessity take up towards much of his work,—the point of view from which he must look at it. I shall be extremely glad if anything which I have said should cause this attitude, this,—this point of view,—to be more clearly kept in mind in the period of training than probably has been hitherto the case.

SECTION H.

ANTHROPOLOGY.

Opening Address by Sir W. H. Flower, K.C.B., LL.D., Sc.D., F.R.S., President of the Section.

It is not usual for the President of a Section of this Association to think it necessary to give any explanation of the nature of the subjects brought under its cognisance, or to emphasise their importance among other branches of study; but so general is the ignorance, or at all events vagueness of information, among otherwise well-instructed persons, that I will ask your permission to devote the short time accorded to me before the actual work of the Section begins to giving some account of the history and present position of the study of Anthropology in this country, and especially to indicate what this Association has done in the past, and is still doing, to promote it.

It is only ten years since the Section in which we are now taking part acquired a definite and assured position in the organisation of the Association. The subject, of course, existed long before that time, and was also recognised by the Association, though with singular vicissitudes of fortune and position. It first appeared officially in 1846, when the "Ethnological sub-Section of Section D" (then called "Zoology and Botany") was constituted. This lasted till 1851, when Geography parted company from Geology, with which it had been previously associated in Section C, and became Section E, under the title of "Geography and Ethnology." In 1866 Section D changed its name to "Biology," with Physiology and Anthropology (the first occurrence of this word in our official proceedings) as separate "Departments"; but the latter does not seem to have regained its definite footing as a branch of Biological Science until three years later (1869), when Section E, dropping Ethnology from its title, henceforward became Geography alone. The Department for the first two years (1869 and 1870) was conducted under the title of Ethnology, but in 1871 it resumed the name of Anthropology, given it in 1866, and it flourished to such an extent, attracting so many papers and such large audiences, that it was finally constituted into a distinct Section, to which the letter H was assigned, and which had its first session at the memorable meeting at Montreal, exactly ten years ago, under the fitting and auspicious presidency of Dr. E. B. Tylor.

The history of the gradual recognition of Anthropology as a distinct subject by this Association is an epitome of the history of its gradual growth, and the gradual recognition of its position among other sciences in the world at large, a process still in operation and still far from complete. Although the word Anthropology had certainly existed, but used in a different sense, it was not till well into the middle of the present century that it, or any other word, had been thought of to designate collectively the scattered fragments of various kinds of knowledge bearing upon the natural history of man, which were beginning to be collected from so many diverse sources. Indeed, as I have once before upon a similar occasion remarked, one of the great difficulties with regard to making Anthropology a special subject of study, and devoting a special organisation to its promotion, is the multifarious nature of the knowledge comprehended under the title. This very ambition, which endeavours to include such an extensive range of subjects, ramifying in all directions, illustrating and receiving light from so many other sciences, appears often to overleap itself, and give a looseness and indefiniteness to the aims of the individual or the institution proposing to cultivate it. The old term Ethnology, or the study of peoples or races, has a limited and definite meaning. It treats of the resemblances and modifications of the different groups of the human species in their relations to each other, but Anthropology, as now understood, has a far wider scope. It treats of mankind as a whole. It investigates his origin and his relations to the rest of the universe. It invokes the aid of the sciences of zoology, comparative anatomy and physiology, in its attempts to estimate the distinctions and resemblances between man and his nearest allies, and in fixing his place in the scale of living beings. In endeavouring to investigate the origin and antiquity of man, geology must lend its assistance to determine the comparative ages of the strata in which the evidences of his existence are found, and researches into his early history soon trench upon totally different branches of knowledge. In tracing the progress of the race from its most primitive condition, the characteristics of its physical structure and relations with the lower animals are soon left behind, and it is upon evidence of a kind peculiar to the human species, and by which man is so preeminently distinguished from all other living beings, that our conclusions mainly rest. The study of the works of our earliest known forefathers—"prehistoric archæology" as it is commonly called—is now almost a science by itself. It investigates the origin of all human culture, endeavours to trace to their common beginning the sources of our arts, customs, and history. The difficulty is, what to include and where to stop; as, though the term prehistoric may roughly indicate an artificial line between the province of the anthropologist and that which more legitimately belongs to the archæologist, the antiquary and the historian, it is perfectly evident that the studies of the one pass insensibly into those of the others. Knowledge of the origin and development of particular existing customs throws immense light upon their real nature and importance; and conversely, it is often only from a profound acquaintance with the present or comparatively modern manifestations of culture that we are able to interpret the slight indications afforded us by the scanty remains of primitive civilisation.

It is considerations such as these that have caused the gradual introduction of the term Anthropology as a substitute for Ethnology—a change which I have traced in the history of this Association, and which is seen in other organisations for the cultivation of our science.

The first general association for the study of man in this country was founded in 1843, under the name of the "Ethnological Society" (three years therefore, before the Ethnological sub-Section of Section D of this Association). It did excellent work for many years under that title, but partly from personal considerations, and partly from a desire to undertake a wider and somewhat different field of research another and in some senses a rival society, which adopted the name of "Anthropological," was founded in 1863. For some years these existed side by side, each representing in its most active supporters different schools of the science. This arrangement naturally involved a waste of strength, and it was felt that the interests of the subject would be promoted by an amalgamation of the two societies. Many difficulties, chiefly, as is usual in such cases, of a personal nature, had to be overcome, one of the principal being the selection of a name for the united society. It was generally felt that "Anthropological" would be most appropriate, but the members of the old Ethnological Society could not bring themselves absolutely to sink the fact of their priority of existence, and all that they had done for science for so many years, by merging their society into that of their younger and active rivals: so after much discussion a compromise was effected, and the new organisation which arose from the coalescence of the two societies adopted the rather cumbrous title of "Anthropological Institute of Great Britain and Ireland." This was in 1871, and since that period, the *Society*, as it is to all intents and purposes both in structure and function, has pursued a peaceful and useful course of existence, holding meetings at stated periods throughout the session, at which papers are read and subjects of interest to anthropologists exhibited and discussed. It has also published a quarterly journal, which has been the principal means in this country of communicating new information upon such subjects. The Institute has for twenty-three years performed this duty in a business-like and unostentatious manner, the only remarkable circumstance connected with its history being the singular want of interest taken by the outside world in its proceedings, considering their intrinsic importance to society, especially in an empire like ours, which more than any other affords a field for the study of man, under almost every aspect of diversity of race, climate, and culture. At the present time it numbers only 305 ordinary members, whose subscriptions afford barely sufficient means to maintain the library and journal in a state of efficiency. The kindred Geographical and Zoological Societies have respectively 3775 and 2985 fellows, so far greater is the interest taken in the surface of the earth itself, and in the animals which dwell upon it, than in its human inhabitants!

Societies similar in their object to that the history of which I have just sketched have sprung up, and are now in a more or less flourishing condition, in every civilised country of the world. But confining our retrospect to our own country, we may take a glance at what has been done in recent years to promote the organised study of Anthropology otherwise than by means of this Association (to which I shall refer again later) or the Society of which I have just spoken.

One of the most potent means of registering facts, and making them available for future study and reference, is to be found in actual collections of tangible objects. To very considerable branches of anthropological science this method of fixing the evidence upon which our knowledge of the subject is based is particularly applicable. These branches are mainly two, very distinct from each other, and each representing one of the principal sides in which Anthropology presents itself.

I. Collections illustrating the physical structure of man, and its variations in the different races.

II. Collections showing his characteristic customs and methods of living, his arts, arms and costumes, as developed under different circumstances and also modified by different racial conditions.

It is very rarely that these two are combined in one general arrangement, and they are almost always studied apart, the characteristics of mind, the general education and special training which are required for the successful cultivation of either being rarely combined in a single individual; and yet the complete history of any race of mankind, especially with regard to its relation to other races, must be based upon a knowledge both of its physical and psychical characteristics, and customs, habits, language, and tradition largely help, when anatomical characters fail to separate and define.

The anthropological museums of this country, as well as elsewhere, are all of recent growth, and they are making progress everywhere with steadily accelerating speed. This cannot be better illustrated than in the place where we are at the present time. Many of those who are now in this room can remember when the materials for the study of either branch of the subject in Oxford were absolutely non-existent. I can myself recall the time when the site of the handsome building which now houses the scientific treasures of the University was a bare field. All who know the modern history of Oxford must be aware that it was mainly owing to the enthusiastic zeal and steady perseverance in the cause of scientific education of one who is happily still amongst us, the veteran Regius Professor of Medicine, Sir Henry Acland, that that building was erected. The possession of a well-selected and representative collection illustrating the anatomical characters of the human species is chiefly owing to the energetic labours of Prof. Rolleston, one of the brightest and noblest of Oxford's sons, a man of whom I cannot speak without feelings of the strongest affection and most profound regret for his untimely loss to the University and the world.

The collection illustrating the arts and customs of primitive people the University owes to the ingenuity and munificence of General Pitt-Rivers, who not only provided the material on which it is based, but also the original and unique scheme of arrangement, which adds so greatly to its value as a means of education, and is so admirably calculated to awaken an interest in the subject, even in the minds of the most superficial visitor. In speaking thus of the method of displaying the Pitt-Rivers collection, I must not be supposed to imply any disparagement of others arranged on different plans. Provided there is a definite and consistent arrangement of some sort, it is well that there should be a diversity in the treatment of different collections, and for such a vast and exhaustive collection as that under the care of Sir Wollaston Franks, at the British Museum, the geographical system which has been adopted is certainly the best. In it every specimen of whatever nature at once finds a place, in which it can at any time be discovered and recognised.

In referring to our great national collection, I cannot refrain from saying that there seemed till lately to be only one element wanting to make it all that could be desired, and that was space, not only for the proper preservation and exhibition of what it already contains, but also for its inevitable future expansion. The provision in this respect was totally inadequate to do justice to the importance of the subject. Happily this consideration will be no longer a bar to the development of the collection. The provident action of the authorities of the Museum, aided by the liberality of the Duke of Bedford, and the wisdom of Her Majesty's Government, has secured for many years to come the necessary room for the expansion of the grandest of our national institutions.

More modern even than museums has been the introduction of any systematic teaching of Anthropology into this country. This is certainly most remarkable, considering that there is no nation to which the subject is of such great importance. Its importance to those who have to rule—and there are few of us now who are not called upon to bear our share of the responsibilities of government—can scarcely be over-estimated in an Empire like this, the population of which, as I have just said, is composed of examples of almost every diversity under which the human body and mind can manifest itself. The physical characteristics of race, so strongly marked in many cases, are probably always associated with equally or more diverse characteristics of temper and intellect. In fact, even when the physical divergences are weakly shown, as in the different races which contribute to make up the home portion of the Empire, the mental and moral characteristics are still most strongly marked. As the wise physician will not only study the particular kind of disease under which his patient is suffering before administering the approved remedies for such disease, but will also take into careful account the peculiar idiosyncrasy and inherited tendencies of the individual, which so greatly modify both the course of the disease and the action of remedies, so it is absolutely necessary for the statesman who would govern successfully, not to look upon human nature in the abstract and endeavour to apply universal rules, but to consider the special moral, intellectual, and social capabilities, wants, and aspirations of each particular race with which he has to deal. A form of government under which one race would live happily and prosperously may to another be the cause of unendurable misery. All these questions then should be carefully studied by those who have any share in the government of people belonging to races alien to themselves. A knowledge of their special characters and relations to one another has a more practical object than the mere satisfaction of scientific curiosity; it is a knowledge upon which the happiness and prosperity or the reverse of millions of our fellow-creatures may depend. The ignorance often shown upon these subjects, even in so select an assembly as the House of Commons, would be ludicrous if it were not liable to lead to disastrous results.

Now let us consider what, amid all the complex, diverse, and costly machinery of education in this country, is being done to satisfy the demands for such knowledge. We may say at once as regards all institutions for primary and secondary education, absolutely nothing. The inhabitants of the various regions of our own earth are treated with no more consideration and interest in all such institutions than if they lived on the moon or the planets. We must turn straight to the higher intellectual centres in the hope of finding any anthropological teaching. Here at Oxford, if anywhere, we may expect to find it, and here, first among the British Universities, have we seen, since the year 1883, among the list of the subjects taught the word "Anthropology," but the teacher, though one of the most learned of men in the subject the country has produced, still only bears the modest title of "Reader." A professorship of Anthropology does not exist at present in the British Isles, and even here the subject, though recognised as a "special," offers little field for distinction in the examinations for degrees, and has therefore never been taken up in a thorough manner by students. Dr. Tylor's lectures must, however, have done much to have spread an intelligent interest in some branches of Anthropology, and have proved a valuable complement to the Pitt-Rivers collection, as have also the courses which have been given by Mr. Henry Balfour upon the arts of mankind and their evolution, one of which I am glad to see is announced among the advantages offered to the University Extension students at present with us. Physical Anthropology has also been taken up by Prof. A. Thomson, who, I understand, gives instructive lectures upon it, open to the members of his class of human anatomy. At the opposite end almost of the subject must be mentioned the extension and organisation of the Ashmolean Museum under the care of Mr. Arthur Evans, which has a bearing upon some branches of Anthropology, and the foundation of the Indian Institute under the auspices of Sir Monier Monier-Williams, which must give an impetus to the study of the characteristics of the races of our great Empire in the East. Last, but by no means least in its bearing upon the origin, divisions, and diffusion of races, is the world-famous linguistic work of Prof. Max Müller and Prof. Sayce, both of whom have presided over this Section at former meetings of the Association.

Of the sister University I wrote thus in 1884: "In Cambridge there are many hopeful signs. The recently appointed Professor of Anatomy, Dr. Macalister, is known to have paid much attention to Anatomical Anthropology, and has already intimated that he proposes to give instruction in it during the summer term. An Ethnological and Archæological Museum is also in progress of formation, which, if not destined to rival that of Oxford, already contains many objects of great value, and a guarantee of its good preservation and arrangement may be looked for in the appointment of Baron Anatole von Hügel as its first curator."

Ten years have passed, and it is satisfactory to know that the teaching of Anthropology has not only been fairly established, but the subject has also found a place in the scheme of University examination. The learned Professor of Human Anatomy continues to take a wide view of its functions, giving a course during the Easter term on the methods of Physical Anthropology, and also museum demonstrations on craniometry and osteometry, by the aid of a greatly increased and continually augmenting collection of specimens. Those students who take anatomy as their subject for the second part of the Natural Science Tripos have both paper work and practical examination in Anthropology, each man having a skull placed in his hands of which he is expected to make a complete diagnostic description. For the first part of the tripos each candidate has one or more questions on the broad general principles of the subject. Prof. Macalister informs me that he has always at least six men who go through a very thorough practical course with their own hands. There has also lately been established a course of lectures on the Natural History of the Races of Man, delivered during the Michaelmas and Lent terms by Dr. Hickson, of Downing College, and Baron von Hügel gives a course of museum demonstrations on the weapons, ornaments, and other objects in the Ethnological Museum, which is open to all students, and of which many take advantage.

In London, owing to the chaotic condition of all forms of higher instruction, which has been brought so prominently into notice by the universal demand for a teaching University (an aspiration which the labours of the late Gresham Commission certainly seem to have brought nearer to realisation than ever appeared possible before), all systematic anthropological teaching has been entirely neglected. The great collections to which I have already alluded, that of arts and customs at the British Museum, and that of osteological specimens at the Royal College of Surgeons, have by their steady augmentation done valuable service in preserving a vast quantity of material for future investigation and instruction, and students have at present all reasonable facilities for pursuing their own researches in them. Lectures have never formed any part of the official programme of the British Museum, but at the College of Surgeons it is otherwise, and though the contents of the collections are specially indicated as the subject on which they should be delivered, for the last ten years at least, Anthropology, notwithstanding the magnificent material at hand for its illustration, has had no place in the annual syllabus. It is also entirely ignored in the examination scheme of the University of London, an institution which prides itself as being on a level with modern educational requirements; and the managers of the new Imperial Institute, casting about in all directions for some worthy object to occupy their energies and their spacious buildings, do not appear to have taken into serious consideration the value to the world and the appropriateness to their original design of a great central school of Anthropology, from which might emanate a full and satisfying knowledge of the characteristics of all the various races of which the Empire is composed.

In Scotland the recent Universities Commission has recognised Physical Anthropology as a branch of human anatomy in their scheme for graduation in pure science, the examination on this subject embracing a knowledge of race characters as found in the skull and other parts of the skeleton, in the skin, eyes, hair, features, and the external configuration of the body generally; the methods of anthropometrical measurement, both of the living body and the skeleton; the possible influence of use and of external surroundings in producing modifications in the physical characters of man, and an acquaintance with the "types" of mankind and the structural relations of man to the higher mammals. These regulations came into operation in the University of Edinburgh in 1892, and in accordance with them Prof. Sir William Turner delivers a special course of twenty-five lectures on Physical Anthropology, and in addition ten practical demonstrations on osteometry. The museum under his charge has greatly increased of late in number and value of the specimens. But "Human Anatomy, including Anthropology," being only one of a series of nine subjects in any three or more of which a final science examination on a higher standard has to be passed, there is not at present any considerable number of students who take it up, and the other Scotch Universities have not yet thought it necessary to establish distinct courses of Physical Anthropology, although it is becoming more and more a regular part of the anatomical teaching to advanced students.

For the following account of what is being done to further the knowledge of our subject in the sister isle I am indebted to Prof. D. J. Cunningham. The only place in Ireland where anthropological work is done is Trinity College. For many years those in charge of the museum have been collecting skulls, and they were fortunate in obtaining the greater part of Sir William Wilde's collection. To these great additions have been recently made, principally in the form of Irish crania from different districts. All the anthropological specimens are lodged in one large room, which is also used as an anthropometric laboratory. Though there has never been any systematic teaching of Anthropology in Trinity College, Dr. C. R. Browne (Prof. Cunningham's able assistant), who takes charge of the laboratory, attends for two hours on three days a week, and gives demonstrations in anthropological methods to any students who are interested in the subject. The laboratory was opened in June 1891, the instruments being provided by a grant from the Royal Irish Academy, and about 500 individuals have already been measured, the greater number of them students of the College. This is, however, only part of the work carried out by the laboratory. Every year the instruments are taken to some selected district in Ireland, and a systematic study of the inhabitants is made. The Aran Islands, and also the islands of Inishboffin and Inishshark, have been already worked out, and this year excursions are organised to Kerry, to a district in Wicklow, and to another in the west of Ireland. The Academy makes yearly grants to the Committee for carrying on this work, the results of which have been published in admirable memoirs by Prof. A. C. Haddon and Dr. C. R.

Browne. The Science and Art Museum in Dublin, under the direction of Dr. V. Ball, contains a small collection, arranged with a view to general instruction, showing by means of skulls and casts the physical characteristics of the different races of man, those of each race being explained by a short printed label, and its range shown on a map.

Though the development of anthropological science has thus not been greatly advanced, in this country at least, by means of endowments, or by aid of the State or, till very recently, by our great scholastic institutions, but has been mainly left to the unorganised efforts of amateurs of the subject, its progress in recent years has been undeniably great. I will give an instance of the strides that have been made in one of its most important branches.

Physical or Anatomical Anthropology, or the study of the modifications of the human body under its various aspects, the modifications dependent upon sex and age, the modifications dependent upon race, and those dependent upon individual variability, studied not many years ago in a vague and loose manner, has gradually submitted to a rigorous and, therefore, strictly scientific method of treatment. The generalities which were formerly used to express the differences that were recognised between the various subjects compared with each other have been replaced by terms conveyed in almost mathematical precision. No one acquainted with the history of the development of this branch of Anthropology can fail to recognise how much it was accelerated by the genius of Broca, and the school which he established in France, although all cultivated nations are now vying with each other in the practice of exactitude in anthropological research, and the time seems rapidly approaching when a common agreement will be arrived at, by which all the observations which may be made, under whatever diverse circumstances, and by whatever different individuals, will be available for comparison one with another.

This branch of our science has received the name of "Anthropometry." Although, as the name implies, measurement is one of its principal features, it includes such other methods of comparison as can be reduced to a definite standard, or to which definite tests can be applied, such as the colour of the hair, eyes, and complexion, the form of the ear and nose. The great desiderata that have been sought for, and gradually attained, in measuring either the skeleton or the living person have been two in number: (1) Exact definition of the points between which the measurements should be taken. (2) Exact methods and instruments of measurement. In both these cases the object looked for has been not only that the measurements taken by the same observer at different times and under different circumstances should coincide, but also that those taken by different observers should be comparable. These requirements seem so simple and natural at first sight that the majority of persons whom I am addressing will wonder that I should allude to them. Only those who are seriously occupied, or perhaps I should rather say, only those who were seriously occupied a few years ago, with the endeavour to solve these problems can have any idea of their difficulty. The amount of time and labour that has been spent upon them is enormous, but the result has, I think, been quite commensurate with it.

We have attained at last to methods of measurement and standards of comparison which, in the hands of persons of ordinary intelligence, and with a moderate amount of training, will give data which may be absolutely depended upon. From these we hope to be able to formulate accurate information as to the physical conformation of all the groups into which mankind is divided, and so gradually to arrive at a natural classification of those groups, and a knowledge of their affinities one to another.

But the exact methods of modern Anthropometry are not only important on account of the aid they give in studying the race characteristics of man. As has so often happened when scientific observation has been primarily carried out for its own sake, it ultimately leads to practical applications undreamt of by its earlier cultivators. The application of Anthropometry not to the comparison of races, but to elucidate various social problems such as the laws of growth, of heredity, of comparative capacities of individuals within a community, and the effects of different kinds of education and occupation, as worked out first by Quetelet in Belgium, and subsequently by Francis Galton, Roberts, and others in this country, and its still more concrete application as an aid in administering justice by methods perfected by Bertillon in France—are striking illustrations of the practical utility of labours originally undertaken under the influence of devotion to science pure and simple.

The importance of being able to determine the identity of an individual under whatever circumstances of disguise he may be presented for examination has, of course, long been apparent to all who have had anything to do with the administration of the criminal law, and rough and ready methods of recognition, depending mainly upon the more or less acute faculty of perception and recollection of differences and resemblances, possessed by the persons upon whom the duty of identification has devolved, have long been in operation. The general conformation, height, form of features, and colour of complexion, hair, and eyes, have also been noted. Much additional assistance has been obtained by the registration of definite physical characteristics, the results either of natural conformation, or of injury, such as mutilations, tattoo-marks, and scars, inflicted by accident or design. The application of one of the most important scientific discoveries of the age, photography, was eagerly seized upon as a remedy for the difficulties hitherto met with in tracing personal identity, and enormous numbers of photographs were taken of persons, the peculiarities of whose career led them to fall into the hands of the police, and who were likely to be wanted again on some future occasion. No doubt much help has been derived from this source, but also much embarrassment. Even among photographic portraits of one's own personal friends, taken under most favourable circumstances, and with no intention of deception, we cannot often help exclaiming how unlike they are to the person represented. With portraits of criminals, the varying expression of the face, changes in the mode of wearing the hair and beard, differences of costume, the effects of a long lapse of time, years perhaps passed in degradation and misery, may make such alterations that recognition becomes a matter at least of uncertainty. That photographs are extremely valuable as aids to identification, when their true position in the process is recognised, cannot be doubted, but as a primary method they have been found to be quite inapplicable, owing partly to the causes just indicated, but mainly to the difficulty, if not impossibility, of classifying them. The enormous expenditure of time and trouble that must be consumed in making the comparison between any suspected person and the various portraits of the stock which accumulates in prison bureaus may be judged of from the fact that, in Paris alone, upwards of 100,000 such portraits of persons interesting to the police have been taken in a period of ten years.

The primary desideratum in a system of identification is a ready means of classifying the data upon which it is based. To accomplish this is the aim of the Bertillon system. Exact measurements are taken between certain well-known and fixed points of the bony framework of the body, which are known not to change under different conditions of life. The length and breadth of the head, the length of the middle finger, the length of the foot, and the length of the forearm, are considered the best, though others are added for greater certainty, as the height, span of arms, length of ear, colour of eyes, &c. All these particulars of every individual examined are recorded upon a card, and by dividing each measurement into three classes, long, medium, and short, and by classifying the various combinations thus obtained, the whole mass of cards, kept arranged in drawers in the central bureau, is divided up into groups, each containing a comparatively small number, and therefore quite easily dealt with. When the card of a new prisoner is brought in, a few minutes suffice to eliminate the necessity of comparison with any but one small batch, which presents the special combination. Then photographs and other means of recognition, as distinctive marks and form of features, are brought into play, and identification becomes a matter of certainty. On the other hand, if the combination of measurements upon a new card does not coincide with any in the classed collection in the bureau, it is known with absolute certainty that the individual being dealt with has never been measured before.

One of the most striking results of the introduction of this system into France has been that, since it has been brought fully into operation, a large proportion of old offenders, knowing that concealment is hopeless, admit their identity at once, and save a world of trouble and expense to the police by ceasing to endeavour to conceal themselves under false names.

Various representations upon this subject have been addressed to the Home Secretary of our own Government during the last few years, and among others one from the Council of this Association, which originated in a resolution of this Section, adopted by the General Committee at the meeting at Edinburgh in 1892, to this effect:

"That the Council be requested to draw the attention of Her Majesty's Government to the Anthropometric Method for the measurement of criminals, which is successfully in operation in France, Austria, and other continental countries, and which has been found effective in the identification of habitual criminals, and consequently the prevention and repression of crime."

In consequence of these representations a Committee was appointed, on October 21, 1893, by Mr. Asquith, consisting of Mr. C. E. Troup, of the Home Office; Major Arthur Griffiths, Inspector of Prisons; and Mr. Melville Leslie Macnaghten, Chief Constable in the Metropolitan Police Force; with Mr. H. B. Simpson, of the Home Office, as Secretary, "to inquire (*a*) into the method of registering and identifying habitual criminals now in use in England; (*b*) into the 'Anthropometric' system of classified registration and identification in use in France and other countries; (*c*) into the suggested system of identification by means of a record of finger marks: to report whether the anthropometric system or the finger-mark system can with advantage be adopted in England either in substitution for or to supplement the existing methods; and, if so, what arrangements should be adopted for putting them into practice, and what rules should be made under Section 8 of the Penal Servitude Act, 1891, for the photographing and measuring of prisoners."

The Report of this Committee, with minutes of evidence and appendices, was issued as a Parliamentary Blue-book in March last, and not only contains a lucid and concise description of the methods of identification already in use in this country, but also most striking testimony from impartial but well-qualified persons to the value of a more scientific mode of dealing with the subject. No pains seem to have been spared to obtain, both by personal observation and by the examination of competent witnesses, a thorough knowledge of the advantages of the Bertillon system as practised in France, and the result has been the recommendation of that system, with certain modifications, for adoption in this country, with the addition of the remarkably simple, ingenious, and certain method of personal identification first used in India by Sir William Herschel, but fully elaborated in this country by Mr. Francis Galton, that called the "finger-mark system," about which I shall have a few more words to say presently.

With the concluding words of the Committee's Report I most fully concur: "We may confidently anticipate that, if fairly tried, it will show very satisfactory results within a few years in the metropolis; but the success of its application in the country generally will depend on the voluntary co-operation of the independent county and borough police forces. This, we feel sure, will not be withheld. When the principles of the system are understood and its usefulness appreciated we believe it will not only save much time and labour to the police in the performance of an important duty, but will give them material assistance in tracing and detecting the antecedents of the guilty, and will afford, so far as its scope extends, an absolute safeguard to the innocent."

It is very satisfactory to be able to add that in the House of Commons on June 26, in answer to a question from Colonel Howard Vincent, the Home Secretary announced that the recommendations of the Committee have been adopted; and that, in order to facilitate research into the judicial antecedents of international criminals, the registers of measurements would be kept on the same plan as that adopted with such success in France, and also in other continental countries.

I have just mentioned the "finger-mark system" and of all the various developments of Anthropology in recent times none appears to be more interesting than the work done by Mr. Galton upon this subject; for though, as indicated above, he is not quite the first who has looked into the question or shown its practical application in personal identification, he has carried his work upon it far beyond that of any of his predecessors, both in its practical application and into regions of speculation unthought of by anyone else. Simple and insignificant as in the eyes of all the world are the little ridges and furrows which mark the skin of the under-surface of our fingers, existing in every man, woman, and child born into the world, they have been practically unnoticed by everyone until Mr. Galton has shown, by a detailed and persevering study of their peculiarities, that they are full of significance, and amply repay the pains and time spent upon their study. It is not to be supposed that all the knowledge that may be obtained from a minute examination of them is yet by any means exhausted, but they have already given important data for the study of such subjects as variation unaffected by natural or any other known form of selection, and the difficult problems of heredity, in addition to their being one of the most valuable means hitherto discovered of fixing personal identity.

As an example of the importance of some ready method to prove identity, apart from its application to the detection, punishment, and prevention of crime, to which I have already referred, I may recall to your recollection that remarkable trial which agitated the length and breadth of the land rather more than twenty years ago; a trial which occupied so many months of the precious time of our most eminent judges and counsel, and cost the country, as well as several innocent persons—I am afraid to say how many—thousands of pounds, all upon an issue which might have been settled in two minutes if Roger Tichborne, before starting on his voyage, had but taken the trouble to imprint his thumb upon a piece of blackened paper. It is wonderful to me, on reading again the reports of the trial, to see how comparatively little attention was paid by counsel, judge or jury, to the extremely different physical characteristics of the two persons claimed to be identical, but which were so strongly marked that they ought to have disposed of the claim, without any hesitation, at the very opening of the case. It was not until the 102nd day of the first trial that the attention of the jury was pointedly called to the fact that it was known that Sir Roger Tichborne had been tattooed on the left arm with a cross, anchor, and a heart, and that the Claimant exhibited no such marks. When this was clearly brought out and proved, the case broke down at once. The second trial for perjury occupied the court 188 days, the Lord Chief Justice's charge alone lasting eight days. The issues were, however, more complex than in the first trial, as it was not only necessary to prove that the Claimant was not Tichborne, but also to show that he was someone else. I feel convinced that at the present time the greater confidence that is reposed in the methods of Anthropometry or close observance of physical characters, and in the persistence of such characters through life, would have greatly simplified the whole case; and I would strongly recommend all who have nothing about their lives they think it expedient to conceal to place themselves under the hands of Mr. Galton, or one of his now numerous disciples, and get an accurate and unimpeachable register of all those characteristics which will make loss of identity at any future period a sheer impossibility.

Partly with this object in view, the Association has, for several years past, during each of its meetings, opened, under the superintendence of Dr. Garson, an Anthropometric Laboratory, on the plan of the admirable institution of the same name which has been carried on in the South Kensington Museum since the beginning of the year 1888, under the direction and at the sole cost of Mr. Francis Galton, in which up to the present time more than 7000 complete sets of measurements have been made and recorded. The results obtained at the British Association meetings have been published in the Annual Reports of the Association, and though on a smaller scale than Mr. Galton's, the operations of the laboratory have been most useful in diffusing a knowledge of the value of anthropometric work, and of the methods by which it is carried on.

For many years an "Anthropometric" Committee of the Association, in which the late Dr. W. Farr, Mr. F. Galton, Mr. C. Roberts, Dr. Beddoe, Sir Rawson Rawson, and others, took an active part, was engaged in collecting statistical information relating to the physical characters, including stature, weight, chest-girth, colour of eyes and hair, strength of arms, &c., of the inhabitants of the British Isles; and their reports, illustrated by maps and diagrams, were published in the annual volume issued by the Association. This Committee terminated its labours in 1883, although, as was fully acknowledged in the concluding report, the subject was by no means completely exhausted.

A great and important work which the Association has now in hand, in some sense a continuation of that of the Anthropometric Committee, though with a more extended scope of operation, is the organisation of a complete ethnographical survey of the United Kingdom based upon scientific principles. In this work the Association has the co-operation of the Society of Antiquaries of London, the Folk-lore Society, the Dialect Society, and the Anthropological Institute. Representatives of these different bodies have been formed into a committee, of which Mr. E. W. Brabrook is now chairman. It is proposed to record in a systematic and uniform character for certain typical villages and the neighbouring districts (1) the physical types of the inhabitants, (2) their current traditions and beliefs, (3) peculiarities of dialect, (4) monumental and other remains of ancient culture, and (5) historical evidence as to continuity of race. The numerous corresponding societies of the Association scattered over various parts of the country have been invited to co-operate, and the greater number of them have cordially responded, and special local committees have been formed in many places to carry out the work.

The result of a preliminary inquiry as to the places in the United Kingdom which appeared especially to deserve ethnographic study, mainly on account of the stationary nature of the population for many generations back, was given in the first Report of the Committee presented at the Nottingham meeting of the Association last year, in which it was shown that in the British Isles there are more than 250 places which, in the opinion of competent authorities, would be suitable for ethnographic survey, and in which, notwithstanding the rapid changes which have taken place during the last fifty years in all parts of the country, much valuable material remains for the committee to work upon. Without doubt, as interest in the subject is aroused, this number will be greatly increased.

A most important step in securing the essential condition that the information obtained should be of the nature really required for the purpose, and that the records of different observers should be as far as possible of equal value and comparable one with another, has been the compilation of a very elaborate and carefully prepared schedule of questions and directions for distribution among those who have signified their willingness to assist, and as a guarantee that the answers obtained to the questions in the schedules will be utilised to the fullest extent, certain members of the committee specially qualified for each branch of the work have undertaken to examine and digest the reports when received.

It may be remarked in passing that the Anthropological Society of Paris has within the past year formed a Commission of its members to collect in a systematic manner the scattered data which, when united and digested, shall form "une anthropologie véritablement nationale de la France," and has issued a circular with schedules of the required observations. These are, however, at present limited to the physical characters of the population.

Among the many services rendered to the science of Anthropology by the British Association, not the least has been the aid it has afforded in the publication of that most useful little manual entitled "Notes and Queries on Anthropology," of which the first edition was brought out exactly twenty years ago (1874), under the supervision and partly at the expense of General Pitt-Rivers. Since that time the subject has made such great advances that a second edition, brought up to the requirements of the present time, was urgently called for. A Committee of the British Association, appointed to consider and report upon the best means of doing this, recommended that the work should be placed in the hands of the Anthropological Institute of Great Britain and Ireland. This recommendation was approved by the Association, and grants amounting to £70 were made to assist in defraying the cost of publication. The council of the Anthropological Institute appointed a committee of its members to undertake the revision of the different subjects, with Dr. J. G. Garson and Mr. C. H. Read as editors respectively of the two parts into which it is divided. The work was published at the end of the year 1892, and is invaluable to the traveller or investigator in pointing out the most important subjects of inquiry, and in directing the observations he may have the means of making into a methodical and systematic channel.

Besides those I have already mentioned, the Association has aided many other anthropological investigations by the appointment of committees to carry them out, and in some cases by the more substantial methods of giving grants from its funds, and by defraying the cost of publication of the results in its Journal. Among these I may specially mention the series of very valuable reports upon the physical characters, languages, and intellectual and social condition of the north-western tribes of the Dominion of Canada, drawn up by Mr. Horatio Hale, Dr. F. Boas, and others, the importance of which has been recognised by the Canadian Government in the form of a grant in aid of the expenses.

Another very interesting investigation into the habits, customs, physical characteristics, and religion of the natives of Northern India, initiated by Mr. H. H. Risley, and carried on under his supervision by the Indian Government, though it has received little more than moral support from the Association, may be mentioned here on account of the illustration it affords of the value of exact anthropometric methods in distinguishing groups of men. Although a practised eye can frequently tell at a glance the tribe or caste of a man brought before it for the first time, the special characters upon which the opinion is based have only lately been reduced to any definite and easily comparable method of description. In Mr. Risley's examination, the nose, for instance (which I have always held to be one of the most important of features for classificatory purposes), instead of being vaguely described as broad or narrow, is accurately measured, and the proportion of the greatest width to the length (from above downwards), or the "nasal index," as it is termed (though it must not be confounded with the nasal index as defined by Broca upon the skull), gives a figure by which the main elements of the composition of this feature in any individual may be accurately described. The average of mean nasal indices of a large number of individuals of any race, tribe, or caste offer means of comparison which bring out most interesting results. By this character alone the Dravidian tribes of India are easily separated from the Aryan. "Even more striking is the curiously close correspondence between the gradations of racial type indicated by the nasal index and certain of the social data ascertained by independent inquiry. If we take a series of castes in Bengal, Behar, or the North-Western Provinces, and arrange them in the order of the average nasal index, so that the caste with the finest nose shall be at the top, and that with the coarsest at the bottom of the list, it will be found that this order substantially corresponds with the accepted order of social precedence. The casteless tribes—Kols, Korwas, Mundas, and the like—who have not yet entered the Brahmanical system, occupy the lowest place in both series. Then come the vermin-eating Musuhars and the leather-dressing Chamárs. The fisher castes of Bauri, Bind, and Kewat are a trifle higher in the scale; the pastoral Goala, the cultivating Kurmi, and a group of cognate castes—from whose hands a Brahman may take water—follow in due order; and from them we pass to the trading Khatris, the landholding Bábhans, and the upper crust of Hindu society. Thus, it is scarcely a paradox to lay down as a law of the caste organisation in Eastern India that a man's social status varies in inverse ratio to the width of his nose." The results already obtained by this method of observation have been so important and interesting that it is greatly to be hoped that the inquiry may be extended throughout the remainder of our Indian Empire.

But for want of time I might here refer to the valuable work done in relation to the natives of the Andaman Islands, a race in many respects of most exceptional interest, first by Mr. E. H. Man, and more recently by Mr. M. V. Portman, and for the same reason can scarcely glance at the great progress that is being made in anthropological research in other countries than our own. The numerous workers on this subject in the United States of America are, with great assistance from the Government, very properly devoting themselves to exploring, collecting, and publishing, in a systematic and exhaustive manner, every fact that can still be discovered relating to the history, language, and characters of the aboriginal population of their own land. They have in this a clear duty set before them, and they are doing it in splendid style. I wish we could say that the same has been done with all the native populations in various parts of the world which have been, to use a current phrase, "disestablished and disendowed" by our own countrymen. We are, however, now, as I have shown, not altogether unmindful of what is our duty to posterity in this respect; a duty, perhaps, more urgent than that of any other branch of scientific investigation, as it will not wait. It must be done, if ever, before the rapid spread of civilised man all over the world, one of the most remarkable characteristics of the age in which we live, has obliterated what still remains of the original customs, arts, and beliefs of primitive races; if, indeed it has not succeeded—as it too often does—in obliterating the races themselves.

NOTES.

THE death is announced of Prof. Rudolph Weber, Berlin, at the age of sixty-five, and of Prof. M. P. J. Rollet, of Lyons Observatory, a correspondent in the Médecine et Chirurgie Section of the Paris Academy of Sciences.

THE University of Halle, on the occasion of the recent bi-centenary celebrations, conferred the honorary degree of Ph.D. upon Prof. Victor Horsley, F.R.S.; Mr. F. G. Kenyon and Mr. H. L. D. Ward, both of the British Museum; Mr. G. A. Grierson, and Prof. W. W. Skeat.

A REUTER telegram reports that Mr. Aagaard, the United States Consular Agent at Tromsö, has despatched Captain Bottolfsen on board the fast-sailing cutter *Malygen* to Spitzbergen with a supply of provisions and clothing for the Wellman Expedition, for which the *Malygen* will search, and which, if possible, it will take back to Tromsö.

THE President of the Photographic Society of Great Britain has received a communication from the Secretary of State to the effect that the Queen has given her consent to the proposal to call the Society "The Royal Photographic Society of Great Britain."

HERR OTTO LILLENTHAL, whose aërial excursions were described in these columns a short time ago, recently met with a serious accident. The wings of his flying machine collapsed while he was at an altitude of about two hundred feet, causing him to fall to the ground. His fall was broken to some extent, but he was badly injured.

AN earthquake disturbance is reported to have occurred at Aci Reale, Sicily, shortly before six o'clock on the morning of August 8. Great damage was done at Zafarana, where six persons were killed and several injured. Both there and at Aci San Antonio, nearly all the houses have fallen in. Slight shocks were felt in Catania and several other communes in the neighbourhood of Mount Etna, but no damage was done.

THE *Times* correspondent at Calcutta, writing on August 12, reports that the Gohna Lake rose 24 ft. 6 in. last week, and is now within 57 ft. of the top of the dam. Its full length is now 4½ miles, the average width being half a mile. The greatest depth is 720 ft. The percolation is very heavy. This, combined with heavy rain, has washed away a large portion of the lower part of the dam, leaving an almost perpendicular drop of 400 ft. The section thus displayed shows a layer of boulders on the top, below which is pulverised rock. The lake is expected to overflow within fifteen days.

WE learn that the arrangements have now been completed for the fourteenth congress and exhibition of the Sanitary Institute, to be held in Liverpool near the end of next month. On Monday, September 24, the Lord Mayor of Liverpool will receive members at the Town-hall, and the President, Sir F. S. Powell, M.P., will deliver the inaugural address in the large theatre of University College; while in the evening the Lord Mayor will formally open the exhibition. Next day there will be conferences in University College on a variety of subjects. In the conference on "Domestic Hygiene," the Lady Mayoress will preside, and the ladies will afterwards hold a reception. At night Dr. G. B. Longstaff lectures at University College. On September 26, Section I., "Sanitary Science and Preventive Medicine," meet under the presidency of Dr. Klein, in the college, and the discussion will be continued next day. The Lord Mayor gives a reception in the Walker Art Gallery on Wednesday evening. Section II., "Engineering and Architecture," meets on Thursday, and the discussions will be continued on the following day, when also Section III., "Chemistry, Meteorology, and Geology," meet under the presidency of Dr. T. Stevenson. The closing general meeting of the congress takes place in the college on Friday evening, September 28, and later, Sir James Crichton Browne will address the working classes in the Picton Lecture-hall. The exhibition will remain open three weeks.

THE tenth meeting of the International Congress of Americanists was held at Stockholm, August 3-8, and was attended by the President, Dr. Rudolph Virchow, Baron Nordenskiöld, Mrs. Zelia Nuttall (of Dresden), M. Charnay, and Dr. Robert Munro, among others. Prof. Gustav Retzius, M. E. W. Dahlgren, and M. O. Montelius were some of the members of an influential executive committee, of which M. Carl Bovallius acted as general secretary. H.M. the King of Sweden, with S.A. the Crown Prince, attended the morning sitting on August 6, and heard the following communications read:—"Recent Finds from South American Tombs," by Dr. R. Virchow; "The Cliff Dwellers," by M. Charnay; and "Remarks on the Calendar System of the Ancient Mexicans," by Mrs. Zelia Nuttall. This lady paid a graceful tribute to the memory of that ardent "Americanist," the late Mrs. Hemmenway, of Boston, whose death was a sad loss to the cause of American archæology, and gave a summary in French of the chief results of her own investigations on the calendar system of the ancient Mexicans. Her paper on this subject was printed in English for distribution among the members of the Congress. The same evening the King gave a *fête* to the members of the Congress at the Palace of Drottningholm, and proposed the toast of "The Americanist Congress" at supper, to which Dr. Virchow suitably replied.

THE letter on a recent change in the character of April, which appeared in our issue of July 12, has led Dr. O. Z. Bianco to examine the meteorological statistics of Turin for evidence of a similar variation. By tabulating the values of the mean temperature in April at that place since 1865, and smoothing them in averages of five, he finds that, in the thirty years considered, the lowest average temperature occurred in 1889 at Turin as well as at Greenwich. The temperature appears to have gradually fallen to this minimum since 1865, and is now rising. If the results of observations are represented diagrammatically, a figure is obtained which agrees very closely with that accompanying the letter to which we have referred. Taking simply the monthly mean temperature in different years, the lowest values belong to 1879 and 1891, and are 10°·1 C. and 10°·2 C. respectively. For Greenwich the corresponding point was a temperature of 43°·5 F. (6°·4 C.) in 1879 and 1888. In the latter year the mean temperature of April in Turin was 10°·8 C., which is nearly a degree below the normal value. Further inquiry may perhaps lead to an explanation of the change to which attention has been directed.

WE have received the first four numbers of a series of Electrical Engineering Leaflets by Prof. E. J. Houston and Mr. A. E. Kennelly, which are being issued in weekly parts. These leaflets are divided into three grades: elementary, which is suited for the use of electrical artisans, wiremen, and elementary students; intermediate, suited to students in technical schools; and advanced, suited to students taking a course in electrical engineering. Although, to judge from the four first numbers, these leaflets will be hardly suitable to form by themselves a complete text-book in this subject, since the points treated are of too wide a scope to admit of sufficient detail and explanation being given in the moderate size of the work (some 300 pages small octavo) to ensure a student, without some other source of information, being able to grasp the subject. They will, however, be found very useful as a book of reference, and for revising and keeping fresh information which has already been acquired, forming as they do a compact and clearly expressed synopsis of the subject. Another useful feature in the numbers under consideration are tables of physical quantities, such as the electromotive force of different cells, specific resistance of solids and liquids, the temperature coefficient being in most cases given as well as the temperature at which the value of the resistance given is measured, together with the observer's name. An elaborate scheme of prefixes used to denote multiples and submultiples of the different units is given, which, as long as the scheme is printed on the opposite page to the table in which these prefixes are used, saves a good deal of space, but will probably cause a great deal of unnecessary confusion if they are used in other parts of the work, unless the value is in every case also given in the index notation.

IN a short communication, made to the French Academy of Science, M. Moureaux says that on examining the magnetograph records of the Parc Saint-Maur Observatory for the night of July 11-12, he finds a disturbance which corresponds in time with the earthquake shock that caused so much destruction at Constantinople. As M. Moureaux has taken the precaution to have non-magnetic copper bars suspended alongside the magnetograph needles, and the records from these bars show no disturbance, it is evident that the effects observed were due to magnetic causes, and not to a mechanical shock. As the magnetic disturbance occurred sixteen minutes before the time at which the earthquake shock was felt at Constantinople, and since the two places are separated by a distance of 3000 kilometres, it would appear that the disturbance travelled at the rate of only three kilometres per second. This is certainly a very slow rate of propagation, and it would be of great interest if the observers at other observatories where a permanent magnetic record is kept, were to examine their curves, and see whether they show a similar disturbance, and if so, if the rate of propagation is about the same as the above. If the values obtained vary much, it is probable that the disturbance noted by M. Moureaux was of solar rather than of terrestrial origin, or at any rate was not connected with the earthquake at Constantinople.

ANYTHING respecting Corea is of special interest at the present time, and the short article on the "Cultivation of Cotton" in that little-known country, which a recent number of the *Journal of the Society of Arts* contains, is certain to have many readers. According to this article, which is based upon a report of the Commissioner of Corean Customs at Fusan, the total area under the cultivation of cotton in Corea is roughly computed to be 872,000 acres, the yield of seed cotton from which per annum is put at 1,200,000,000 lbs. The yearly consumption of "cleaned" or raw cotton is estimated at 300,000,000 lbs. The Corean fibre is reported to be superior to that produced in Japan. The method of cultivation is as follows:—The ground is usually ploughed up during the early winter, and allowed to remain in this condition until the frost is well out of it, when it is broken up with a hoe, and manure, mixed with wood ashes, spread over it. The fields are now ready for the reception of the seed, which is generally sown about April to May. The seed, of which there is but one kind, is not placed in drills, as is done in Japan, but is sown broadcast, and then trodden in and covered up with the feet, sesamum seed being very often sown in the same field with it. The young shoot shows above ground about the tenth day, and at maturity attains a height of from 2 feet to 2½ feet. The plant blossoms in August, and on an average bears forty pods, each containing four cells, as a rule within a double capsule. The gathering of the crop, which begins about October, continues until frosts sets in, some time in November. No attention is paid or skill displayed in the cultivation once the seed is in the ground; everything is then left to nature. No further manure is added, nor are they ever thinned out or given water in times of drought. The crops are principally gathered by women, who also are largely employed afterwards in separating the seed.

DURING the last few years, alloys of tin and lead have been employed in manufactures in which the constancy of melting points after successive meltings played an important part. Rudberg, one of the earliest workers in this field, noticed that the thermometer stopped at two points during the solidification of these alloys; the higher point varied with their composition, while the lower was constant, being about 187°, and was identical with the melting point of the "chemical alloy" represented by the formula $PbSn_3$. In the current number of *Wiedemann's Annalen*, Bernhard Wiesengrund gives the results of a complete series of experiments with tin-lead alloys ranging from $PbSn_{12}$ to $Pb_{12}Sn$. They were melted in a crucible of sheet iron covered with a lid provided with two brass tubes to admit and withdraw dry hydrogen during heating. An iron tube closed at the bottom was attached to the lid. It dipped into the alloy, and served to contain the thermometer, the bulb of which was surrounded by mercury. The thermometer was graduated from 0° to 360° C., and contained nitrogen above the mercury column. The crucible was surrounded by a sheet-iron water-jacket kept at 150° C., and the heating was done by means of a triple Bunsen burner. As regards the densities of the alloys, it was found that they were all lighter than might have been expected from the densities of their constituents. This increase of volume was greatest in the case of the "chemical alloy" $PbSn_3$, and decreased as one or the other constituent preponderated. The process of solidification showed Rudberg's two points distinctly. The higher one, called the melting point, was really a point at which the cooling became somewhat less rapid. The lower, called the point of solidification, was a truly stationary point, except in the alloys containing much lead. The most regular curve of cooling is shown by the alloy $PbSn_3$. At about 178° there is a dead stop lasting for seven minutes, not preceded by a perceptible stop at the melting point. The latter becomes more pronounced as the percentage of tin increases, and appears as a point of inflexion in the alloy $PbSn_{12}$. As the lead is increased, the melting point rises, the point of solidification falls slightly and becomes less pronounced, and all breaks in the curve of cooling tend to disappear. The author gives a plausible explanation of the phenomena analogous to the theory of saline solutions, tin being regarded as the solvent. After twenty-four successive remeltings a mechanical rearrangement was observed, producing a slight elevation of the fusing point and an approximation of the point of solidification to that of the "chemical alloy." This was due to the excess of the heavy lead, or the light tin gradually separating out from the alloy $PbSn_3$.

THE *Transactions and Proceedings* of the New Zealand Institute (vol. xxvi.), containing papers read before the Institute during 1893, has been published, and is obtainable from Messrs. Trubner and Co.

THE *Quarterly Journal* of the Geological Society (No. 199, August) has been issued. It contains five plates, illustrating papers by Mr. A. Harker, Mr. W. W. Watts, Mr. Frank Rutley, and Sir J. W. Dawson and Dr. W. Hind.

THE August number of the *Journal* of the Royal Microscopical Society is almost entirely taken up with summaries of current researches. The only two papers are by Mr. F. Chapman and Mr. T. Comber, the former dealing with the foraminifera of the gault of Folkestone, and the latter with the characters generally accepted for specific diagnosis in the Diatomaceæ.

THE Romanes Lecture on "The Effect of External Influences upon Development," delivered by Prof. Weismann, at Oxford, last May, and reported in these columns (vol. l. p. 31) has been published in English by the Clarendon Press. The translation has been done by Mr. Gregg Wilson. In the preface, Prof. Weismann adds his tribute to the many that have been paid to the memory of the late Dr. Romanes.

MESSRS. J. AND A. CHURCHILL will shortly publish a new edition of Dr. F. Kohlrausch's indispensable handbook to practical physics—"An Introduction to Physical Measurements." The edition has been translated from the seventh German edition, published in 1892, and it contains nearly four times the number of pages that the first one did in 1869. Mr. T. H. Waller and Mr. H. R. Procter are the translators.

GLACIAL action in Australasia has much attention devoted to it in the *Proceedings* of the Royal Society of Tasmania for 1893. Mr. R. M. Johnston contributes an elaborate review of the evidences of former glaciation in Australasia, with critical observations upon the principal hypotheses which have been advanced to account for glacial epochs generally, and there are several papers on the discovery of glacial action in Tasmania.

IN the current number of *Mind*, Mr. Francis Galton contributes an article on "Discontinuity in Evolution," which should be read by all who are interested in modern biological theory. It owes its origin to the publication of Mr. Bateson's recent work, and contains a summary of the views on discontinuous or "transilent" variation and on "organic stability," which Mr. Galton has published in "Natural Inheritance," in "Finger Prints," and in the preface to a reprint of "Hereditary Genius." The data on which these views are based lie somewhat off the beaten track of biological inquiry, and Mr. Galton's conclusions have not received the consideration due to results based on careful and prolonged observation.

THE Royal Meteorological Institute of the Netherlands has published a new edition of "The Tides on the Dutch Coast," containing, among other useful information, the results of tidal observations made at several stations during recent years. The tables show that on the North Hinder Bank, for instance, the temperature of the air from September to February is lower than that of the sea surface; but from March to August it is higher, and that the prevalence of thunderstorms increases with the latitude. Tide rips are most frequent in the month of April and during the first four days of full and new moon.

THE Meteorological Council have recently issued a second edition of a Barometer Manual for the use of seamen, in which many alterations and improvements have been made. The work contains carefully drawn charts showing the mean atmospheric pressure and prevailing winds for January and July, and also many valuable hints on the management of the barometer. The portions dealing with winds and storms, and especially with practical rules for seamen in tropical cyclones, are of especial value, and this small work of forty pages contains all the necessary information for the safe navigation of a vessel which may be in the vicinity of these storms.

WE have received the *Journal of the Anthropological Institute* for August, containing papers read at meetings of the Institute during the first quarter of this year. Among other papers, we notice one on flint implements of a primitive type from old (pre-glacial) hill-gravels in Berkshire, by Mr. P. A. Shrubsole, and a note on the poisoned arrows of the Akas, by Prof. L. A. Waddell. The Akas are one of the Lohitic tribes of the Asam Valley, occupying independent territory to the north of the Brahmaputra. They poison their arrows for use in warfare, the poison being derived, as has been found in other cases, from the roots of a species of *Aconitum*. A translation of the second part of "Shamanstoo," being Prof. Mikhailovskii's important account of Shamanism in Siberia and European Russia, is contributed by Mr. O. Wardrop.

A THIRD edition, enlarged and partly rewritten, of "Select Methods in Chemical Analysis," by Prof. W. Crookes, F.R.S., has been published by Messrs. Longmans, Green, and Co. During the eight years which elapsed between the publication of the second edition and the preparation of this, various new processes have been introduced, and old ones have either been displaced, or become so well known in ordinary laboratories that their retention in a "select" work, like that of Prof. Crookes', is unnecessary. For it will be remembered that the work is "not intended to provide the student with a complete text-book of analysis, but rather with a laboratory companion, containing information not usually found in ordinary works on analysis." In the present edition, volumetric operations have been almost entirely omitted, and also processes of technical importance. These omissions have made room for the addition of a series of electrical separations, and other processes from Dr. Classen's "Quantitative Chemical Analysis by Electrolysis." As Prof. Crookes only includes in the volume such methods as have been proved in his own laboratory, their practicability is assured. A disadvantage of this eclectic method, however, is that good methods of analysis are passed over because they do not happen to have been personally tested by the author.

THE additions to the Zoological Society's Gardens during the past week include a Black Ape (*Cynopithecus niger*, ♂) from the Celebes, presented by Mr. Gambier Bolton; a Slender Loris (*Loris gracilis*) from Ceylon, presented by Mr. Thos. E. Remington; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Captain Philip Langdale; four Alpine Newts (*Triton alpestris*), European, presented by Mr. Malcolm O. Smith; four Land Crabs from Jamaica, presented by Mr. Percy Walter Jarvis; a Black-backed Jackal (*Canis mesomelas*) from South Africa, deposited; a Weka Rail (*Ocydromus australis*) from New Zealand, purchased; a Cayenne Lapwing (*Vanellus cayennensis*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

RECENT OBSERVATIONS OF MARS.—Mars now rises shortly after nine p.m., and is on the meridian between four and five o'clock in the morning. He will be in opposition on October 20. Two important papers, containing the results of recent observations of the planet, are contributed to the August number of *Astronomy and Astro-Physics*. Mr. Percival Lowell, whose observatory was described in these columns on June 14, began to observe the planet at the end of May, and the observations recorded in his article were made between then and June 24. The clearness of the atmosphere at Flagstaff, Arizona, where the observatory is situated, is responsible for the early date at which it was possible to scrutinise the face of the earth's ruddy brother. And the success with which his features were made out may be judged from the fact that Mr. Lowell recognised a dozen of Schiaparelli's canals two and a half months before the summer solstice of the planet's southern hemisphere. At the beginning of the period of observation, the southern snow-cap was found to have a diameter of about forty-seven degrees; that is, it covered nearly the whole frigid zone. On June 19, the cap measured thirty-nine degrees. Throughout all the period, the outer edge appeared to be perfectly elliptical, indicating that the boundary line of the cap was really a circle. The snow was continuously bordered by a dark streak of nearly uniform width. Mr. Lowell thinks that this belt was water at the edge of the melting snow; in fact, a polar sea. His view finds support in the observation that the streak was widest where the dark markings on the planet's face—the markings intrepreted as seas—were greatest in extent. Several brilliant star-like points flashed out upon the snow-cap at different times and disappeared after being conspicuously visible for a few minutes. The imaginative mind may think that these flash lights represent signals from the Martians, but a more probable explanation is that they are produced by snow slopes being illuminated in such a manner that the sunlight after glancing across them is reflected at a particular angle to the Earth. The great rift in the snow-cap was observed and found to be about twelve hundred miles long, and rather more than two hundred miles wide. Mr. Lowell did not see any irregularities upon the terminator of Mars, so he concludes that there are few, if any, great mountains on the planet. The first canal, thought to be Cerberus, was observed on June 7, and two days later it was seen double for an instant. Other canals were glimpsed from time to time, and some were seen well enough to be sketched. Prof. W. H. Pickering has also observed Mars at the Lowell Observatory. He remarks: "What appears to me to be the most important conclusion deducible from our work is that Mars does not always present the same appearance at the corresponding time upon two successive Arean years. This remark does not apply merely to small details, but to large and prominent features. Moreover, this difference does not seem to be due simply to the fact that one season is a few weeks later than the other, but that the phenomena presented upon the two years are really different." Prof. Pickering has noticed slight notches in the terminator, but he thinks these are produced by variations in the inclination of the surface of the planet rather than by differences of level.

THE ROTATION OF THE TERRESTRIAL POLES.—Dr. S. C. Chandler has lately been investigating the question whether either component of the polar rotation deviates from a uniform circular motion (*Astr. Jour.* No. 323, July 27). The discussion furnishes clear proof that the figure described by the pole of rotation and pole of figure approximates to an ellipse with a major axis of about 0''·55 and a minor axis of about 0''·30. Dr. Chandler refers this departure from circular, or rather epicyclical motion, to the annual term alone. A computation based upon this assumption shows that the figure is "a very eccentric ellipse with a major axis of 0''·32, lying in the line 53°–233°, and a minor axis of about 0''·10; the period being manifestly about a year, and the motion being from west to east. The angular velocity seems to stand in some inverse relation to the radius."

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 6.—M. Lœwy in the chair.—On the variations of *Spirifer Verneuli*, by M. Gosselet.—New anthropological and palæontological researches in the Dordogne. Abstract of a memoir by M. Émile Rivière. Certain details are given concerning palæolithic remains from the "Grottes des Combarelles," the "Grotte Rey," the "Grotte de Cro Magnon," and the "Grotte de la Fontaine," including bones from a numerous fauna and carved and sculptured fragments. Neolithic remains from Pageyral, Sireuil, and Pagenal will be described in a future communication.—The Secretary announced the deaths of the following correspondents: M. A. Hannover, July 7; M. Rollit, August 2.—On groups of substitutions isomorphous with symmetrical or alternate groups, by M. Maillet.—On the zeros of certain discontinuous functions. Principle of the method for finding the zeros of certain functions, by M. Desaint.—On the equations of dynamics, by M. R. Liouville. A claim for priority in reference to the subject matter of two notes by M. W. Vladimir de Tannenberg, of dates July 30 and May 25 respectively.—On carbonic hydrate and the composition of hydrates of gases, by M. P. Villard. The author determines the composition of a hydrate of carbon dioxide formed by himself to be $CO_2.6H_2O$, and calls attention to the remarkable resemblance between this substance and the hydrate of nitrogen monoxide $N_2O.6H_2O$. They have apparently the same crystalline form, the same heat of formation, and are both optically inactive. The hypothesis is made that hydrates of gases should, in general, have a composition expressed by the formula $M.6H_2O$. This assumption is supported by the formulæ found by the author for the similar compounds of sulphur dioxide and methyl chloride. The hydracids are excepted from the rule. Doubt is thrown upon the formula $Cl_2.8H_2O$ for chlorine hydrate.—Basic salts of calcium, by M. Tassilly. The best method of preparation and thermal data concerning calcium oxybromide and calcium oxyiodide are given. These substances have an exactly similar composition to that of André's oxychloride, $CaCl_2.3CaO.16H_2O$. They have the same heat of solution and a heat of formation increasing with increasing atomic weight of the halogen present.—On the use of selected ferments, by M. Charles Fabre. The following conclusions are given—(1) The selected ferment cannot be employed with *any* must for the production of high-class wines. (2) The must in which the ferment is sown should have been obtained from grapes belonging to or vines long acclimatised in the region from which the selected ferment has been obtained.—Peripheric applications of alkaloids in the treatment of acute maladies with cutaneous determination, by MM. L. Guinard and Gustave Geley. The external application of sparteine in cases where the skin is the active seat of disease has been found to give remarkable curative results, more particularly in cases of erysipelas.—On coprolitic bacteria of the Permian age, by MM. B. Renault and C. Eg. Bertrand. *Bacillus permiensis*, occurring in coprolites from the Permian at Autun, consists of rectilinear bacillus elements, isolated or in pairs, and having the dimensions 14 to 16μ by 2·5 to 3·3μ by 0·4μ. It sometimes occurs curved or twisted in spirals or chains.—On the nature of the great crevasse caused by the last earthquake at Locrides, by M. Socrate A. Papavasilion.—On the existence of *lentilles récifales* with Ammonites in the *Barrêmien* near Châtillon-en-Diois, by MM. G. Sayn and P. Lory.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—The Aborigines of Western Australia: A. F. Calvert (Simpkin).—Theoretical Mechanics—Fluids: J. E. Taylor (Longmans).—A Treatise on Astronomical Spectroscopy: Prof. Dr. J. Scheiner, translated, &c., by E. B. Frost (Ginn).—Controversen in der Ethnologie, IV., Fragestellungen der Finalursachen: A. Bastian (Berlin, Weidmann).—Coal Dust an Explosive Agent: D. M. D. Stuart (Spon).—Geological Guide-Book for an Excursion to the Rocky Mountains: S. F. Emmons (K. Paul).—British Rainfall, 1893: G. J. Symons and H. S. Wallis (Stanford).—Systema Naturæ; Regnum Animale, editio decima 1758: C. Linnæi (Leipzig, Engelmann).—Le Centre de l'Afrique, Autour du Tchad: P. Brunache (Paris, Alcan).—Memoirs of the International Congress of Anthropology: edited by C. S. Wake (K. Paul).—The Water Supply of Towns and the Construction of Waterworks: Prof. W. K. Burton (Lockwood).

PAMPHLETS.—Supplement to 41st Report of the Department of Science and Art (Eyre and Spottiswoode).—Representation and Suffrage in Massachusetts, 1620-1691: Dr. G. H. Haynes (Baltimore).

SERIALS.—School Review, June (Hamilton, New York).—Proceedings of the Royal Physical Society, Session 1892-93 (Edinburgh).—American Journal of Science, August (New Haven).—Papers and Proceedings of the Royal Society of Tasmania for 1893 (Hobart).—Zeitschrift für Physikalische Chemie, xiv. Band, 4 Heft (Leipzig, Engelmann).—Engineering Magazine, August (Tucker).—Notes from the Leyden Museum, January to April (Leyden, Brill).—Astronomy and Astro-Physics, August (Wesley).—Journal of the Royal Microscopical Society, August (Williams and Norgate).—Sechzehnter Jahres-Bericht über die Thätigkeit der Deutschen Seewarte für das Jahr 1893. Beiheft i. (Hamburg).

THE PHYSIOLOGY OF THE CARBOHYDRATES.

The Physiology of the Carbohydrates: their Application as Food, and Relation to Diabetes. By F. W. Pavy, M.D., F.R.S. (London: Churchill, 1894.)

AMONG the most debated subjects of physiology the ultimate fate of carbohydrates within the body stands out as one of the greatest difficulty. A great amount of work has been expended on it, but still many points of vital importance remain undecided. We accordingly hail with pleasure a work containing the results and conclusions of one whose name is indissolubly associated with the subject, as the author of one of the two rival theories around which much of the work of the last thirty years has centred. The book before us contains a revised description of the many researches of the author upon this subject, with a criticism of his earlier results by the light of his later work, and the greatly increased knowledge of the chemistry of the carbohydrates which is now available. Embodying as it does the results of a "life's labour, attended with unceasing laboratory work," we turn to it with more than ordinary interest.

The book is arranged in sections, in the first of which the author gives us a short account of the main chemical characters of the principal carbohydrates, and special stress is laid upon the production of osazones as enabling us to distinguish the different sugars from one another. This is followed by an account of the hydrations produced by ferment action and the changes known to occur through the agency of protoplasm. Succeeding sections deal almost entirely with Dr. Pavy's researches, arranged not in the order in which they appeared, but in such a manner as to gradually unfold the author's argument.

Thus we find described the experiments upon which he concludes that many proteids have the constitution of glucosides. Next the path of absorbed sugar is traced to the liver, and his experiments proving its conversion into glycogen are given. Many experiments upon the amounts of sugar present in arterial and venous blood, in blood from the portal and hepatic veins, and in the liver and other tissues, are given, as well as quantitative results of the amount of glycogen and other carbohydrates present in these positions. The sugar in urine is next discussed, and here he brings evidence to prove that normal urine contains sugar.

Dr. Pavy for his quantitative results relies almost entirely upon the ammoniated cupric solution, and contends that the results obtained by its careful use are thoroughly trustworthy. Where he gives duplicate estimations, however, we note that there are often considerable differences in the two values obtained. Thus, his figures give a further confirmation of the difficulty, if not impossibility, of obtaining very accurate results as to the quantity of sugar present in a solution, by means of a standard copper solution. It is of essential importance to keep this constantly in mind in those cases, such as determination of the quantity of sugar in blood from portal and hepatic veins, or from carotid artery and jugular vein, in which the results, which we know must be very close to one another, are to be compared. For this reason especially we do not consider that Dr. Pavy has satisfactorily established his position, though it is a most important one for his further conclusions.

His experiments upon the glucoside constitution of proteids are very suggestive and important, but before they could be conclusive it would be necessary to pay much greater attention to the proper purification both of the proteid with which he starts and the "cleavage carbohydrate" which he obtains, and to give quantitative analyses of this latter body. For instance, in the case of egg albumin, which is one of the bodies he uses, we know that it contains a considerable amount of glycogen, and that it is extremely difficult to completely free the proteid from it. But as this latter point does not seem to have been thoroughly attended to in these experiments, we must await further corroboration.

There are many other points about which we expect much discussion may arise, and among these we may mention his conclusions—firstly, that sugar is present in urine; and secondly, that it is present in proportion to the amount present in the blood. In connection with the first of these two points we would refer to the recently published paper of Carl Baisch,[1] who uses the benzoyl chloride method, which is certainly to be regarded as capable of producing more accurate results than the use of the copper test. He, in confirmation of Dr. Pavy, finds that a reducing carbohydrate is present, and he further shows that dextrose is present to the extent of ·04 to ·09 per 1000 of urine. total-reducing carbohydrates amounting to as much as ·06 to ·16 per 1000. Dr. Pavy, on the other hand, finds a much larger quantity, which, calculated as glucose, he states, amounts to as much as ·5 per 1000.

Now, if we compare the figures given on page 189 as to the amount of sugar present in urine as a consequence of an abnormal small excess in the blood, with the result he gives as present in normal urine, we cannot, from their study, at all agree that these amounts are proportional to that present in the blood. Still less would this conclusion be acceptable were we to take the above-quoted figures of Baisch.

Perhaps the conclusions upon which Dr. Pavy would lay by far the greatest amount of stress is that the major part of the sugar absorbed from the alimentary canal is immediately combined with the peptone simultaneously absorbed to form a proteid, which is then transmitted to the general circulation, and thus to the tissues generally. Dr. Pavy considers that this synthesis is in part effected by the epithelial cells covering the villi. Under one set of conditions, viz. defective oxidation, &c., this proteid may break down and result in the production of fat, or again under another set, *e.g.* excessive oxygenation of the blood associated with vaso-dilatation, a second form of katabolism is produced, characterised by the production of sugar, which is then eliminated in the urine. Before, however, we can accept these views it will be necessary that much of Dr. Pavy's work should be corroborated. It is of course known, that under the right conditions within the body, fat or sugar can be formed as a result of unusual proteid katabolism; but that proteid is usually syn-

[1] *Zeit. fur Physiol. Chemie*, xix. p. 357.

thesised in the simple manner suggested by Dr. Pavy, namely, by the direct combination of a glucose molecule or molecules with a peptone or some similar molecule, requires far more rigid proof than is here attempted.

We should have liked to have seen a greater amount of criticism of some of the many important researches which have been lately published by so many workers; but throughout the whole work, Dr. Pavy bestows but little space in criticising conflicting evidence, much of which remains completely unnoticed.

Though it is thus easy to criticise and point out where errors may have crept in, we can but thoroughly admire the energy and careful thought which are in evidence throughout the work. There is much in it that is suggestive, much that is most valuable. The experimental work which is here set forth so plentifully, forms a field which must be studied and consulted by all future workers in this direction.

PTOLEMY AS A PHILOSOPHER AND ASTROLOGER.

Studien uber Claudius Ptolemäus; ein Beitrag zur Geschichte der griechischen Philosophie und Astrologie. Von Franz Boll, Dr.Phil. (Leipzig: Druck und Verlag von B. G. Teubner, 1894.)

IT is somewhat strange that in the article on Ptolemy in the "Penny Cyclopædia," he is spoken of only as a geographer. His fame is undoubtedly built upon his two great works on astronomy and geography. But the present publication treats of him rather as a philosopher, and discusses also the genuineness or otherwise of the less-known works of the great Alexandrian. A few lines are devoted to his life, of which scarcely anything is known. Dr. Boll sees no reason for calling in question the statement of Theodorus Meliteniota, that he was born at Ptolemais Hermii, in Upper Egypt. He lived to his seventy-eighth year, and died in the reign of Marcus Aurelius, who became emperor in A.D. 161; but it is somewhat doubtful whether the last observation referred to in the "Almagest" was made in 141, or ten years later. At any rate, it is clear that that work preceded the description of the earth's surface (written, Sir E. Bunbury remarks, much more in the spirit of an astronomer than of a geographer), which remained during more than twelve centuries the paramount authority in geographical questions where physical matters were not concerned.

However, as we have said, the present treatise is not occupied with any consideration of these great works. Astronomical and geographical questions do not form its subject-matter, which is rather concerned with the comparatively untrodden ground of Ptolemy as a philosopher, besides a discussion of the genuineness of his writings on astrology in the present acceptation of the term. His work, *Περὶ κριτηρίου καὶ ἡγεμονικοῦ*, has been generally overlooked, the first apparently to refer to it being Heinze, in his edition of Ueberweg's "Grundriss der Geschichte der Philosophie von Thales bis auf die Gegenwart.' But besides this professed treatise, Ptolemy touches upon philosophical questions in several places in his other writings.

Dr. Boll's "Studien" is distributed into three principal sections. The first gives, in three chapters, a discussion of his author's views on questions of this nature, as they may be derived from passages in his undoubtedly genuine works. The second is devoted to a critical examination of the genuineness of the *Τετράβιβλος Σύνταξις*, which is astrological, and generally considered as unworthy of the writer. An inquiry into the source of the so-called astrological geography in the second book of that treatise forms the third section of the present "Studien" of Dr. Boll.

Our space in this brief notice enables us only to indicate the general conclusions arrived at under these three heads. A detailed discussion of the views propounded by Ptolemy on psychological and other philosophical questions shows that he must be classed as an eclectic, but with distinctly peripatetic principles. This appears in the "Harmonics" as well as in the work first mentioned. But in his teaching a number of stoical propositions is also to be found, and it is not in these only that Aristotelian ideas are rejected or set aside, for a tendency is manifested to accept some Platonic doctrines on psychology, whilst Pythagorean speculations on numbers form the foundation of the third book of the "Harmonics."

A very careful and elaborate comparison of expressions used in the *Τετράβιβλος*, and in the smaller work *Καρπός* (which is in fact a collection of aphorisms), with Ptolemy's great astronomical and geographical works, proves that the former is genuine, but the latter is not, being evidently the production of some astrologer of later date.

Dr. Boll's conclusion with regard to the *Τετράβιβλος* agrees with that of previous writers; thus the author of the article "Astrology" in the "Penny Cyclopædia" says: "Though its genuineness has been doubted by some merely because it is astrological, there appears no sufficient reason to reject it." We would gladly do so if we could; but the present examination seems to confirm the Ptolemean authorship but too fully. The admiring English translator in the last century (John Whalley, Professor of Physic and Astrology) affirms that "there is nothing in Astrology but what is there comprehended, nothing there comprehended, but the Quintessence and Divinity of Astrology."

The second book of this treatise gives a system of what Dr. Boll calls astrological ethnography, *i.e.* the stellar influence on different parts of the world and their inhabitants according to the signs of the zodiac which are especially supposed to rule over each. The sources of this, by a comparison with earlier writers, are discussed by Dr. Boll (led so to do by a small treatise published at Berlin by Paul Wendland in 1892) in the third section of his work, which shows great industry and research, it being difficult to disentangle the subject from that of the effects of climate on the human race, so that matters of this kind require very careful handling. We may take an instance of this from our own Shakespeare. When Prospero says his zenith doth depend upon a most auspicious star, the allusion to astrology is patent. But when the melancholy Jaques, in *As You Like It*, is made to describe human life as divided into seven stages, it is somewhat straining a point (Dr. Boll refers to Steevens as having anticipated him in this, but he means Malone) to assume that reference is intended to the notion that each age was dominated by one of the seven planets. However, he shows a close correspondence between many expressions in the Τετράβιβλος and in Roman writers under the empire, Manilius, Vitruvius, and Pliny.

The work concludes with an *excursus* on the date of the ἀστρολογούμενα of Petosiris and Nechepso, which had been referred to the first century before, but Dr. Boll gives reasons for placing in the first century after, the Christian era. W. T. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Platinum Resistance-Thermometers.

AT the meeting of the British Association, just coming to an end, it was pointed out to the Committee of Section A, by Mr. E. H. Griffiths, that the general adoption of the method of thermometry, founded on the variation of the electric resistance of platinum with temperature, that has been worked out by Prof. Callendar and himself, is seriously hindered by the existence of a report presented to the Belfast meeting of the Association in 1874 (British Association Report, 1874, pp. 242–249), by a Committee "appointed for the purpose of testing the new pyrometer of Mr. Siemens." As I was secretary of this Committee and drafted the report, and as all the experiments were made either by myself or under my direction, I was desired by the Committee of Section A to ask you to allow me to state in the columns of NATURE (what is indeed obvious to anyone who refers to the 1874 report) that the tests carried out by the Committee of 1874, and the conclusions arrived at by them, had reference solely to the pyrometers supplied to them for examination by Messrs. Siemens Brothers, and that they have consequently no bearing on the question of the trustworthiness or accuracy of the platinum resistance-thermometers of the kind devised by Messrs. Griffiths and Callendar.

August 15. G. CAREY FOSTER.

International Courtesy.

I LEARN from a speech of Prof. Ludwig Boltzmann, in Section A to-day, and also from some Englishmen well acquainted with German Universities, that I have unintentionally offended the physical philosophers of Germany by one or perhaps two ill-considered and hasty expressions employed in the first edition of my "Modern Views of Electricity."

These remarks do not occur in the second edition, but mere silent withdrawal of them does not convey the information that I desire to convey to my illustrious leaders and *confrères* in the foreign scientific world. I therefore request you to permit me space to make the following *amende*.

When I said that the four great names in connection with our partial knowledge of the nature of electricity were (excluding living persons) Franklin, Cavendish, Faraday, and Maxwell, I ought to have interpolated the adjective *British* before the word "names," in order to avoid entering upon much larger questions than were at all appropriate to the expository course of lectures on which the book "Modern Views" was based.

The second remark was this:—When emphasising the great achievements of Hertz, in my lecture at the Royal Institution on "The Discharge of a Leyden Jar" (reprinted as appendix to same book), I spoke of him as "no ordinary German." Literally of course it is true, but it may easily be interpreted in a discourteous sense. It was, however, less widely known then than it is now that Hertz was a German savant of the highest type, and this fact I wanted to express; but if the proverbial odiousness of implied comparisons had only happened to strike me, I would certainly have altered the mode of expression before any reprints of my lecture were made.

Prof. Boltzmann seems to think that the context to this remark indicates that some rancour was felt in this country that the fruits of Maxwell's theory should have been reaped by a German. That, if true, would be a serious accusation, but I can assure him that it is conspicuously untrue. To an Englishman my words would not even convey the impression. I honestly think that at the present era no trace of international jealousy exists among English and Irish physicists.

August 14. OLIVER J. LODGE.

A Remarkable Meteor.

WHILE at Pasadena, eight miles north-east of Los Angeles, California, on July 27, a few minutes before half-past seven, the writer had his attention suddenly drawn towards the north-western horizon by a bright flash of light as of the bursting of a meteor; but on keeping his gaze fixed on the point where this flash appeared, he was surprised still more to see that instead of disappearing, as usually happens with meteors when they explode, there remained a very luminous figure, somewhat of the shape of the new moon but with more wavy outlines, and of an intense whiteness, something as of an electric light, in well-defined relief against the pale golden glow of the sky. The whole time during which this luminosity was visible was something over twenty minutes, and it had ceased to be visible at eight minutes before eight. The crescent shape was not maintained more than about three minutes, then it took the appearance of a luminous vapour or cloud rising vertically for a little distance and then bending off sharply to the left in almost an horizontal line, but not showing any tendency to dissipate or grow thinner at the end farthest from the point of origin. As time went on, the whole figure became more wavy in outline, but persistently remained fixed in the same part of the sky. The bottom, the point of origin, was slightly brighter than the rest of the figure, and a little reddish in colour, and the underside of the arm outstretched to the left was brighter than the upper side. It was clearly beyond, and in no wise connected with, the Sierra San Gabriel, which cut the sky with a dark, well-defined lune under the luminous figure. All who were watching it perceived that it was no common cloud; the north-western sky was cloudless and free from haze, and no cloud in the west at such an hour can shine with this sort of light, which indeed had more the lustre of white flame.

The cloud seemed unbroken so long as it was visible at all. It would be idle to speculate beforehand on the exact locality of this outburst, since no accurate estimate of its distance could be formed at the time; but the direction, as nearly as the writer could judge by reference to the pole star, was about north 35° to 40° west, which, projected on a map of the State, gives about the direction of Tehachipi Peak from Pasadena.

The direction in which the meteor was seen to explode, as stated by other observers all the way from the Needles in the south-eastern part of the State to Lodi and Oakland in the central counties, that is to say, from points five hundred miles apart, enables one, by projecting those bearings which are reported in most detail, viz., Fresno, whence it seemed a little north of west; Keeler, whence it also seemed a little north of west and directly beyond Mount Whitney; Tracy, whence it seemed to be in the south-east; and Pasadena, whence it seemed, as above stated, to limit the spot over which it exploded to some point in the north-western part of Fresno county or the south-western part of Merced county, both being in the San Joaquin Valley, and 250 to 300 miles from Pasadena. With much greater diffidence the writer would estimate its angular height above the true horizon at not to exceed 3°.

Los Angeles, July 29. EDWARD WESSON.

[From newspaper cuttings sent with the foregoing it appears that the meteor was seen at the Lick Observatory at 7h. 35m., and that the explosion was heard at 7h. 36½m. At Benicia the meteor was extremely brilliant for a moment, and then disappeared in a column of white vapour about two degrees long. This cloud remained visible for a quarter of an hour. At Fresno and at Redlands the luminous stream was visible for twenty minutes. An observer at Tracy says that a loud report, resembling a clap of thunder, was heard in the south-east, five minutes after the meteor disappeared. According to the news from Fresno, the meteor left a track of great beauty, consisting of an irregular spiral curve, the lower end of which was little more than a tangle of threads. The upper part of this track was pale red, and farther down blue. The lower part was almost yellow, and still farther down were two detached bright red spots, like the sun breaking through clouds.—Ed. Nature.]

Height of Barometer.

Mr. Pearson will find much information as to extreme readings of the barometer in two papers published in the *Quarterly Journal* of the Royal Meteorological Society; one by Mr. H. Sowerby Wallis, in vol. viii. p. 147, and the other by Mr. C. Harding, in vol. xiii. p. 201. The lowest known reading is stated, on the authority of Mr. Blanford (Nature, vol. xxxv. p. 344), to be 27·135 ins. observed on September 22, 1885, at False Point, on the coast of Orissa; this requires a subtractive correction of ·011 to bring it to English standards, reducing it to 27·124 ins. The highest known reading is given, on the authority of Prof. Loomis, as 31·72 ins. at Semipatalinsk, on December 16, 1877, giving an extreme range of 4·6 ins.

The lowest reading recorded in these Islands is 27·332 ins. at Ochtertyre, near Crieff, on January 26, 1884, while at Belfast the barometer fell to 27·38 ins. on December 8, 1886, and on the same day at Newton Reigny to 27·566 ins., which seems to be the lowest recorded in England. The highest pressures recorded in this country during recent years were on January 18, 1882, when 30·990 ins. was registered at St. Leonards, but on January 9, 1820, 31·056 was recorded at Kinfauns, Perth, and appears to be confirmed by other readings in Scotland.

Henry Mellish.

THE BRITISH ASSOCIATION.

By the kindness of the Secretary of the British Association we were able to give in our last issue a list of the grants awarded by the General Committee just as we were going to press. Upon referring to this, it will be seen that the grants amount to very nearly £1100, that is £400 more than those awarded at the previous meeting. The increase of funds available for research is due to the large number who attended the Oxford meeting, the receipts being as much as £2175. In this matter, and indeed from every point of view, the meeting was a most successful one. The membership reached a total of 2321—a number greatly in excess of the average. In moving a vote of thanks to the authorities of the city for the hospitable reception accorded to the Association, Sir John Evans remarked that the meeting had been notable both for the large attendance of members and associates, and for the great scientific interest and importance of the papers read. In fact, it was the opinion of all that rarely, if ever, has a more brilliant meeting of the Association been held. No less than seventy-seven foreign members, eminent in many branches of scientific knowledge, honoured it with their presence. The exchange of ideas, which results from the meeting of investigators from all parts of the world, must lead to real progress. "Science," as someone has said, "is cosmopolitan." She recognises no differences of nationality between workers devoted to extending her domains. Therefore men who live "for the promotion of natural knowledge" meet on common ground at the British Association, for they know that anything that will help on this object will be appreciated.

Several changes in the constitution of the sections were adopted by the General Committee. Section D will in future be called Zoology instead of Biology, and there will be a separate section for Botany. Section I, which met this year for the first time, is to consist of Physiology with Experimental Pathology and Experimental Psychology. As pointed out by Prof. Bayley Balfour in his address, Section D has had its constitution changed oftener than any other section of the Association. Experience will show whether the new arrangement is the one best calculated to bring together investigators with similar scientific interests.

The continual division of this section suggests that Astronomy should be removed from Section A (Mathematical and Physical Science), and have a section of its own. It may also be well to point out that there should be a sub-section of Section H (Anthropology) dealing with large questions of Archæology—that is to say, with Assyrian and Egyptian Archæology—and with the various points which, from an archæological point of view, are common to the earlier races.

Another matter worth the attention of the General Committee is the introduction of evening reunions of physicists and biologists, such as are provided in German meetings. Under the present conditions it is very difficult to meet and talk with fellow-workers, especially with foreign members, at each meeting.

The meeting will be held next year at Ipswich, under the presidency of Sir Douglas Galton, K.C.B., F.R.S. Liverpool will be the place of meeting in 1896. The Association was invited to meet in Toronto in 1897, but as arrangements are never made more than two years in advance, nothing definitely could be settled in the matter. There was a strong feeling, however, in favour of accepting the invitation when the proper time arrives for doing so.

The University testified to its interest in the welfare of science by conferring the degree of D.C.L. *honoris causâ* on the following eminent foreign investigators present at the meeting:—Prof. Edouard Van Beneden, Prof. Ludwig Boltzmann, Dr. E. Chauveau, Prof. Cornu, Prof. Theodor W. Engelmann, Prof. Wilhelm Förster, Prof. C. Friedel, Prof. L. Hermann, Prof. Gosta Mittag-Leffler, Prof. S. P. Langley, Prof. G. Quincke, Prof. E. Strasburger. The degrees were conferred by the Vice-Chancellor, and the Latin oration was delivered by Prof. Goudy. The following brief notes show the character of the recipients' chief researches:—

Edouard Van Beneden, Professor of Zoology and Comparative Anatomy, has not only contributed a long series of memoirs on the structure of various Invertebrata to the literature of zoological science, but has especially gained the highest recognition and esteem for his work on the microscopic details of the process of fertilisation in relation to karyokinesis and cell-structure. His investigations on this process in Ascaris megalocephala form the starting-point of recent theories and researches on the subject of the partition of the nuclear matter by the splitting of the chromosomes in spermatozoon and ovum and in the fertilised egg. In addition to these investigations, Prof. Van Beneden's researches on the formation of the blastoderm in the rabbit and the bat have been of the greatest importance, and are cited in all modern treatises as classical. Recently, Prof. Van Beneden has occupied himself largely with the study of Anthozoa (especially Cerianthus and its larva Arachnactis), and has arrived at most important conclusions as to the relationship of these forms to the Vertebrata.

Ludwig Boltzmann was born in Vienna in 1844, and is now Professor of Theoretical Physics in the University there. His first paper was on the distribution of electricity on a sphere and cylinder, and his second one on the mechanical significance of the second law of Thermodynamics. His subsequent papers are too numerous to mention in detail, and have been published principally by the Academy of Science at Vienna, and recently at Munich. The most important of these treat of the steady state of kinetic energy in gas molecules and its connection with the second law of Thermodynamics, of the specific inductive capacity of solids and gases, and other thermodynamic and electromagnetic subjects. Along with Clausius and Maxwell, he is a founder of the kinetic theory of gases, especially in its more com plicated aspects and in its connections with the second law of Thermodynamics. Recently he has devoted himself to popularising Maxwell's electromagnetic theory in Germany.

French physiologists are represented by Prof. Chauveau of Paris. Two only of his achievements need be mentioned—his investigations of the movement of the heart, conceived in the same spirit, and pursued with the same desire to search out the secrets of nature that animated our own Harvey; and secondly, his inquiries as to the nature of the process by which infectious diseases are communicated from one individual to another. It would be difficult to estimate which of these is most worthy of our admiration, for whereas the first were experiments of light, the others were experiments of fruit, and served, with those of Pasteur and our own Lister, as the foundations of a new science—that of Bacteriology—pregnant with promise for the future welfare of mankind.

M. Cornu, Professor of Physics at the École Polytechnique, Paris, is renowned for his numerous experimental researches. His investigations on the velocity of light earned for him a high place among experimenters twenty years ago, and his work on the ultra-violet part of the solar spectrum is still the standard of reference. The telluric spectrum also, and the spectrum of hydrogen, have engaged his attention, as well as various problems in astronomical physics. But his investigations have not been confined to optical physics, one of the most important of them being concerned with the determination of the density of the earth. He was elected a Foreign Member of the Royal Society in 1884, and received the Rumford medal in 1878.

The career of Prof. Engelmann of Utrecht as an investigator has been very fruitful. His work, like that of Hermann, has related to the very *principia* of physiology—to those vital endowments which are common to ourselves and to organisms of the simplest structure. These he has studied with a view to the eventual solution of the most elementary, yet the most difficult, problems which living nature presents to the investigator.

Prof. W. Forster, the Director of the Observatory of Berlin University, is well known for his great activity in furthering astronomical inquiry, both in the institution under his charge and elsewhere. Quite recently he succeeded in establishing an International Bureau for undertaking and conducting astronomical computations. He has also played an important part in the work of the Geodetic Union. Most of his earliest work belongs to geodesy, a number of carefully-made pendulum observations calling for special mention. By directing attention to luminous clouds, and pointing out the importance of photographing and accurately observing them, he has done a service which will lead to results interesting alike to astronomers and meteorologists. His astronomical works, though not numerous, are such as add to his renown, and, with his rare and active administrative faculty, they single him out as well deserving the honour done to him.

Prof. Friedel, the eminent occupier of the chair of Organic Chemistry at the Paris Sorbonne, and one of the six members of the Chemistry Section of the Paris Academy of Sciences, has carried out numerous investigations of the highest value. His first work was on the relations between thermo-electric properties and crystalline form, but his chief researches relate to organic compounds, in the synthesis of which he has been very successful. A few of his earlier papers refer to the artificial production of minerals, and he has made some important contributions to the inorganic side of chemistry.

The name of Prof. Hermann of Königsberg is familiar to students of physiology in all parts of the world, as the author of a general treatise on the subject which has been translated into every European language. He is also the author of several monographs on special subjects, and of innumerable smaller papers, in each of which some permanent additions to knowledge are recorded. His investigation of the chemical processes which are concerned in muscular contraction, published a quarter of a century ago, and his more recent inquiries as to the electrical concomitants of these processes, constitute the foundation of what Physiology is as yet able to teach on these difficult but fundamental questions.

It was at the Allegheny Observatory, Pennsylvania, that Prof. S. P. Langley began his investigations in solar physics, which have resulted in so great an extension of our knowledge in this direction. About 1878 he turned his attention to the question of solar radiation. Finding the thermopile quite inadequate for the work he had undertaken, he was led to invent his now well-known bolometer, with which instrument he has since carried out some very important investigations. After the death of Prof. Henry, he was offered the position of Assistant Secretary of the Smithsonian Institution by Prof. Baird. He removed to Washington, but for a time continued to carry on his work at Allegheny. A few years ago, however, he built a small astro-physical observatory on the grounds of the Smithsonian Institution, and he has there continued and extended his work on the infra-red spectrum of the sun.

All mathematicians are familiar with the name of Gosta Mittag-Leffler, Professor of Pure Mathematics in Stockholm University. He is the editor of the authoritative journal *Acta Mathematica*, devoted to the extension of mathematical knowledge. His work in pure mathematics has been of a very varied character, the most noteworthy, perhaps, being concerned with linear differential equations and their integration, and with the theory of the uniform functions of a variable.

The Royal Society elected Prof. Georg Quincke of Heidelberg as a Foreign Member in 1879, for his researches in physics. He is one of the veterans of science, his first paper having been published so long ago as 1856. All branches of physics have been benefited by his careful experimentation and acute reasoning. Few workers, indeed, can claim to have added so much as he to our knowledge of physical laws, or to have studied natural phenomena in a more comprehensive and profound manner. His researches on capillarity, carried on thirty-seven years ago, led up to the important work in which he showed that the movements of amœbæ and protoplasm can be fully explained by physical laws.

Prof. Strasburger is Professor of Botany in the University of Bonn, having previously been Professor in the University of Jena. He is a Foreign Member of the Royal Society. Having made his mark in Morphology by his monumental work on the Gymnosperms ("Die Coniferen und Gnetaceen," 1872), he has since chiefly devoted himself to the study and investigation of the nucleus of the cell, with special reference to the reproductive processes of plants in their connection with the phenomena of heredity. His researches fill several volumes, such as "Zellbildung und Zelltheilung," "Angiospermen und Gymnospermen," "Unters. ueb. d. Befruchtungsvorgang," and his recent "Histologische Beiträge." It is not too much to say that to Prof. Strasburger's researches is due nearly the whole of our present knowledge of the processes of cell-division in plants.

SECTION I.

PHYSIOLOGY.

Opening Address by Prof. E. A. Schäfer, F.R.S., President of the Section.

Before beginning the subject matter of my address I had conceived it to be necessary, appearing before you as we do as a new Section, to offer some sort of apology for our presence. But, on looking up the history of the Association, I find that my task is somewhat different. If I have any apology to offer at all it is that the Section of Physiology has ceased to appear for many years.

The British Association was founded at York in 1831; and at the subsequent meeting, which was held in this very city of Oxford, amongst other Sections which were established, was one for Anatomy and Physiology. Now, when we consult the records of this Section we are struck with the fact that Medicine early shows a marked preponderance. Thus, in 1833 a physician is selected as President for the Section, with two surgeons as secretaries: one of them, be it noted, being Mr. Paget. This preponderance soon came to be recognised in the designation of the Section, for in 1835 we find it entitled Section E, Anatomy and Medicine.

As time went on the interests of medical men became gradually more absorbed in the rapidly growing British Medical Association; and in 1841 the medical title was dropped, and the Section came to be called simply Physiology, which title it retained until 1847. Under that designation the Section has now been revived.

The fact that Physiology as a separate section in this Association was allowed to lapse for so long a period is not remarkable when we remember that during the first half of this period Physiology as a science was practically non-existent in this country. The teachers of Physiology were, almost without exception, practising physicians and surgeons, and even when a professor was expected to devote the whole of his time to the teaching of Physiology he was not expected to devote part of that time to the prosecution of physiological research. During all these years, from 1833 to 1847, we do not find amongst the officers of the Section any actual working physiologists. Most of the officers were distinguished medical men, with an anatomist here and there amongst them. Far be it from me to say that there was no actual work being done in Physiology at this time; for Charles Bell and Marshall Hall were engaged in elucidating the functions of the nervous system; whilst Bowman, Wharton Jones, and others were producing good and permanent work in various other departments of Physiology. Their labours, however, were isolated, and formed but oases in the Sahara of neglect into which the pursuit of Physiology had fallen in this country; and this during a period when it was being pursued with signal success and activity both in Germany and France.

After 1847 a revival of Physiology began to manifest itself even here; and this was followed by the establishment, from time to time, of a sub-section to Section D, which was devoted to Physiology, and had a special President. Whether, however, owing to their subordinate character, or from some other reason, these sub-sections had not usually any great measure of success, and for the last twelve years they have been wholly dropped. During that period Physiology has only twice been represented in the chair of Section D, and has usually had no secretarial representation. This decadence of Physiology in the British Association during the last eleven or twelve years is the more remarkable because it is obviously not due to any want of outside activity in regard to the subject; for during this period we find an extraordinary revival of interest in physiological research, a revival which in its most active stage dates from about twenty-five years ago, but still some twenty or thirty years later than the corresponding revival in France and Germany. I have taken the trouble to prepare a list of prominent physiological workers who flourished during the thirty years prior to 1870. My list comprises, in all, thirty. Of these four are English, five French, and twenty-one German or Dutch. Of the four English working physiologists not one is a teacher of Physiology. Of the five French and twenty-one German all are recognised teachers. It was not, in fact, until it came to be understood that teaching and work in Physiology, as in all branches of science, ought in the main, to be successful, to go hand in hand, that the science had any possibility of revival.

Let us glance for a moment at the history of the revival of Physiology in this country as compared with its revival in Germany. In each country the revival may be said to have been largely due to the influence of one teacher. In Germany the teacher was Johannes Müller; in this country, William Sharpey. Both of these remarkable men were pupils of Rudolphi, who was professor of Anatomy and Physiology in Berlin until 1833. It is stated regarding Rudolphi that "he was an enemy to subjective speculation in biological science: he looked on the so called philosophy as mistaken and futile in its application to the phenomena of the animal economy, and based his physiology chiefly, and perhaps rather exclusively, on the study of the animal structure." The influence of Rudolphi is apparent in both Müller and Sharpey.

Muller was born in 1801, Sharpey in 1802; they were therefore of about the same age. But Muller's scientific and intellectual development was more rapid than that of his contemporary. Thus we find that already in 1826, when he was but twenty-five years old, Muller attained so great a reputation as to be made Professor Extraordinary in the University of Bonn; and before very long he was promoted to the grade of Ordinary Professor there. In 1833, whilst still a young man, he was called to the chair of Anatomy and Physiology at Berlin, which had just become vacant by the death of his master and friend, Rudolphi. Sharpey, on the other hand, occupied himself until 1829 with perfecting both his general and his special anatomical education. It was not until 1830 that he published his first essay in anatomical and physiological research entitled "On a Peculiar Motion excited in Fluids by the Surfaces of Certain Animals"—observations which were preliminary to the discovery of the existence of cilia in vertebrates. And it was not until 1836 that he was called to the newly instituted professorship of Anatomy and Physiology in University College, London, which he filled for so many years with such signal success. Both of these distinguished men owed, there is no doubt, their success as teachers of Physiology to their early anatomical training. The general anatomical bent of Johannes Muller is evidenced by the fact of his scientific work being turned so much in the direction of comparative Anatomy and Physiology. And Sharpey, although great, and deservedly great, as a teacher of Physiology, remained to his dying day, above all, an anatomist. Physiologists of this school are rare at the present day; but it is probable that in some respects the progress of Physiology may suffer thereby. Helmholtz began his public career as professor of Anatomy; but it would be unfair to attach too much weight to this particular incident in the case of so many-sided a man as the great Berlin Professor of Physics. Nevertheless, the necessity of a close and careful training in Anatomy for those who are afterwards to work at or to teach Physiology is so important that I do not hesitate to say that the younger physiologists who neglect the study of Anatomy will find that before very long they must abandon the pursuit of many byways of Physiology which might otherwise be followed up with manifest advantage.

The influence of Johannes Müller upon the revival of the pursuit of scientific Physiology in Germany, and indeed generally, cannot be over-estimated. We have only to look at the names and eminence of his pupils in order to recognise the immense influence which his teaching has exerted upon the progress of Physiology ever since his time. Some of these pupils are still amongst us, others have joined the majority. But the pupils of these men, again, are now great names in many departments of our science, and through them we cannot fail to recognise the influence which was exerted by this truly great man.

We may say the same in almost identical words of William Sharpey. The practical pursuit of Physiology in this country has mainly radiated from the centre where Sharpey taught. Michael Foster was his pupil. The physiological investigations of Burdon-Sanderson were assisted and encouraged by him. From Sharpey, therefore, we may trace the rise of the great school of Physiology at Cambridge, and we have only to look at the magnificent laboratory which has been erected here to observe a monument of the influence of the same teacher. And there have emanated either directly from the physiological school established by Sharpey at University College, or indirectly from those at Cambridge and Oxford, many of the most active teachers and workers in Physiology in the kingdom.

In these respects there is much in common between the revival of Physiology in Germany and in this country. In other respects, however, the two cases have been entirely under different conditions. There its revival, in common with that of science generally, has been assisted and stimulated by the active and beneficent co-operation of every German State. Here, also, in common with science generally, it has had to make its way against every conceivable obstacle; and almost without assistance, either moral or material, from the Government or from public bodies. But not only has it not met with assistance, there have been actual obstacles placed in the way of teaching and work in Physiology. Some have been unintentional, others intentional. As an instance of the unintentional may be mentioned the practice which has obtained in medical schools and on examining boards—a practice which, I am happy to say, is gradually being discarded—of appointing as teachers and examiners in Physiology men who may have a good general knowledge of the science, yet with whom it is not the business of their lives; and who cannot, therefore, be expected to be as familiar with its details, and absorbed in its interests, as those who devote their entire time and attention to its pursuit.

The more virulent opposition, in some measure, to science generally, but in the greatest measure to Physiology, appeared almost simultaneously with the active revival of the subject. This opposition, which has come to be known as the Anti-vivisection Movement, but which might equally well be called the Anti-scientific Agitation, has hitherto met with no measure of success, except that it has to a certain extent hampered the full development of the science by diverting to its defence some of the energy which might be devoted to its pursuit. Indeed, the actual results of this unreasoning agitation furnish an illustration of the old-established principle that persecution of a good cause will in the long run tend towards its development and propagation. And in this case the chief results have been the following:—

(1) The most immediate effect of the anti-vivisectionist attack was the establishment of the Physiological Society, which in the first instance was only a small gathering of working physiologists, who met to discuss measures of defence in a drawing-room in Queen Anne Street. This society, which had such a small beginning, is now large and important. Its doors are besieged by applicants for admission, although it is a necessity for such admission that the applicant be either a teacher of Physiology or a worker at Physiology, or both. Its numerical strength has grown from ten to fifteen to more than 150; and its numbers are every year increasing. And, besides the work which it has done in this country in promoting the interests of Physiology, and co-operation between English physiologists, it has succeeded in establishing a succession of triennial International Congresses of Physiology, which are amongst the most successful of such gatherings, and which have been the means of bringing us into communication with the most prominent physiological workers and teachers on the continent.

(2) A second result of the agitation was the passing of the so-called Cruelty to Animals Act. This Act, which was intended to restrict the performance of experiments upon animals, was in no sense called for, since it had been found by a Royal Commission that there was no evidence to show that there had been unnecessary experimentation upon animals, or any desire on the part of physiologists to neglect the use of anæsthetics. On the other hand, it is of inestimable advantage in that it gives the public a definite guarantee that the excesses of which physiologists used to be freely accused are not possible. Such excesses never did actually occur; although, to believe all the publications which have been issued by Anti-vivisection Societies, one would come to the conclusion that a physiologist is a being who spends his whole time in torturing sensitive creatures, careless of the suffering which he may cause, or even of the scientific results which he may obtain. The fanatical supporters of the agitation would have you to believe that we are all neither more nor less than "fiends"; they cry with Ferdinand that "hell is empty and all the devils are here."

I am told there was even a feeling of this sort in this University at the time when it was proposed to establish the Wayneflete Professorship of Physiology, and that an agitation was set on foot having for its object, first, the prevention of the establishment of such professorship; and secondly, that being impossible, the prevention of the professor's practising physiology. The common-sense of the University stifled this agitation, and the more intimate acquaintance with physiologists, which has resulted from the establishment of the school, has been sufficient, I believe, to smother the little fire which was still left smouldering.

(3) A third result of the Anti-vivisection Agitation was the establishment of the Association for the Advancement of Medicine by Research. This immediately followed a unanimous resolution of the International Medical Congress of 1881, affirming the necessity of experiments upon animals. To the ignorant accusation that physiological experiments had been and were of no use or influence in the advancement of medicine, the leaders of the profession unanimously affirmed that it is upon Physiology hat Medicine and Surgery are based, and that there can be no real progress in those sciences without a corresponding progress in experimental Physiology and Pathology. The Association for the Advancement of Medicine by Research has been of the greatest possible value and assistance to Physiology in this country. It has shown physiologists that they have the great medical profession at their back, and it has acted as an impartial and independent medium of communication between physiologists and the successive Secretaries of State, whose business it has been to administer the Act.

(4) A fourth result of the attacks of the anti-vivisectionists has been, I may perhaps be permitted to believe, the re-establishment of this Section of Physiology of the British Association. Those who were present at the meeting of the Association in Nottingham may have remarked that the gutters of that town were strewn with papers which had been forced upon the members of the Association by the anti-vivisectors of the place. This literature, which in a double sense may be termed "gutter literature," teemed with flagrant misstatements, and with vicious calumnies, directed against physiologists, and especially called forth, I presume, by the fact that for the first time in the history of the British Association a physiologist was called upon to occupy the presidential chair. We may look upon the establishment of this Section as the reply of the Association to the false witness which was borne against us at Nottingham.

But although a special section for Physiology has been re-established, it may not be advantageous that there should be one at every meeting of the Association. Physiology is above all things a practical science. It requires laboratories and means of demonstration. Physiologists are rarely satisfied with the opportunity of hearing and reading papers, but require that, as much as possible, the actual methods of research employed should be capable of demonstration. By this I am not to be supposed to advocate the demonstration of experiments upon animals, for there are very many subjects in Physiology which can be both worked at and illustrated in a manner involving in no sense whatever the word vivisection. But in order that the methods should be shown, it is important to have the appliances of a laboratory at hand, and the Association frequently meets in towns which are not university towns, and have no laboratories, in which, therefore, it would be difficult or impossible to arrange for demonstrations of the sort that I am alluding to. On this account we may well imitate the practice of the British Medical Association, which establishes a Section of Physiology only when its meetings are held in such a centre as is likely by the applicances which are to be found in that centre to render the Section useful and efficient. Hence, in recommending the establishment of a Physiological Section, it is expressly reserved that the Section shall be held only at such future meetings as may seem to the council to be desirable.

I will now invite you to consider with me one or two of the more obscure subjects in the range of Physiology, subjects which are, however creating a great, almost an absorbing, interest at the present moment The first of these subjects relates to the structure and function of every cell in the body. All are aware that the body of every animal and of every plant is made up of minute corpuscles which are formed of protoplasm, and which contain in every case at least one nucleus. The protoplasm and the nucleus form the living substance of the cell. Other substances may be present, but they are, in a sense, outside the nucleus and protoplasm, not incorporated with their substance. Apart from a few details relating to the structure of the nucleus, this was, until quite lately, practically all that we knew regarding the parts composing either the animal or the vegetable cell. There appears, however, to be yet another something which, although in point of size is of very insignificant dimensions, yet in point of function may perhaps be looked upon as transcending in importance, in some respects, both the protoplasm and the nucleus. Not many years ago it was noticed by various observers that in certain specialised animal cells the protoplasm showed a tendency to radiate from or converge towards a particular point, and on further investigation it was found that at this point there was a minute particle. This observation, which began, as we have seen, upon specialised cells, was, after a little while, found to hold good for other and yet other cells, until, at the present time, we believe that in every cell of the animal or plant body such a particle exists Now, it may well be asked, why after all should so great importance be attached to this observation? To this it may be replied that, in the first place, it is of importance, because it shows conclusively that the whole cell is not of a uniform nature, since there is this one point within the cell that exerts a special attraction upon the rest of the cell-substance: and, indeed, on this account the particle has come to be termed the "attraction particle." And in the second place, because of the apparent universality of the occurrence of such a particle. And, thirdly, because of the fact that one of the most important phenomena exhibited by the cell hinges upon the behaviour of this particle; for it is found that before a cell or its nucleus divides this minute attraction particle begins by itself dividing, and is, in fact, more commonly met with double than single. Nor is it until the two particles thus produced have evolved, either from themselves or from the substance of the protoplasm or nucleus, a system of communicating fibres, the so-called *achromatic spindle*, that those changes in the nucleus and protoplasm take place which produce the division and multiplication of the cell. This *attraction particle*, which is also called the *central particle* or *centrosome*, has absorbed so great an interest that, short as is its history, many papers have already been devoted mainly to it, the latest of these being an elaborate treatise of some 300 pages by Martin Heidenhain. I shall not here attempt to follow out the details of all these researches, but will be satisfied with putting before you the conclusion which Heidenhain has come to regarding this particle, viz. "that it is morphologically, physiologically, and chemically a structure *sui generis;* not merely a separate portion of nucleus or of protoplasm, but an organ of the cell with definite functions, and having a definite existence of its own." Nevertheless, it is almost as minute an object as it is possible to conceive. In a cell which is magnified a thousand diameters the central particle appears merely the size of a pin-point. Yet this almost infinitely small object exerts an extraordinary influence over the whole cell, however large (and the cell may be many thousand times its size); for it initiates and directs those processes which result in the multiplication of the cell, and indirectly, therefore, it is concerned in directing the general growth of the individual, and ultimately the propagation of the species.

A former President of the Association took as the subject of his presidential address what he was pleased to call the "Next to Nothings." In considering this central particle, of the actual structure of which, and of its chemical constitution, we know at present hardly anything, we may surely regard it as a striking instance of the supreme importance of the "next to nothing" in Physiology.

The other subjects to which I desire to draw your special attention relate to the physiology of certain organs the functions of which have always been extremely obscure, and which, although they differ greatly from one another in almost every point of structure, and presumably also in function, it has been usual to group together under the name of ductless glands. The name "gland" is given to such organs of the body as take materials from the blood, and convey those materials in an altered or unaltered form, by a tube or duct, to a surface either internal or external. Such material is termed the secretion of the gland, and has for its object either the performing some function which is useful to the organism or the getting rid of material which would be detrimental if retained. In the case of the ductless glands there is no such possibility of pouring out material produced by the gland upon a surface, because these organs do not communicate with any surface by a duct; and whatever material they may furnish must therefore, if it is to reach the body generally, pass into the blood; that is to say, the blood on the one hand must furnish the materials for the secretion of the gland, and on the other hand it must take up those materials after they have been manufactured into something else, and carry them away to other parts of the body. Now, in the case of a certain number of the ductless glands there has not appeared to be any very great obscurity as to their function; for some of them seem very obviously to be devoted to the formation of corpuscles which are found within the blood itself. But with regard to others of these bodies it has not hitherto been possible to find any special material in the blood which they have furnished to it, and our knowledge of them is derived almost entirely from experiments. I will take the case of two of these to illustrate the vast influence which small and almost disregarded organs may exert upon the whole economy. But in the first place I may be permitted to point out what is indeed a self-evident statement, that there is no part of the body which does not exert some influence upon the rest. Every single portion of the body is continually taking materials from the blood, and furnishing to the blood other materials which are formed within it, whether we call that portion which performs such functions a gland or not; and it is quite certain that the removal of any portion of the body would be followed by some permanent alteration in the blood were it not that other similar parts may by increased activity compensate for the alterations which the blood would otherwise undergo from the loss of any one such part. Take the case of a limb. The changes which the blood undergoes in circulating through it affect the body generally through that fluid, for the composition of the blood becomes modified in traversing the limb. And not only is the body affected thus through the medium of the blood, but, by means of the nerves which pass to and from the limbs, the central nervous system is itself affected by the movements and alterations of various kinds which are proceeding in the muscles and other parts, and through the nervous system the whole organism must constantly be influenced from the limb. There is, however, no evidence that the removal of a limb or part of a limb permanently modifies either the condition of the blood or of the nervous system. Nor is such a result to be expected, for in this case there are other parts of the body possessing similar organs and performing similar functions, the increased activity of which may easily compensate for the loss which is sustained through removal of such a part.

But if we deal with an organ which is not multiple, but unique, and completely remove this from the body, it is easy to see that the case may be very different. This organ, like every other organ of the body, is continually taking from the blood some materials and giving up to it certain other materials. Now it is clear that its removal must make a permanent difference in the blood, and since the whole organism is remarkably sensitive to even slight changes in the composition of the circulating fluid, very marked results may well follow the removal of such organ. And this is in fact found experimentally to be the case.

It has long been known that extensive disease of the thyroid gland, a small reddish organ, weighing about one or two ounces, found at the front of the throat, is followed by extensive alterations in the nutrition of the body generally. The patient becomes swollen from the overloading of the connective tissues with a mucinous exudation; the nervous and muscular systems are seriously affected; the power of generating heat is greatly modified; and the final result is, in the first instance, the production of a condition of semi-idiocy, ultimately followed, if the disease be extensive, by death. Precisely similar results have been found in animals, and in fact in man as well, to follow the complete removal of this body. Yet the weight of this organ is not more than one sixteen-hundredth part of the whole weight of the body; and even this figure does not represent the enormous influence which a relatively small organ can exert upon the general nutrition of the body; for it is found that even if a minute part of the thyroid gland be left whilst the greater part is removed, the symptoms above enumerated do not supervene. Indeed, certain contradictory results which have been got by some observers after removal of the thyroid are explained by the fact that in some individuals there are minute detached particles of thyroid gland lying apart from the main organ; and that after the latter has been removed these detached particles may sufficiently carry on the function of the organ in relation to the blood and the nervous system to prevent the supervention of the deleterious symptoms which usually occur after its removal. Here is, then, a notable instance of the enormous influence exerted by a "next to nothing" upon the general organism.

Another illustration may be given from these ductless glands. It was noticed in 1849 by a celebrated physician, Dr. Addison of Guy's Hospital, that certain cases, accompanied by extreme debility, occurring in the human subject were associated with the appearance of peculiar bronzed patches on parts of the skin and mucous membranes; and on post-mortem examination of these cases, which always sooner or later have a fatal termination—and indeed sooner rather than later—he found the symptoms in question to be accompanied by disease and destruction of the supra-renal capsules—small bodies which are placed close to the kidneys, but which, so far as we know, have no physiological connection with them. Now when experiments came to be directed upon these bodies in order to elucidate their functions, and especially to observe whether their injury or removal was accompanied in animals also by symptoms similar to those occurring in man as the result of disease, it was found by Brown-Séquard that when these bodies are totally removed in any animal the removal is speedily followed by a fatal result. These experiments of Brown-Séquard's were made in 1858, and at the time attracted some attention. They were repeated by other experimenters with similar effects. But some of those who removed the supra-renal capsules obtained contrary results, and for many years the matter remained in an undecided condition. It was even supposed that the fatal results which were got by Brown-Séquard might be due to the shock of the operation or to the fact that the removal necessarily involves certain parts of the sympathetic nervous system, and were not necessarily due to the removal of the supra-renals. Recently, however, attention has been again directed to the subject, and the experiment of Brown-Séquard has been repeated by Tizzoni (1889) and by Abelous and Langlois (1891 to 1894) in various animals, viz. frogs, guinea-pigs, rabbits, and dogs. I have myself performed two confirmatory experiments in monkeys. The result of all these recent observations is to show that the complete removal of the supra-renal capsules is not compatible with prolonged existence of life, and Abelous and Langlois have shown that it is accompanied by an alteration in the blood, which renders that fluid poisonous to other animals. The contrary results which have been obtained by some investigators are apparently due to the fact that in certain cases there are, as with the thyroid body, small isolated portions of supra-renal substance ("accessory capsules," as they are sometimes called) which have not been noticed and removed at the time of the operation, and that these small portions of supra-renal substance have served to maintain that proper relation between the blood and the gland which is sufficient to prevent the supervention of the symptoms in question.

Now the weight of both supra-renal capsules taken together is not more than three drachms, and their weight, as compared with that of the whole body, is only as 1 to 6000 or less. The accessory supra-renal capsules which may be left after the removal of the main bodies probably do not originally weigh more than one-twentieth of the whole structure, and yet this minute proportion of material (a material, so far as we know, unique in the organism) is nevertheless sufficient to maintain the composition of the blood and the nutritive equilibrium of the body, and thus to prevent the necessarily fatal result of complete removal.

Now it has been found in the case of the thyroid gland that patients in which this structure has been so diseased that its function is seriously interfered with, and animals in which it has been removed entirely, may be greatly benefited, if not indeed cured, by the inception, either subcutaneously or with food, of the thyroid glands of animals, or of the juice of such glands. Even where no affection of the thyroid can actually be detected, the exhibition of thyroid juice is frequently beneficial in certain conditions of the system, and it was noticed by Dr. Oliver, of Harrogate, that this is especially the case where there is a too marked constriction of the blood-vessels, the juice of this body tending in such cases to reduce the extreme tone of the vascular walls, which is the cause of this condition. Encouraged by this result, Dr. Oliver was led to examine the effects of other animal extracts, and among them that of extract of supra-renal capsule. The effect of this was precisely the reverse of that which he had got with the thyroid body, for he obtained evidence tending to show that in certain cases in man extract of supra-renal capsule can produce an *increase* of vascular tone and a diminution in the size of the arteries. Beyond this point, however, Dr. Oliver was unable to proceed by clinical experiment, and he accordingly came to my laboratory with the object of determining the precise physiological effect of the active substance of the capsules. The results which were obtained show that there is present in both alcoholic and watery extracts of the gland a most potent physiological substance which when injected into the body of an animal produces, even in minute doses, a remarkable effect upon certain parts of the nervous system, upon the muscular system, upon the heart, and upon the blood-vessels. If only as much as a grain by weight of supra-renal capsule be extracted with alcohol, and if this alcoholic extract be allowed to dry, and then be redissolved in a little water or salt solution and injected into the blood of a dog, the results which are obtained, considering the minute amount of substance added to the blood, are certainly most extraordinary. The nervous centre which regulates the action of the heart is powerfully affected, so that the heart either beats very slowly and weakly, or the auricles may even for a time stop beating altogether. If, however, these inhibitory influences be cut off by division of the vagi nerves, the effect of the poison upon the heart is of an opposite character. There is great acceleration of the rate of the beat and a great increase of force. This is accompanied by a strongly marked influence upon the blood-vessels, and especially upon the arterioles. The walls of these are chiefly muscular, and the drug exerts so powerful an action upon this muscular tissue as to cause the calibre of the vessels to be almost obliterated. The heart being thus increased in force and accelerated, and the calibre of the vessels almost obliterated, the result is to raise the pressure of the blood within the arterial system to an enormous extent, so that from a blood-pressure which would be sufficient to balance a column of some four inches of mercury the pressure may rise so high as to be equal to a column of mercury of twelve or more inches.

This result is obtained, as we have seen, by a very minute dose. We have to do here with a substance which is as potent, although in a different direction, as strychnia. Whether it is a useful substance formed by the supra-renals from materials furnished by the blood, and subsequently gradually used in the economy for the virtue of its action upon the circulatory system, or whether it is to be regarded as a poison, formed by the tissues during their activity and carried by the blood to the supra-renals, there to be rendered innocuous, we do not as yet certainly know. These are important points which must form the subject of further investigation. But, however this may be, it is clear that in this gland also we again meet with an instance of the physiological importance of what Sir Frederick Bramwell called the "next to nothing."

I will give one more instance, taken this time from a gland which is provided with a duct. Until quite recently it might have been thought that there was nothing very obscure regarding the functions of the pancreas. The pancreas is a digestive gland which lies below and behind the stomach: it has a duct which carries its secretion into the beginning of the intestine, and that secretion acts powerfully upon all constituents of the food, digesting starch, meat, and fat. It was not supposed that the pancreas had any other function to perform. Animals can live without this secretion, and to a large extent can continue to digest and absorb their food much as before; for it has been possible to divert the secretion from the intestine and to collect it at the surface of the body; and it is found under these circumstances that, although the food is not quite so readily digested, nevertheless the animal does not materially suffer from the lack of the secretion. It was discovered, however, a few years ago (by v. Mering and Minkowski) that if, instead of merely diverting its secretion, the pancreas is bodily removed, the metabolic processes of the organism, and especially the metabolism of carbohydrates, are entirely deranged, the result being the production of permanent diabetes. But if even a very small part of the gland is left within the body, the carbohydrate metabolism remains unaltered, and there is no diabetes. The small portion of the organ which has been allowed to remain (and which need not even be left in its proper place, but may be transplanted under the skin or elsewhere) is sufficient, by the exchanges which go on between it and the blood generally, to prevent those serious consequences to the composition of the blood, and the general constitution of the body which result from the complete removal of this organ. Now, some years ago it was noticed by Kuhne and Sheridan Lea that, besides its proper secreting structure composed of tubular alveoli, lined by granule containing cells, there are highly vascular patches of peculiar epithelium-like cells scattered here and there in the substance of the pancreas, which are wholly unconnected with the ducts and, so far as one can judge, with the secretion of the gland. We do not know anything whatever about the function of these patches, although from their vascularity it is extremely probable that they are not without importance physiologically, and it is tempting to conjecture that it is these cells which are specially concerned in effecting that influence upon the metabolism of carbohydrates which experiment has shown to be peculiar to the pancreas.

The lesson to be drawn from these results is clear. There is no organ of the body, however small, however seemingly unimportant, which we can presume to neglect; for it may be, as with the supra-renal capsules, the thyroid gland, and the pancreas, that the balance of assimilation and nutrition, upon the proper maintenance of which the health of the whole organism immediately depends, hinges upon the integrity of such obscure structures; and it is the maintenance of this balance which constitutes health, its disturbance, disease. Nor, on the other hand, dare we, as the investigation of the attraction-particle has shown, afford to disregard the most minute detail of structure of the body.

> "All is concenter'd in a life intense,
> Where not a beam, nor air, nor leaf is lost,
> But hath a part of being."

PHYSICS AT THE BRITISH ASSOCIATION.

AFTER the President's address on Thursday morning, Lord Kelvin opened the proceedings in Section A with an account of some preliminary experiments made by himself and Mr. Maclean on the electrification of air by the subtraction of water from it. The subject is one in which Lord Kelvin has been for many years interested, and he commenced experimenting on it as far back as 1868. The nature of the results now obtained was illustrated by his insisting that the proper title of the paper was "Preliminary experiments *to find if* subtraction of water from air electrifies it" (and not as in the *Journal*—"Experiments *proving* the electrification of air"). In the present investigation a large U-tube was used. One branch of this was filled with pumice-stone soaked in sulphuric acid; the other was simply varnished inside and out. By means of a platinum wire touching the pumice, connection was made with a quadrant electrometer. A metal cylinder screened the tube from external influence. Air from an ordinary blow-pipe bellows was blown through the tube steadily for an hour; and the electrometer showed an electrification rising gradually to about nine volts positive. This shows that the passage of the air through the tube gave positive electricity to the acid, and therefore sent away the dried air electrified negatively. No such effect was observed when the pumice was moistened with water instead of sulphuric acid. The experiments are to be repeated with precautions to prevent any bubbling of the air through liquid in the tube; for it was observed that the strong positive electrification of the tube (when acid or calcium chloride was used) seemed to commence suddenly as soon as a gurgling sound, due to bubbling through free liquid, began to be heard. The authors have reversed the conditions, and have first dried air by passing it over sulphuric pumice, and then passed it through a tube containing moistened pumice. The tube became negatively electrified, but this may have been due to the negative electrification of the dry entering air. This experiment is to be repeated with dried and dis-electrified air. Lord Kelvin also described certain preliminary experiments made by himself and Mr. Galt with the object of comparing the discharge of a Leyden jar through different branches of a divided channel. The metallic part of the discharge channel was divided between two wires of conducting metal, each consisting in part of a test-wire. Each of the two test-wires consisted of 51 cm. of platinum wire of 0·006 cm. diameter and 12 ohms resistance stretched in a glass tube. One end was fixed to a solid brass mounting, and the other was attached to a fine spring carrying a light arm for multiplying the motion. The testing effect was the heat developed in the test-wire by the discharge, as shown by the elongation, the amount of which was measured by a tracing on sooted paper carried by a drum. The wires to be tested were generally of the same length. When they were of the same material but of different diameters, the testing elongation showed, as might be expected, that the test-wire in the branch containing the thicker wire was more heated than the other. With wires of various non-magnetic materials, of the same resistances but different lengths and diameters, the testing elongations were very nearly equal. In one experiment two equal copper wires were used, but one of them was coiled into a helix; the testing elongation in this branch was less than half of that in the straight branch. Lastly an iron wire was compared with a platinoid wire of equal resistance but greater diameter. The heating effect in the platinoid branch was nearly one-and-a half times as great as in the iron branch. This is interesting in relation to Lodge's experiments on alternative paths, which were not decisive in showing any general superiority of copper over iron of the same steady ohmic resistance, but even showed a seeming superiority of the iron for efficiency in the discharge of a Leyden jar.

Prof. Oliver Lodge followed with a communication on "photo-electric leakage." It is known that a negative charge on an electrified surface escapes much more rapidly when the surface is illuminated with ultra-violet light (Hallwach's experiment). Prof. Lodge has investigated the rate of discharge for a number of substances under positive as well as negative electrification, and in hydrogen as well as air. He finds that when the inside of an electrified pewter-pot is illuminated, it does not leak; but when the edge is illuminated, it leaks rapidly. Thus the leakage appears to be a matter of surface-tension, and not of potential. In the discussion which followed, Prof. S. P. Thompson stated that he had verified the statement made by Elster and Geitl, that when the light is polarised the effect depends upon the plane of polarisation, the leakage being most rapid when the Fresnellian vibrations are in such a direction as to "chop into" the surface. He has found an analogous difference in the action on selenium cells.

Mr. G. H. Bryan presented the second part of his report on the present state of knowledge in thermodynamics. In a lengthy and valuable paper he discusses the limitations to the law of distribution of energy in the kinetic theory. He deals primarily with the so-called Boltzmann-Maxwell law of distribution of energy among the molecules of a gas, which law forms the basis of the kinetic theory of gases. One of the main points kept in view has been to show, as far as possible, where to draw the line between dynamical systems which do, and dynamical systems which do not satisfy the law in question. A great advance in the subject is due to the extension of the use of generalised co-ordinates, by which greater generality has been given to results, and the analysis has been much simplified, as a comparison of Boltzmann's early papers with modern writings abundantly testifies. A further simplification has been effected by the extensive use of the Jacobian notation in this report. The report is divided into three sections. In Section I. the law is regarded in the aspect of a general dynamical theorem without reference to any particular applications, and without taking into account the effect of collisions. Section II. treats of its application to a system of bodies colliding with one another indiscriminately, and partaking of the nature of gas molecules. Section III. deals briefly with certain researches relating to the connection between the Boltzmann-Maxwell law and the Theory of Probability, the Virial Equation, and the Second Law of Thermodynamics. With regard to non-colliding systems (Section I.), it may be asserted that a large portion of our progress has been made in, firstly, showing that Maxwell's demonstrations are faulty and unsatisfactory, and by subsequently discovering fresh methods of proof, which, while leading to the same general conclusions, show more clearly the limitations and conditions under which these conclusions hold good. Test cases of Maxwell's law are given, and also an account of Mr. Culverwell's criticism of the "decisive" test case by which Lord Kelvin claims to have effectually disposed of the law. It is urged that uniformity of nomenclature is most desirable in this as in other branches of science, and hence that some definite understanding should be agreed on as to what precisely constitutes the Boltzmann-Maxwell law. The following statements are recommended:—(1) That the distribution of a large number of molecules or other dynamical systems of the same or different kinds in which the coordinates (q) and momenta (p) of each system are so arranged that the number of systems in the neighbourhood of any given state is proportional to

$$e^{-hE}dp_1 \ldots dp_m dq_1 \ldots dq_m$$

h being the same for all the kinds of molecules or systems, be called the Boltzmann-Maxwell distribution. (2) That the law which asserts the permanence of the Boltzmann-Maxwell distribution in any particular case be called the Boltzmann-Maxwell law. (3) That in future these names be not applied to any corollaries such as that which asserts the equality of the average value of the squares into which the kinetic energy can be split up. That corollary may be called Maxwell's law of partition of kinetic energy.

The proof of the Boltzmann-Maxwell law, and the assumptions involved in it, may now be regarded as fully satisfactory for gases whose molecules collide with one another to a certain extent at random, but in a medium in which the molecules can never escape from one another's influence the subject still presents very grave difficulties.

On Friday the Section held a joint meeting with Section G, at the headquarters of the latter in Keble Hall. The first subject of importance was a discussion on integrators, harmonic analysers and integraphs, and their application to physical and engineering problems. A number of these were exhibited, both models and working instruments, some of the latter being beautiful specimens of Swiss workmanship. For the discussion an hour and a half had been allowed: of this the opener, Prof. Henrici, occupied the greater part, but did so to the entire satisfaction of his audience. The subject had been discussed at previous meetings by Sir Frederick Bramwell at Brighton, and by the late Mr. Merrifield at Swansea; Prof. Hele Shaw had also read a paper on the subject before the Institute of Civil Engineers. The first planimeter was invented by a Bavarian engineer named Hermann. It was lost sight of, but was subsequently reinvented in 1825 and 1826, and from it our present planimeters are derived. Amsler invented his instrument in 1854, and first published an account of it in 1856. Planimeters may be classified in two ways. As Prof. Hele Shaw subsequently remarked, it is natural for an engineer to classify instruments with reference to their mechanical action, and thus planimeters may be divided into two classes, according as the wheel does or does not slip. Prof. Henrici prefers a classification depending upon the geometrical properties involved in the action of the instrument. A planimeter measures the area swept out by a line. The length of the line may either be fixed or variable. Again, a line in a plane may either move or turn. To obtain general areas we have a choice of two combinations (for only special areas could be traced, *e.g.* by a line moving parallel to itself). The first class of planimeters depends upon the motion of a line which can both turn and move parallel to itself, but which remains of fixed length. The line takes the form of a rod of fixed length, one end of which is jointed to another rod so as to move on a circle about a fixed point (the pole), while the other end is provided with a tracing-point to be moved around the figure whose area is to be evaluated. These planimeters can only be used to integrate around closed curves. It does not matter where the wheel is placed along the rod, but its axis must be parallel to the axis of the rod. This introduces one of the most serious difficulties with which the maker has to contend. In Amsler's planimeter the rod can only be used on one side, so that the error is always in the same direction; but an improved form was exhibited in which the rod can be used on both sides, so that this error is eliminated. Then there is the slipping error. Maxwell drew attention to this, and was the first to propose an instrument in which there was no slipping at all. There are a number of planimeters in which the wheel, instead of rolling on the paper, rolls on a prepared surface. There is always some resistance to the motion of the wheel and counters, and this increases the slipping. The error can be reduced to a minimum by diminishing as far as possible (1) the friction between the paper and the wheel (as by using a prepared surface); (2) the resistance to the motion of the wheel. In using the instrument we should also avoid getting the instrument in such a position that the wheel has to move much at right angles to its own plane, for then the friction and slipping error is greatest. Amsler, in his first paper (1856), foreshadowed many improvements which have since been carried out; and in his second paper (he only published two), he described a planimeter depending upon the action of a cylinder rolling on a sphere, in which there was no slipping. Maxwell suggested two forms of instrument in which slipping was altogether avoided; but they were never made. The second class of planimeters depends upon the motion of a line of variable length which moves without turning. They give the value of definite integrals between any fixed limits, and may be called integraphs. Instruments of this type have been devised by Lord Kelvin, Abdank-Abakanowitz, Vernon Boys, and Conradi. To engineers it is more important to be able to integrate a curve than an expression; and an integraph can give the integral of a curve as a curve. Lord Kelvin and Boys have shown how instruments may be made to integrate a differential equation. The idea of a harmonic analyser was given by Amsler in his first paper as early as 1856, but Lord Kelvin first actually constructed one. It has been of great service in analysing tidal motion; but it is bulky, and cannot be carried about. Prof. Henrici has devised two others, one of which will give five terms in the expansion according to Fourier's theorem of any curve. These analysers should prove of great use to engineers and electricians, *e.g.* in investigating the action of valve-gear and the behaviour of dynamos. In the discussion which followed, Prof. Hele Shaw drew attention to the Hatchet planimeter as a most simple and efficient workshop instrument. Prof. Boys explained why it was so much more difficult to construct an instrument for differentiating than for integrating. An automatic differentiator appeared at present to be an impossibility. A person can differentiate with a machine; but a machine cannot of itself well differentiate. It is of the very nature of an integraph to smooth over the irregularities of a curve; whereas a differentiator would exaggerate all the irregularities of a curve.

Mr. Arnulph Mallock followed with a note on the behaviour of a rotating cylinder in a steady current. Lord Kelvin was in his best British Association form when discussing the resistance experienced by solids moving through fluids. As the time approached for Mr. Hiram S. Maxim's paper on flight, the audience grew to dimensions most easily explained by supposing that an experimental demonstration in Keble Hall was expected.

After Friday, on account of the large number of papers, the Section had to split up into two or three departments sitting simultaneously (and continuously, without any luncheon interval). Only the more important physical papers can be noticed here. On Saturday, Prof. Osborne Reynolds described and illustrated experimentally the successive stages in the motion of water passing under gradually increasing pressure through a vertical tube constricted in the middle. At first the water leaves the constriction in the form of a narrow, steady jet. As the pressure increases it fills the lower part of the tube, and eddies appear below the constriction; but the motion is still steady. The third stage is that of turbulent motion. Finally, there is an appearance as of air-bubbles at the constriction, accompanied by a singing or hissing sound; the water is now boiling under diminished pressure. Prof. S. P. Langley gave an account of his recent researches on the infra-red spectrum to an audience most unwilling to allow him to stop, and rather impatient at the manner in which his lantern slides were exhibited. The President (Prof. Rücker) and Prof. Norman Lockyer heartily congratulated Prof. Langley on the magnificent success of his work, which will be fully described in a subsequent number of NATURE. Dr. E. Pringsheim followed with an account of his new determination of the ratio of the specific heats of certain gases.

The first paper on Monday was one by Dr. A. Schmidt, on a new analytical representation of terrestrial magnetism. Prof. Schuster followed with two papers: in one of these he examined a suggested explanation of the secular variation of terrestrial magnetism, and in the other he discussed the minimum current which could be observed in a galvanometer of given dimensions wound in various ways. Lord Rayleigh followed with three papers.

In the first of these he described experiments made by him to determine the minimum current audible in the telephone. The estimates previously put forward vary widely: Preece gives 6×10^{-13} ampere; Tait, 2×10^{-12}, and De la Rue 1×10^{-8} ampere. Ferraris is the only experimenter who has given satisfactory details of his experimental methods; he found that the current diminished when the frequency increased, and that a minimum current of 5×10^{-9} ampere was required at a frequency of 594. His experiments were made with a make-and-break apparatus, which would give higher harmonics in addition to the stated frequencies. In Lord Rayleigh's experiments electromotive forces of the harmonic type were produced by the revolution of a magnet in the neighbourhood of an inductor coil of known construction. The revolving magnet consisted of 2·5 cm. of clock-spring driven, windmill fashion, by air from an organ bellows. The magnetic moment of the magnet was deduced from observations with a magnetometer. The inductor coil was the one which had been used as the "suspended coil" in the determination of the electro-chemical equivalent of silver, and it was placed with its centre vertically below that of the magnet. From the known data the induced electromotive forces were calculated. The current was carried to a distant part of the house through leads, and was varied by introducing a resistance-box going up to 10,000 ohms; the adjustment of the sound could thus be made by the observer at the telephone. Theory shows that the minimum current required in a telephone should be inversely as the square root of the resistance. Two telephones of the Bell unipolar type were used: the data given below refer to one which had a resistance of 70 ohms. When the magnet was driven at full speed the frequency was 307, and the minimum current observed was $3 \cdot 0 \times 10^{[illegible]}$ amperes. In order to extend the determinations to higher frequencies, recourse was had to magnetised tuning-forks vibrating with known amplitudes. With a frequency of 512 the minimum current was $7 \cdot 0 \times 10^{-8}$, and with a frequency of 640 it was $4 \cdot 4 \times 10^{-8}$ amperes. Lord Rayleigh's second paper was on the quantitative theory of the telephone. About this so little is known that even an attempt to determine the order of magnitude of the physical quantities involved is of great value. The method adopted is to consider first the case of an infinitely long thin rod of iron, divided by a transverse gap, and encompassed by an infinite coaxial magnetising coil. He finds the force exerted across the gap by a periodic current, and then replaces one-half of the infinite rod by the plate of the telephone, and reduces the coil to the actual dimensions used in practice. The force in dynes exerted at the centre of the telephone plate is calculated to be equal to $1 \cdot 7 \times 10^{6}$ C., where C is the current in amperes. By actual experiment the force was found to be equal to 0·6 C. Experiment also showed that the displacement of the plate produced by a current C was C × 0·08 cm. The amplitude of the motion produced depends largely upon the relation between the frequency of the impressed vibration and those natural to the plate. For the telephone in question, assuming the plate to be clamped all round the edge, the frequency of the gravest symmetrical mode is calculated to be about 991. On making the plate speak on its own account, the frequency found was 896. As it is almost impossible to estimate the amplitude when the frequency of the force is near any of the free frequencies, the vibration number 256 is taken for calculation. At this pitch the minimum recorded current is $8 \cdot 3 \times 10^{-7}$ amperes; and the amplitude corresponding to this is $6 \cdot 8 \times 10^{-8}$ cm. Assuming the telephone to be applied closely to the ear, so as to include 20 c.c. of air, it is shown that the condensation (in atmospheres) produced is $1 \cdot 4 \times 10^{[illegible]}$. For higher frequencies than 512 the actual sensitiveness, in virtue of resonance, is greater than the value calculated by the above method.

Prof. J. A. Ewing exhibited an apparatus for measuring small strains. The measurement of Young's modulus for considerable lengths of wires, as carried out in physical laboratories, is an easy matter; but engineers have to investigate the behaviour of short bars, and require an instrument which should be convenient and expeditious in use. In the instrument described these ends are achieved without any sacrifice of accuracy. There is only a slight mechanical magnification of the extension, but by means of a microscope forming part of the instrument, readings are made to 1/100,000th of an inch, and the readings are calibrated by a simple device which forms part of the instrument. If the arms have the same coefficient of expansion as the material of bar, there is automatic compensation for change of temperature. Difference readings were given for the extensions produced in a half-inch steel bar by twelve successive loads increasing each time by half a ton: these only varied between 10·4 and 10·7. The instrument is attached to the bar under examination in such a way as to measure strictly the *axial* elongation. It is well adapted for the investigation of small strains in parts of structures (*e.g.* members of railway bridges).

Mr. F. G. Baily made an important and interesting communication on hysteresis in iron and steel in a rotating magnetic field. It has long been known that, up to the limits of experiment, the value of hysteresis in an alternating magnetic field increases continuously. But it is a deduction from Prof. Ewing's molecular theory of magnetism that in a rotating magnetic field the hysteresis should diminish at a high induction, or at least show a reduction in the rate of increase. The following experiment substantiates this deduction in a very complete manner.—An electromagnet is rotated on bearings concentric with the bore of its own pole-pieces, which were bored out cylindrically. In the polar cavity a finely-laminated armature is suspended between centres, and held by a spiral spring attached to the axle and to a fixed support. Movement of the armature is indicated by a beam of light reflected from a mirror on it. On rotating the magnet, the armature tends to rotate with it by reason of hysteresis. The motion is checked by the spring, and the consequent deflection is proportional to the instantaneous value of the hysteresis per revolution. The curve of hysteresis and induction obtained is somewhat like that in an alternating field, rising very slowly at first, then more rapidly, but finally reaching a maximum and bending over. The fall is very rapid so far as the experiments have been tried, shows no sign of becoming asymptotic, but runs straight towards the zero line. Soft iron and hard steel give the same results, the differences between them corresponding to their differences in the **B H** curve. The three states of molecular arrangement, which are the essential point of the molecular theory, are exactly reproduced in the hysteresis curve. This first stage of quasi-elastic movement gives a very small hysteresis value. The second stage of irregular molecular groups and magnetic combinations gives a value approximately proportional to the induction at a steep inclination; this extends to the knee of the **B/H** curve. The third stage of approaching saturation gives a rapidly diminishing hysteresis when the molecular magnets are ranged in regular order along lines of force, and new combinations and irregular movements are prevented. Since the non-appearance of a correspondence between the **B H** curve and the hysteresis curve in alternating fields has been urged as an argument against the molecular theory of magnetism, this complete accord and verification of the deduction previously made is important as giving powerful support to Prof. Ewing's theory.

Prof. S. P. Thompson briefly explained how he had verified the magnetic analogues of well-known propositions respecting optical images in plane mirrors. The experiments were made by placing a magnetic pole in front of a sheet of iron, and investigating the field by an exploring coil connected to a ballistic galvanometer. Prof. A. M. Mayer showed how beats and beat-tones could be produced by two vibrating bodies whose frequencies of vibration are so great as to surpass the limit of audibility. He has also employed the transverse vibration of bars at various temperatures to determine the variation of the modulus of elasticity with change of temperature.

On Tuesday morning there was a joint meeting with Section I, to discuss theories of vision. Prof. Oliver Lodge showed experiments to illustrate Maxwell's theory of light. Electromagnetic waves produced by a small vibrator were allowed to fall upon a detector placed inside a large copper "hat." The detector consisted of a glass tube containing iron borings forming part of a circuit with a galvanometer. On account of its mode of action, this detector is called by Prof. Lodge a "coherer." Under the action of the waves its resistance diminishes and the galvanometer current increases. The coherer was used to demonstrate the reflection, refraction, and polarisation of electromagnetic waves. The audience, which filled every part of the large museum lecture-room, repeatedly showed its warm appreciation of Prof. Lodge's beautiful experiments. His electrical theory of vision may be briefly described as a suggestion that light-waves do not directly produce the sensation of vision, but that their action (like that of the electromagnetic waves in these experiments) is a kind of "trigger" action.

In the subsequent Section-meeting, Principal Viriamu Jones gave the results of further determinations of resistance in absolute measure by the Lorenz method. The apparatus had previously been used to determine the absolute resistance of mercury, and has now (with modifications ensuring still greater accuracy) been employed to measure certain coils whose resistance in terms of the Cambridge Standards is known. He also exhibited a new form of standard coil of low resistance.

In the absence of Prof. J. J. Thomson, his paper on the velocity of the cathode rays was read by Prof. Fitzgerald. The phosphorescence shown by glass in the neighbourhood of the cathode was ascribed by Crookes to the impact of charged molecules driven off from the negative electrode. The remarkably interesting experiments of Hertz and Lenard, which show that thin films of metal interposed between the cathode and the walls of the tube do not entirely stop the phosphorescence, have led some physicists to doubt whether Crookes' explanation is the true one, and to regard the phosphorescence as being due to a kind of ultra-violet light. The view to which Lenard has been led by his experiments—that the cathode rays are ethereal waves—demands the most careful consideration; for if it is admitted, it follows that the ether must have a structure either in time or space. A magnet produces no effect upon ultra-violet light unless this is passing through a refracting substance. Now these cathode rays are deflected by a magnet, so that on the above view it must follow that in the ether in a magnetic field there must either be some length with which the wave-length of the cathode rays is comparable, or else some time comparable with the period of vibration of these rays. Prof.

Thomson first proved by experiment that a magnet acts on the cathode rays through the whole of their course, and does not merely affect the place on the cathode at which they have their origin. He then proceeded to investigate the velocity with which the cathode rays travel, for it seemed that a knowledge of this velocity would enable us to discriminate between two views as to their nature. If they are ethereal waves, we should expect them to have a velocity comparable with that of light; if they are caused by molecular streams, their velocity should be that of the molecules, which we should expect to be very much smaller than that of light. The value found for the velocity of the cathode rays was $1 \cdot 9 \times 10^7$ cm./sec., which is small compared with the velocity of the main discharge from the + to the − electrode. It is much greater than the velocity of mean square of the molecules; it agrees very nearly with the velocity which a negatively electrified atom of hydrogen would acquire under the influence of the potential fall which occurs at the cathode.

On Wednesday, M. Cornu exhibited some brilliant optical experiments illustrating Babinet's principle. Prof. W. Förster described the displacements of the rotational axis of the earth. His results had been deduced by investigating the results of 6000 determinations of latitude in various parts of the globe. The maximum amplitude amounts to nearly half a second, which corresponds to a motion of the pole amounting to 40 or 50 feet. It appears that we are now approaching a period of minimum amplitude.

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE meeting of Section B at Oxford will be remembered as one of quite exceptional interest. That portion of the President's address urging upon the University fuller recognition of the claims of science in their curriculum will doubtless have valuable results. Certain of the communications brought forward in the course of the meeting may be described as epoch-making. The presence of a large number of eminent foreign chemists served further to render the proceedings memorable and attractive.

The Committee for preparing an International Standard for the Analysis of Iron and Steel reported that their work was now completed, and that it is proposed to shortly deposit the standards with the Board of Trade, or with some other suitable authority where they will be at the public service.

Prof. Clowes gave an account of his experiments on the proportions of carbonic acid in air which are extinctive to flame, and which are irrespirable. He finds that the flames of candles, oil, paraffin and alcohol are extinguished by air containing from 13 to 16 per cent. of carbonic acid. The flame of coal-gas, however, required the presence of at least 33 per cent. of the extinctive gas, and the flame of hydrogen was not extinguished until the amount of carbonic acid in the air reached 58 per cent. Comparing his experiments with those of Mr. J. R. Wilson on the percentage of carbonic acid required to suffocate a rabbit, Prof. Clowes concludes that air, containing at least 10 per cent. of carbonic acid more than is required to extinguish a candle flame, can be breathed with impunity. By taking advatage of the extraordinary vitality of the hydrogen flame in presence of high proportions of carbonic acid, it is possible to maintain the flame of the composite safety-lamp (previously described by the author), after the oil flame has been extinguished.

Mr. Haldane concluded from some experiments he has made on the respirability of air containing carbonic acid, that the percentage of this gas, considered by Prof. Clowes to be respirable, is too high.

Much interest was shown in the successful experiments of Dr. Lobry de Bruyn, demonstrating the properties of free hydroxylamine. On heating a small amount in a test-tube, a sharp explosion took place. Left exposed to air, it was shown by its action on iodised starch-paper to have become converted into nitrous acid. In a series of test tubes its behaviour with various reagents was demonstrated. With potassium permanganate, and with chromic acid oxidation took place, accompanied by flame; potassium bichromate produced an explosion. The anhydrous sulphates of copper and cobalt were reduced by the substance. Free hydroxylamine was dissolved in anhydrous ether, and sodium added, hydrogen was evolved and the very explosive sodium compound of hydroxylamine produced. Chlorine and iodine were shown to act spontaneously on hydroxylamine, producing inflammation. It is of interest that hydroxylamine will dissolve many salts which are soluble in water, the order of solubility differing in the two solvents.

Dr. Bernthstein described a new bacterium which occurs in milk, whose chief property is that of peptonising the caseine, thus forming a soluble compound, and rendering the milk transparent, and more readily digested.

On Friday a discussion took place on the behaviour of gases with regard to their electrification, and the influence of moisture on their combination. It was opened by Prof. J. J. Thomson, who exhibited some brilliant experiments illustrating the connection between chemical change and electrical discharge through gases. The gases were confined, under a pressure of about 100 mm. in glass bulbs which were placed in the centre of a coil of wire connecting the exterior of two Leyden jars, the interior coatings of which were connected with the two poles of a Wimshurst machine. As each spark passes between the poles of the machine, a rapidly alternating current is set up in the coil, and hence by induction in the gas. In the case of oxygen it was found that the moist gas gives a vivid incandescence, followed by an afterglow or phosphorescence, on removing the bulb from the coil. With the dry gas, on the other hand, incandescence does not take place. The incandescence, can however, be started in the dry gas by a brush discharge, and if once started continues under the influence of the induced current. With air the phenomenon is reversed; damp air does not glow, dry air will. By making use of two coils in one of which was a beaker of fairly strong sulphuric acid, and in the other a bulb containing moist oxygen, the presence of the acid was shown to prevent the incandescence in the bulb, showing the conductivity of the gas to be much greater than that of the acid. As the glow is only given in gases forming polymeric modifications, it is suggested by Prof. Thomson that the drops of water present may act as conductors causing the original molecules to dissociate. In the case of dry gases this preliminary dissociation can only be brought about by expenditure of a large amount of energy. Alcohol vapour will behave similarly to water, and it becomes of interest to study other solvents.

Mr. Brereton Baker followed with some experiments on the influence of moisture on chemical substances. He showed that ammonia and hydrochloric acid when dry do not combine. He also exhibited tubes containing dry sulphur trioxide and cupric oxide, and dry sulphur trioxide and lime, side by side without action upon one another, a kind of "chemical happy family," as he expressed it. He concludes that the function of moisture is physical rather than chemical from the fact that on heating together a dry mixture of cupric oxide, carbon and oxygen, no action takes place. He has obtained analogous results to Prof. Thomson, by using semi-vacuous tubes, into one end of each of which a platinum wire is fused and which contain a small quantity of mercury. On shaking these tubes in a dark room incandescence takes place in those containing moist oxygen. This is less if nitrogen is present, and ceases if the gas is dry. It was resolved in committee that Prof. Thomson's and Mr. Baker's papers should be published in full.

Dr. Ewan read a paper on the rate of oxidation of phosphorus, sulphur and aldehyde, a portion of which has already appeared in NATURE. The results obtained with aldehyde are free from the uncertainty produced by the correction for the changing rate of evaporation. When proper precautions are taken this reaction goes perfectly regularly at 20°, and its velocity is proportional to the product of the pressure of the aldehyde and the square root of the pressure of the oxygen. These results are most simply explained by assuming (in accordance with Williamson's theory), that the oxygen first splits up to some small extent into atoms, and that these alone take part in the oxidation.

In the discussion which followed the reading of these papers, Prof. Schuster spoke of the difficulty experienced in passing a discharge through mercury vapour.

Prof. Pringsheim noted the importance of ascertaining the relation between the spectrum given by the discharge, and that of the after-glow in the gas.

Mr. Vernon Harcourt remarked that Mr. Baker's results show that the part played by water in these reactions is probably unique, and is not shared by many, if any, other substances.

With reference to the dissociation of molecules, Mr. Baker pointed out that the atoms of gases can change their mode of combination independently of water, *e.g.* in the decomposition of potassium chlorate, and in the combustion of carbon disulphide. He suggested that the residual glow is due to the reformation of the original molecules.

Prof. Fitzgerald drew attention to the high specific inductive capacity of water, and contended that Prof. Thomson's explanation of his results meant simply that in a large molecule the atoms can change places.

The President understood Prof. Thomson to hold that water was present in actual drops, and queried whether that could be so in the explosion of carbon monoxide, where a very high temperature is reached.

Prof. Thomson, in his reply, seemed of opinion that minute drops might be present even in the case mentioned by Prof. Dixon. In conclusion he urged the desirability of the preparation of pure compounds in the large laboratories of the country, which might be sent to the physicist for investigation.

Prof. Hartley then described some new methods of spectrum analysis and some Bessemer flame spectra. He has found that if a mixture containing alkalies and alkaline earths be fused with borax or silica, the alkalies are first volatilised and give their characteristic spectra very clearly. For obtaining spectra at high temperatures it has been found useful to heat the substance in the oxy-hydrogen flame on a rod of kainite, pipe-clay, or dried alumina. The elements can be classified according to the type of spectrum given under these conditions. On vapourising alloys, those constituents which, when free, give band spectra, are found to produce line spectra, *e.g.* silver, in an alloy of copper and silver. This is thought to be due to the difference between the vapour pressure of the element when alloyed, and when in the free state.

The spectrum of the Bessemer flame has been studied with special reference to the bands produced by manganese.

Mr. J. W. Thomas read a paper on the chemistry of coal formation, in which he endeavours to trace the connection between the properties of a coal and the character of the vegetation from which it probably originated.

On Monday a large audience assembled to hear the announcement by Lord Rayleigh and Prof. Ramsay of the existence of a new gas in the atmosphere. It appears that certain experiments of Cavendish pointed to the presence, in air, of some substance other than the gases with which we are familiar. Attention was recalled to this substance by the fact that the density of nitrogen obtained from atmospheric air differs by about ½ per cent. from the density of nitrogen obtained from other sources. It was found that if air (with excess of oxygen) be subjected to electric sparks, the resulting nitrous fumes absorbed by potash, and the excess of oxygen by alkaline pyrogallate, there remains a residue which is neither oxygen nor nitrogen, as can be seen from its spectrum. The same gas can be isolated by exposing nitrogen obtained from air to the action of magnesium. As the magnesium gradually absorbs the nitrogen, the density of the residual gas gradually rises to nearly 20. The newly discovered substance constitutes nearly 1 per cent. of the atmosphere, and gives a spectrum with a single blue line much more intense than a corresponding blue line in the nitrogen spectrum.

Sir H. E. Roscoe, in proposing a vote of congratulation on the discovery, spoke of the special interest which attached to it as being the outcome of a purely physical observation.

Prof. Emerson Reynolds noted the place which the new substance, if it proved to be an element, would occupy in Mendeleef's table among the platinum metals.

Prof. Roberts-Austen suggested that this gas might be the one which is frequently found as a residue among the gases extracted from steel.

The President, in putting the vote of congratulation to the meeting, drew attention to an observation made by Prof. Dewar, that while a mixture of pure liquefied oxygen and nitrogen forms a clear liquid, air in a similar state shows a turbidity. The President suggested that this turbidity might be due to the new gas.

The question is discussed by Prof. Dewar in a letter to the *Times* for August 16, in which he states that the substance causing turbidity does not amount to 1 per cent. of the whole liquid.

The next communication was by Prof. McLeod, on Schuler's yellow modification of arsenic. This is produced as a yellow sublimate when pure arsenic is heated in vacuo. The substance rapidly changes to the black modification.

Some very interesting experiments on the electrolysis of glass were described by Prof. Roberts-Austen. In conjunction with Mr. Stansfield he has found that if a bulb of soda-glass be filled with sodium amalgam and immersed in a vessel of mercury heated in a sand-bath to rather over 200°, on connecting the sodium amalgam and the mercury respectively with the terminals of a battery, sodium will pass from the amalgam through the glass into the mercury. At the end of the experiment the glass is unchanged. If lithium amalgam be substituted for the sodium amalgam, however, a certain percentage of lithium is found in the glass at the end of the experiment, sodium from the glass is driven into the mercury, and the glass is altered in appearance and frangibility. With potassium amalgam and soda-glass no change takes place. These phenomena are believed by Prof. Roberts-Austen to depend on the relative atomic weights and consequent atomic volumes of the elements concerned. Lithium, having a smaller atomic volume than sodium, is able to follow in the galleries left by the atoms of the latter metal; potassium, on the other hand, having an atomic volume greater than sodium, cannot force a passage. From the results he has obtained, using other amalgams, such as those of gold and copper and different kinds of glass, Prof. Roberts-Austen hopes to throw light on the formation of mineral veins in rocks which apparently have not undergone fusion.

Mr. J. W. Rodger gave an account of the experiments which have been conducted by Prof. Thorpe and himself on the relations between the viscosity of liquids and their chemical nature. The method adopted allowed a rapid succession of experiments to be made on the same liquid, at different temperatures. In the case of the fatty acids and alcohols examined, evidence has been found of the existence of molecular aggregates.

Dr. J. H. Gladstone described some experiments on the rate of progress of chemical change. The chief reaction investigated was that which takes place when platinum chloride and potassium iodide are mixed, resulting in the formation of the dark coloured iodide. This change begins rapidly, with no period of inertness or "reluctance." Its completion is much retarded, however, by the presence of potassium chloride. A change which does require time to attain a maximum rate is that which takes place when cuprous oxide is immersed in a solution of silver nitrate, the silver which is produced making its appearance only after some time.

A similar change to the latter was described by M. Paul Sabatier, in which litharge added to silver nitrate solution is converted into the puce-coloured oxide of lead, with simultaneous deposition of silver.

A paper was read by Mr. Vernon Harcourt, in the name of the late Mr. Percy B. Lewis, on a new and very delicate method for determining the freezing points of very dilute solutions.

Dr. M. Wildermann gave an account of experiments he had made with Mr. Lewis's apparatus, and said that they fully confirmed the predictions of the Van't Hoff Arrhenius theory.

Mr. W. W. Randall described his apparatus for measuring the colour-tint of dilute solutions. His experiments, instituted in order to determine whether dissociation takes place in dilute solutions, are of a qualitative character. At their commencement he was not aware of the careful spectrometric work of Dr. Ewan on the same subject.

Mr. Philip Hartog read a paper on the distinction between compounds and homogeneous mixtures, a portion of which recently appeared in a letter to NATURE. He showed that until lately there was no satisfactory experimental criterion for distinguishing easily between true compounds and such mixtures, but the recent work of Raoult showed that the freezing point of a pure compound was always lowered, and its boiling point raised, by any admixture.

Prof. J. A. Wanklyn's paper on new evidence as to the atomic weight of carbon was received with interest, though not with unanimous support, by the chemists present. By fractionating Russian petroleum the author has obtained hydrocarbons of constant boiling point, whose vapour densities point to their all containing carbon atoms of the weight 6.

Dr. J. B. Cohen described a simple form of apparatus for determining carbonic acid in the air, depending on the length of time required by the carbonic acid in a given volume of air to neutralise a known amount of standard lime solution insufficient to combine with all the carbonic acid present.

Mr. A. P. Laurie contributed a paper on "The Diffusion of very Dilute Solutions of Chlorine and Iodine." The interesting result has been obtained that these elements in solution follow the law of gaseous diffusion, the chlorine diffusing twice as fast as the iodine.

Prof. J. W. Brühl gave an account of his investigations on tautomerism. By determining the molecular dispersion of compounds, he has been able to obtain values which are independent of temperature, and thus he has arrived at a sure means of distinguishing between bodies containing the group HC—C=O, or "keto" bodies, and those containing the group C=C(OH), which he termed "enole" compounds. With simple ketones and di-ketones no tautomerism or change from the keto to the enole form was found to occur. Nor did it occur with the alkyl derivatives of ketonic acids; when, however, the alkyl was replaced by an acid radical in these cases, tautomerism occurred. The author had investigated derivatives of camphocarboxylic and of malonic and succinic acids, and found the above rule to hold good in these cases, although enolisation was found to depend not only on the number of negative groups present, but also on the position of these in the molecule, and on the simultaneous presence of alkyl groups, which latter sometimes rendered the molecule more stable. An interesting compound had been obtained, namely, mono-brom-formyl camphor, which was a true ketone, and which was the only compound known in which the keto form of the formyl radical was present. In conclusion the assumption of Lahr, that ketonic compounds possess a "labile" constitution, was shown to be untenable, no continuous internal atomic movement being probable. In the case of benzene derivatives, on the other hand, such changes probably occur, and are termed by the author "phasotropic."

Prof. E. Noelting read two papers entitled, respectively, "On Di-nitros Derivatives of the Aromatic Series," and "On the Formation of Indazoles from Diazo-compounds." Both papers dealt with compounds, which showed the dependence of stability on molecular grouping.

Dr. Caro described the method of obtaining a new rhodamine, or pink colouring matter, by the interaction of chloral hydrate and an alkyl derivative of metamidophenol. A salt of a leuco base is formed, which latter on oxidation by ferric chloride gave a blue colouring matter. It was shown by experiment that on heating a solution of this blue compound in water it turned to a fine pink, owing to an intra-molecular change.

A paper followed, by Drs. G. G. Henderson and A. R. Ewing, on "Tetrarsenites." The sodium salt, which was prepared by adding arsenious oxide to acid sodium tartrate, was easily soluble in water, and might be conveniently used for hypodermic injections of arsenic. Other salts had been prepared, and also a solution which probably contained the hypothetical tartrarsenious acid from which they were derived.

Dr. J. B. Cohen read a paper on "The Constitution of the Acid Amides," in which he showed that these might be divided into two classes—those which formed compounds with silver and crystallised in needles or prisms, and those which did not form silver compounds and crystallised in plates. To account for these differences he fell back on Hantzsch's theory of the stereo-isomerism of nitrogen compounds, and concluded that the amides contain a hydroxyl group.

A short discussion followed the paper, in which Prof. Dunstan quoted experiments which he had made on the action of trichloride of phosphorus on acetamide, which did not bear out Dr. Cohen's view of the constitution of the latter body.

Dr. Caro, however, did not consider Prof. Dunstan's experiment conclusive.

The report of the Committee on Isomeric Naphthalene Derivatives was read. Work had been done on chlor-sulphonic and brom sulphonic derivatives of naphthalene, and the results tended to confirm the previous conclusions of the investigators.

The report of the Committee on the Action of Light upon Dyed Colours was read by the secretary, Prof. Hummel. The colours experimented with this year were chiefly yellows. Of these by far the largest number, ranging from "moderately fast" to "very fast," were to be found among the azo colours. The azoxy colours give good fast tints upon silk and cotton. The fastness of alizarin orange is probably greater than that exhibited by most other colours of the alizarin group. Very few fast yellows are derived from the natural colouring matters. The cultivation of weld, which yields the only fast and, at the same time, bright, natural yellows, is being gradually given up. It is fortunate then that efficient substitutes can be obtained from coal-tar, which, contrary to popular opinion, is the source from which the greatest number of colours fast to light are derived at the present time.

Dr. W. Meyerhoffer read a paper on "Certain Phenomena of Equilibrium during the Evaporation of Salt Solutions." For a given mixture of salts in a saturated solution it was found that there existed a certain transition temperature above which double decomposition took place. Thus with a saturated solution containing ammonium chloride and sodium nitrate, sodium chloride was formed above 6° C., while below that temperature no change took place.

GEOLOGY AT THE BRITISH ASSOCIATION.

OF the forty-three papers presented to Section C this year, comparatively few are of lasting importance, geologists having apparently saved up their best work for presentation at Zurich, or else having exhausted themselves at the excellent and successful session of the previous year. The President's address, containing an excellent epitome of the recent progress of mineralogy, was rather fitted for quiet and thoughtful perusal than for reading to a mixed audience, but it will be looked back upon as one of the most valuable of the contributions to the forthcoming volume of *Proceedings*. It was followed up by only one paper dealing with pure mineralogy, that of Mr. H. A. Miers, on a new method of measuring crystals. The two fundamental laws of crystallography—namely, (1) the constancy of the angle in crystals of the same substance, and (2) the law of simple rational indices—seem to be violated by those crystals which are liable to irregular variations in their angles, or those which have the simple faces replaced by complicated "vicinal" planes. Both these anomalies are exhibited by potash- and ammonia-alum. Brilliant and apparently perfect octahedra of these salts show large variations in the octahedron angle; other crystals show low vicinal planes in place of the octahedron faces. If it be true, as is supposed, that the octahedron angle varies in different crystals, it would be interesting to ascertain whether progressive variations can be traced during the growth of a single crystal, and whether some or all of the octahedron faces change their direction in space if the crystal be held fixed during growth.

In order to solve this problem a new goniometer has been constructed, in which the crystal is fixed at the lower end of a vertical axis, so that it can be immersed in a liquid during measurement. This device is in reality an inversion of the ordinary goniometer with horizontal disc; the liquid is contained in a rectangular glass trough with parallel-plate sides; one side is placed rigidly perpendicular to the fixed collimator, and the other is perpendicular to the telescope, which is set at 90° to the collimator. The trough is supported on a table which can be raised and lowered, so that the crystal can be placed at any required depth in the liquid. If the liquid used be its own concentrated solution the crystal can be measured during growth, and the changes of angle, if any, can be observed at different stages. In order that it may be held rigidly, the crystal is mounted, when small, in a platinum clip, which it envelops as it grows larger.

The results derived from the measurement of a large number of alum crystals are as follows:—

(1) The faces of the regular octahedron are never developed upon alum growing from aqueous solution.

(2) The reflecting planes (which are often very perfect) are those of a very flat triangular pyramid (triakis octahedron) which overlies each octahedron face.

(3) The three faces of this triangular pyramid may be very unequal in size.

(4) The triakis octahedron which replaces one octahedron may be different from that which replaces another octahedron face upon the same crystal.

(5) During the growth of the crystal the reflecting planes change their mutual inclinations; the triakis octahedron becomes in general more acute, *i.e.* deviates further from the octahedron which it replaces, as the crystal grows.

(6) This change takes place not continuously, but *per saltum*, each reflecting plane becoming replaced by another which is inclined at a small angle (generally about three minutes) to it.

(7) During growth the faces are always those of triakis octahedra; if, owing to rise of temperature, re-solution begins to take place, faces of icositetrahedra are developed.

These observations prove that the growth of an alum crystal expresses an ever-changing condition of equilibrium between the crystal and the mother liquor. It does not take place by the deposition of parallel plane layers; new faces are constantly developed: since these succeed one another *per saltum* they doubtless obey the law of rational indices, though not that of *simple* rational indices. From the mutual inclinations of these vicinal faces it is possible to calculate with absolute accuracy the angle of the faces to which they symmetrically approximate. This angle is found to be that of the regular octahedron 70° 31¾'. The octahedron angle of alum is not, therefore, as appeared from the observations of Pfaff and Brauns, subject to any variation.

Mr. Howard Fox described a remarkable rock which occurs at Dinas Head in Cornwall, between a greenstone and a slate, and apparently intruded upon by the former. It has the composition of albite felspar, with as much as 10 per cent. of soda, and is like the keratophyres in composition as well as in the possession of concretionary and spherulitic structures. The nodules and spherulites stand out as the rock weathers, and the latter are shown by the microscope to consist of blades of albite radiating round centres of cryptocrystalline material. On the other hand, the rock might belong to the altered sediments called adinoles, of which some, in the Harz, yield 7.5 per cent. of soda, and with this the field evidence and the presence of idiomorphic crystals of ferriferous carbonate appear to agree. Mr. W. W. Watts exhibited photographs of a stack of Keuper sandstone at the Peakstones, near Alton, Staffordshire, which, he claimed to have proved, owed its resisting power to the existence of almost vertical planes in the rock cemented by the deposit of barium sulphate. These planes strike along a prominent ridge between two valleys, and at the end of it is the projection of the Peakstones rock. Other cases in which basement beds of the Keuper sandstone are similarly cemented were quoted by the author.

Amongst the papers dealing with Oxfordshire geology, that by Prof. Green demands attention first. In it he described the sections displayed at Fawler and Stonesfield, Shotover, Faringdon, Culham, and Swindon. The thinness of the Upper Lias at Fawler was remarked upon, and a curious case of contemporaneous erosion in the Forest Marble described; the peculiar character of the iron-sands was explained by their having been deposited in a long strait, in which Faringdon was a sheltered bay, suited for the growth of the organisms which here make up almost the whole deposit. In the section at Culham, which shows Gault resting directly on Kimmeridge or Portland limestone, the denudation of the iron-sand was described as a local phenomenon, it being found in full force at another section hard by. The excavations at Stonesfield, carried out by Mr. Walford, were the subject of a report by him, in which he showed that about 30 feet of limestone with clay seams, presenting on the whole the aspect of the great oolite, occurred beneath the "slate" bed. He intends to continue his excavations in order to determine the relationship of these deposits to the Chipping Norton limestone and the Clypeus grit of the Oxfordshire Inferior Oolite. In another paper the same author points out that the terraced hill slopes occur in one geological line in Oxfordshire, the outcrop of a band of micaceous marl in the Middle Lias just below the "red rock bed." The water penetrates from above where the Upper Lias has been stripped off by denudation and filters through to the top of the clay of the *margaritatus* zone, where it makes its escape. The saturated marls are continually creeping down hill, and, in doing so, give rise to the terraces.

Prof. W. Boyd Dawkins endeavoured to trace the submerged folds of palæozoic rocks under the mantle of newer formations in Oxfordshire, by means of the principle originally laid down by Godwin-Austen and elaborated by Bertrand in recent papers, that the great pre-carboniferous folds form lines of weakness, along which the upper skin of later rock wrinkles and cracks. The northern rim of the South Wales syncline, which contains the coal-basin, was traced eastwards through the Forest of Dean, the partially covered fields north of the Mendips, through Gloucester, Blenheim, Kirtlington, Quainton, Bishop's Stortford, Braintree, and Colchester. From this it is reasonable to infer that coalfields will be found in the area between this line and that from the Mendips to Hythe. One such the author claims to have been discovered at Burford, and he advises that further investigation should be carried on, there and in the neighbourhood, to set at rest the question whether workable coals occur in this syncline. Three other papers by the same author dealt with evidence from borings. The first drew attention to a seam of oolitic iron ore (grains of hydrated oxide embedded in calcium and iron carbonates) of Kimmeridgian age, met with at the Dover boring. The second dealt with the Permian strata of the north of the Isle of Man, consisting of 913 feet of red Roth-liegende sandstone, followed by 455 feet of calcareous conglomerates and breccias, which were correlated with the magnesian limestone; these rocks form a connecting link between those of Cumberland and North Ireland. The third communication described three borings in the north of the same island, one of which had penetrated 33 feet of salt-bearing marls apparently at a greater depth than 450 feet from the surfaces: the Triassic sandstones and saliferous marls again present another link between Carrickfergus and the English coast. A paper by Prof. Bonney instituted a comparison between the pebbles in the trias at Cannock and Budleigh Salterton, as a result of which he concluded that those of Budleigh must have come from the south-west, but that similar fragmental rocks fringed the ancient western land in localities far apart.

Sir Archibald Geikie corroborated Heddle's identification of the Pitchstone of Hysgeir, an island about eighteen miles west of Eigg, with that of the latter island. This lava, which flowed into a river channel sloping from east to west, is exactly like that of the Scuir of Eigg, but unfortunately its base cannot be seen. The old river channel would be at least 20 miles long, with a fall of perhaps as much as 35 feet in a mile. Gravels containing masses of volcanic rocks (some of them possibly thrown direct from volcanoes), with water-worn blocks of Torridon sandstone, grit, quartzite, and other rocks, rapidly thinning out or passing into fine tuff or volcanic mudstone, are to be found in the islands to the north of Hysgeir, intercalated at various horizons in the bedded basalts, and have doubtless been formed by the flooding and torrential action of contemporaneous rivers.

A joint discussion on the plateau implements of Kent, held by Sections C and H, was opened by Prof. Rupert Jones, who agreed with Prof. Prestwich that the implements were of human origin and dated back to an ancient time when the physical geography of the Weald was very different from its character to-day. Mr. Whitaker followed with a paper, in which he stated that he did not consider the plateau gravels so ancient as had been supposed by other authors, but that part of the deposit, at any rate, was a residuum which had grown where it stood, and is still growing, so that implements in it might be of almost any age. He further stated that he could find no evidence to connect men with preglacial or even glacial times. Amongst the other speakers were Mr. Montgomerie Bell, Sir John Evans, Dr. H. Hicks, Prof. Boyd Dawkins, General Pitt-Rivers, Sir Henry Howorth, Mr. Clement Reed, and Lieut.-Colonel Godwin-Austen.

The more important palæontological communications included Prof. Rupert Jones's eleventh report on Palæozoic Phyllopoda, Mr. Laurie's second report on the Eurypterids of the Pentlands; recording the obtaining of a large amount of material from which important results are to be expected; Dr. Traquair's preliminary notice of a new fossil fish from the upper Old Red Sandstone of Elginshire; Mr. Jeffs' descriptions of forms of Saurian footprints from the Cheshire Trias, some of which were new, while apparently none of them could be referred to any known species of Labyrinthodont; and Dr. Hicks's conclusion that the original home of the earliest forms of animal life was at some point in the Atlantic. Mr. Montagu Browne's third paper on Rhætic Vertebrata, in which teeth of "Saurichthyan" type were described in the same jaws as Labyrinthodont teeth, proving that the remains attributed to Saurichthys must be assigned to Labyrinthodonts, Plesiosaurus, Hybodus, and Gyrolepis, also called attention to remains of Rysosteus, Metoposaurus or Trematosaurus (?), and Dinosauria.

The consecration of Monday to pleistocene geology has almost become an institution, probably because, although new facts of consequence may not have been discovered within the year, at least one new interpretation of them, or a new theory founded on some of them, can always be relied upon. The day was opened by Mr. Bell's report on the well and borings at Chapelhall, near Airdrie, which completely proved that there was now no shelly clay to be found in the well or in borings in its immediate neighbourhood. Mr. Kendall followed with a report on the boulders examined and collected during the year.

Dr. Hicks next endeavoured to prove that the stratified gravels, sands, and clay of the plateaux of Hendon, Finchley, and Whetstone, which are covered by chalky boulder clay, had been formed in a lake dammed to the east and west by ice in a moraine, a view which elicited considerable comment and disagreement from a number of glacialists present. Prof. Blake described areas in the Harlech Mountains, some of which were floored by bare, ice-scratched rocks, side by side with others covered by thick drift deposits. Prof. Bonney, judging by the temperature at which glaciers now form in the Alps, came to the conclusion that a fall of 15° to 20° F. would be quite sufficient to cause all the known glaciation in the northern hemisphere. Mr. E. P. Culverwell read a paper entitled "An Examination of Croll's and Ball's Theory of Ice Ages and Genial Ages," in which he stated that an appeal to figures conclusively proved the inadequacy of the astronomical theory as at present formulated. By calculating the comparative solar heat of the high eccentricity winter of 199 days, and that of 199 coldest days of the present winter, he showed that the isochimenals would be about 4° of latitude further south, and the isotherals more than 4° further north, then than now. In the "genial age" the shifting would not be more than $2\frac{1}{2}$°. This cause he considers totally inadequate to account for glacial and genial ages, and therefore falls back on changes in physical geography for the former, and shift of the pole, or greater solar and terrestrial activity, for the latter. In the discussion Sir Robert Ball defended his position, but was further attacked by Prof. Fitzgerald and other speakers.

Prof. Blake endeavoured to show that by the lowering of its centre of gravity as a whole the further end of an ice-sheet might be raised and carry boulders and detritus up a slope. The Rev. E. Jones presented the final report on the Elbolton Cave, stating that no palæolithic remains had been found, and that the investigation was consequently abandoned. The preliminary work, however, in the Calf Hole Cave, near Skipton, was more hopeful, and already a hafted implement, made of a chisel-like tooth bedded in antler and mounted in wood, had been found. In a short paper on the palæolithic section at Wolvercote, near Oxford, Mr. Montgomerie Bell described the section as follows: (1) a "northern drift" and subangular gravel resting in eroded hollows of the Oxford clay. (2) A river gravel containing shell seams, and in whose lowest bed palæolithic implements associated with mammoth, *Cervus elaphus*, *Bison priscus*, &c., have been found. (3) A bed of peat containing the remains of local plants. (4) Sand, mud, and hail close the section. Two palæolithic implements were recorded by Mr. Bruce Foote from an old alluvium, through which the Sabarmati river in Guzerat had cut a channel, varying from 100 to 200 feet in depth.

Dealing with questions of physical geology, Mr. Lobley tried to show that the contraction theory would not explain volcanoes and earthquakes. Dr. Tempest Anderson described three types of subsidences occurring in connection with volcanic rocks in Iceland; the most common type was due to a falling crust where the inner lava stream escaped, others were due to earthquakes, and still others to faulting, probably caused by subsidence of a volcanic centre as a whole. Dr. Johnston-Lavis recorded his observations on the activity of Vesuvius during the year. Mr. De Rance reported in underground waters. Prof. Herdman drew attention to the geological results flowing from his investigation of the bed of the Irish Sea. Prof. Sollas announced that arrangements were in progress for commencing the boring of a coral island. Prof. Hennessy described the channels of streamlets in estuaries as possessing a section constructed of two catenary curves, the only shape which gives a constant velocity whatever the depth of the stream; and Sir H. Howorth passed a series of strictures on current geological nomenclature, with suggestions for its revision, which will doubtless receive the attention due to so high an authority in these matters.

Mr. C. Davison's report on earth tremors contained an account of the trial and modifications of Mr. H. Darwin's bifilar pendulum, and of the horizontal pendulum used at Nicolaiew; then followed an elaborate analysis of the pulsations of the Greek earthquake of this year, showing how they spread to one observatory after another, and were felt at Rome, Siena, Nicolaiew, Potsdam, Kew, and Birmingham. In his report on geological photographs, Mr. Jeffs stated that the collection now amounted to 1055, and that the time seemed to have arrived when it should be housed in some convenient and central position, although it was still necessary to add to the collection, so as to make it thoroughly representative of the whole country. A number of photographs were exhibited and slides from some of them displayed at the second conversazione.

NOTES.

M. GUSTAVE COTTEAU, a Correspondent of the Paris Academy, in the Section d'Anatomie et Zoologie, died at Paris on the 10th inst.

MR. M. A. RYERSON has presented to the University of Chicago the Ryerson Physical Laboratory, built at a cost of 250,000 dollars.

THE International Congress of Applied Chemistry, which has just finished a session at Brussels, will hold its next meeting at Paris in 1896.

DR. D. F. OLTMANNS has been appointed Extraordinary Professor of Botany at the University of Freiburg-i. B.

THE Imperial Acclimatisation Society of Moscow has founded a botanical section for the purpose of collecting materials for a Flora of Russia. The co-operation is invited of all who are able to assist in this work. Communications should be addressed to the Director of the Polytechnic Museum, Moscow.

MR. H. W. UNTHANK informs us that while shore-hunting at Brightlingsea on August 4, he came upon a stranded Aurelia which exhibited a pentamerous instead of the usual tetramerous symmetry. The specimen is at present in the Brightlingsea Marine Laboratory of the Essex County Council.

MR. FRED N. SCOTT, Assistant Professor of Rhetoric in the University of Michigan, has issued, in the form of a leaflet, a series of questions on the psychology of usage. He wishes to ascertain the origin of dislikes, especially of arbitrary, unreasoning dislikes, for certain words and phrases. He will be glad to send a copy to anyone who is interested in the subject and who will take the trouble to answer the questions.

THE annual general meeting of the Federated Institution of Mining Engineers will be held in Newcastle-upon-Tyne, on Wednesday, September 5, in the Wood Memorial Hall of the North of England Institute of Mining and Mechanical Engineers. The papers down for reading are:—"The Stetefeldt Furnace," by Mr. C. A. Stetefeldt; "Walling and Sinking simultaneously with the Galloway Scaffold," by Mr. John Morison; "Timber Bridges and Viaducts," by Mr. Morgan W. Davies; "Explosions in Nova Scotian Coal-mines," by Mr. Edwin Gilpin, jun.; and "The Shaw Gas-tester for detecting the Presence and Percentages of Fire-damp and Choke-damp in Coal-mines, &c.," by Mr. Joseph R. Wilson. There will also be discussions on other papers, and various excursions.

THE cholera epidemic is slowly spreading, especially in European Russia. Since the end of June, fifteen new districts in Russia have been declared to be infected, making a total of about forty. In Austria-Hungary, in many towns situate on the Vistula, and in Belgium, the disease has extended, and a number of fatal cases have occurred in places in Northern Holland. The Local Government Board is keeping a close watch on the progress of the epidemic, and every precaution is being taken to prevent it from obtaining a foothold in this country. Some anxiety will be felt for a month or so, for during this period the risk of infection is greatest. The dismal weather we have been experiencing this summer, though hardly conducive to pleasant holidays, has one redeeming feature, for it is decidedly unfavourable to the development of a cholera epidemic.

BY the death of Dr. C. R. Alder Wright, at the end of last month, science lost a tireless and enthusiastic worker. He was educated at the Owens College, Manchester, and early showed an aptitude for scientific research. His work extended over a large part of the domain of chemistry. It comprises, says the *Chemical News*, "investigations of simple substances, like hydriodic acid, and some of the most complex substances, like the vegeto-alkaloids, upon which he laboured for many years—sometimes alone, and sometimes in conjunction with Matthiessen and others. These researches deserve to be classical if any researches do, and they occupy an entire department of organic chemistry." Another subject to which Dr. Wright devoted great attention was the determination of chemical affinity in terms of electromotive force. The versatility of his genius is shown by the different subjects of his numerous papers. Isomeric terpenes, the smelting of iron in blast-furnaces, some points in chemical dynamics, and certain voltaic combinations, are a few of the subjects taken up by him. In 1889 he commenced a series of valuable communications to the Royal Society, on "Ternary Alloys," and the seventh part of the series was read before the Society at the beginning of last year. Thorough and conscientious in everything he undertook, Dr. Wright will always be regarded with esteem throughout the world of science.

THE Paris Société d'Encouragement pour l'Industrie Nationale is constantly giving evidence of its usefulness. The latest proof of this is to be found in the publication of a circular on the "Unification des Filetages et des Jauges de Tréfilerie." The Society has had the question of a standard screw-pitch and wire-gauge in hand since the end of 1891. It was, however, only three months ago that a meeting was held for the purpose of discussing the various systems suggested, and at that meeting the scales expounded in the pamphlet before us were accepted. To secure uniformity in the manufacture of screw-threads, the Society proposes a system, to be known as the "Système Français," in which the pitch increases in steps of half a millimetre, from a screw having a diameter of six millimetres and a pitch of one millimetre (No. 0) to one having a diameter of 148 millimetres and a pitch of 10·5 millimetres (No. 19). The formula which, in this system, allows the diameter (D) corresponding to any pitch to be deduced is $D = p(p + 8) - 1{\cdot}5 \div 1{\cdot}3$, where p is any pitch expressed on the adopted scale. By means of this, it is possible to extend the new system to screws of any diameter, and the number of the screw of which the diameter had been thus determined would be equal to the number of half-millimetres expressing the pitch, *minus* two. For screws less than six millimetres in diameter the standard drawn up by M. Thury for the Société des Arts of Geneva is adopted. In addition to promulgating these standards of screw construction, the Société d'Encouragement has developed a decimal system of gauging wires. In this system, the numbers of the wires express their diameters in tenths of millimetres; thus, a No. 7 wire has a diameter of 0·7 mm. Such a method of designating wires is as simple as it is scientific. In France and other countries using metric standards, the introduction of the new system will be comparatively easy; but we regret to say that in this land of complicated weights and measures, there is little hope of its adoption.

THE general sitting of the German and Austrian Alpenverein was held this year in Munich from August 8 to 11. At the end of the Congress several tours were conducted into the Bavarian and Austrian highlands. The Congress was attended by more than 6000 members, by delegates representing Alpine clubs in other countries, by Bavarian State delegates, and others. Business matters were smoothly arranged, the Central Committee showing an annual income of £9850, and in addition £5000 in hand. There are now 214 local sections of the Alpenverein, each of which pays a certain portion of the fees of membership to the Central Committee and retains the rest for independent income and outlay. Out of an unostentatious beginning, twenty-five years ago, has grown a club with a membership of over 31,000, and a many-sided activity and vigour of life promising a still greater future. The object of the Verein is to improve travelling in the Alps, and to increase our knowledge of them. Again, the management of the guides is entirely conducted by the Verein; the guides being occasionally placed for a short course of training in some central town. The Munich section is the largest of the Alpenverein sections, and was therefore well able to entertain the members generously. The halls in which the great festival of the Congress was held on Thursday, the 9th inst., were decorated on a magnificent scale. An exhibition of maps and models was held in the Academy of Sciences. The relief of the Jungfrau Group, by Simon, modelled to a scale of 1:10,000, attracted great attention. The surest proof of the success of the Alpenverein in its efforts for Alpine travelling is its popularity among the mountain inhabitants. They honour it for the good it has done their wild country and for the intercourse it has opened up. Meanwhile the Alpenverein plays its part worthily in the wider arena of science as journalist, cartographer, meteorologist, geologist, botanist, and all in no small measure.

DR. P. MIQUEL contributes to the *Diatomiste* an important paper on the re-establishment of the size of diatoms. This takes place, according to this observer, mainly by the activity of the nucleus. The protoplasm within a micro-frustule clothes itself with a thick extensible membrane, frees itself from the valves which imprison it, attains the normal size, and then secretes a siliceous envelope. No process analogous to conjugation could be detected by Dr. Miquel in a vast number of observations on many different species. He proposes the abolition of the terms auxospore and sporangial frustule, as not expressing accurately any process which actually takes place in the multiplication of diatoms.

THE Department of Science and Art has issued the following list of successful candidates for National Scholarships, Royal Exhibitions, and Free Studentships, awarded upon the results of the May Examinations this year. National Scholarships for Mechanics—Arthur H. Barker, 23, fitter, Pontefract; Edward R. Amor, 18, engineer apprentice, Devonport; John T. Rieley, 25, science teacher, Birmingham; Charles B. Brodigan, 24, draughtsman, London. National Scholarships for Chemistry and Physics—Charles A. West, 24, teacher, Tottenham, Middlesex; William H. White, 15, student, Ipswich; Harry Dean, 17, student, Manchester; William C. Reynolds, 24, pharmacist, London; John Lister, 18, student, Stockport. National Scholarships for Biological subjects—Ernest Smith, 25, assistant teacher, Huddersfield; Frank H. Probert, 17, student, London. National Scholarships—George M. Russell, 22, shipwright apprentice, Portsmouth; Samuel Stansfield, 21, engineering student, Todmorden; Gilbert T. Morgan, 23, chemist, Huddersfield; William G. Hall, 18, student, Nottingham; Arthur S. Cox, 17, student, Southampton; Frederick T. Munton, 25, joiner, Derby; George Wilson, 22, mechanical engineer, Sheffield; George E. Ashforth, 16, student, Manchester; George L. Overton, 19, watchmaker, Bradford, Yorks; Norton Baron, 21, engineering student, Ulceby, Lincs.; Ernest E. L. Dixon, 18, student, London. Royal Exhibitions—Frank Fisher, 19, engineer, Brighton; Clarence Smith, 18, student, Brighton; William H. Eccles, 18, apprentice druggist, Barrow-in-Furness; Frank G. Edmed, 17, student, Brighton; Henry T. Hildage, 19, fitter, Altrincham; Robert H. Watson, 24, student, Dublin; Harold Hibbert, 16, student, Manchester. Free Studentships—John W. Button, 23, tool fitter, Oldham; George H. Stanley, 17, student, London; Walter Eraut, 19, mechanical engineer's apprentice, London; I. William Chubb, 23, draughtsman, London; Robert H. H. Duncan, 15, student, Sunderland; George George, 18, student, Bristol. Percy

Nicholls, 23, engineer, of Pontefract, obtained the third place in order of merit in the competition for National Scholarships, &c., but withdrew before the awards were actually made.

The separation of minerals of high specific gravity has recently been greatly facilitated by the introduction of the fused double nitrate of silver and thallium, originally due to Dr. J. W. Retgers. When these nitrates are brought together in the molecular proportion of 1 : 1, they yield a double salt, which fuses at 75° C. to a clear, mobile liquid, having a specific gravity of about 5 and miscible with water in all proportions at temperatures between its melting point and 100° C. The melting point also diminishes rapidly as water is added, going down to 50° or 60° C., and fusion and solubility pass uninterruptedly into one another. We have thus at our command for the separation of mineral particles a liquid far exceeding in specific gravity any of the previously described heavy solutions, and which has the advantage of being practically colourless, neutral, soluble in water, and of being readily recovered from the aqueous solution by simple evaporation on the water bath. Some further hints upon the use of this convenient medium are given in the current number of the *American Journal of Science*, by Messrs. Penfield and Kreider. Separations may be made in test tubes heated in a water bath. After a separation is completed and the fusion cooled, the test tube is broken and the solid cake divided, when the heavier and lighter portion may be obtained by dissolving the double salt. If fractional separations are required, the fused salt may be placed in a tube with a narrow neck at the bottom, into which is ground a glass rod to serve as a stopcock. This apparatus slips inside of a test tube to within a few millimetres of the bottom. The whole is heated in a beaker of hot water, and the liquid is stirred by means of a glass rod bent into a semicircle at the bottom. Heavy particles are drawn off by raising the ground glass rod. Small particles getting caught in the stopper can usually be ground out by twisting the rod, but in no case will such an accident cause great inconvenience.

The annual report for 1893, just received from the Department of Mines and Agriculture, New South Wales, states that the Government metallurgical works will probably be started this year. These works in conjunction with the School of Mines which has been established at the Sydney University, enables the colony to offer as complete and effective a course of training in mining and metallurgy as can be obtained in Great Britain. The report consists largely of statistics relating to the output, value, &c., of various minerals. A boring made at Cremorne Point is of interest. Prof. T. W. E. David made some determinations of the temperature of this bore. The hole was 2929 feet deep, but the bottom 29 feet (about) was silted up with the powdered rock produced by the cutting action of the diamond drill used in the boring. From 2900 feet to within 300 feet of the surface, the bore was filled with water, the column being, therefore, 2600 feet high, and giving a maximum pressure of, approximately, a trifle over half a ton per square inch. The thermometers used were hermetically sealed in wrought-iron tubes and surrounded with brass filings and brass turnings. The readings obtained showed that the rock temperature at a depth of 2730 feet was 97°·5 F. The mean surface temperature at Sydney is about 63° F., so the rate of increase was 1° F. for about every 78 feet 10 inches.

The *Bulletin* of the Royal Gardens, Kew, No. 92, for August 1894, is entirely occupied by a summary of information relating to Bananas and Plantains, with descriptions of the species and principal varieties of *Musa* grown for use and ornament.

From thirty to forty volumes are issued yearly in the comprehensive "Encyclopédie Scientifique des Aide-Mémoire" series published jointly by MM. Gauthier-Villars and M. Masson. The whole collection, when completed, will number three hundred volumes. The latest addition to the series is "Les Machines Thermiques," by Prof. Aimé Witz. The theory of steam, hot air, and gas engines is well described by the author, and the relations between different heat engines are set forth in a manner which brings out clearly the special characters of their respective cycles.

The third volume of the *Seismological Journal of Japan*, corresponding to the *Transactions* of the Seismological Society, has reached us. Prof. John Milne, F.R.S., contributes to it a paper on "Seismic, Magnetic, and Electric Phenomena," in which he discusses the evidence as to the connection between those phenomena. Observations are adduced which seem to show that there may be a connection between earthquakes and magnetic and electric manifestations. But, concludes Prof. Milne, though "a variety of experiments and investigations have been made to test whether earthquakes were preceded, accompanied, or followed by magnetic or electric phenomena, the results obtained do not guarantee the existence of such connections. It does not seem likely that earthquakes can result from electric discharges, and it has not yet been proved that they give rise to electric phenomena. When they have resulted in the displacement of large masses of rocky strata, as happened in 1891 in Central Japan, slight local changes in magnetic curves have resulted, but beyond this and effects due to the mechanical shaking of earth-plates, our certain knowledge is exceedingly small."

The "Geological Sketch-Map of Western Australia," by Mr. H. P. Woodward, the Government geologist, shows in a very clear manner the geology of the explored districts; but it also shows of how large an area the geology is quite unknown. The scale is 1 : 3,000,000 (1 inch to 47·3 miles). The rock-divisions coloured are: Recent and Tertiary, Mesozoic, Palæozoic, Metamorphic, Crystalline (schists and granite), Volcanic, and Plutonic (basalt and granite). The distribution is shown of gold, copper, lead, tin, and coal; gold and copper are indicated by solid colour, which somewhat interferes with the general effect of the map, as the colours appear to represent special formations; the other minerals are shown by coloured lines. The chief gold-fields are situated on metamorphic rocks; a few are in the crystalline areas. The geology of the Coolgardie and Dundas gold-fields is not indicated. The map is clearly printed, both in its topography and colouring. It is published, for the Government of Western Australia, by G. Philip and Son, Fleet Street, London.

The *Monist* for July contains an interesting article by Mr. Wm. R. Thayer, on Leonardo de Vinci as a pioneer in science. Of the thousands of MS. pages which this indefatigable experimenter left, one volume alone has been edited. At first no one could decipher them, for Leonardo wrote backwards from right to left. The pioneer work in science, astronomy, physics, geology, botany—in fact, the whole circle of the sciences—contained in this one volume is briefly but clearly sketched, and some of his pithy and epigrammatic notes are quoted. "His curiosity was insatiable; his methods were observation and experiment; his advance was from the known to the unknown. . . . To search out all things, to experiment and verify, to let his eyes test, and reason be the judge. This was Leonardo's method." Prof. Hermann Schubert's article on "Monism in Arithmetic" is a lucid statement of fundamental principles in continuation of a previous paper on "The Notion and Definition of Number."

Experimental psychology is represented in *Mind* by an article on "Mediate Association," by Mr. W. G. Smith, the results of which do not appear to be very conclusive. In the *Psychological Review*, Prof. Ladd describes the results of experimental work on the "direct control of the retinal field." A class of sixteen students were asked to close the eyes, allow after-images to die away, and then to cause, by attentively willing, a cross, circle, or some other simple figure, to appear in the retinal field. In two cases, where the results were successful, a coloured figure was distinctly visualised, and when the eyes were opened after these voluntary crosses were obtained, and were immediately focussed on a sheet of white paper, a cross was found to appear on the paper in the complementary colour. It is clear that these experiments open up interesting psychological problems. Prof. Jastrow, in the same journal, describes experiments on Helen Kellar, a blind and deaf girl. The sensibility of her finger-tips and the palm of her hand were found to be decidedly more acute than in the average individual; her verbal memory is decidedly above the normal; and she shows that sensitiveness to vibration and jars which has frequently been noted in the deaf.

Mr. Thomas R. Sim, Curator of the Botanic Garden, King William's Town, South Africa, has done good service by collecting and systematically arranging the records of Kaffrarian plants, in a pamphlet recently published at Cape Town. As a botanical district, Kaffraria is described as an oblong tract of country two hundred miles long by about one hundred miles wide, bounded at one end by the Karoo, and at the other end by Natal. Mr. Sim finds that the flora includes 2449 species, of which 1690 are dicotyledons, 656 monocotyledons, and 103 vascular cryptogams. The richness in species is shown by a comparison with Great Britain—an area much greater than that of Kaffraria, but containing only about 1700 species. The opinion is expressed that were the Kaffrarian plants as well known as our own, they would number more than three thousand species. Though Mr. Sim's list is incomplete, it is an excellent groundwork upon which a detailed description of the flora of the district surveyed may be built.

For some years past Lieut.-General Pitt-Rivers has supplied the means for physical and mental recreation near his country seat at Rushmore. He has had the Larmer Grounds laid out as pleasure grounds, and opened them free to the public every day. In 1887 the number of persons who availed themselves of this privilege was 15,351, and last year the number was 24,143. To those interested in breeding and acclimatisation, some of the animals in the grounds at Rushmore will be found of interest. But the museum at Farnham, established and supported by General Pitt-Rivers, is most attractive to us. It consists of eight rooms and galleries devoted mainly to antiquities, and containing models of the excavations carried on by the generous donor in the neighbourhood. During last year, more than seven thousand persons visited the museum. Another building open is King John's House at Tollard Royal. This building contains a series of pictures illustrating the history of painting from the earliest times, commencing with Egyptian paintings of mummy heads of the twentieth and twenty-sixth dynasties, B.C. 1200–528. Descriptions of all these places are given in a short guide, recently received, together with illustrations of some of the most interesting features.

Statistics relating to the distribution of rain over the British Isles have been collated by Mr. G. J. Symons, F.R.S., in "British Rainfall," for thirty-four consecutive years. The volume for 1893 resembles former issues so far as the tabular matter is concerned; but the great drought rendered the year an exceptional one in several respects. At twenty-five stations, only about an inch of rain fell from the end of February to the end of June, that is, during a period of four months. A curious point mentioned in connection with the discussion of this remarkably low rainfall is that among the stations recording droughts exceeding 120 days, two of the three which head the list were situated on promontories or projecting parts of the coast. These were Dungeness, with a period of 127 days, during which only 1·27 inches of rain were measured, and East Dean (near Beachy Head), where 1·18 inches fell in 126 days. Several remarkably heavy falls in short periods occurred during the year. At Preston, 1·25 inches is estimated to have fallen in five minutes on August 10; but this record is hardly trustworthy. A fall of 0·62 inch in five minutes was measured at Shirenewton Hall on June 14. This is at the rate of 7·44 inches per hour. An extraordinary fall of rain occurred at Eastbourne in July, and a waterspout (or cloud burst) caused great damage on the Cheviots in the same month. Various other remarkable falls of rain are recorded in the notes which the observers send to Mr. Symons with the results of their rain-gauge observations. A discussion of the relation of the total fall of rain in 1893 to the average shows that, taking the whole of the British Isles, the deficiency was 14 per cent.

The additions to the Zoological Society's Gardens during the past week include a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. H. P. Nicholls; an Ocelot (*Felis pardalis*) from South America, presented by Miss Edith Zambra; two Ring Ouzels (*Turdus torquatus*) from Hungary, presented by Mr. John Young; a Herring Gull (*Larus argentatus*), British, presented by Mr. George Hayes; a Common Viper (*Vipera berus*) from Gloucestershire, presented by Mr. Barry Burge.

OUR ASTRONOMICAL COLUMN.

Solar Electrical Energy.—According to Dr. M. A. Veeder (*Proceedings* of the Rochester Academy of Sciences, vol. ii., July 1894), there is conclusive evidence that magnetic perturbations are not of thermo-electric origin, and are not connected with heat and light radiations. He holds, in short, that there is no correspondence whatever between the behaviour of magnetic storms and the manner in which thermal and luminous radiations are originated and propagated from the sun to the earth. His idea is that electrical disturbances upon the sun are transmitted to the earth not by radiation but by conduction through the impalpable dust and debris with which interplanetary space is filled. Such meteoritic particles are composed of good conducting material, and an examination of a large number of meteorites has shown Dr. Veeder that they all possess magnetic properties which might have been produced by long-continued induction. Therefore he thinks that the origin of magnetic storms is as follows:—"Particular portions of the sun's surface and cooler immediate surroundings are electrified by what has every mark of being volcanic action. The motion of rotation of the sun carrying forward these charged portions of its surface, develops currents dynamically which act inductively along lines of force wherever there is conducting material within their scope. There is no conveyance by radiation or in a manner similar to that in which heat and light are conveyed from the sun. The laws governing the process are entirely different from those of radiation, and have reference to the principles of conduction as they appear under the conditions existing in interplanetary space. It is a mode of solar action that is distinct, and that must be considered by itself."

Tempel's Periodic Comet.—This comet, rediscovered by Mr. Finlay at the Cape, on May 8, is still visible, and promises to be within the grasp of moderately large instruments for some time. M. Schulhof points out in the *Astronomische Nachrichten* that it is desirable that the comet should be followed as long as possible. The object is becoming more favourably situated for observation, and there will be very little diminution in its light during the next three or four months. Using recent observations of the position of the comet, M. Schulhof has computed a new orbit. The following positions are extracted from the ephemeris based upon the new elements:—

Ephemeris for Paris Midnight.

1894.		R.A. h. m. s.		Decl. ° ′ ″
Aug. 27	...	3 53 39·6	...	+3 32 39

A NEW VARIABLE STAR.—The Rev. T. E. Espin informs us, through a Wolsingham Observatory *Circular*, that the star DM + 50°·2251, the position of which is R.A. 16h. 1·5m., Decl. + 50° 47′, is variable.

ON THE NEWTONIAN CONSTANT OF GRAVITATION.[1]

III.

FIG. 8 is a view of the apparatus with the optical compass in position, and with the microscopes focussed upon the wires. They are then ready to be withdrawn by the focussing slide, so as to transfer the distances directly to the small glass scale, as already described.

When this is completed the proper windows are put in position, the screen tubes, the octagon house, and the felt screens are all placed ready for operation 10, in which the deflections are measured, and the period with the balls is determined. As this is the operation in which variations of temperature produce so serious an effect, I prefer to leave everything undisturbed for three days, to quiet down. A few hours are quite useless for the purpose.

In operation 11 the period with the counter-weight in the place of the gold balls is measured; also the deflection, if any, due to the lid and lead balls upon the mirror alone. This is only 1/10 division, but its existence is certain. In the later operations the deflections, if any, due to the lid alone on the mirror alone, and to the lid alone on the mirror and gold balls, are separately determined. Neither of these can be detected. The actual elongation of the fibre may also be observed at this stage, but this is of interest only as bearing on the elastic properties of quartz fibres under longitudinal strain.

Before I come to the treatment of the observations, I should like to refer shortly to the kind of perfection of conditions which by the employment of every practicable refinement that I could devise, I have succeeded in obtaining. Taking experiment 8 as an example, favourable in that the conditions were good, *i.e.* I was not badly disturbed by trains, wind, or earth tremors, I give the worst and the best sets of four points of rest obtained from six elongations. They were:—

Worst set + position	Best set position
24491	20795·4
24493	20795·7
24493·5	20795·5
24492	20795·5
(24491·7)[2]	
	20795·5 mean.
24492·4 mean.	

Taking all the mean points of rest, as determined above, in groups of three to eliminate slow shifting, if any, of the points of rest, the series of deflections were:—

3696·0
3696·3
3696·0
3696·8

(Interval of one hour, in which oscillations of large amplitude were observed for period.)

(3697·7)
3696·0

Immediately after the oscillations of large amplitude, which in this case at the end were rather badly disturbed by trains or otherwise, a rather different deflection was observed, but not seriously different. As examination of the figures shows only one anomalous point of rest immediately after the large amplitude disturbance, I feel justified in rejecting the only discordant figure, and in taking the mean of the rest as the true deflection. The unit in this case is 1/10 division. It corresponds to an angular movement of 1/280000, *i.e.* about three-quarters of a second of arc. Now a calculation of the angular twist due to a rotation of the air based upon the period, the moment of inertia, and the logarithmic decrement, shows that if the air in the tube were made to whirl round at the rate of one turn in six weeks, so that the air would blow past the gold balls at the rate of one inch in a fortnight, the deflection produced would be 1/10 division, an amount which is greater than the uncertainty of the deflection on this particular night. Again, an examination of the points of rest through the night in the positive and in the negative positions shows a very small steady creep, the same in each case. Creepage of this sort has been, I believe, mentioned as a defect of quartz fibres. When it gives trouble it is due to draughts, as already explained, or to imperfect attachment of the fibres.[1] In the present instance the creepage observed corresponds to a surface rate of movement on the fibre of a millionth of an inch a month.

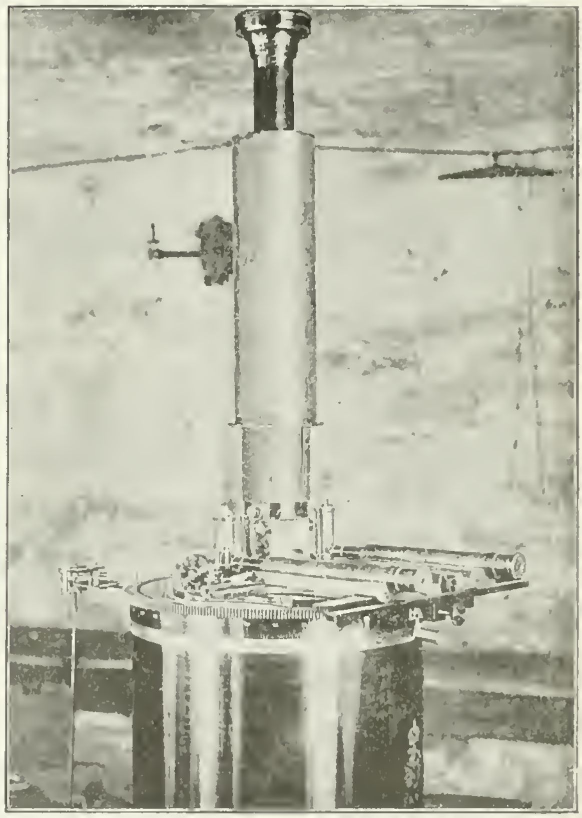

FIG. 8.

An examination of the mobile system of the beam and suspended gold balls, of which I exhibit a greatly enlarged and working model, at once shows that all the parts are capable of independent movement to an apparently perplexing degree. This in the theory of the instrument I have

[1] Continued from p. 363.

[2] Disturbed by trains.

[1] See my paper on "Attachment of Quartz Fibres," *Phil. Mag.*, May [illegible].

treated provisionally as a rigid system moving all as one piece, which it certainly does not seem to be. For instance, the lead balls, by their attraction of the gold balls, pull them out of the perpendicular, so that their distance from the axis is greater than that given by measurement by the optical compass. The error amounts, in the case of the lower ball, when the lead is at its nearest point, to 1/10,000,000 inch, and I have not taken any notice of it. When the beam is oscillating through so great an angle as 100,000 units the centrifugal force only makes the gold ball move out four times as much, and I have taken no notice of that. Again, when the mirror is under acceleration by the fibre, the gold balls, hanging 5 and 11 inches below, do not follow absolutely; they must lag behind, and so affect the period. Now in this case the gold balls are suspended in a manner which is dynamically equivalent to being at the end of a pendulum 5¾ miles long, the shortest equivalent pendulum that has ever been employed in work of this kind; but short as it is, I have not thought it worth while to be perturbed by an uncertainty of a few inches. There is one point which in some of the experiments only has amounted to a quantity which I do not like to ignore. It is due to the torsional mobility of the separate fibres, about which each gold ball hangs, allowing them in their rotation to slightly lag behind the mirror. As I did not see how to allow for it, I applied to Prof. Greenhill, who immediately told me what to do, and who, with Prof. Minchin, spent a day or two in the country, covering many sheets of paper with logarithms, in finding and solving for me the resulting cubic equation. The correction on this account is 1/7850 on the stiffness of the torsion fibre.

There are four remaining corrections depending on the fact that besides the gravitating spheres there are the ball-holders and supporting wires and fibres, all of which produce small but definite disturbances in the gravitation. These are all calculated and allowed for. They are:—

Disturbances due to brass-holders of lead balls ... 1/7320
,, ,, copper ,, gold ,, ... 1/265,000
Attraction of lead balls for quartz fibres .... + 1/200,000
,, gold ,, phosphor-bronze wires − 1/115,000

Then in experiment 9 gold cylinders were employed. Mr. Edser, of the Royal College of Science, calculated for me the correction to be applied if they were treated as spheres; this amounted to 1/3300.

I have already mentioned that experiment 8 was made under more than usually quiet conditions. Such extreme quiet is desirable, that I manage to reserve Sunday nights, from midnight to six or eight in the morning, for observations of deflection and period. All the other operations can be carried on in the daytime. Sunday is the only night that is suitable, as the railway companies spend every other night shunting and making up trains about a mile away, and this causes such a continuous clatter and vibration, that hours of work may be lost. A passing train does not seem so injurious; but, fortunately for me, most of the observations were made during the coal strike, and fewer trains than usual were running. However, though I may escape from the rattling traffic of St. Giles by working at night, and on Sunday nights am not so badly affected by the trains, I am still not sure of quiet even when there is no wind. For instance, at a quarter to four on Monday morning, Sept. 10, 1893, I was recording chronographically the passage of every ten divisions. Everything was quite quiet, and at the particular moment the marks on the drum recurred at intervals of about three seconds. Suddenly there was a violent non-vibrating lurch of fifteen divisions, or 150 units, which is enormously greater than anything that either trains or traffic could produce; of course, I could make no further record. The time of the last mark was, allowing for the known error of the clock, 15h. 44m. 14·3s. This was entered the same day in my note-book as an earthquake, and in Tuesday's *Standard* I read an account of a violent earthquake in Roumania at about the same time. I have not yet particulars from Vienna, for which Mr. Horace Darwin has written; but though the shock recorded in the newspaper seem to have been too late, preliminary shocks are by no means unknown, and I cannot help thinking that what I observed was the dying out and distant effect of one of these. Of this, however, I am sure, that it was an earthquake that I observed, and not any disturbance due to human origin.

Owing to the viscosity of the air, which limits the time during which an observation for period can be made to about 40 minutes, on account of the resistance that the slowly moving mirror and gold balls experience in their passage through it, I made one experiment, with the view of reducing this difficulty, by the use of an atmosphere of pure dry hydrogen gas, which possesses a viscosity only half that of air. I did find that on this account a great advantage could be gained; but this was more than counterbalanced by the difficulty of getting up a sufficient swing in the gas, and of efficiently controlling the mirror. At the same time, I think that if I had had time to provide means for feeding the gas into the tube without entering the corner, and at the same time were to prevent diffusion at the lower screw, that a little trouble in this direction would be well rewarded. Meantime I found within the limits of error, which were greater than without the hydrogen, that the deflection and the period corrected for the diminished damping were the same. The chief interest of this experiment lies in the fact that it revealed an action unknown to me, and I believe to others, that a thin plane glass mirror, silvered and lacquered on one side, definitely bends to a small extent, becoming slightly convex on the glass side when in hydrogen, and instantly recovers its form when surrounded by air again. This happened many times, producing a change of focus in the telescope of about five-eighths of an inch. I do not offer any explanation of the fact.

There is an observation which should be of interest to elasticians. In experiments 4 to 8 the torsion fibre carried the beam mirror and the ·25 inch gold balls, weighing, with their hooks and fibres, 5·312 grammes. In experiment 9, gold cylinders were substituted, weighing, with their hooks and fibres, 7·976 grammes. The weight of the mirror was ·844 gramme. In consequence of the small increase of load the torsional rigidity of the fibre fell more than 4 per cent., an amount far too great to be accounted for by the change of dimensions, even if Poisson's ratio were as great as ½. There is no doubt about the great reduction in stiffness, for this figure is one of the factors in the final expression for G, which does not show a change of more than 1 part in 1570.

It will not be possible at this late hour to explain how the observations are treated so as to obtain the value of G. It is sufficient to state that in one of these clips all the observed deflections and corrected periods are collected. In the second all the geometrical observations are collected and reduced, so as to obtain what I call the geometrical factor, *i.e.* a number which, when multiplied by the unknown G, gives the torsion on the fibre. In the third, the moments of inertia and periods are made use of to find the actual stiffeness of the fibre in the several experiments, and in the fourth these are combined so as to find G. From G the density of the earth Δ immediately follows.

The annexed table contains the important particulars of each experiment. From this it will be seen that the lead balls were twisted and interchanged in every way, so as to show any want of gravitational symmetry if it should exist. For instance, after experiment 7 the ball that was high was made low, the side that was outwards was turned inwards, and their distance apart was reduced by 1/50 inch, but the change in the result was only 1 part in 2764. The experiments 7, 8, 9, 10 were made under widely different circumstances. After experiment 8 the gold balls were changed for heavier gold cylinders, which, as has already been stated, reduced the torsion of the fibre by 4 per cent., but the result is practically the same as that of experiment 7. I then broke the end of the torsion fibre. After keeping it in London three months, I broke the other end. I then resoldered each end and put the fibre back in its place, and after making every observation afresh, found with the new shorter and stiffer fibre a result differing from that of experiment 8 by only 1 part in 27,635. These four experiments were all made under favourable circumstances, and on this account I feel more able to rely upon them than on the earlier ones, which were subject to greater uncertainty. The last experiment was made under most unfavourable conditions. The periods and deflections were taken in the first four hours after midnight, then, after a few hours' sleep, and far too soon for the temperature to have quieted down, I took the period with the counterweight, but was only able to give ten minutes, as I had to catch a train in order to be able to give my midday lecture at South Kensington. It is not surprising that under such conditions a difference of 1 part in 600 should arise. There is a difference of about the same order of magnitude between the earlier experiments and the favourable four. There is one point about the figures that I should like to mention. No results were calculated till long after the completion of the last experiment. Had I known how the figures were coming out, it would have been impossible to have been biassed in taking the periods and deflections. Even the calculating boys could not have discovered whether the observed elongations were such as would give a definite point of rest. I made my observations, and the figures were copied at once in ink into the books, where afterwards they left my hands and were ground out by the calculating machine. The agreement, such as it is, between my results is therefore in no way the effect of bias, for I had no notion till last May what they would be.

My conclusion is that the force with which two spheres weighing a gramme each, with their centres 1 centimetre apart, attract one another, is $6·6576 \times 10^{-8}$ dynes, and that the mean density of the earth is 5·5270 times that of water.

It is evident, from what I have already said, that this work is of more than one-man power. Of necessity I am under obligations in many quarters. In the first place, the Department of Science and Art have made it possible for me to carry out the experiment by enabling me to make use of apparatus of my own design. This belongs to the Science Museum, where I hope in time to set it up so that visitors who are interested may observe for themselves the gravitational attraction between small masses. Prof. Clifton, as I have already stated, has given me undisturbed possession of his best observing room, his only good underground room, for the last four years. The late Prof. Pritchard lent me an astronomical clock. Prof. Viriamu Jones enabled me to calibrate the small glass scale on his Whitworth measuring machine; and Mr. Chaney did the same for my weights. I would especially refer to the pains that were taken by Mr. Pye, of the Cambridge Scientific Instrument Company, to carry out every detail as I wished it, and to the highly skilled work of Mr. Colebrook, to which I have already referred. Finally, I am under great obligations to Mr. Starling, of the Royal College of Science, who performed the necessarily tedious calculations.

In conclusion, I have only to say that while I have during the last five years steadily and persistently pursued this one object with the fixed determination to carry it through at any cost, in spite of any opposition of circumstance, knowing that by my discovery of the value of the quartz fibre, and my development of the design of this apparatus, I had, for the first time, made it possible to obtain the value of Newton's Constant with a degree of accuracy as great as that with which electrical and magnetic units are known, though I have up to the present succeeded to an extent which is greater, I believe, than was expected of me, I am not yet entirely satisfied. I hope to make one more effort this autumn, but the conditions under which I have to work are too difficult; I cannot make the prolonged series of experiments in a spot remote from railways or human disturbance; I cannot escape from that perpetual command to come back to my work in London; so I must then leave it, feeling sure that the next step can only be made by my methods, but by some one more blest in this world than myself.

SCIENCE IN THE MAGAZINES.

IN the August magazines received by us, science is but poorly represented. A brief mention of the more important articles will therefore be sufficient this month.

Mr. Benjamin Kidd's work on "Social Evolution" has furnished material for much criticism. In the *National Review* Mr. Francis Galton, F.R.S., discusses the part of religion in human evolution as set down in the book; and Mr. Kidd adds a short note on the opinions expressed in the article. The same magazine contains a paper on "Sleeplessness" by Mr. A. Symons Eccles, and one on "Colliery Explosions and Coal Dust," by Mr. W. N. Atkinson. An experience of fifteen years in investigating explosions in coal-mines has led him to believe that "coal dust has been the chief, or only, agent in all recent widespread colliery explosions." It is regretted that "no experiments have been made on a scale large enough to yield visual demonstration of the effect of an explosion of coal-dust, under conditions approximating as closely as possible to those existing in mines. The nearest approach to such experiments in this country were those recently made by Mr. H. Hall, H.M. Inspector of Mines, in an old pit shaft fifty yards deep. The length of such a shaft is insufficient to develop the whole force of a coal-dust explosion, and the conditions under which the explosions or ignitions took place were necessarily different from those obtaining in the practical working of mines. These experiments, however, are valuable, as demonstrating that the dust ordinarily existing in a great number of mines (not particular exceptional coal-dusts) are capable of propagating flame to the full limits admitted by the conditions of the experiments."

A psychological paper, entitled "How We Think of Tones and Music," is contributed to the *Contemporary* by Mr. R. Wallaschek. Mr. Andrew Lang tilts at Prof. Huxley's treatment of the Bible story of Saul and the Witch of Endor "as a piece of evidence bearing on an important anthropological problem," and treats the matter from a less scientific point of view.

Eight recent books on Iceland furnish the subject of an interesting account of the island in the *Quarterly Review* (No. 357). The same publication contains a long article on "Forestry," in the course of which the author says that the three great faults noticeable in the treatment of woods in Great Britain are: (1) Discrimination has seldom been shown with regard to the choice of the kinds of trees for given soils and situations. (2) Plantations have not usually been formed of the best degree of density for the given kinds of trees selected for planting. (3) A sufficient density of crop has not always been maintained during the subsequent periods of the natural development of the trees. It is finally concluded that—"Better results than can at present be reasonably expected would probably be obtained if State aid were freely granted towards the dissemination of sound instruction concerning sylviculture; and the only proper places for bringing this within the reach of the future landowners, and of young men of good education, are undoubtedly the great Universities."

Messrs. T. G. Allen and W. L. Sachtleben continue, in the *Century*, the description of their journey "Across Asia on a Bicycle," from Constantinople to Pekin. Dr. W. T. G. Morton's claims to the discovery of anæsthesia are championed by Mr. E. L. Snell. It will be remembered by readers of this monthly summary that the January number of the *Century* contained an article in which Miss E. B. Simpson told the story of her distinguished father's discovery of the anæsthetic properties of chloroform in 1847. It is now shown that, in the preceding year, Dr. Morton publicly demonstrated the use of sulphuric ether in producing anæsthesia, at the Massachusetts General Hospital.

A passing mention will suffice for the remaining articles of scientific interest in the current magazines. Mr. A. H. Savage-Landor describes a visit to Corea, in the *Fortnightly*. Some of the possibilities of the phonograph are foreshadowed in *Scribner*, by Octave Usanne. *Longman's Magazine* contains "White Sea Letters, 1893," by Mr. A. Trevor-Battye. Naturalists will find the letters interesting. Under the title "Land Crabs," Mr. E. Step contributes to *Good Words* a popular description of such terrestrial crustaceans as *Gecarcinus ruricola* and various members of the genus *Gelasimus*. Finally, the vivisection controversy is continued in the *Humanitarian*, and the man-like apes in the Gardens of the Zoological Society are described in the *English Illustrated*.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 21.—"Researches on the Structure, Organisation, and Classification of the Fossil Reptilia. Part IX. Section 4. On the Gomphodontia." By H. G. Seeley, F.R.S.

"On an Instrument for Indicating and Measuring Difference of Phase between E.M.F. and Current in any Alternating Current System." By Major P. Cardew, R.E.

"On the Difference of Potential that may be established at the Surface of the Ground immediately above and at various Distances from a Buried Mass of Metal Charge from a High Pressure Electric Light Supply." By Major Cardew, R.E., and Major Bagnold, R.E.

PARIS.

Academy of Sciences, August 13.—M. Lœwy in the chair.—The death of M. Gustave Cotteau (August 10) was announced; the deceased correspondent was an authority on sea-urchins.—Note on the long-period meteorograph to be placed in Mont Blanc Observatory, by M. J. Janssen. A description is given of the arrangements for automatically registering during eight months the indications of the barometer, thermometer, and hygrometer, and the speed and direction of the wind.—New researches on the infra-red region of the solar spectrum, by M. Langley. The author shows that a perfected arrangement of the bolometer is able, by means of automatically photographing the movements of the galvanometer needle, to furnish a complete record in an hour of the infra-red region of the solar spectrum with very great accuracy. The accuracy obtained is illustrated by the case of the D lines in the visible part of the spectrum; the method indicates very clearly the Ni line occurring between D_1 and D_2. Crystals collect at the upper part of a less dense solution, by M. Lecoq de Boisbaudran. If a saturated solution of carbonate and thiosulphate of sodium be saturated with sodium sulphide ($Na_2S.9H_2O$) and a quantity of the latter placed at the bottom of the solution and a small fragment supported near the surface, in the course of a few days or weeks the additional sodium sulphide is found collected round the fragment on the support. By the solution of the crystallised sulphide the bulk of the solution increases in a greater ratio than the weight, and hence its specific gravity is lowered.—A new use of Plucker's conoid, by M. A. Mannheim.—New arithmetical theorems, by Père Pepin.—Remarks on the electrochemical graphic method of studying alternating currents, by M. A. Blondel.—Application of auto-collimation to the measurement of indices of refraction, by M. Féry.—On the specific heat of liquid sulphurous anhydride, by M. E. Mathias. A general method is described. The true specific heat of liquid sulphur dioxide is always positive and increases constantly and indefinitely with the temperature. A table is given showing the value of m between $-20°$ and $+155·5°$. Between $-20°$ and $+130°$, $m = 0·31712 + 0·0003507t + 0·000006762t^2$. At $155·5°$, $m = 2·980$.—On benzoylquinine, by M. A. Wunsch. The base has been obtained in clear, colourless prisms, insoluble in water. It dissolves easily in alcohol, benzene, chloroform, petroleum ether, carbon bisulphide, and ether. It has the composition $C_{20}H_{23}(C_6H_5CO)N_2O_2$, and melts at 139° without decomposition. The following salts have been examined: the basic and normal hydrochlorides, and the basic salicylate, tartrate, and succinate.—On the heart in some orthoptera, by M. A. Kowalevsky.—On the peritheca of the vine mildew (*Uncinula spiralis*), by M. Pierre Viala. The abundance of peritheca found in 1893 fully confirms the identity of *Erysiphe Tuckeri* with *Uncinula spiralis*. The parasite noted by Bary on the conidiophores of mildew, *Cicinnobolus Cesatii*, was abundantly developed in 1893 in the peritheca of *Uncinula spiralis*. The author also describes a peculiar parasitic bacterium.

THURSDAY, AUGUST 30, 1894.

A THEORY OF THE GLACIAL DEPOSITS.

Papers and Notes on the Glacial Geology of Great Britain and Ireland. By the late Henry Carvill Lewis, M.A., F.G.S. (London: Longmans, Green, and Co., 1894.)

THEY are wrong who think that little is left in England for a geologist to discover or do. Not only are there gaps to be filled up, and doubtful points to be made certain, but even whole fields remain where if labourers have been at work they have as yet reaped little fruit. Especially may an Alexander, sighing for a fresh world, be invited to turn his attention to what are called the glacial deposits. In area they extend over the greater part of the British Isles; in variety they far exceed the Archæans; in difference of opinion about them they would also exceed Archæans, if such an excess be possible. They have difficulties peculiarly their own. It is well said by the editor of this volume that in glacial geology not merely the interpretation of facts is debated, but there is dispute as to what the facts are themselves. Geologists of repute go to the same section, see the same phenomena, and describe them in contradictory terms. Mr. Clement Reid surveys the Cromer cliffs, and figures chalk masses ploughed up by glaciers. Mr. Mellard Reade examines the same cliffs, and sketches chalk masses dropped down by ice-floes. The questions connected with these deposits have been raised on the hills of Nicaragua and the banks of the Amazon. As their range of space, so their range of time: glacial phenomena have been described from the Permian epoch, and the Carboniferous. They seem to claim all time and all space as their province.

To conquer such a world is needed an Alexander in truth. Such an one some friends hoped they saw risen in the student whose remains are now given to the world. Those who knew Carvill Lewis, who knew his ability, energy, enthusiasm, perseverance, with his equipment of knowledge, travel, and means, when they saw him devote all these to his study of glacial deposits, thought that now at last order would emerge out of chaos; that what Sedgwick and Murchison did for the Grauwacke he might do for the Drift. His early death destroyed these hopes, quenching a kindled light. We have, however, in this volume a not unworthy memorial; no mean contribution to science. It is a record of the ideas he had formed or was forming, in some respects more valuable than a completed treatise would have been. For here we discover his plans, ideas, observations; his opinions, formed, corrected, abandoned; together with an immense mass of materials, collected out of previous writers, abstracted, arranged, and criticised. Dr. Crosskey has performed his most difficult task of editing with extreme tact and judgment. "I venture," he says in his introduction, "to set aside the injunction laid upon me to 'criticise' as well as to arrange and edit." A high proof this of fitness for such a task; it makes of correspondingly high value the two or three criticisms which he does pronounce. Sad that we should be presented with a volume doubly posthumous; that science must mourn the loss of editor as well as of author. But science should be grateful for what she has gained. The gain is great. Here we have presented a theory of the glacial deposits which, whether the truth or no, is certainly clear, consistent, rational, and moderate in its demands. Probably it will not ultimately be accepted as complete; assuredly it will not at once convince every sceptic, or even create an orthodox belief; but it may do much to destroy some current absurdities, it does bring out clearly some neglected truths, and it should form a very convenient working hypothesis to direct our reflection and research.

The volume consists of introductions by Dr. Crosskey and Mrs. Lewis, five entire papers, a mass of extracts from note-books, some memoranda and brief essays, with two appendices. One of these might, perhaps, be spared. We are keen to know what Carvill Lewis thought, but not so much what another thinks he would have thought on sections which he did not see. The other appendix, "Field Notes from Switzerland," though introduced with an apology, is inseparably connected with the rest of the notes, an essential part of the book. If dates could have been added to the extracts from note-books, it would have helped a reader to perceive which of the writer's varying views was his latest.

Prof. Lewis concerned himself little with the causes of the glacial epoch, though one or two shrewd remarks will be found. He devoted his research and thought to the interpretation of the effects which that epoch produced, of what occurred during the period, of what its phenomena represent. His fundamental idea pictures many separate glaciers originating from separate centres of high ground, spreading from these centres till they meet, then still retaining their separate individualities in the motions of the continuous ice-cap into which they have joined. His guiding principles are that such separate individualities can be traced by the peculiarities of the stones transported; still more, that the furthest advance of such glaciers must be marked by a moraine, or by some visible boundary of like nature. The tracing of these boundaries he made an especial work, and he believed himself to have followed them across England, through Yorkshire wolds and Welsh mountains, from the Humber to the Bristol Channel. As a consequence of prime importance, he lays down that such advancing glaciers would frequently dam the courses of rivers, and that the lakes formed by the ponded-up waters would produce deposits of their own. Such deposits he continually recognises and describes. Especially he maintains that the Scandinavian ice met the British, and damming the waters of the Humber and the Wash, created an enormous lake, which drowned all England east of the Pennines and north of the Thames. This vast sheet of fresh water he regards as the manufactory and manufacturer of all those deposits in East Anglia and the Midlands which are commonly called by us glacial. And whatever difficulties may lie in the way of this hypothesis, it is certainly remarkable that the highest level of such deposits at Flamborough Head (according to Lamplugh), on the Lincolnshire Wolds (according to Jukes-Browne), in East Anglia (according to Survey Memoirs), together with the lowest level of passes across the central watershed (as I infer from a map of

Stanford's), should all deviate little from the 400-feet contour line.

The volume is full of minute observations and acute remarks. Readers will find many cherished beliefs rudely handled; perhaps may feel some of them shaken. What a heresy is his denial of the three-fold division of the Drift. In disbelief of interglacial periods he has had predecessors. Herr Penck will find the assertion that frequent and finely striated stones in a clay are an argument against that clay being ground-moraine. Neither contortions nor groovings are here invariably ascribed to a glacier; on the contrary, he explains most such when they occur as products of his lakes or his moraines. He has seen no evidence (in Switzerland) for glacier excavation of lakes). He expresses opinions freely and forcibly: it is refreshing to read that "much rubbish has been written on the Cromer cliffs." The doctrine of a post-pliocene great marine submergence he believes "the most pernicious one ever propounded in geology." Amusing is his description of the "remarkable properties of this sea, wholly unlike any known sea. It made till and eroded till: it filled some regions with drift, while others it cleared utterly of all drift: its icebergs made striæ, while its waters washed them away." It is true that like language might be applied to the effects of glaciers, as described by some of their admirers. Probably it did not occur to him that with regard to them any expression of opinion was needed.

The author's own views offer points for an opponent's attack. While he cannot induce himself to believe in a thousand feet of submergence, it seems to him simple for Scotch ice to have climbed a thousand feet up a Welsh hill, and easy for it to have pushed portions of the sea-bottom to the top. He repeatedly distinguishes between clay formed under a glacier (till) and clay formed in a glacier lake (boulder-clay). But when he sees only till at Filey, and only boulder-clay in East Anglia, it is not easy to make out which of their points of difference are the critical ones. He makes several references to striæ as indicating direction of ice-motion. Yet his ultimate conclusion appears to be that the shape of the striæ depends only on the slope of the rock, and, except on level ground, gives no guide to the direction of motion. He frequently insists on the effects of great floods and débâcles which would result from his glacier-dam lakes, but he does not indicate the way in which these catastrophes would be brought about. "I believe," he says, "that the Scandinavian ice-sheet would temporarily dam up the Humber and form a great inland lake, which would pour over the country to the south in débâcles, making gravels. . . . ." The water would rise steadily to a level of overflow, but how would a débâcle be thereby produced? Such floods seem no necessary part of his theory; however, his belief in them is firm.

To decipher field notes intended only for the writer's own eye, must have been a most difficult task. It has been performed with remarkable success: of course, mistakes have not entirely been avoided, but probably each will be obvious to and easily corrected by any reader who is concerned with the case. In the illustrations on page [illegible] some clays are marked "Permian." There [illegible] clay in that neighbourhood; the word should evidently be Pennine, a designation for a division of the Midland boulder-clay.

Prof. Carvill Lewis began his studies in Pennsylvania, and there obtained his conceptions of moraines as "high-tide marks" for glaciers. He came to the British Isles for explanations of phenomena which perplexed him in America. In Ireland he sought and thought he found a solution of Transatlantic problems. He extended his researches over England and Scotland, and visited the Alps to see existing glaciers. The ideal order of study would be to begin by learning all about ice, and then applying the acquired knowledge to these questions. But practically all, even Carvill Lewis, begin upon deposits said to be glacial, though all do not go on to examine actual ice; and very few can study its grandest manifestations. It is much to be wished that such a geologist as he could spend some summers and winters round Greenland and Hudson's Bay. If to this he could add an acquaintance with Antarctic ice, he would have an equipment of appropriate knowledge such as no one has yet brought to bear on the question. Yet even so there is, perhaps, no spot on the earth where we can now see a glacier advancing across unglaciated lands: a cause whose effect is freely invoked by various writers on this question. However, we must use as best we can such means as we possess. Two characteristics of Carvill Lewis seem especially worthy of our imitation, viz., his untiring assiduity—we are told that he traversed the country between Cork and Mallow six separate times; and his readiness to acknowledge mistake and correct it—he completely retracts more than one opinion at first freely expressed. If any critic had condemned this as "a complete change of front," he would probably have answered, "I am ready to front any way where I see a road to truth."

An estimate of the advance which this book will have made towards a full and true theory is only possible to an infallible critic. His idea, that there ought to be a definite mark of the furthest extension of a glacier, seems to me a correct one: if so, such marks should be sought for. His clear conception of the power and action of floating ice deserves to be studied and developed. His distinctions between the products beneath an ice-sheet (till), adjacent to an ice-sheet (moraine), beyond the ice-sheet, but in waters washing it (boulder clay), are real distinctions of the highest importance. Surely there must be criteria of difference, whether the author has arrived at them or not. Surely when such criteria are ascertained, we shall be very near the solution of one side of the glacial problem. Still would remain for study another side: What brought that problem into existence; what was really the cause of the Ice Age?

E. Hill.

UNIVERSITY EXTENSION.

Aspects of Modern Study. Pp. 187. (London: Macmillan and Co., 1894.)

THIS volume consists of addresses delivered by Lord Playfair, Sir James Paget, Prof. Max Muller, the Duke of Argyll, and Canon Browne, among others, to students of the London Society for the Extension of University Teaching, at annual meetings held at the

Mansion House since 1886. In most of the addresses, special aspects of study are considered, but those by Lord Playfair and Canon Browne deal with the Extension movement itself.

Men of science, as a rule, look askance at University Extension lectures. They know that there is no royal road to scientific knowledge, and believe that popular lectures of a "peep-show" kind have no place in a properly organised educational system. This is true to some extent. Popular lectures of any sort, whether delivered at the Royal Institution or in a village club, are of little use to the practical student of science. They are useful, however, in bringing people into touch with current opinions, and in creating an interest in scientific things.

The subject of Lord Playfair's address is the evolution of University Extension as a part of popular education. After people have heard lectures, they desire to found institutions in which instruction is regularly given. Out of the single and unconnected penny readings in the early part of this century grew the Mechanics' Institutes that, in the Midlands and the North, have helped on the cause of education. It was, of course, inevitable that the committees of these institutes should sometimes have had queer ideas as to the kind of programme which should be offered to the community. Lord Playfair says that one of the most prosperous of them asked him to give a single lecture on chemistry in 1846, and sent him the programme for the preceding year as an inducement to accept the invitation. It was as follows:—"Wit and Humour, with Comic Songs—Women Treated in a Novel Manner—Legerdemain and Spirit-rapping—The Devil (with illustrations)—The Heavenly Bodies and the Stellar System—Palestine and the Holy Land—Speeches by Eminent Friends of Education, interspersed with Music, to be followed by a Ball. Price to the whole 2s. 6d. Refreshments in an Anteroom." Even now, programmes of this motley character can be found at many of the large workmen's clubs in the East End, and though most educationists consider them to be "awful examples," the fact that the science lectures are usually very largely attended testifies to a desire for knowledge, which often leads to systematic study. The University Extension scheme has certainly done something to mould this demand for popular instruction. When interest has been awakened by a pioneer lecture, it becomes a comparatively easy matter to run a successful course of six or twelve lectures. And if such courses are linked together in proper sequence, it cannot be denied that advantage must accrue from them. For, to use a simile of Lord Playfair's, not only does the lecturer scatter information broadcast among his audience, trusting that some of it will fall on fertile soil, but, in the class after each Extension lecture, he acts as a tutor and is able to treat the students individually, giving each mind the attention conducive to the production of good results. The great difficulty, however, is with regard to practical work. Every man of science feels that, so far as serious study is concerned, lectures should take a secondary place in a scheme of instruction. Observations in the field, laboratory, or observatory, are absolutely necessary for a proper appreciation of the facts and phenomena of nature; and, until some provision is made for this kind of work, the science lectures will be considered little more than a form of recreation.

Sir James Paget's address is concerned with the study of science. He points out that a scientific mind should be educated in four ways, viz. (1) in the power of observing, (2) in accuracy, (3) in the difficulty of ascertaining truth, (4) in proceeding from the knowledge of what is proved to the thinking of what is probable. The subject of Prof. Max Müller's address is "Some Lessons of Antiquity," and that of the Duke of Argyll, "The Application of the Historical Method to Economic Science." The addresses are interesting from many points of view, and they help to define the *rôle* of courses of University Extension lectures in our educational system. R. A. Gregory.

SOME RECENT WORKS ON ELECTRICITY.

(1) *Electric Traction on Railways and Tramways.* By Anthony Reckenzann, C.E. (London: Biggs and Co.)

(2) *Portative Electricity.* By J. T. Niblett. (London: Biggs and Co.)

(3) *First Principles of Electrical Engineering.* By C. H. W. Biggs. New edition, partly rewritten and extended. (London: Biggs and Co.)

(4) *Electrical Distribution, its Theory and Practice.* Part i., by Martin Hamilton Kilgour. Part ii., by H. Swan and C. H. W. Biggs. (London: Biggs and Co.)

(5) *Town Councillors' Handbook to Electric Lighting.* By N. Scott Russell, M.Inst.C.E. (London: Biggs and Co.)

(1) The present state of electric traction is precisely given, and the various methods and constructive details at present in use described. The best modern examples of traction are explained, with many excellent illustrations. In particular may be mentioned the proposed St. Louis and Chicago high-speed electric railway, designed to convey passengers 250 miles in two and a half hours. Much useful information has been collected from the various electrical journals and *Transactions*, and a handbook formed, which is sure to be of great service to practical men. We notice that the words "energy," "power," and "work" are used in the popular rather than in the exact scientific sense; but this circumstance detracts little from the value of the work.

(2) This little work is described as being "A Treatise on the Application, Methods of Construction, and the Management of Portable Secondary Batteries." It has been written mainly for the benefit of those who find this form of stored energy of service for economic, artistic, or scientific purposes. Part i. deals with applications to mining operations, domestic use, medical and other scientific purposes, the Army and Navy, carriage lighting, and traction and decoration. In a popular form we are presented with much information that will be very useful to anyone contemplating some of these special uses of electricity. Many of these are recent and novel, and not to be found in any other work with which we are acquainted.

Part ii. is occupied with the description and management of primary and secondary batteries and their adjuncts. It is an excellent small book, suitably illustrated.

(3) This is described as an "attempt to provide an elementary book for those who are intending to enter the profession of electrical engineering." In a very entertaining and humorous preface the author at once enlists the sympathy of the ordinary reader in general, and of the reviewer in particular. After its perusal the latter feels prepared to find much that is novel in treatment and revolutionary in substance in the work itself, but he finds that his anticipations are only realised to a moderate degree. The so-called "Inductive Circuit" is easily recognised as an old friend under a new name. The equation of the condenser, usually written

Quantity = Capacity × Potential-Difference,

is given by the autbor in the form

Accumulation × Resistance = Electrical Pressure,

wherein he regards inductive resistance as bearing the same relation to capacity that electrical resistance does to electrical conductivity. The only advantage we can see in this notion is that it brings out clearly the fact that condenser capacities combine according to the same law as electrical conductivities. Again, the author imagines the "sapient critic" to laugh at his views of "loops" and "unlooping" in connection with the lines of force of a magnetic field, and puts a question to him which he evidently regards as a poser of the first water. He says: "Your teaching involves cutting here, there, and everywhere—first in this direction, then in that; but though you tell us what happens when you cut 'lines of force,' you say nothing of what happens when your conductor leaves those lines of force. You bring your conductor to be acted upon by lines of force, but although you also take your conductor from those lines of force, you recognise no reverse action. All your cry is 'Cut,' 'cut,' 'cut,' &c., &c."

This is of course veritable moonshine. Every electrician is aware that every line of force forms a closed loop, and that "cutting" necessarily involves looping or unlooping, as the case may be, and *vice versa*, whenever the conductor forms a closed circuit.

The first principles of the dynamo are clearly and accurately given, though a worse illustration than that of a gramme ring on p. 152 is not often to be seen. However, it is good to see a clear distinction between "energy" and the "rate of its production," all the more noticeable by reason of its rarity in recent electrical books.

Notwithstanding its eccentricity, the book will be useful to a certain class of student.

(4) Mr. Kilgour considers scientifically the design of systems of distribution which shall give maximum economy with satisfactory working results. This subject was initiated by the valuable papers of Lord Kelvin and of Profs. Ayrton and Perry. In 1881 the former considered the problem of finding the cross-sectional area of copper required for a conductor to transmit a given current in order that the total annual expenditure for the energy wasted in the conductor, and for interest, depreciation, and repairs on the conductor should be a minimum. This problem is now historical. It was on this occasion, the meeting of the British Association in the year mentioned, that Lord Kelvin first brought before engineers the fact that the relation between the size of the conductor and the current strength should be governed by economical considerations. As stated by Mr. Kilgour, six quantities are involved in an important manner, viz.:—V, the pressure in volts at end of feeder near to generators; v, the pressure in volts at end of feeder remote from generators; C, the current strength in ampères flowing through the feeder; P, the watts delivered to feeder; p, the watts delivered by feeder; and x, the cross-sectional area in square inches of the copper of feeder. These six quantities are obviously connected by three relations; we may further assume two other relations between them, and then a sixth relation deduced from economical considerations suffices to determine the whole of the six quantities. The two assumed relations may take the form of two of the quantities being given. This is what usually happens, and is always the case in the author's discussion. Of the fifteen possible cases Lord Kelvin investigated, that in which v and C are given; Prof. Ayrton, that in which V and C, and also that in which V and x are given; while Prof. Ayrton and Perry, in conjunction, before the Society of Telegraph Engineers and Electricians in 1886, considered V and p to be given quantities. The remaining eleven cases are completely examined by Mr. Kilgour, and in doing so, as well as by giving a clear exposition of the whole subject, he has rendered valuable service. To all those who are concerned with the design of systems of distribution, this part of the work will be found to be of high interest and usefulness. In Part ii. will be found a collection of descriptions of the systems which practical men have gradually evolved by knowledge and experience. The best mains and culverts, and also the means of maintaining them in a state of efficiency, in use in England and on the continent, are described in detail with a large number of excellent illustrations. The compilers have shown good judgment in the selections they have made from the many systems that have been adopted.

(5) This work is intended to afford to County Councillors and others similarly placed some information likely to be of use to them in dealing with questions of central station lighting. It is a small and unpretending work of some forty pages, and seems to have accomplished the object in view.

OUR BOOK SHELF.

The First Technical College. By A. Humboldt Sexton. Pp. 188. 1894. (London: Chapman and Hall.)

When John Anderson became Professor of Natural Philosophy in the University of Glasgow, in 1786, he began to give instruction in science to persons engaged in industries. This was the beginning of technical education, and the future of the new line of study was to some extent provided for in Glasgow by its founder bequeathing the whole of his property "to the public for the good of mankind and the improvement of science in an institution to be denominated Anderson's University." The total value of the property, however, was only about £1000, and this, as Prof. Sexton remarks, was a small sum wherewith to start a new university which was to revolutionise the education of the country. But the gift formed a nucleus which attracted other benefactions, and, after a short time, sufficient funds were raised to appoint a Professor of Natural Philosophy and Chemistry. Dr. Thomas Garnett was nominated for this post in May, 1796. Three years later Count Rumford founded the Royal Institution, and Garnett accepted the first professorship in it. He was succeeded at the Anderson's Institution by Dr. George Birkbeck, who afterwards assisted in founding the well-known Birkbeck Institution in London. Dr. Ure next occupied the chair, and when he retired it was decided to appoint two professors—one of Natural Philosophy and one of Chemistry. Among the men who occupied the former chair at different times were Dr. William Heron, Dr. John Taylor, Prof. Carey Foster, and Prof. A. S. Herschel. The chair of chemistry was successively filled by Thomas Graham, Dr. William Gregory, Dr. Penny, Dr. T. E. Thorpe, and Prof. Dittmar. About 1830 Graham established a public laboratory for experimental work in chemistry, the first of its kind in Great Britain, and among the students who worked in it were Dr. James Young, Lord Playfair, and Dr. Walter Crum. Into the various changes which the institution has undergone we do not propose to enter. Suffice it to say that Anderson's College, the Mechanics' Institute, and the Allan Glen's School were united in 1882 to form the Glasgow and West of Scotland Technical College. The Mechanics' Institution, or College of Science and Arts, mentioned in this connection, was founded in 1823 as the result of the secession of some members of the Anderson's Institution. Lord Kelvin and his brother, the late Prof. James Thomson, studied for some time at the former institution.

The present Technical College, and the institutions from which it was formed, has had many distinguished men among its teachers and students. Prof. Sexton's history of the whole organisation is not merely of local interest, but appeals to all interested in the growth of technical education. The illustrations in his book are numerous, but mostly very bad, and the descriptive text might have been far more brightly written.

Practical Work in General Physics. By W. G. Woollcombe, M.A., B.Sc. Pp. 83. (Oxford: Clarendon Press, 1894.)

INSTRUCTION in practical physics is steadily, though very slowly, gaining ground in our schools and colleges. The tardy recognition of the great importance of this kind of work is doubtless due to the fact that practical physics does not bear directly on industrial and commercial pursuits. But, for training the mind, there is no better means than a course of physical laboratory practice. The hand is exercised in delicacy of manipulation; the eye is led to perceive instead of seeing things vacantly; and the mind is trained to make scientific deductions from observed facts. Whether a boy is designed to be a politician or a preacher, whether it is intended that he should follow the law or be sacrificed to science, in fact, no matter what the calling or profession in which he has to work his way through life, by far the best mode of obtaining the accuracy of observation and deduction desirable in everyone, is through instruction in practical physics. It is because we believe this, that we welcome any indication of the extension of such knowledge. Mr. Woollcombe is the author of a little book on practical work in heat, which we were able to commend when it appeared. The present volume deserves the same praise that we gave the previous one. It begins with descriptions of such instruments as the linear vernier, sliding callipers, micrometer screw gauge, and balance, and passes on to the measurement of length, area, and volume. The experiments performed under these heads lead naturally to the determination of the densities of solids, liquids, and gases, and then to Boyle's Law, the barometer, and capillarity. This order is practically the same as that followed in "A First Course of Physical Laboratory Practice," by Prof. A. M. Worthington, F.R.S., published eight years ago. Indeed, Mr. Woollcombe's book reminds us of Prof. Worthington's in more than one respect; but a similarity of gradation and general treatment almost inevitably exists between books covering the same ground.

The author is among those who take every opportunity of correcting the sense in which the word *weight* is generally understood. An aphorism of his worth quoting is: "We can no more lock up forces in a box than Pandora could imprison Hope in a casket, so that it is incorrect to talk of a *box of weights*—the correct term being a *box of masses*." We hope that a time will come when books similar to the one under notice will be required in all our public schools and colleges.

Manual of Practical Logarithms. By W. N. Wilson, M.A. (London: Rivington, Percival, and Co., 1894.)

THE great importance of a sound knowledge of the use of logarithms, and the frequency of their application in the majority of sciences, is sufficient to account for the appearance of such books as that under review, entirely devoted to their exposition. The subject is treated to a small extent in many of the larger text-books on algebra and trigonometry, but their insertion there is more to acquaint the student with the principles than to give him a good working knowledge, which can only be obtained by constant solving of problems.

In the book which we have under notice, the author assumes that the reader has had such a smattering of the subject as above suggested, since he purposely omits the propositions and formulæ found in most of the text-books, and devotes his whole attention to the treatment of various methods of solving problems with their aid. The examples dealt with, illustrate those branches of arithmetic, algebra, plane trigonometry, and mensuration, and those that are worked out are given in the forms that the student himself is advised to adopt.

The author deviates here from the usual method of writing the characteristic before the mantissa, by placing it afterwards. His reason for doing so is that he thus avoids the necessity of using the old and clumsy notation, as he calls it, for denoting the combination of a negative characteristic with a positive mantissa. The method here adopted has, no doubt, its advantages, and might facilitate matters for beginners, who nearly always find this a difficult point to surmount.

The reader is supplied with plenty of examples to practise his ingenuity upon, many of them being selected from various examination papers for the Army, Navy Oxford, and Cambridge, &c.

In the absence of any external assistance, close attention to the methods of solution employed in the book should give the reader a good insight not only in the right way of handling and becoming familiar with tables, but in the art of successfully attacking problems by their aid.

W. J. L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Towards the Efficiency of Sails, Windmills, Screw-Propellers, in Water and Air, and Aeroplanes.

THE discussion of this day week, on flying machines, in the British Association was not, for want of time, carried so far as to prove from the numerical results of observation put before the meeting by Mr. Maxim, that the resistance of the air against a thin stiff plane caused to move at sixty miles an hour through it, in a direction inclined to the plane at a slope of about one in eight, was found to be about fifty-three times as great as the estimate given by the old "theoretical" (!) formula, and something like five or ten times that calculated from a formula written on the black-board by Lord Rayleigh, as from a previous communication to the British Association at its Glasgow meeting in 1876.

I had always felt that there was no validity, even for rough or probable estimates, in any of the "theoretical" investigations hitherto published: but how wildly they all fall short of the truth I did not know until I have had opportunity in the last few days, *procul negotiis*, to examine some of the observational results which Maxim gave us in the introduction to his paper. On the other hand, I have never doubted but that the true theory was to be found in what I was taught conversationally by William Froude twenty years ago, and which, though I do not know of its having been anywhere published hitherto, is clearly and tersely expressed in the following sentence which I quote from a type-written copy, kindly given me by Mr. Maxim, of his paper of last week:—

"The advantages arising from driving the aeroplanes on to new air, the inertia of which has not been disturbed, is clearly shown in these experiments."

Founding on this principle, I have at last, I believe, succeeded in calculating, with some approach to accuracy, the force required to keep a long, narrow, rectangular plane moving through the air with a given constant velocity, V, in a direction perpendicular to its length, l, and inclined at any small angle, i, to its breadth, a. In a paper, which I hope to be able to communicate to the *Philosophical Magazine* in time for publication in its next October number, I intend to give the investigation, including consideration of "skin-resistance" and proof that it is of comparatively small importance when i is not much less than 1/10, or 1/20, of a radian, and the "plane" is of some practicably smooth, real, solid material. In the meantime, here is the result, with skin-resistance neglected:—The resultant force (perpendicular, therefore, to the plane) is $2\pi V^2 \sin\theta \cos\theta\, la$; which is $\frac{4\pi \cos\theta}{\sin\theta}$ times (or for the case of $\sin\theta = \cdot 8$, one hundred times), the old miscalled "theoretical" result. KELVIN.

Eastern Telegraph Company's Cable Steamer *Electra*; crossing the mouth of the Adriatic, August 17.

Geological Maps of Baden.

IT may interest some of your readers likely to visit the Black Forest, that Herr Winter, of Heidelberg, has begun the issue of an official series of geological maps, each 19½ × 17½ inches, with memoir. Two are already out, one east of Heidelberg, the other giving the Mooswald district, north-east of Gengenbach. The scale is 1 : 25000; *i.e.* 10 cm. to 2½ km., or practically two and a half inches to the mile. Three sections are given on the sheet; the memoir has about 100 pages. The price for the map and memoir is only two marks; if the map is mounted, three marks. I had intended to comment on the contrast between this marvellous cheapness and our own Survey issues, as our inch ordnance cannot approach this for detail; for instance, the contour lines are given for every ten metres. But a paragraph read to-day in the New York *Nation* of August 9, in a letter signed "W. M. D." will speak for me:—". . . unfortunately the publications of the British Surveys are rarely found complete at home outside of the Governmental bureaus in Washington. Very few copies of the British geological reports and maps are presented to libraries in foreign countries, and the prices at which they are sold practically forbids their purchase. The maps are, moreover, coloured by hand, so every copy is expensive; while ours are lithographed, and 'additional copies' are of only nominal cost, perhaps three or four cents apiece. . . . The British practice almost seals up the costly results of the geological surveys. . . . It was a satisfaction to learn that this opinion, formed at home, was shared and emphatically expressed over here" (at Edinburgh).

The Baden State geology maps are also, of course, lithographed, and so are the equally cheap Imperial maps of all Germany, another series, now being published by Justus Perthes, and of which also the first two are just issued and cover the same region, South-west Germany. That the policy pays seems certain. Three other purchases, for instance, were the immediate result of my own, whereas my friends have always been content to *borrow* my English maps, when I could see my way to lend them. J. EDMUND CLARK.

York, August 21.

Variation of "Aurelia."

I SEE that you note (p. 413) the occurrence of an *Aurelia* with pentamerous symmetry. In an expedition of the Liverpool Biological Society to Hilbre Island, a few weeks ago, we found several such specimens, and remarked upon the frequency of the variation. I think the number was either four or five pentamerous forms out of twelve examined.

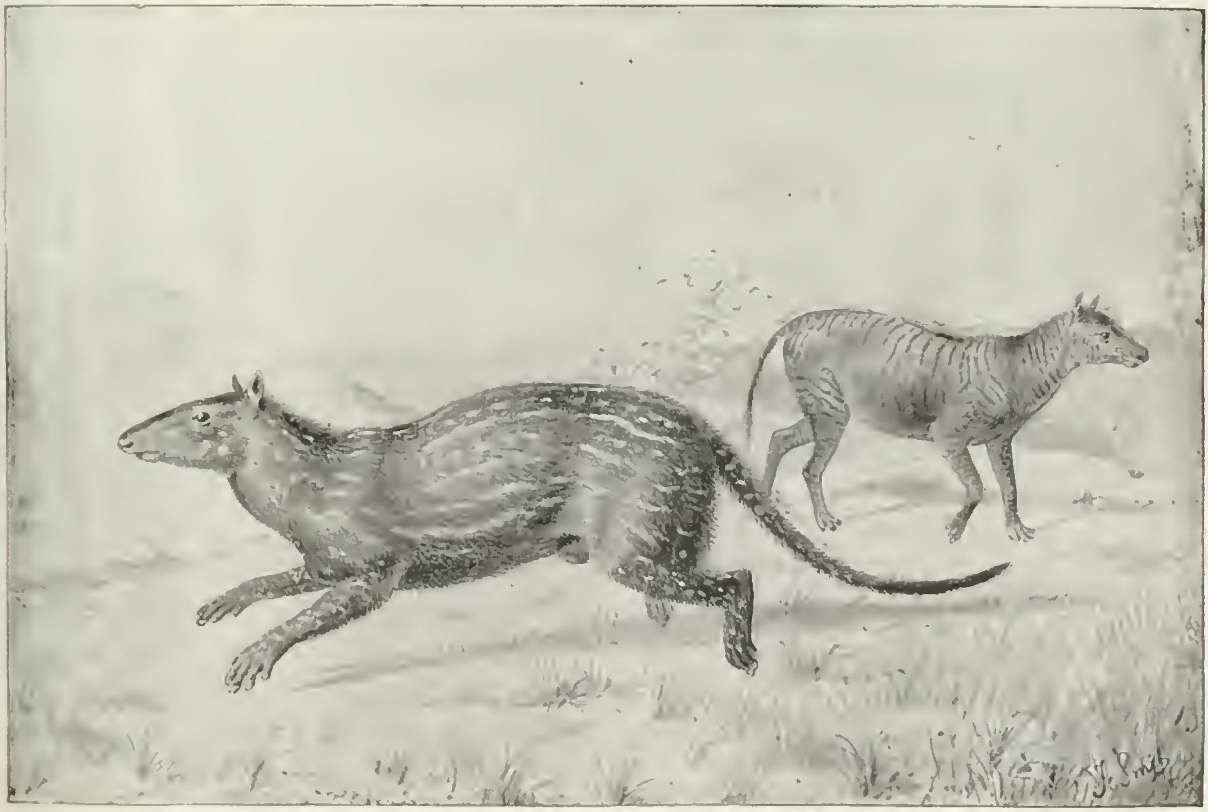
Port Erin, August 25. W. A. HERDMAN.

CREATURES OF OTHER DAYS.[1]

"CREATURES of Other Days" is a work of literature rather than science, and is yet so full of reference to scientific facts and discoveries that it appears like a work of learning. It narrates the history of extinct animals laboriously discovered, and in many cases still undergoing laborious interpretation by palæontologists, in language which is free from technicality. There is no reference to the anatomical structure of the skeleton which necessitates technical language. There is no critical digest of the facts enumerated, or of the nomenclature under which the fossils are described. No attempt is made to state the osteological characters which distinguish these fossils from each other. Materials which any author has supplied are accepted impartially, and the same animal type is illustrated by dissimilar restorations. Thus Mr. Hulke made a quadrupedal restoration of *Hypsilophodon Foxi*, an animal which once was termed a young *Iguanodon*, out of which Mr. Smit has restored a vigorous-looking lizard. If these interpretations are correct, it is improbable that the vertical bipedal restoration of *Anchisaurus*, given by Prof. Marsh, and restored by Mr. Smit, can also be satisfactory. Many of the original restorations endeavour to convey an idea to the unlearned of the skin and aspect of the living animals. And as these are based upon published figures, or restorations, the author has no doubt gone to the best material which was available, even when the result is unsatisfactory. Sir William Flower, in his preface, fairly states the claim of the restorations to consideration. He says: "In the restoration of the external appearance of extinct animals, known only by bones and teeth, there is much of imagination, much indeed of mere guess-work, and I should therefore be sorry to guarantee the accuracy of any of the representations of animals in this book, the majority of which were never seen in the flesh by the eyes of mortal man. I think, however, I may safely say that Mr. Hutchinson and his accomplished artist, Mr. Smit, have done their work carefully and conscientiously, and given us, in most cases, a fair idea of the appearance of the creatures they have endeavoured to depict according to the best evidence at present available." Sir William commends the figures because they give a better idea of the animals than most persons who only saw their fossil remains would be able to carry away. This unscientific attitude of the book is its chief merit. It is only when the author becomes an expositor of science that scientific men are likely to disagree with him. More care was needed in some of the restorations. The old red sandstone fishes, for example, are drawn without any regard to their relative sizes, those of the upper and lower beds swimming together as though they were of the same geological age, while at the bottom of the water are Trilobites, Brachiopods, and Cephalopods, which no one ever saw in the old red sandstone.

[1] By Rev. H. N. Hutchinson, B.A., F.G.S., author of "Extinct Monsters." With numerous illustrations by J. Smit and others. (London: Chapman and Hall, Limited, 1894.)

FIG. 1.—A restoration of Hypsilophodon.



(Phenacodus).[1] (Hyracotherium).

FIG. 2 —Ancestors of the Horse. Eocene Period.

Protorosaurus is classed under the Rhynchocephalia, apparently on the author's judgment, though the proposition might be hard to sustain. There are chapters given to Anomodonts, Crocodiles, newly-discovered Dinosaurs, and ancient birds; in which curious illustrations appear, some of the funniest being reproductions of the animals created by Mr. Waterhouse Hawkins for the Central Park, New York. The concluding chapters describe and illustrate mammals. *Palæotherium* and *Coryphodon*, *Dinotherium* and *Mastodon*, are fairly well illustrated. Horses and their ancestors give illustrations of *Phenacodus* and *Hyracotherium*. There is some account of the extinct marsupials of Australia, and of the extinct mammals of South America, such as *Toxodon*, *Macrauchenia*, and *Machærodus*.

The *Bos urus* of Cæsar, which probably became extinct in Britain before the Roman occupation, is represented by a spirited drawing. Appendices give a table of strata, an enumeration of the orders of animals, and a list of books for reference. H. G. S.

ERNEST MALLARD.

THE following paragraphs are extracted from an obituary notice of this distinguished mineralogist, contributed to the *Mineralogical Magazine* by M. G. Wyrouboff:—

In the history of scientific mineralogy the name of M. Mallard will undoubtedly occupy a place beside that of Hauy, to whom is universally conceded the honour of originating this branch of human knowledge. It may be asserted without exaggeration that M. Mallard created anew the science of crystallised bodies by bringing that science into close and intimate union with general physics. Only a few years ago mineralogy was regarded as a purely descriptive science, and crystallography was no more than a special chapter of abstract geometry.

He was a close follower of Bravais, whose beautiful theory he, to his great credit, adopted, developed, and popularised. Bravais, however, viewed the problem of crystalline structure as a geometrician, and saw only one side of the question. His conception of the lattice is based upon the homogeneity of the crystal; now, experience had long ago shown that crystals are far from being always homogeneous. To M. Mallard is due the honour of explaining this apparent contradiction by demonstrating, theoretically and experimentally, that crystals frequently consist of several lattices distributed in a certain regular manner about an axis which does not belong to any one of them.

M. Mallard did more than this, and hereon rests his claim to imperishable fame: he deduced from the theory of lattices and of reticular assemblages all the physical phenomena observed in crystallised bodies, including what were called the optical anomalies. Owing to his labours crystallography became a completely rational science to the same extent as any other branch of physics.

The crowning work of M. Mallard was his "Traité de Cristallographie," which was intended to comprise three volumes. Two only of these have been published; the third was to have dealt with crystalline assemblages, polymorphism and isomorphism, the most complex problems in crystallography, and those in which his most original work was done. The materials from which this volume was to be constructed are to be found in the memoirs published by M. Mallard since 1879. Some of these are real masterpieces, and have become classical; such are the papers on optical anomalies, on the quasi-cubic form of all crystallised bodies, on the transformations of polymorphous substances, and on isomorphous mixtures.

When we add to these the many detailed researches which he published in the *Bulletin* of the French Mineralogical Society, some relating to improved instruments of precision, and some to particular mineral species such as boleite, lussatite, tridymite, and melanophlogite, we cannot but feel that since the time of Haüy no one has done so much to advance that section of physical science which is concerned with crystallised bodies.

NOTES.

M. Cotteau, whose death we announced last week, has bequeathed his fine collection of living Echinoderms to the Paris Muséum d'Histoire Naturelle.

Reuter reports that an earthquake shock of short duration was felt at Athens at a quarter to eight on the morning of the 26th inst., and also at Corinth, Vastizza, Zante, Thebes, Chalcis, and Atalanti.

It is announced that a laboratory for the manufacture of tuberculin, mallein, anthrax, vaccine, &c., will shortly be established in Rome in connection with the laboratories of Hygiene of the Ministry of the Interior.

We learn that Prof. Pettenkofer has resigned the chair of hygiene and the directorship of the Hygienic Institute in the University of Munich, on account of his advanced age. He is succeeded by Prof. Hans Buchner.

The *British Medical Journal* says that the President of Queen's College, Belfast, has received information that the Government will grant the sum of £2,500 for the erection and equipment of a physiological and pathological laboratory. Plans are being prepared, and the buildings will be at once proceeded with.

Mr. H. C. Russell, of Sydney Observatory, writing to us with reference to an aurora observed on July 20, says that he noticed that while the display lasted there was a fog or haze over the southern sky bright enough to hide 5th magnitude stars, and when these began to reappear the auroral light vanished, as if the fog or haze had been necessary for its manifestation.

Mr. Richard Langdon, station-master at the Silverton Station of the Great Western Railway, Devon, died on July 18. Nearly thirty years ago he began to study astronomy, in which he took an absorbing interest to the end of his life. Being a skilful mechanician, and having acquired a knowledge of optics, he employed his spare time in constructing an eight-inch silver-on-glass equatorial reflector, grinding the mirror with a machine which he made for the purpose. He was a keen and accurate observer, and in 1872 he read a paper "On certain Markings on the Planet Venus" before the Royal Astronomical Society.

For just a year the Birahi Ganga River has been dammed back by the great landslip at Gohna. We noted this event shortly after its occurrence, and on July 5 gave an abstract of Mr. T. H. Holland's report upon it. In this report Mr. Holland estimated that the lake would overflow the barrier about the middle of August. The news has now come that the water reached the top of the dam early on Sunday morning, and cut through the temporary dam which had been constructed to prevent its escaping during the night. Combined percolation and overflow caused the water to fall rapidly, until its length was reduced from five miles to about two and a half miles. Telegraphing on Monday, Reuter's correspondent at Simla says that the water thus released has swept away all the Government buildings on the banks of the river. At Hardwar a torrent of water 6ft. in depth rushed through the town, but there was no loss of life, owing to the precautions taken. All the buildings, however, between Gohna and Hurdwar have been destroyed. The lake formed by the landslip is now empty. Though considerable damage has been done to property by the escape of the water, no loss of human life is reported. The Indian Government is to be commended for the ample precautions taken to avert disaster at the time of overflow, and for the scientific manner in which the formation of the lake has been investigated.

THE journey to Greenland, modestly referred to by Prof. G. F. Wright in our correspondence columns on July 12, promises to lead to results of scientific value. We understand that the excursion was organised by Dr. Frederick A. Cook, anthropologist of Peary's first expedition, and consists of fifty persons, of whom a good part are students of science. Among the scientific members are Prof. W. H. Brewer, of Yale College, Prof. B. C. Jillson, of Pittsburg, Pa., who with Prof. G. F. Wright and his son, of Oberlin, Ohio, and a party of six, will disembark in Umenak Fiord about latitude 71°, to study the border of the ice-sheet, the neighbouring glacial deposits, the glaciers entering the fiord, the Tertiary deposits of the vicinity, and make a collection of the plants and animals. Prof. L. L. Dyche, at the head of the department of zoology and taxidermy at the State University of Kansas, is the official naturalist of the expedition. He will make a point of collecting birds and mammals. With him are Mr. S. P. Orth and Mr. B. F. Stanton (both of Oberlin), as assistant naturalists, to make general collections. Mr. E. A. McIlhenney, of Louisiana, accompanies the expedition as an ornithologist. Prof. C. E. Hite, of Philadelphia, with three assistants, goes to Labrador for general exploration. Prof. E. P. Lyon, of Chicago, goes for the general study of biology. The expedition expects to return about September 20.

PROF. H. B. DIXON's report on the explosion that occurred at the Albion Colliery, near Pontypridd, South Wales, at the end of last June, has been published as a Parliamentary paper. Although it was not possible to examine all the workings, the evidence obtained justifies the opinion that the explosion throughout its main extent was purely a dust explosion. Prof. Dixon thinks it would have been practically impossible for fire-damp to have accumulated in the main intake air-roads, or to have been introduced suddenly into them in sufficient quantity to feed an explosion throughout the extent of road actually traversed by the flame. On the other hand, sufficient dust was found lying in a dry and fine state along the main roads to feed the flame throughout the parts penetrated by the explosion. As to the origin of the explosion, the belief is expressed that a dynamite shot raised a cloud of inflammable particles and set them on fire. If precautions were taken always to water the dust near the spot where a cartridge is going to be fired, such explosions as that at the Albion Colliery would be less frequent.

THE twenty-third meeting of the French Association for the Advancement of Science was held at Caen, from August 9 to 15, under the presidency of M. Mascart. In his opening address, the president paid homage to the many men of light and leading who were born and nurtured in the little province of Normandy, in which the meeting was held. Pierre Varignon, the celebrated geometer, was born at Caen in 1654. The two chemists, Ronelle and Vauquelin, and the intrepid traveller Dumont-Durville, were born in the same neighbourhood. Other names associated with the province are the great astronomer Laplace; Elie de Beaumont, one of the founders of French geology; Augustin Fresnel, whose work in physical optics has become classical; and that intellectual giant, Le Verrier. The second section of M. Mascart's address was devoted to brief descriptions of some of the institutions designed for scientific study in the United States. Praise was especially given to the generous donors whose lavish benefactions had helped on the cause of science in America. If M. Mascart had followed the traditions attached to a president's office, he would have given his audience his reflections upon the progress accomplished in the branch of knowledge to which he has paid most attention, that is, meteorology. This, however, he did not do, but passed in review some points in the history of electricity. The meeting was not favoured with fine weather, nevertheless the number of members was about the same as in previous years. The total receipts amounted to 91,182 francs, of which, however, only 55,551 francs came from annual subscriptions. The sum of 15,624 francs was disbursed in grants for scientific research. The Association will meet next year at Bordeaux, and in 1896 the place of meeting will be Tunis.

THE *London Gazette* for Friday last contains the following new denominations of standards for electrical measurement, adopted by the Privy Council on the previous day: (1) *Standard of Electrical Resistance*. The standard of electrical resistance, denominated one ohm, being the resistance between the copper terminals of the instrument marked "Board of Trade Ohm Standard Verified 1894" to the passage of an unvarying electrical current, when the coil of insulated wire forming part of the aforesaid instrument, and connected to the aforesaid terminals, is in all parts at a temperature of 15°·4 C. (2) *Standard of Electrical Current*. A standard of electrical current, denominated one ampere, being the current which is passing in and through the coils of wire forming part of the instrument marked "Board of Trade Ampere Standard Verified 1894," when, on reversing the current in the fixed coils, the change in the forces acting upon the suspended coil in its sighted position, is exactly balanced by the force exerted by gravity in Westminster upon the iridio-platinum weight, marked A, and forming part of the said instrument. (3) *Standard of Electrical Pressure*. A standard of electrical pressure, denominated one volt, being one-hundredth part of the pressure which, when applied between the terminals forming part of the instrument marked "Board of Trade Volt Standard Verified 1894," causes that rotation of the suspended portion of the instrument which is exactly measured by the coincidence of the sighting wire with the image of the fiducial mark A, before and after application of the pressure, and with that of the fiducial mark B during the application of the pressure, these images being produced by the suspended mirror, and observed by means of the eye-piece. In the use of the above standards the limits of accuracy attainable are as follows:—For the ohm, within one-hundredth part of one per cent.; for the ampere, within one-tenth part of one per cent.; for the volt, within one-tenth part of one per cent. The coils and instruments referred to are deposited at the Board of Trade Standardising Laboratory, 8 Richmond-terrace, Whitehall, London.

THE Department of Science and Art has issued the following list of candidates successful in this year's competition for the Whitworth Scholarships and Exhibitions. Scholarships of the value of £125 per annum (tenable for three years)—John Ball, 22, engineer, Derby; James H. Smith, 23, student, Manchester; Harry Verney, 24, fitter, Bristol; Charles F. Smith, 21, mechanical engineer, Bristol. Exhibitions of the value of £50 (tenable for one year)—Frank Fisher, 19, engineer, Brighton; William M. Thornton, 24, student, Liverpool; John W. Hinchley, 23, student, Lincoln; William D. Young, 23, engineer, Westfield (N.B.); Alexander L. Mellanby, 22, engineer, West Hartlepool; William T. F. Trunchion, 22, fitter, Bedford; Henry Deanesly, 25, draughtsman, Wincanton;

William T. Swinger, 19, engineer apprentice, Plumstead, Kent; Arthur W. Ashton, 21, fitter, Plumstead, Kent; Arthur E. Mascall, 18, engineer, Woolwich; William Rosbotham, 25, student Belfast; Joseph J. Kirwin, 20, engine fitter apprentice, Devonport; Charlie W. Cairns, 21, apprentice engineer, Newcastle-on-Tyne; John W. Button, 23, fitter, Oldham; Sydney Eraut, 22, mechanical engineer, London; Charles E. Pickles, 18, student, Bradford; Richard G. Allen, 21, fitter apprentice, Southsea; Alexander Craig, 22, engineer, Crewe; Thomas S. Usherwood, 20, engineer apprentice, London; Walter Eraut, 19, mechanical engineer apprentice, London; Lewis E. Limming, 21, shipwright apprentice, Southsea; Sidney E. Lamb, 20, fitter apprentice, Devonport; Francis J. Russell, 20, fitter apprentice, Portsmouth; Edgar R. Sutcliffe, 19, draughtsman, Leeds; George F. Hambly, 20, engineer apprentice, London; William Gore, 23, engineer, King's Lynn; Thomas S. Cockrill, 25, marine engineer, London; William H. James, 21, engineering student, Cardiff; Harry J. Peachey, 18, engineer apprentice, Stratford (London); James N. Boot, 25, engineer, London.

During a severe hailstorm at Vicksburg, in May last, a remarkably large hailstone was found to have a solid nucleus, consisting of a piece of alabaster from one-half to three-quarters of an inch. During the same storm at Bovina, eight miles east of Vicksburg, a gopher turtle, six by eight inches, and entirely encased in ice, fell with the hail. Commenting upon this, in the *Monthly Weather Review*, Prof. Cleveland Abbe says that apparently some special local whirls or gusts carried the enclosed objects from the earth's surface up to the cloud region, where they were encased by successive layers of snow and ice, until they fell as hailstones. He points out that the fact that hailstones, as well as drops of water and flakes of snow, often contain nuclei that must have been carried up from the earth's surface, is entirely in accord with the general principle that ascending currents precede the formation of cloud and rain, and that solid nuclei are needed to initiate the ordinary precipitation of moisture.

Dr. Hergesell has sent us the results of the meteorological observations made in Alsace and Lorraine during the year 1892, containing hourly values for Strassburg, and monthly and yearly summaries at various other stations. The results obtained from two anemometers at the central station are very interesting; one of the instruments is erected at about 170 feet, and the other at about 470 feet above the ground. The wind velocity at the higher level has a daily range corresponding exactly with that of mountain stations, the minimum occurring in the morning, and the maximum during the night. The results show that the indications of an anemometer fixed more than 150 feet above the ground are much more comparable than those at a lower level, where the indications are affected by local conditions. We look forward to the promised publication in the next volume of a chart showing the distribution of rainfall for a long series of years.

We have received from M. E. Durand-Gréville two pamphlets entitled "Les grains et les orages," in which the author has endeavoured to show the connection between certain squalls, which accompany large barometric depressions, and thunderstorms. It is generally admitted that important thunderstorms occur at the same time on different points of an isochronous line moving towards east-north-east. Before the storm there is a gradual fall of the barometer, a rapid rise during the storm, and a sudden change in the direction of wind. But opinions differ considerably as to the conditions under which the thunderstorms occur. The author has investigated certain special cases, and has endeavoured, with some success, to co-ordinate the various views. He shows that several of them, while contradictory, at least in appearance, are capable of reconciliation, and are founded upon facts, which have been diversely interpreted. The papers are accompanied by several explanatory diagrams showing the line taken by the squalls, and the various forms of the isobaric curves which accompany them.

In an interesting report issued by the United States Department of Agriculture, Mr. Alexander McAdie gives an account of the statistics concerning the position, &c., of buildings struck by lightning, and also of the best methods to be employed to protect buildings, &c., from being damaged by lightning. One interesting point which is very prominently brought out by the statistics is the decreased liability to accident from lightning strokes in thickly populated districts. In fact, it may be said that, in general, the risk in the country is five times as great as in a city. The report concludes with a number of rules which ought to be observed with reference to lightning, from which we may select the following:—If the conductor, at any part of its path, goes near water or gas mains, it is best to connect them to it. Independent grounds are better than connection to water or gas-pipes. Clusters of points or groups of two or three along the ridge of the roof are recommended. The top of the rod should be plated, or in some way protected from rust, and chain or linked conductors are of little or no use. Finally, if you should be in the vicinity of a person who has just been struck by lightning, no matter if the person struck appears to be dead, go to work at once and try to restore consciousness. There are many cases on record proving the wisdom of this course, and there is reason for believing that lightning often brings about suspended animation rather than somatic death. Try to stimulate the respiration and circulation, and do not cease in the effort to restore animation for less than an hour's time.

At a recent meeting of the Vienna Academy of Science, Herr Bruno Piesch gave an account of his recent work on the change in the electrical resistance of aqueous solutions, and of the electric polarisation with change of pressure. The author has examined a large number of liquids, both acids and salt solutions. The apparatus was so arranged that the resistance and polarisation would be simultaneously measured. The high pressures used were obtained by means of a Cailletet's compression apparatus, and experiments were carried on up to a pressure of 600 atmospheres. The vessel in which the liquid to be experimented upon was placed was enclosed in the iron receptacle of the pump, being insulated by means of an ebonite plug. The following results have been obtained:—A change in pressure is always accompanied by a change in the electrical resistance, the resistance decreasing with increase of pressure. No definite connection is observable between the amount of the pressure change and the concentrate of the solution, but in the case of most of the substances investigated the change was greater in the case of very dilute solutions than in more concentrated ones. The magnitude of the change in resistance with change in pressure is very small, as is also the case with the change in the polarisation. In most cases an increase of the polarisation with increase of pressure was observed, but the irregularities were in this case greater than those observed in the resistance measurements. In conclusion the author examined a solution of ammonium nitrate in alcohol, when he obtained changes in the same sense as in the case of aqueous solutions.

At the same meeting, Herr J. Liznar read a paper on the 26-day period of the earth's magnetism. In a previous communication the author had compared the diurnal variation in stations in middle and high latitudes. In the present paper the magnitude of the 26-day period variation for declination and inclination at the stations of Pulowsk and Jan Mayen are compared and it is shown that the amplitude of the variation at the northern station is four times as great as at the southern. The author also considers that the small variations which constitute the 26-day period variation are not due to a direct magnetic action of the sun, but that they must have their origin in some secondary action of the same.

IN cases where it is desired to investigate a ray of light reflected perpendicularly from a surface, it is usual to employ a transparent plate of glass which transmits the incident ray before it falls upon the surface, and partially reflects it aside on its return. Such an arrangement, best known in Gauss's eye-piece, may be called a Gauss's plate. The best position of such a plate is, as pointed out by Herr B. Walter in the current number of *Wiedemann's Annalen*, not the commonly accepted one of 45°, but another depending upon the refractive index of the material of the plate, and upon whether the light is polarised and in what manner. From theoretical considerations, he concludes that for light polarised either in or at right angles to the plane of incidence the greatest possible intensity of the reflected light is 15 per cent. of the original intensity, whatever may be the refractive index. If the light is polarised in the plane of incidence, the plate must be placed at a lesser angle to the ray the smaller the index of refraction. For light polarised at right angles to this plane the reverse holds good. But for refractive indices about 1·4 this angle reaches the common value of 7° 46′ 16″. The best position for ordinary light may be determined by regarding it as composed of the two species of polarised light. For crown glass the inclination should be 10½°, at which position the intensity of the reflected light is 2·84 times that obtained with the usual inclination of 45°.

A NEW automatic sounding instrument has lately been brought into use by Captain G. Rung, the director of the Copenhagen Meteorological Institute, under the name of the universal bathometer. Unlike the instruments hitherto constructed, which register the depth attained by the compression undergone by a column of air, Captain Rung's bathometer, as described in *Hansa*, measures the density of a small volume of the compressed air cut off at the bottom of the sea. This density is directly proportional to the depth attained, and is measured by allowing the compressed air to expand until it is under atmospheric pressure only. Its volume will then be proportional to the density it had reached during compression. The whole apparatus is very neat and compact. A metallic tube contains two other tubes side by side, both communicating with a small chamber at the top. A valve shuts off the communication with the one or the other of the tubes, accordingly as the sounder is being lowered or raised. When the bathometer is being let down, water enters the "air tube" from the bottom, and compresses the air in the tube and in the small chamber. The whole is enclosed in another heavy tube, in which it can slide a little up and down. When the bathometer touches the bottom, the inner tube slides down, thereby turning the valve so as to close the communication with the air tube and open to the "measuring tube." At the same time, a couple of spring catches prevent the inner tube sliding up again. The bathometer is then drawn up to the surface, and the reading on the measuring tube at once indicates the depth. This tube is made of glass, and is graduated in fathoms or other units of length at equal intervals. This constitutes the chief advantage of this over previous types. In instruments measuring the depth by the volume of the compressed air the graduations had to be at smaller and smaller intervals as the depth increased, since the amount of compression decreases at high pressures. Captain Rung's instrument, on the other hand, can be graduated directly up to any limit of depth which it is likely to attain.

MR. W. J. MOENKHAUS has lately studied a species of American freshwater Percidæ—*Etheostoma caprodes*, Rafinesque—with a view to ascertain the extent of its variation, the relation of its variation to its geographical distribution, the extent of variation in each locality, and the variation with age. He gives an account of his investigation in the *American Naturalist* for August, and from it we learn, among other points, that the difference between specimens from the same locality is very slight. The greatest variation was found to be in the colour-patterns of the fish, but the most complicated colour-pattern can be connected with the simplest by means of intermediate stages. These variations, however, could not be connected with the latitudes inhabited by the different varieties. Slight variations were found in proportions and number of fin rays.

THE Plankton Expedition has yielded some very interesting results with regard to the bacteriology of the ocean, which are now published by Dr. B. Fischer in "Die Bakterien des Meeres nach den Untersuchungen der Plankton-Expedition." Except at very great depths, germs capable of germination were found everywhere. The number in the Canary, Florida, and Labrador currents was larger than in the south equatorial, north equatorial, and Guinea currents. None could be detected with certainty in the bed of the ocean; but bacteria abound at a depth of 400 m., and are certainly present at depths between 800 m. and 1100 m. The prevailing form of microbe is the spiral; but bacterium forms are also frequent; micrococci are rare. Forms more or less resembling the cholera-vibrio, both in their form and in their mode of motion, were very common. Most marine bacteria are aerobic, but some appear to be also facultatively anaerobic. Not a few form pigments, and a large number are luminous in the dark; the phosphorescent forms were most commonly met with on the surface of living fish. A number of new species are described.

SOME interesting points await settlement in the natural history of the mollusk *Gundlachia*, whose shell presents such puzzling and anomalous features. In a recently published paper on the Australasian forms (*Proc. Linn. Soc. N.S.W.* viii. 1893), Mr. Charles Hedley briefly reviews our knowledge of the genus and its distribution, and gives descriptions and figures of *G. petterdi* and *G. beddomei*. In the case of the former species, he describes a series of young shells showing the method by which the primary *Ancylus*-like shell is transformed into the curious double shell of the adult. Stimpson's suggestion that the septum which partially closes the aperture of the primary shell should be compared physiologically with the epiphragm of the Helices—as a protection during hibernation—well deserves some attempt at verification; as also does the unproved impression that under particular conditions the shell of *Gundlachia* never attains its normally double form, but remains simple and patelliform throughout life.

THE July number of *Modern Medicine and Bacteriological Review* contains an article entitled "The Value of Prof. Koch's Discovery," in which it is mentioned that the State of New York has recently passed a law authorising the use of tuberculin as a means of determining the presence or non-presence of the tuberculous process in cows. It is pointed out that though Koch's tuberculin has not fulfilled the expectations raised for it as a curative agent, as a means of diagnosis it may be of great service. Two or three drops of tuberculin injected beneath the skin of a cow will, if the animal is tuberculous, give rise within a few hours to an elevation of temperature of several degrees, whilst this characteristic reaction is absent in the case of animals free from this disease. Amongst the bacteriological notes is one on soap as a germicide, from which it appears that the so-called antiseptic soaps containing salicylic acid or carbolic acid, yield no better results than ordinary toilet soap, the latter destroying the cholera bacillus in from ten to fifteen minutes when applied in the proportion of 2·5 parts of soap to 1000 parts of water. The same journal contains an account of an electric-light bath, consisting of a small cabinet large enough to permit of one person sitting comfortably, the walls of which are completely covered with mirror-glass. From forty to fifty electric lights are so distributed that every part of the body of the "bather" is almost equally exposed to the light. Dr. Gebhardt, who communicates the article, reserves his opinion as to the curative merits of this novel bath, but mentions that the intense light, contrary to his anticipations, did not produce an unpleasant or exciting effect, but exercised a calming influence upon him. Like the ordinary vapour bath, the electric light bath is followed by the application of cold water.

PART V., completing the fifth volume of the *Transactions*, has been issued by the Norfolk and Norwich Naturalists' Society, which fully maintains the interesting character of its publications. The first paper consists of the annual "Presidential Address," in which the President (Mr. Thomas Southwell) avails himself of the twenty-fifth anniversary of the formation of the Society to give a slight sketch of its history and the work it has accomplished; and we cannot but congratulate the members on the excellent results it has to show, the five thick volumes forming not only an epitome of the natural history of the county for the past twenty-five years, with excellent lists of the fauna and flora, but numerous biographical sketches are given, often with portraits, of the men whose labours in the past have proved so valuable to their successors. The address then gives some very interesting information as to the physical features of the county in times past, as well as of its natural productions. The establishment of a branch of the Society at Great Yarmouth called for a second "address," which is devoted to an account of the local naturalists, collectors, and gunners, for which, ever since the latter part of the last century, that favoured locality has always been celebrated, as well as to the enumeration of the many ornithological rarities which have there been obtained. Prof. Newton contributes a very interesting account of the great flood in South-West Norfolk in 1852-53, which resulted in the temporary return to the fens in that district of birds, such as the black tern and black-headed gull, which had long ceased to frequent the locality. The occurrence of the bearded seal on the Norfolk Coast, for the first time in Great Britain, is announced. Mr. Stacy-Watson has a very useful paper on the varieties and distribution of the herring. There are also papers on the local occurrence of fungi and flint implements, with lists of Norfolk earthworms, ichneumons, mammalia, fishes, birds, hemiptera, and flowering plants. Of the twenty papers in the number before us there are only two which have not a strictly local bearing.

THE last number of the *Izvestia* of the Russian Geographical Society contains two papers which are sure to be welcome to geographers. The first, by G. I. Tanfilieff, is on the tundras of North-East Russia, on the shores of the Arctic Ocean, between the rivers Mezen and Pechora. Middendorff's descriptions of the tundras of northern East Siberia are classical for the subject. So are also Beketoff's "Flora of Arkhangelsk" and his additions to the Russian translation of Griesebach's work. But so much has lately been written about the tundras and the features they have in common with the steppes, that the necessity of new researches in this direction was very much felt. M. Tanfilieff fully confirms this view, and shows the further likeness which exists between the black-earth, the clay, and the sandy steppes on the one side, and the peat-bog, the clay, and the sandy tundras on the other. And he gives, moreover, a very vivid description of the inner processes of the life of the tundra, and enters into very interesting considerations relative to the extension of the ever-frozen soil, and the limits put by it to the northward spreading of forests. The southern limits of the former, and the northern limits of the forest region, are identical, and wherever there are in the tundra islands of ground which does not freeze, groves of fir-trees appear upon them; while even in the forest tracts the appearance of peat-bog islands, which remain frozen to a great depth, is always followed by a disappearance of the trees. The rivers act as drainage channels, which prevent water from percolating the soil, and therefore prevent it from freezing; this is why their courses are always followed by trees, which penetrate into the treeless tundras along the watercourses. The author's remarks on the Samoyedes and the reindeer are also very valuable. He fully confirms the excellent reputation of these children of the tundra, who, in consequence of the extremely slow growth of the reindeer lichen (*Cladonia rangifera*) are deprived of their pasture grounds, and reduced to complete ruin, by the Zyryanes and the Russians, who bring their herds of over 2000 head of reindeer into the Samoyede domains.

THE other paper, also of great interest, is by V. M. Obrucheff, on the orography of the Nang Shan. The Russian geologist has crossed this system of mountains both in the west of Lake Kuku-nor, at the western end of these highlands, and in the east of the lake; and, with the information previously gathered by Przewalsky and Potanin, he was enabled to draw a scheme map of the whole system, appended to the *Izvestia*. It appears that the highlands of Nang Shan consist of a series of parallel ridges running west-north-west to east-south-east, both in the north and in the south of Kuku-nor. The first chain is the Lung-thu-shan, in the north-east of the towns Su-choi and Han-chou. Then comes the Richthoffen ridge, continued in the east by the Momo-shan; then comes Humboldt's ridge, which is supposed by the author to have its continuation in the Maling-shan, while Ritter's ridge is continued east-south-eastwards by the Tsing-shi-ling. However, some doubt still prevails as to these last two points, on account of a want of exploration in the middle part of the highlands. The chain which rises just on the southern coast of Lake Kuku-nor (South Kuku-nor chain of Przewalsky) is continued towards west-north-west by a ridge, to which M. Obrucheff gives the name of Mushketoff's ridge, while the last chain of the group is named Semenoff's ridge. This classification brings some order, which was most desirable, into this grand group of mountains. Their geological history and later dislocations are also discussed in the same paper.

A RECENTLY published *Bulletin* of the U.S. Fish Commission (vol. xi., 1891) contains the results of a search for a fish-hatching station in the Gulf States. The character of the biological station which the United States Government desired to establish is indicated in the following extract from the instructions to Prof. Evermann: "To unite in one station the facilities for fish-cultural work with the salt-water species, for the pond culture of fresh-water species, for the investigation and development of methods for the propagation and rearing of the oyster, and for the investigation of the marine life of this coast. This means, of course, a laboratory of marine biological research, not large or expensive, but thoroughly equipped in all respects for its work." The explorations led to the conclusion that no point on the coast examined offered entirely satisfactory conditions for the establishment of a combined fresh and salt water station, though a site near Galveston presented some advantages. In addition to the reports prepared by Prof. Evermann, the volume referred to above contains reports on matters connected with his investigations. Such, for instance, is a statistical report on the fisheries of the Gulf States, by Mr. J. W. Collins and Dr. H. M. Smith; a report on a collection of fishes from the Albemarle region of North Carolina, by the latter author; a paper on the spawning habits of the shad, by Mr. S. G. Worth; a report on the aquatic invertebrate fauna of the Yellowstone National Park, and of the Flathead region of Montana, by Prof. S. A. Forbes; and a report on the fisheries of the South Atlantic States. Finally, the volume contains a description, by Mr. Bashford Dean, of the methods of oyster-culture in Italy, Spain and Portugal, Germany, Holland, Belgium, and England. Oyster-culture, as practised in France, had previously been reported upon in connection with the U.S. Fish Commission. This article, like most of the others, is excellently illustrated. They all help to disclose the possibilities of fish industries in the United States, and indicate how "the harvest of the sea" may be increased in value.

WE have received a ponderous volume (vol. vi.) of the transactions of the Reale Accademia delle Scienze Fisiche e Mathematiche, Naples. The volume contains nineteen fine plates and eighteen papers, most of which refer to natural science subjects.

MR. ROWLAND WARD, the well-known taxidermist, has published the seventh edition of his "Sportsman's Handbook," containing information on the "practical collecting, preserving, and artistic setting-up of trophies and specimens, to which is added a synoptical guide to the hunting grounds of the world."

THE second volume of Priestley's "Experiments and Observations on Different Kinds of Air"—that is to say, the one in which he first gave an account of the discovery of oxygen in 1775—is reproduced in the seventh number of the handy "Alembic Club Reprints," published by Mr. W. F. Clay, Edinburgh. The next volume in this series will contain Scheele's work in connection with the discovery of oxygen.

THE Robert Boyle lecture, delivered by Lord Kelvin before the Oxford University Junior Scientific Club, in May last, on "The Molecular Tactics of a Crystal," has been published by the Clarendon Press. No student of crystallography should neglect to read the lecture, for in it the geometry of crystalline structure is dealt with in the simplest manner. The substance of the lecture is contained in a paper read by Lord Kelvin before the Royal Society on January 18, and reprinted in these columns on March 8.

MESSRS. GEORGE PHILIP AND SON have lately published a book, of fifty pages, entitled "Knowledge through the Eye," by Mr. A. P. Wire and Mr. G. Day. The authors explain how to use the optical lantern in illustrating lectures in science and other branches of knowledge, and describe a new method of preparing lantern slides without the use of a camera. A drawing of the required illustration is first made. A piece of specially prepared transparent paper (sold by Messrs. Philip) is then placed over it, and the drawing is transferred by tracing. A lantern slide is obtained by making a contact exposure in the ordinary manner, using the picture on the transparent paper as a negative. This method, however, has very little to commend it. Line drawings are easily made upon a plate of smoked or varnished glass, or upon glass having a thin film of collodion upon it; and as the illustrations have to be drawn in any case, it is just as well to do the work directly as to make a lantern slide of a tracing made from a drawing in the way described by the authors.

THE additions to the Zoological Society's Gardens during the past week include a Hairy Armadillo (*Dasypus villosus*) from South America, presented by Mr. George Simpson; a —— Bamboo Rat (*Rhizomys*, sp. inc.) from India, presented by Mr. Angus M. Kinloch; a Himalayan Monaul (*Lophophorus impeyanus*) from the Himalayas, presented by Captain H. R. H. Helpman; two Sharp-nosed Crocodiles (*Crocodilus acutus*) from Jamaica, presented by Dr. Poole; two Common Chameleons (*Chamæleon vulgaris*) from North Africa, presented by Mr. E. Palmer; two Smooth Snakes (*Coronella lævis*) from Hampshire, presented by Mr. E. Penton; two Common Vipers (*Vipera berus*), British, presented by Mr. Hugh Bromley; a Sykes's Monkey (*Cercopithecus albigularis*) from East Africa; two Heloderms (*Heloderma suspectum*) from Arizona, deposited; three Blood-breasted Pigeons (*Phlogœnas cruentata*) from the Philippine Islands, purchased; a Yak (*Poephagus grunniens*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

SOLAR ECLIPSE PHOTOGRAPHY.—Mr. Albert Taylor recently read a paper before the Royal Dublin Society, on the selection of suitable instruments for photographing the solar corona during total solar eclipses. The photographs obtained by other observers and himself during the total eclipse of April 1893, have indicated the best methods, both photographic and instrumental, to be adopted for the next observable total solar eclipse, on August 8, 1896. One of the most disputed points in eclipse photography, says Mr. Taylor, refers to the proper exposure required to obtain the faint extensions of the corona without fogging the plate by the sunlight. Two opposite opinions are held as to the best method of photographing these diaphanous coronal extensions. Short exposures and slight photographic action are believed by some observers to give the best results, but others hold that long exposures and great photographic action are necessary to attain the desired end. An examination of the photographs obtained during the eclipse of April 1893, shows that the latter view must be abandoned; and that nothing is to be gained by using photographic actions exceeding 15 or 16. Photographic action is determined by the formula $100 \frac{a^2}{f^2} t. s.$, where a is the aperture of the instrument employed, f the focal length, t the time of exposure, and s the sensitiveness of the plate. For obtaining photographs showing the detailed structure of the inner and middle coronæ, short exposures and a long-focus object-glass are recommended. The opinion is expressed that, with a twelve-inch object-glass of between forty and sixty feet focus, one hundred seconds' exposure would give nearly all the corona that is within reach of the photographic method of attack in the present state of photography. It is believed that with an instrument having a focal length equal to ten times the aperture, all the external corona would be obtained in about fifteen or sixteen seconds.

OBSERVATIONS OF SATURN AND URANUS.—Since the beginning of this year Prof. E. E. Barnard has used the 36-inch of the Lick Observatory in some observations of Saturn and Uranus (*Astronomy and Astro-Physics*, August). Measurements of the former planet were undertaken with a view of determining whether the ball was situated in the exact centre of the rings. Between the end of the ring and the limb on the following side of Saturn the angular distance was 11″·287, while similar measures on the preceding side gave 11″·167. The difference is less than one second of arc, and it may very well be due to some peculiarity in the measures. It is certainly not sufficient as yet to suggest that the planet is not exactly at the centre of its rings. Prof. Barnard has also made a series of measures of the polar and equatorial diameters of Uranus, and a series of measures of the position angles of the equator. From these it appears that "the equator of the planet coincides with the planes of the orbits of the satellites, thus verifying the supposition that Uranus rotates on an axis deviating but little from the plane of its orbit."

BIOLOGY AT THE BRITISH ASSOCIATION.

SECTION D, in spite of the loss of Physiology, had so many papers that it was necessary to meet on most days under the two departments of Zoology and Botany. A noteworthy feature was the large number of papers by distinguished foreigners, and the theoretical nature of a large proportion of the communications.

On Thursday, in addition to the Presidential Address (NATURE, p. 371), the following reports of Committees were taken:—

(1) The Naples Zoological Station. This contains an interesting letter from Dr. Dohrn on the future maintenance and administration of the station, statistics as to the work of the station during the past year, and an account by Mr. J. E. S. Moore of his investigations on the reduction division in cartilaginous fishes. He finds that the spermatogenesis stops short at a point corresponding to the formation of the first ovicyte in ovigenesis, and also that the archoplasmic vesicle of the Elasmobranch spermatid has an intranuclear origin, while in the mammalia it is of purely cytoplasmic construction.

(2) The Plymouth Biological Laboratory. This report contains a preliminary notice of Dr. Hickson's investigation of the anatomy and development of *Alcyonium*, and of Mr. Allen's researches on the later stages in the development of Decapod Crustacea. Mr. Allen's work has been chiefly on the cells and fibres of the central nervous system.

(3) The Zoology of the Sandwich Islands. Mr. Perkins has continued his explorations since the last report, and the Committee now propose that he should return to this country and give assistance in working out the extensive collections formed.

(4) The Zoology and Botany of the West Indies. Since last year ten reports have been published, on the insects and plants, chiefly from St. Vincent. The Committee have still to deal with the Coleoptera, and propose to explore Margarita.

(5) Index Generum et Specierum Animalium. The MS. consists now of 180,000 slips, representing 90,000 genera and species.

In the Zoological Department, Prof. Hubrecht (Utrecht) read a paper on the didermic blastocyte in mammalia, in which he showed the distinctness of the trophoblast cells from the embryonic cells of the blastoderm. Mr. W. Garstang, in a paper on the ancestry of the Chordata, gave reasons for his conclusion that the Echinoderms, Enteropneusta, and Chordata trace back their descent to a common pelagic ancestor which had many striking points of resemblance to the Holothurian larva "Auricularia."

Mr. W. E. Collinge read papers on the structure of the integument in *Polyodon*, in which he showed that the occurrence of scale-plates was very similar to those found in the embryos of *Lepidosteus*, &c., and indicated a relationship to the Palæoniscidæ of the coal measures; and on the vertebræ of *Amphisile*, in which the unique character of the vertebral column of this fish was described and the views of previous writers criticised.

In the Botanical Department, Prof. Johnstone showed Algæ which deposit calcareous matter in their tissues, and so probably are better able to resist the attacks of animals. He also exhibited Algæ which are able to dissolve calcareous matter and bore minute holes in the shells of Mollusca. In a second communication he discussed the genus *Pogotrichum*. Prof. Phillips described the great variety found in the development of the cystocarps of *Polysiphonia nigrescens* and other species. Mr. A. Church exhibited collections of Algæ.

On Friday a joint meeting of zoologists and botanists was held to discuss a few important papers dealing with protoplasm, the cell, and allied matters.

Prof. E. Van Beneden led off with a paper on the relations of protoplasm, in which he gave an account of his observations on the phenomena seen in the division of cells. He regards the nucleus as being not an independent organ in the cell, but as closely connected with the ordinary protoplasm. Some discussion followed, and, on the whole, the opinions expressed were highly favourable to Van Beneden's view.

Prof. Strasburger followed next, on the periodic variation in the number of chromosomes. He thinks that the reduction in the number of chromosomes in sexual generation has a phylogenetic interpretation, and is a recurrence to the primitive number of chromosomes possessed when the organism was asexual only. He considered that many cases of asexual plants were to be regarded as due to the loss of sexuality.

The third paper was Prof. Ray Lankester's, on chlorophyll in animals. He gave an account of its occurrence in severalt groups of the Invertebrata, and pointed out that in these casesi starch is produced as in plants, and that the animal does not become green if kept in the dark. He referred to the view that all such cases were to be explained by the presence of unicellular parasitic algæ, but pointed out that these arguments would apply as well to the presence of chlorophyll in plants, and he urged that the same interpretation should be given to the facts in the case of animals as in plants.

In the Zoological Department, Prof. E. Van Beneden read a paper on the origin and morphological signification of the notochord He described the formation of the notochord and mesoblast in some bats from the external layer (apparently epiblast). He proposed that the two embryonic layers should be called blastophore and lecithopbore. He also instituted a comparison with the young *Amphioxus* and *Cerianthus* (where the axis corresponds to the long axis of the vertebrate body), and pointed out how their essential similarity bore out the conclusions as to the origin of the Chordata reached by Sedgwick fifteen years ago.

Prof. Struthers gave a paper on the carpus of the Greenland right whale compared with that of finner whales. He showed that the arrangement of the cartilages in the wrist has no functional significance (the carpus merely functioning as a whole), and can only be explained by descent with modification from the less rudimentary condition seen in other mammals. He showed that the pisiform is actually the most important element, and the only one which has a distinct function.

Miss Kirkaldy gave a critical account of the various species of *Amphioxus*. She described in all eight species, referable to three genera (*Branchiostoma*, *Heteropleuron*, and *Asymmetron*), one of which, *Heteropleuron Singalense*, she considered to be new to science.

In the Botanical Department, Miss Benson described her investigations on the fertilisation of the Chalazogamic Amentiferæ, and showed that the pollen tube passes through the chalaza in *Corylus*, *Carpinus*, *Betula*, and *Alnus*. Miss Pertz had a paper on the hygroscopic dispersal of fruits in certain Labiatæ, in which she showed that there are cases where the capsule opens when moist; and Dr. J. Clark gave an account of his investigations on the hybridisation of orchids.

On Saturday, in the Zoological Department, after the reports (1) on the migrations of birds as observed at lighthouses (the digest of which has at length been completed by Mr. Eagle Clark), and (2) on the legislative protection of wild birds' eggs (in which the recent Bill was explained and criticised by Prof. Newton, Canon Tristram, and others), the following papers on the occurrence, distribution, &c., of marine animals were taken:—

On a tow-net for opening and closing under water, by Mr. W. E. Hoyle. Mr. Hoyle described his electrical tow-net, and explained that he was now waiting for an opportunity of getting into water of over 100 fathoms depth in a steamer fitted with electric power.

On temperature as a factor in the distribution of marine animals, by Dr. O. Maas (Munich). Dr. Maas considers that the great ocean currents are of primary importance in limiting the distribution of free-swimming forms, different species being found to north and south of them. He attributes greater importance to temperature than to pressure. He points out that the existence of eurythermal and stenothermal animals must be borne in mind, and that in drawing conclusions as to distribution all animals are not equally important.

On the marine zoology of the Irish Sea, by Prof. W. A. Herdman. The object in this investigation has been not merely to collect animals, but to investigate the condition of the sea-bottom in the various parts of the area, and correlate, if possible, the fauna with the environment. This report of the year's work gives (1) details of the dredging expeditions, (2) additions to the fauna—these include four new species of *Ecteinosoma*, one of *Bradya*, one of *Pseudocyclopia*, one new Amphipod, *Nannonyx spinimanus*, and one Bopyrian, *Pleurocrypta nexa*—and (3), finally, a discussion of the submarine deposits met with, their nature, distribution, origin, and influence upon the fauna. The importance of the nature of the bottom to the animals living on it is specially emphasised.

Prof. M'Intosh gave an account of the recent marine fish-hatching operations of the Scottish Fishery Board at Dunbar. He described the ponds and buildings, their mechanism and he movements of the hatching-boxes, and gave statistics showng how remarkably successful the first season's operations had been.

In the Botanical Department papers were read by Prof. L.

Kny on the correlation between root and shoot, and an exhibition of diagrams; and by Prof. Pfeffer on the sensitiveness of the root-tip.

On Monday forenoon a series of papers dealing with various points in the theory of evolution was taken before the Zoological Department. After the report of the Committee on Telegony, Prof. D'Arcy Thompson read a paper on some difficulties of Darwinism. He doubts the efficacy of the struggle for existence in the case of humming-birds, &c., and in these cases he regards the profusion of forms, colours, and other modifications as due merely to laws of growth, and thinks that growth may be more exuberant in the absence of struggle and hardship. In other cases which are usually interpreted as the result of natural selection, Prof. Thompson gave another explanation, *e.g.* he considers the form of the Guillemot's egg is merely the natural result of the pressure caused by a relatively large egg passing down a narrow muscular passage.

Then Prof. C. V. Riley followed, on social insects and evolution. He gave a summary of what is known of the habits and economies of bees, wasps, ants, and termites, especially as to the development of the young. He considered that the varied structures and habits of neuters are perfectly explicable upon the general principles which have governed the modification of organisms, amongst which he believes natural selection plays an important but limited part. He showed that the differences between the queen and the neuter resulted entirely from the treatment of the larva, and was at the control of the colony. In ants also the differences between the different individuals is again the result of food and nurture. He believed with Darwin that the variations in social insects have been guided by natural selection amongst colonies; but that this remarkable and somewhat unexpected social selection among individuals, as exemplified in these insects, simplified the origin of neuters. Competition had been between colonies rather than individuals. The author finally pointed out that just as in man among mammals, the higher intellectual development and social organisation is found correlated with the longest period of dependent infancy.

Prof. Haycraft read a paper on the *rôle* of sex in evolution, in which he argued that variation is a quality of protoplasm, and that it has and can acquire this quality in varying degree and apart from sexual conjugation; also that sexual conjugation tends to limit or diminish variations, and that this is the *rôle* of sex in evolution; to sex therefore we owe our fairly well-defined generic and specific groups.

Dr. F. A. Dixey, in a paper on the relation of mimetic characters to the original form, gave some interesting examples of mimicry amongst butterflies, and showed how a very perfect scheme of mimicry may be established by gradual changes from a very small initial resemblance.

Prof. Osborn treated of certain principles of progressively adaptive variations observed in fossil series. He appealed for a systematic analysts and investigation of variation, and for a suspension of judgment in regard to the factors of evolution. Recent works show a lack of analysis, since all adult variations are classed together without regard to the two following lines of cleavage; first, as to adaptation, whether progressive, retrogressive, or neutral; second, as to time of origin in the individual, whether palæogenic or neogenic. Neogenic variations which point to the future may be conveniently divided into (*a*) gonagenic; (*b*) gamogenic; (*c*) embryogenic; and (*d*) somatogenic according to lines suggested by the work of Kölliker, Weismann, Roux, and others. All previous inductions as to variation have failed to recognise that the adult may exhibit variations which have their immediate causes in all these periods, although all alike spring from the potentiality of the germ. A distinct consideration rises whether, besides the "minute variations" of Darwin and the "saltatory variations" of Bateson, there may not be variations so slight as only to be measurable by the comparison between two individuals separated by a long genetic series. Evidence for variation of this kind is seen in the contrast between the evolution of the premolars and of the molars in the eocene horse series. The limitation of variation to certain lines is seen in a comparison between the horse and rhinoceros molars of the miocene. The general conclusion drawn from these facts is that the pure selection principle is contradicted by them, and there is some unknown principle of teleological mechanics yet to be discovered.

In the discussion which followed, Prof. Poulton criticised Osborn's classification of variations, and argued in favour of the action of natural selection in picking out the minute characters which distinguish individuals and in building them up into varieties. The discussion was continued by Profs. Mivart, Lankester, Seeley, Hartog, and others.

In a paper on the wing of *Archæopteryx* viewed in the light of that of some modern birds, Mr. W. P. Pycraft showed that in the development of the primary wing-feathers, as well as in the general form of the manus, in the nestling of certain gallinaceous birds there was evidence that they had descended from a strictly arboreal form in which the manus of the nestling was armed with claws to assist it in climbing the trees in which it was reared, just as is the case in the young of *Opisthocomus cristatus* to-day. He showed that there is reason to believe that the claws of *Archæopteryx* were of prime importance only during the nestling period of life. A model of a restoration of the wing of *Archæopteryx* was exhibited, in which it was demonstrated that the remiges rested upon the third digit, the bases abutting against that of the second digit, the top of which was free. It was, however, suggested that this digit supported the semiplume-like feathers seen in the fossil which possibly functioned as coverts.

In the Botanical Department:—On the origin of the sexual organs of the Pteridophytes, by Prof. Douglas H. Campbell. Notwithstanding the radical differences, especially in the Archegonium, between the Bryophytes and the Pteridophytes, a comparison of the structure and development of the sexual organs of the higher Hepatics with those of the Eusporangiate Pteridophytes shows points of resemblance enough to warrant the hypothesis that here is to be sought the connection between the Bryophytes and the Pteridophytes. Notes upon the germination of the spores of the Ophioglosseæ, by Prof. Douglas H. Campbell. The author succeeded in germinating two species, *Ophioglossum pendulum* and *Botrychium virginicum.* In both the first division of the spore occurs before any chlorophyll is formed. On sterilisation and a theory of the strobilus, by Prof. F. O. Bower. The following are some of the leading points in Prof. Bower's theory:—The spore-bearing parts of the sporophyte are to be regarded as primary in the evolutionary history and in function. The homosporous vascular cryptogams attained the climax of numerical spore-production. As a consequence of increased spore-production arose sterilisation of sporogenous tissue in form of septa partitioning off loculi, and subsequently the formation of synangia, and separation of the sporangia. The sporogonial head is the correlative of the strobilus or flower, the latter has eruptions of the surface to form sporophylls upon which sporangia are borne. The evolutionary history of the sporophylls shows progress from small and simple to large and complex forms. Foliage leaves may have been derived from sterilisation of sporophylls. The following are the remaining papers brought before the Botanical Department:—Miss N. Layard, a method of taking casts of the interior of flowers; Prof. E. Zacharias, the function of the nucleus; Prof. Errera, exhibition of diagrams; Mr. G. Murray, on *Pachytheca*; Dr. Scott, the structure of fossil plants in its bearing on modern botanical questions; Prof. Marshall Ward, a Thames bacillus; Prof. Green, influence of light on diastase; and Mr. Seward, a contribution to the geological history of Cycads.

The following are the remaining papers and exhibitions brought before the Zoological Section; most of them were taken on Tuesday:—

Dr. W. B. Benham expounded a new classification of the Polychæta, which gave rise to some discussion. Prof. Jeffrey Bell exhibited lantern slides of some magnificent colonies of reef-building corals lately acquired by the British Museum.

Dr. W. B. Benham, on the blood of *Magelona.* It differs from that of any other Chætopod hitherto examined. Instead of a red (hæmoglobin) liquid plasma in which float either a few nucleated colourless corpuscles or free nuclei, the blood-vessels of *Magelona* are completely filled with very small spherical globules of a madder pink colour, in an extremely small amount of colourless plasma. These coloured globules are *not* cells. There are free nuclei scattered amongst them, but the coloured globules are not nucleated. The colour is due to a pigment similar to hæmerythrin occurring in some Sipunculids. The globules exhibit a very marked tendency to run together like oil-drops and fuse. This viscid mass seems to be intermediate between the absolutely liquid coloured plasma of chætopods and the red corpuscles of mammals which float in a small amount of colourless plasma. Further, these globules in

Magelona probably originate within cells, from which they are released.

Prof. G. Gilson (Louvain), on the nephridial ducts of *Owenia*.

The Rev. T. R. R. Stebbing, on zoological publication, &c., suggested that the leading biological societies should arrange the work of publishing between them, so as to avoid the overlapping which now takes place. He proposed that for every country there should be a single authorised journal to receive the names of new genera and species with brief descriptions, all claims to priority being dependent on the date of this record.

Mr. J. T. Cunningham, on the significance of diagnostic characters in the Pleuronectidæ, discussed the evolution of the characters which distinguish flat-fishes into sub-families, genera, and species. He considers that the specific and many of the generic characters are not known to be adaptational, and are more probably due to generative isolation and divergent variation. His general conclusion is that animal variation is to be regarded as the resultant of two opposing influences, one internal and one external to the organism. The one is the internal tendency to definite divergent variations which have no direct relation to the struggle for existence, the other is the direct influence of adaptation, whether due to the selection of individuals or to the direct modification of individuals.

Mr. Goodrich described some of the methods adopted recently in displaying specimens in the zoological part of the Oxford University Museum. Dr. F. A. Dixey, on the plantar surface in infants, showed that his investigations on the skin of the foot in very young infants who had never walked, do not lend any support to the view that acquired characters can be transmitted by heredity.

Mr. W. E. Collinge, in a paper on the relations of the cranial nerves to the sensory canal system, showed that the canals are innervated in the Elasmobranchs chiefly by the facial nerve, in the Ganoids by the trigeminal and facial, and in the Teleostei chiefly by the trigeminal. Dr. H. B. Pollard exhibited, with remarks, models of the cranial skeletons of some rare South American and African siluroid fishes, made after the method of Born, with the addition that they were electroplated in order to give them sufficient firmness. Attention was drawn chiefly to the barbules round the mouth. These were maintained to be the homologues of the oral tentacles of *Myxine* and the cirri of *Amphioxus*, and a new theory of the origin of the head in Vertebrata, termed the cirrhostomial theory, was based on these homologies. The author contrasted this theory with the old vertebral theory of Goethe and Oken, and the subsequent theories of Gegenbaur, Balfour, v. Wijhe, and others.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

AT the Oxford meeting the popularity of the Geographical Section showed no abatement. Crowded meetings were the rule, even when papers of a severely scientific character were being read. This may be explained to some extent by the favourable situation of the section-room in close proximity to the reception-room; but perhaps the general use of lantern illustrations had more to do with it. By means of effective lantern diagrams the audience was able to follow with interest and pleasure, papers on detailed oceanography and climatology. The characteristic of the meeting may be given as the general high level of the papers offered, and the interesting discussions to which they frequently gave rise.

The President, in his address, dealt with oceanography in its widest sense, and was followed by a number of papers of similar character, though narrower scope. Unfortunately, it was found impossible for papers on similar subjects to be taken in all cases on the same day, as the convenience of the authors frequently made it necessary to alter the provisional arrangements which had been made. Mr. H. N. Dickson gave an account of the share he had taken on board H.M.S. *Jackal* in the international oceanographical observations initiated by Prof. Petterson, of Stockholm. The general conclusions arrived at were as follows:—

While the Atlantic current flowing over the Wyville-Thomson ridge attains its maximum velocity in winter, its speed is maintained during summer by the greater warmth of the upper layers of water in the Atlantic, and consequent higher level of the surface of that ocean compared with the Norwegian Sea. Passing over the ridge, the Atlantic current is cooled by mixture with the cold water of the Norwegian sea lying at the bottom of the Faeroe-Shetland Channel, and loses its horizontal motion. The warmer the Atlantic current the more rapidly does this mixture take place. Hence in a hot, windless summer a mass of Atlantic water, extending to a great depth, tends to collect on the northern and north-western edge of the North Sea bank. At all seasons Atlantic water is drawn from the Faeroe-Shetland Channel and forced into the North Sea by the tides between Orkney and Shetland. The tidal streams run north-west and south-west, and an eddy is formed to the north-west of the Orkneys, into which North Sea water is drawn, and perhaps also water from below. As the season advances the surface water of the North Sea becomes warmer, the upper layers probably receive smaller supplies of fresh water, but they become specifically lighter than the under layers, which they protect from the warming influences of the atmosphere. The upper layers becoming ultimately warmer than the Atlantic current, the surface of the North Sea becomes higher, and the surface water spreads outwards into the Faeroe-Shetland Channel, checking the surface supply of Atlantic water. Meanwhile, the mass of Atlantic water, collecting at the edge of the North Sea Bank, seeks entrance into the North Sea. Mixing with the cold bottom water already there, it increases its salinity, but reduces its specific gravity by warming it, and, at a certain stage of mixture, the temperatures and salinities of the two waters combine to form a ridge or axis of maximum specific gravity. This axis, which probably runs north-east from Shetland in the end of May or in June, turns slowly toward a north to south direction, and moves eastward. As it retreats, Atlantic water is gradually admitted round the north end of the Shetlands, passes down the east side of the groups, joins the tidal stream at the south end, and, guided by the axis of heavy water, is distributed along the east coast of Scotland, probably during July and August. Later in the summer, as the axis retreats still further, the Atlantic water is probably distributed more towards the eastward, perhaps until the latter part of September, when the diminishing supply from the Faeroe Channel, and the increasing outflow from the eastern side of the North Sea, bring about a gradual return to the conditions with which we started. Obviously the controlling conditions are complex, but it appears that the greater the winter cold and the spring supply of ice-cold water from the continent, the more slowly will Atlantic water penetrate into the North Sea below the surface; and the warmer the summer, the more will the surface supply be checked. At the same time, the warmer the summer the larger the quantity of Atlantic water seeking admission, and the greater its thermal power to drive back the axis of maximum weight.

M. A. Delebecque, of Thonon, sent an account of his methods of surveying and constructing bathymetrical maps of the French lakes, a series of which was exhibited. The geographical conditions of the English lakes were described by Dr. H. R. Mill, and in the discussion which ensued, Prof. Guido Cora, of Turin, took a leading part. Mr. J. Y. Buchanan, F.R.S., sent an account of the researches being carried out by the Prince of Monaco and himself on board the Prince's yacht *Princesse Alice*, in the Mediterranean and North Atlantic, which received considerable attention. He found that even at a distance of 600 miles south-west of the Strait of Gibraltar the salt water from the Mediterranean occupied the lower half of the whole depth, the upper half alone being occupied by Atlantic water. Numerous observations were made in the narrowest part of the Straits, with the effect of defining the manner in which the surface current of Atlantic water entering the Mediterranean is related to the deeper current of dense water escaping to the ocean.

Dr. John Murray gave a discourse on the geographical and bathymetrical distribution of organisms in the ocean, focussing all our knowledge of the distribution of marine life, and concluding with the belief that the existing distribution is a result of the gradual restriction of a universal fauna which flourished in a climate of world-wide warmth, possibly due to the larger size of the sun. This paper gave rise to an animated discussion. Although not formally organised, this was practically a joint discussion between Sections D and E, the participants in the discussion comprising Dr. Gunther, Mr. P. L. Sclater, Dr. O. Maas, Canon Norman, Dr. H. O. Forbes, and Mr. Garstang.

Papers dealing with new exploration were unusually numerous.

Mr. Osbert H. Howarth gave a magnificent series of new views of the Cordillera of North America, in illustration of a paper on the Sierra Madre of Mexico, from which he had just returned. Mr. D. G. Hogarth summarised the result of his recent journey in the valley of the Euphrates. The river was found to be so difficult of passage as to form a natural frontier of the most effective kind. Very fine remains of Roman bridges, aqueducts, and forts were found and photographed. Mr. Weld Blundell, just returned from an even more adventurous journey in the Libyan Desert, gave a paper full of interest describing his observations and photographs. Dr. A. Markoff gave a comprehensive general description of Russian Armenia. Travel papers of minor importance, but no less popular on that account, were read by Mr. W. H. Cozens-Hardy on Montenegro, and by Miss Baildon on a visit to New Guinea.

An animated discussion was also called forth in connection with a valuable paper by Mr. Somers Clarke, on the geography of Lower Nubia. He vividly described the scenery and present economic state of the site of the proposed great Nile reservoir. He said that the Wadi Kenus, the abode of the Beni Kensi tribe, is nearly coincident with the projected Nile reservoir, and if the proposed scheme is carried out the population to be displaced numbers about 30,000, inhabiting a cultivated area of some 10,000 acres. Population in the Ptolemaic times must have been greater, as there are tracks about Korti and Dakkeh, once under cultivation, now abandoned. In the Dodeka-Schoenus there is a number of temples and remains of antiquity, a further proof of considerable population; and the district is protected by a line of forts, some of very high antiquity, others of later date. The existence of Egyptian civilisation side by side with the ruder customs of the natives, is especially to be observed in the method of burial. The present inhabitants on the course of the Nile valley from Assuan to Wadi Halfa exhibit very slight variations in modes of dress, particularly among the women. Men go to Cairo, women stop in the villages, so that the men adopt the ordinary dress of fellahin in Egypt. The manner of building houses from lumps of earth, crude brick, with flat wooden or vaulted brick roofs, constructed in the same way as those used by the ancient Egyptians, was noticed. Reed shelters are also in use. Not only the unique antiquities but the present people, with all life, animal and vegetable alike, are affected by the projected reservoir. In view of the contemplated destruction it is of the utmost importance to make an exhaustive scientific investigation of the valley before it is submerged.

Mr. Norman Lockyer, in commencing the discussion on this paper, said that if the dam were constructed it might after all, if preceded by an exact scientific survey, prove to be a blessing in disguise even to Egyptologists, and that the advancement of science and the advancement of Egypt might proceed hand in hand.

Papers of more technical interest were contributed by several authors. Mr. A. Montefiore sent a detailed account of the equipments of the Jackson-Harmsworth Arctic expedition; Mr. John Thomson gave an account of the methods of photography best adapted for the use of travellers; and Mr. B. V. Darbishire showed a new method of representing the surface configuration of the British Islands. Mr. G. G. Chisholm initiated a valuable discussion on the spelling of geographical names, the purpose of which was to show that the indispensable preliminary requirement, with a view to the end stated, is to have an adequate scheme of orthography, making up for the deficiency of such signs by clear rules to be followed with respect to the sounds for which signs are lacking. To leave it to the individual judgment to decide what is the nearest sound represented in the scheme to one for which no express provision is made, is bound to lead to confusion. The inadequacy of the latest version of the Royal Geographical Society's scheme from this point of view was pointed out, and suggestions of remedies made. The addition of some subordinate rules likely to promote the efficiency with which the scheme is carried out was recommended. Attention was drawn to special difficulties in connection with Russian and Greek names, and reasons given for entertaining the hope that, with the aid of Oriental scholars, special rules might usefully be framed with regard to the spelling of Chinese and Indo-Chinese names. Finally, it was urged that, once an adequate scheme clearly expounded is adopted, it would be of great importance to make special arrangements to secure the co-operation of all contributors to the *Geographical Journal* and other geographical periodicals, of publishers and authors, and, above all, of the newspaper press towards getting the scheme carried out.

Mr. H. Yule Oldham attracted much attention to his statement of evidence, from a MS. map at Milan, of date 1448, of the discovery of Brazil before that date. In the long discussion which followed, the evidence was criticised by several speakers who were reluctant to accept it without more ample proof.

Colonel Feilden read a brilliant paper on current polar exploration, in which he explained the position of the various expeditions now in the field, and expressed a strong opinion as to the folly of inexperienced travellers adventuring themselves lightly into regions so fraught with danger.

Mr. E. G. Ravenstein presented a discussion of the climatology of tropical Africa, resulting from the observations collected by the Committee on African Climate appointed some years ago. The results present the first satisfactory generalisations on the tropical climates of Africa, but its scope cannot be conveniently summarised. Mr. Theodore Bent gave an admirably illustrated account of his recent visit to the Hadramut in Southern Arabia. The proceedings of the Section were assisted by several eminent foreign geographers, amongst whom Prof. Vambery, of Budapest, and Prof. Guido Cora, of Turin, took a leading place.

MECHANICS AT THE BRITISH ASSOCIATION.

THE sittings of Section G, at the recent meeting of the British Association at Oxford, were held in the Common Hall of Keble College, which afforded more than ample accommodation for the purpose.

We have already printed the presidential address of this Section. Prof. Kennedy, who some time ago resigned his chair, was one of the pioneers of the modern movement towards technical education in mechanical engineering, and it was natural, therefore, that he should largely deal with the training of engineering students in his address.

There was a very long list of papers down for discussion at the meeting. The first sitting was held, according to custom, on the Thursday, and the Section met on the Friday, Saturday, Monday, and Tuesday following, that is to say, from August 9 until August 14. With so long a list of papers to deal with, we can do no more in the space at our command than simply refer to some of them by name, and we therefore give the following, which is a complete list of the papers read:—

Thursday.—(1) Some reminiscences of steam locomotion on common roads, by Sir F. J. Bramwell, F.R.S.; (2) bore-hole wells for town-water supply, by H. Davey.

Friday.—(1) Joint meeting with Section A:—(*a*) On integrators, harmonic analysers and integraphs, and their application to physical and engineering problems, by Prof. O. Henrici, F.R.S.; (*b*) note on the behaviour of a rotating cylinder in a steady current, by Arnulph Mallock; (*c*) on the resistance experienced by solids moving through fluids, by Lord Kelvin, P.R.S.; (*d*) discussion on flight, in which Lord Rayleigh, Mr. Langley, Mr. Maxim, and others took part; (2) the strength and plastic extensibility of iron and steel, by Prof. T. Claxton Fidler; (3) tunnel construction by means of shield and compressed air, with special reference to the tunnel under the Thames at Blackwall, by M. Fitzmaurice.

Saturday.—(1) On methods that have been adopted for measuring pressures in the bores of guns, by Sir Andrew Noble, K.C.B., F.R.S.; (2) the most economical temperature for steam-engine cylinders, by B. Donkin.

Monday.—(1) Signalling through space, by W. H. Preece, F.R.S.; (2) some advantages of alternate currents, by Prof. S. P. Thompson, F.R.S.; (3) continuous current distribution of electricity at high voltage, being a description of the lighting of the city of Oxford, by T. Parker; (4) a special chronograph, by H. Lea; (5) a direct-reading platinum pyrometer, by G. M. Clark.

Tuesday.—(1) Report of committee on dryness of steam, by Prof. W. C. Unwin, F.R.S.; (2) the temperature entropy diagram, by H. F. Burstall; (3) the hunting of governed engines, by J. Swinburne; (4) engineering laboratory instruments and their calibration, by Prof. D. S. Capper; (5) lighthouse apparatus and lighthouse administration in 1894, by J. Kenward; (6) on spring spokes for bicycles, by Prof. J. D. Everett, F.R.S.

Sir Frederick Bramwell's paper was one of considerable interest, the veteran engineer described the experience of his youth when he was a protégé of Hancock, who was then running a steam carriage for ordinary purposes of carrying passengers on the public roads. Sir Frederick stated how he used to travel from work to his home when an apprentice, Hancock generally giving him a lift on his return journey with the steam carriage. Under the existing state of the law steam locomotion of this nature is, of course, an impossibility, the restrictions which have been put on this method of transportation being absolutely prohibitive. These restrictions were brought about in consequence of the introduction of traction engines, as we now see them on our country roads. The pace of steam-propelled vehicles is limited to three miles an hour, and it is necessary that a man should walk in front of the engine with a red flag; naturally such regulations make the carriage of passengers out of the question.

This is much to be regretted, for steam carriages, as has lately been proved by continental experience, can be made both safer and more expeditious than those drawn by horses. They are more under control, being easily stopped and turned, and they are naturally far cheaper.

To return, however, to Sir Frederick Bramwell's paper, the details of the early road steam carriages possess considerable interest at the present time, as pipe boilers were used in nearly all of them, and now that the water-tube boiler is coming to the front so rapidly, it is interesting to see what was done by the pioneers of steam engineering. Many inventors whose brains are active in this field would do well to study the earlier records, for old types are now being reinvented at an expenditure of much useless brain work and anxiety.

The second day of meeting of Section G (Friday, August 10) was a very busy one, a joint sitting having been arranged with Section A. Four subjects were down for discussion, as stated in the above list of papers.

Prof. Henrici's contribution was one of great interest, as also was Mr. Mallock's note on the behaviour of the rotating cylinder. Lord Kelvin also gave a valuable lecture on the resistance of solids moving through fluids.

Public interest, however, was chiefly centred in the paper read by Mr. Maxim, in which he described his flying machine. To hear this part of the transactions a large number of members flocked into the hall, many of them being ladies. Some of the members present did not appear to take much interest in the more abstruse subjects dealt with by the previous lecturers, and their want of attention made it a little difficult to follow the first three speakers.

Two papers, relating purely to Section G, were taken on this day; the first was Prof. Fidler's monograph on the extensibility of iron and steel, a valuable contribution which, however, was read to a very thin audience.

The author pointed out that the stress-strain diagram of ductile material as autographically drawn does not indicate any definite relation between tensile stress and plastic strain. The unit stress varies in different parts of the bar; the elongation measure by the diagram being that of the whole bar. The author's experiments indicated that the plastic extensibility under any given stress is nearly the same in all segments of the bar's length, even when the ultimate elongation varies. Volumetric measurements of the successive segments indicate that there is no sensible telescopic shear, and justify the general application of the assumption of unchanging volume. It might at first sight be supposed that a bar of uniform plastic extensibility ought to draw out uniformly over its whole length, but beyond a certain critical point a uniform extension is almost impossible. In order to illustrate these points in a bar of mild steel a diagram had been prepared. The law of plastic extension is determined by the curve, fixed mathematically the curves of the plastic limit, and it fixed also the breaking weight per square inch of original area. In regard to the possibilities of deformation in a bar of nearly uniform extensibility, as the plastic limit is approached the slightest irregularity in section or in extensibility tends to precipitate the formation of a contracted region, and beyond that limit the further extension of the bar and the further contraction of area will be confined to the same region. For stresses below the plastic limit the probabilities of deformation might be examined by considering the relative time rates of extension at two elements which may have been unequally stretched, and at first the tendency is theoretically in favour of preserving the cylindrical form of the bar. But beyond the plastic limit these conditions are reversed, and the tendencies are all in favour of precipitating the most rapid contraction of area at the point where any contraction already exists. Referring to the yield-point, sudden elongation takes place at different stresses in the different segments, while in any one short element it seems to be instantaneous. If the yield is arrested midway and the bar examined, it may be found that the elongation has been completed in some segments and not commenced in others.

In the discussion which followed, Profs. Unwin, Ewing, and Hele-Shaw and Sir Benjamin Baker took part. Prof. Hele-Shaw pointed out that certain bronzes, unlike steel, would contract in several places at once.

Mr. Fitzmaurice's paper on the Blackwall Tunnel gave an interesting description of that important work, now being carried out under Mr. Binnie, for the London County Council.

Two papers only were read on Saturday of the meeting. The first an extremely interesting contribution by Sir Andrew Noble, of Elswick. The author referred to the early experiments of Count Rumford to ascertain the pressures in the bores of guns, and pointed out the errors into which that investigator was led. He referred to the researches of Robins, Cavalli, Rodman, and those of the Prussian Artillery Committee of 1854. He also gave details of experiments made by himself, from which it would appear that with projectiles of increasing weight very different results are obtained, in regard to pressure, with modern slow-burning powders than with the older fine grain powders.

Mr. Bryan Donkin's paper was also one of considerable interest, and gave details of an extensive series of experiments made by the author. He pointed out that in most cases cylinder walls of engines are much colder than the steam, and often one-half the weight of steam is condensed during admission. The details of this will be published later, and at greater length, in the Proceedings of the Institution of Mechanical Engineers. It may be said generally, that throughout the experiments an increase of economy with hotter walls was always verified.

On Monday the proceedings were largely devoted, according to custom, to electrical engineering.

Mr. Preece's paper, on signalling through space, was of a very popular nature, and attracted a large audience. He described the operations which took place at Kilbrannan Sound. It is satisfactory to know that the Post Office authorities are introducing metallic returns wherever possible for telephone circuits.

Prof. Sylvanus Thompson's paper was in praise of alternate currents. The author expressing his opinion that the alternate current system would entirely supersede continuous currents for lighting and power distribution purposes. The continuous current being superior for electrolytic purposes alone. Mr. Preece supported the paper, whilst Prof. Kennedy and Mr. T. Parker took entirely different views.

Mr. Parker's paper was an excellent description of the electric lighting in the city of Oxford. Mr. Lea described a special form of chronograph he had had made to his own designs. Mr. Clark's paper was also one of value, and should be studied in the original by those interested in the measurement of high temperatures.

Tuesday's proceedings commenced with the reading of the Report of Prof. Unwin, of the Committee on the Dryness of Steam. This is a long and valuable report, but as it will appear in full in the Transactions of the Association, it is not necessary we should deal with it on the present occasion.

Mr. Burstall, in his paper, and by aid of a model which he exhibited, has given a new means of illustrating the temperature entropy diagram. This model will doubtless be seen on future occasions. Considerable ingenuity has been shown in its construction. Mr. Swinburne's paper was one of practical interest to engineers, whilst Prof. Capper's contribution on the calibration of laboratory instruments will prove of value, and is worthy of passing notice. The author stated that the reliance to be placed upon observations made with measuring instruments evidently depends upon the accuracy with which those instruments record. Neglect of this fundamental truth often leads to inaccurate and erroneous deductions from experiments which are themselves of the highest scientific value; not infrequently the whole value of observations may be destroyed by insufficient care in the calibration of the instruments used. The subject is therefore one of some importance. The author described the chief sources of error in some of the most common engineering investigations, and their probable value, and pointed out some of the possible methods of correction where such exist. For example, in engine trials there are many possible sources of error. Most of these may be reduced in percentage value by continuing the trial for a sufficient period. But this is not the case with errors which may occur in the indicators, gauges, or spring balances used in the determination of power. In these, unless properly calibrated before trial, very serious errors may be introduced, amounting in some cases to 5 or 6 per cent. of the total power indicated. It is therefore, he said, absurd, even if proper precautions have been taken, to rely upon horse-power measurements to two places of decimals. With regard to tension and compression experiments with standard 10-inch bars, calibration of the testing machine is extremely difficult, and can in general only be carried out over a small portion of the range of the experiments. Deductions have therefore to be made from the less to the greater, with the result that small errors in the calibration will tend to be magnified. Vertical testing machines have fewer sources of error, and can be calibrated with more certainty, than horizontal machines. Extensometers are, however, much more easily applied to a horizontal bar than a vertical, and variable jockey weights, which are requisite if the same accuracy is to be maintained at low loads as at high, are also more readily adapted to horizontal machines. Extensometers can be made and calibrated well up to the accuracy of the testing machine. With standard bars and a measuring instrument true to the ten-thousandth of an inch, the modulus can be relied upon to the second significant figure. It is doubtful if more can be obtained without very special construction and calibration of the testing machine. The difficulty in bending experiments, again, lies in the accurate application of load. Unless the beams are very short or of unmanageable cross-sections, the load measurement must be very delicate if readings approaching the accuracy of those in tension are to be obtained. It is possible that some of the discrepancies in published beam experiments may be due to this cause. The paper dealt briefly with other cases where calibration is specially needed.

Mr. Kenward's paper was of value, both from an historical and a practical point of view. It was illustrated by a number of drawings and photographs.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

THURSDAY, August 9.—Dr. E. B. Tylor read a paper on the distribution of mythical beliefs as evidence in the history of culture. The author showed that the wide distribution of several mythical beliefs, such as the idea of souls being weighed in a spiritual balance, and that of the Bridge of the Dead, gave evidence of connecting links between the great religions of the world. The theory that the pre-Columbian culture of America took shape under Asiatic influence was supported by evidence of a similar nature. Thus, in the religion of ancient Mexico four great scenes in the journey of the soul in the land of spirits are depicted in a group in the Aztec picture-writing known as the Vatican Codex: first, the crossing of the river of death; second, the passage of the soul between two mountains that clash together; third, the soul climbing up a mountain set with sharp obsidian knives; fourth, the dangers resulting from these knives being carried about by the wind. There is a close resemblance between these Mexican pictures and certain scenes from the Buddhist purgatory depicted on Japanese temple scrolls. Here are seen, first, souls wading across the river of death; second, souls passing between two huge iron mountains, which are pushed together by demons; third, souls climbing the mountain of knives, whose sharp blades cut their hands and feet; fourth, knife-blades flying through the air. Dr. Tylor also referred to Humboldt's argument from the calendars and mythic catastrophes in Mexico and Asia, and to the correspondence in Bronze-Age work and in games in both regions, and expressed the opinion that the evidence was sufficient to justify anthropologists in considering that ancient American culture was due to a great extent to Asiatic influence.

Dr. Beddoe read a paper on complexional differences between the Irish with indigenous and exotic surnames. The author showed that dark hair and light eyes are much more prevalent among the former class of Irishmen than among the latter.

The following reports were also read:—Report of the Anthropometric Laboratory Committee, report of the Ethnographical Survey Committee, report of the Anthropometry in Schools' Committee.

Friday, August 10.—The greater part of the day was devoted to a joint discussion with the Geological Section on the plateau flint implements of North Kent. The discussion was opened by Prof. T. Rupert Jones, in a paper in which he expressed general concurrence with the views of Prof. Prestwich as to the genuineness and antiquity of the implements found in the plateau gravels. He argued that the gravel in which the flints were found must have been of pre-Glacial Age. Mr. Whitaker could not admit that there was any good evidence to connect the men who worked the flints with pre-Glacial or even with glacial times, as there were no deposits of undoubted Glacial Age in or near the district. Mr. Montgomerie Bell stated his reasons for believing that the collections of flints from the plateau gravels were of human handiwork. He said that all the evidence pointed to the working of a race of men with strongly-developed body but weakly-developed mind, and this was exactly the conclusion we should expect. Sir John Evans said that the evidence as to the Palæolithic Age in Suffolk being locally post-Glacial was irrefragable, and that the principal outcome of the recent discoveries was, to his mind, the fact that the existence of palæolithic man could be carried further back in time than the valley gravels, inasmuch as his implements are now found in gravels on plateaus at far higher levels. General Pitt-Rivers contended that a single bulb of percussion was not in itself sufficient to prove human workmanship. The bulb of percussion shows the direction in which the blow was given, but any hard knock would produce it, and it was necessary that two or three blows at least should have been given in some definite direction in order to prove design on the part of the fabricator. Dr. H. Hicks, Prof. Boyd Dawkins, Sir Henry Howorth, and Lieut.-Colonel Godwin Austen also took part in the discussion. Mr. H. Stopes read a paper on the evolution of stone implements, and the following reports were presented:—Report of the Prehistoric and Ancient Remains in Glamorganshire Committee, report of the Elbolton Cave Exploration Committee, report of the Explorations at Oldbury Hill Committee.

Saturday, August 11.—Mr. Arthur Evans read a paper on the discovery of a new hieroglyphic system, and pre-Phœnician script in Crete. During the exploration of the ancient sites of Central and Eastern Crete, the author had succeeded in bringing to light a series of stones presenting pictographic symbols of a hieroglyphic nature, and was now able to put together over seventy symbols belonging to an independent hieroglyphic system. More than this, he had discovered partly on stones of similar form, partly engraved on prehistoric vases and other materials, a series of linear characters, a certain proportion of which seemed to grow out of the pictorial forms. As in the case of the Egyptian and Hittite symbols, the Cretan hieroglyphics fell into certain distinct classes, such as parts of the human body, arms and implements, animal and vegetable forms, objects relating to maritime life, astronomical and geometrical symbols. Some of them belonged to that interesting class of pictographs which is rooted in primitive gesture language. The symbols occurred in groups, and there were traces of a boustrophedon arrangement in the several lines. The comparisons instituted showed some interesting affinities to Hittite forms. The linear and more alphabetic series of symbols fitted on to certain signs engraved on the walls of what was apparently a Mycenean palace at Knôsos, and again to two groups of signs on vase handles from Mycenæ. It was thus possible to construct a Mycenean script of some twenty-four characters, each probably having a syllabic value. The author gave reasons for believing that the Philistines, who, according to unanimous Hebrew tradition, came from the Mediterranean islands, and who were actually called Kretbi in the Bible, in fact represented this old indigenous Cretan stock, and that they had here the relics and the writing of "the Philistines at home."

Mr. Arthur Evans exhibited a number of prehistoric objects collected during his journey and explorations in Central and Eastern Crete.

Mr. H. Balfour, in a paper on the evolution of the bow as a musical instrument, gave the aboriginal races of Africa and India the credit of providing us with the prototype of many of our best string instruments.

Miss Weld read a paper on the possibility of a common language between man and beast, in the course of which she mentioned that she had herself reduced a large and savage dog to a state of the most abject terror by imitating some of the deeper tones of his growl.

The Rev. G. Hartwell Jones read a paper on the relation between the body and mind, as expressed in early languages, customs, and myths. The conclusions at which the author arrived were that (1) the primitive condition of the pioneers of civilisation was no higher than that of modern savages; (2) the parallels presented by words and ideas in countries widely separated from one another cannot be satisfactorily explained by mere coincidence; and (3) the civilisation of Western Europe viewed as a whole began in contact with the East.

The following papers were also read:—Prof. A. Macalister, on the heredity of acquired characters; Prof. Arthur Thomson, notes on skin, hair and pigment; Dr. Louis Robinson, the anthropological significance of ticklishness; H. Ling Roth, on the presence of Negritoes in Borneo; Prof. B. Windle, on mythical pygmy races; report of the Mental and Physical Condition of Children Committee.

Monday, August 13.—A paper by Prof. J. Kollmann, on pygmies in Europe, was read. Near Schaffhausen, in Switzerland, a prehistoric settlement has been discovered, in which the remains of two races were found interred side by side. The average stature of one of these races was that of Frenchmen of the present day, but the average height of the other race was only 1424 mm., and they must be looked upon as pygmies of the Neolithic period in Europe. There have recently been discovered some living pygmies in Sicily and Sardinia, and in the author's opinion these small types must be regarded, not as diminutive examples of normal races, but as a distinct variety of mankind which occurs in several types dispersed over the globe; and he believes that they have been the precursors of the larger types of man.

The present state of prehistoric studies in Belgium was described in a paper by Count Goblet d'Alviella. The manufacture of flint implements appeared to have been an important industry, extending all over Belgium, and there have been recent discoveries of megalithic monuments, the existence of which was till lately denied.

General Pitt-Rivers described the explorations of British camps and a long barrow near Rushmore. The skeletons of upwards of twenty-five persons found in and around the barrow give evidence of a people of small stature with long, narrow skulls. They belonged to the polished stone age.

The following communications were also received:—Dr. E. B. Tylor, on some stone implements of Australian type from Tasmania; H. Ling Roth, on Tasmanian stone implements; Dr. Emile Cartailhac, on the art and industry of the Troglodytes of Bruniquel, France; Dr. Emile Cartailhac, on a new ivory statuette of a woman in the reindeer period; Dr. Emile Cartailhac, on the close of the stone period on the borders of the Mediterranean; Prof. Max Lohest, observations relative to the antiquity of man in Belgium; General Pitt-Rivers, on a new craniometer; Dr. J. G. Garson, on the long barrow skeletons from near Rushmore; Dr. R. Munro, notes on ancient bone skates; Prof. A. C. Haddon, exhibition of lantern slides illustrating the people of Western Ireland and their mode of life; report of the Glastonbury Exploration Committee.

Tuesday, August 14.—Mr. Theodore Bent read a paper on the natives of the Hadramut. This valley was formerly the great centre from which frankincense and myrrh were exported to Europe by caravan routes across the desert, and the modern inhabitants of this district are quite distinct from the Bedouins of northern Arabia; they have many curious customs and a religion of their own, and are in all probability an aboriginal race.

Mr. J. Gray contributed a paper on the distribution of the Picts in Britain as indicated by place names. The evidence of place names showed that probably the whole country from the north of Britain to the south of Gaul was at one time or another occupied by the same race. The pre-Pictish inhabitants were Iberians, and prevailed mostly in Ireland, South Wales, Cumberland, and South Scotland.

The following communications were also received:—Mrs. H. Stopes, on three neolithic settlements in Kent; Lionel Decle, on the native tribes of Africa between the Zambezi and Uganda; Prof. Max Kovalevsky, on the Lex Barbarorum of the Daghestan; J. D. C. Schmeltz, on snails and mussels in the house-keeping of the Indoneses; Basil H. Thomson, on the ancient religion of Fiji; B. P. Kehlpannala, on ceremonies observed by the Kandyans in paddy cultivation.

Wednesday, August 15.—Prof. L. Manouvrier described the brain of a young Fuegian, and pointed out that the external morphology of this brain showed little or no distinction from that of a European.

The Rev. Lorimer Fison read a paper on the classificatory system of relationship. The Fuegian system of relationship divide the sexes in any one generation into groups of non-marriageable persons and other groups of marriageable persons, and it was shown that precisely the same groups appeared as the result of the division of the community into two exogamous intermarrying divisions such as are found in Australia. The inference was that wherever the classificatory terms appeared these divisions had existed in the past.

Mr. J. Graham Kerr read a paper on the Tobas of South America. These Indians are nomadic in their habits, and live entirely on the products of the chase. They believe in the existence of numerous minor evil spirits who cause diseases, accidents, and other misfortunes, but the author had not discovered that they had any notion of a supreme deity.

Mr. Alfred P. Maudslay read some notes on native buildings at Chichen Itsa, Yucatan, and the customs of the Maya Indians. The author gave an account of some excavations of a burial mound in the Vera Paz of Guatemala, and the discovery of small jars containing the bones of little fingers, probably deposited by mourners. The earliest notices of the great Maya ruins at Chichen Itsa were discussed, and extracts were given from a document recently discovered in Seville, in which are described the ceremonies performed by the Mayas at the time of the Spanish conquest.

The other communications received were: Prof. L. Manouvrier, on a method of valuation of proportional dimensions in the description of the brain; H. Bellyse Baildon, notes on some of the natives of British New Guinea; Miss A. W. Buckland, on the philosophy of holes; report of the North-western Tribes of Canada Committee.

SCIENTIFIC SERIALS.

American Journal of Science, August.—On certain astronomical conditions favourable to glaciation, by G. F. Becker. The elements of the earth's orbit undergo slow variations, some of which affect climate. These are the time of perihelion, which affects the length of the two great seasons; the eccentricity of the earth's orbit, and the obliquity of the ecliptic. The winter of the period of maximum eccentricity in the rigorous hemisphere would be intensely cold as compared with that of the period of zero eccentricity, but the difference would be most marked in the tropics. The summer would be intensely hot, and also wet. On the whole, the period would be most unfavourable to glaciation; the snowfall being the smallest, and the warm rainfall the largest that can occur with the present obliquity. A difference of 1° 9', however, in the obliquity would make the area to the north of the Tropic of Capricorn 1,800,000 square miles greater than it is to-day, this area being rather more than the combined areas of the Mediterranean and the Gulf of Mexico. The area of evaporation supplying precipitation to the northern latitudes would thus be increased, and the conditions would be favourable to glaciation. Thus a glacial age would be due to the combination of a low eccentricity and a high obliquity, more than to any other set of circumstances pertaining to the earth's orbit. The epochs of such combinations should be deducible from astronomical data.—Development of the lungs of spiders, by Orville L. Simmons. The connection between Limulus and the Arachnida can only be established by a study of the development of the lungs and tracheæ of spiders. The lungs arise as infoldings upon the posterior surface of the appendages of the second abdominal somite, in the same manner as described by Kingsley for the gills of Limulus. The tracheæ develop from the next pair of limbs. The lung-book condition is the primitive, the tracheæ of the Arachnids being derived from it. No ground is left for those who regard the "Tracheata" as a natural group of the animal kingdom.—The generation of chlorine for laboratory purposes, by F. A. Gooch and D. A. Kreider. Chlorine may be conveniently generated by the action of hot hydrochloric acid in a half-strength solution upon lumps of potassium chlorate. These are placed in the upper chamber of a side-neck test tube constricted in the middle. The tube is fitted with a funnel tube reaching to the bottom, and immersed in a flask filled with hot water. When the acid is at 81° the percentage of chlorine in the gas given off is 84. The chlorine dioxide may be destroyed by passing the gases through a wash bottle containing a saturated solution of $MnCl_2$ in strong hydrochloric acid at 90°, and may be still further eliminated by passing the gas through a hard glass tube filled with asbestos and heated.

The Quarterly Journal of Microscopical Science for March contains studies in mammalian embryology (iii.). The placentation of the Shrew (*Sorex vulgaris*, L.), by A. A. W. Hubrecht. (Plates 31 to 39.) The author shows that the placenta is essentially an embryonic neo-formation, which is permeated by maternal blood that circulates in spaces devoid of endothelium. This embryonic neo-formation is preceded by a considerable proliferation of maternal epithelium, which, however, does not enter into the coostitution of the ripe placenta, but affords facilities of fixation and nutrition for the embryonic neo-formation in its earliest stages. The discoid placenta is, in the later stages of pregoancy, the only connection between fœtus and mother.—On some further contributions to our knowledge of the minute anatomy of *Limnocodium Sowerbii*, by R. T. Gunther. (Plate 40.) Some further details regarding the structure of the tentacles, the sense organs, and the male reproductive organs are added to those already recorded by Allman and Lankester. Allman placed this medusa among the Leptomedusæ; Lankester, on the contrary, referred it to the Trachomedusæ. The author writes: "*Limnocodium Sowerbii* is a medusa descended from Leptomedusan ancestors, which has developed sense organs, with an endodermal axis independently of the Tiachomedusæ." Allman's paper on *L. victoria*, in which he adopts Lankester's specific name of *Sowerbii*, was published in July 1880, not in 1881, as stated in the list of authors quoted.—Note on the mesenteries of Actinias, by A. Francis Dixon.

June.—Contains studies on the comparative anatomy of sponges (vi.). On the anatomy and relationships of *Lelapia australis*, a living representative of the fossil Pharetrones, by Arthur Dendy. (Plate 13.) By far the most interesting feature of this species is the very remarkable reticulated fibrous character of the skeleton, which appears to have hitherto escaped notice. This character is unknown in any other living calcareous sponge, while it forms the most prominent feature in the large fossil group "Pharetrones" of Zittel, hitherto regarded as extinct. *Lelapia australis* may therefore be regarded as the only known living representative of this important group. The author sums up his interesting and important paper by introducing the family Pharetrones into the system of recent Calcarea, and regards Lelapia as a very specialised type of Grantidæ.—The structure of the bill and hairs of *Ornithorhynchus paradoxus*, with a discussion of the homologies and origin of mammalian hair, by Ed. B. Poulton. (Plates 14, 15, and 15A.)—A contribution to our knowledge of the Oligochæta of tropical Eastern Africa, by Frank E. Beddard (plates 16 and 17), describes eight new species belonging to the genera *Eudriloides*, *Polytoreutus*, and *Gordiodrilus*, and describes the new genera *Pareudrilus*, *Alluroides*, and all the species collected in Zanzibar and Mombassa.—A further contribution to the anatomy of *Limnocnida tanganyicæ*, by R. T. Gunther. (Plates 18, 19.) The author bases his researches on material caught and fixed in osmic acid by Mr. A. Swann, on the shores of Lake Tanganyika.—Notes on the minute structure of *Pelomyxa palustris* (Greeff), by Lilian J. Gould. (Plates 20 and 21.) The appearance of "a central mass of doubtful significance" is noted; the "glanzkorper" of Greeff were found to stain with several reagents, and the rod-like bodies appear to be certainly bacteria.

The Mathematical Gazette, No. 2. (Macmillan, July.)—W. J. Greenstreet gives a summary of Herbart's views of the place of mathematics in education. The key-note to Herbart's position is "no one can be expected to think himself into the strict uniformity of nature, who has had no training in the rigorous discipline of mathematics and its deductions." G. Heppel takes for the first of his mathematical worthies Edward Wright, who was "probably born about 1560, and died in 1615." In the matter of the New River, Wright appears to have afforded an illustration of the Virgilian "Sic vos non vobis," as he conceived the project, but was ousted by Sir Hugh Middleton. Further interesting particulars of this too-little-known mathematician are given by (De Morgan?) in the *Penny Cyclopædia*, and in Ball's "History." E. P. Rouse contributes a note on the "Director circle of a conic inscribed in a triangle." Solutions of questions, and questions and short notes complete a good number.

Bulletin of the New York Mathematical Society, vol. iii. No. 10. (New York: Macmillan, July.)—Prof. A. Vasiliev (pp. 231–235) furnishes many items of interest in his note, Lobachèvsky as Algebraist and Analyst. In this it is shown that Lobachèvsky's genius was not confined to geometry only. In Macfarlane's "Algebra of Physics" (pp. 235–242), Dr. Chapman analyses the Principles of the Algebra of Physics, and the paper on the Imaginary of Algebra, by that mathematician. Dr. G. A. Miller supplements his note in the April number by a note on the substitution groups of eight and nine letters (pp. 242–245). Prof. Webster (pp. 245–248) reviews Byerly's elementary treatise on Fourier's series and spherical, cylindrical, and ellipsoidal harmonics, and at the outset discusses "a rather singular review (of the book) in a leading New York paper, in which a number of curious statements are made." Prof. D. E. Smith's review of Cajori's history (see NATURE, No. 1288, p. 235) is the subject of a critique, by Prof. Halsted, to which Prof. Smith replies (pp. 249–251). The concluding notice is on orthogonal substitutions, by Prof. H. Taber (pp. 251–259). A long list of publications, notes, and an index closes vol. iii.

Memoires de la Société d'Anthropologie de Paris, tome i. (3e serie), 2e fascicule.—Recherches Ethnologiques sur le Morvan, by Ab. Hovelacque and Georges Hervé. The district known as Morvan includes parts of four Departments—Yonne, Côte-d'Or, Nièvre, and Saône-et-Loire; it is distinguished from the surrounding country by the volcanic nature of the soil, and the central portion, or Upper Morvan, has a mean elevation of 600 to 700 metres (about 2000 feet) above sea-level. The climate is exceedingly inclement, the temperature cold and variable, the winters long and severe. Morvan is essentially Celtic, and the primitive inhabitants have been very slightly influenced by contact with the people around them. The stature indicates two ethnic elements, the one moderately tall—the Kymric; the other shorter—the Celtic, such as we find distributed over a great part of Central Europe. About two-thirds of the population of Morvan have grey or sometimes blue eyes; the others have brown eyes, light rather than dark. Usually the children have auburn hair, and the adults dark brown hair.

Memoires de la Société d'Anthropologie de Paris, tome i. (3e serie), 3e fascicule.—The Anthropology of France—Dordogne, Charente, Creuse, Corrèze, Haute-Vienne—by Dr. R. Collignon. The author has turned to good account the observations made during recruiting operations in the five departments mentioned in the title. The mean stature shows greater variation than in any other part of France, the maximum being 1·667m., while a minimum of 1·568m. was observed at Saint-Mathieu (Haute-Vienne). All the tall cantons are grouped at the circumference of the five departments, and the people of short stature are collected in groups in the centre. As the result of his investigations, the author shows that in this district we have three great groups: first, the brachycephalic—some dark, others fair—tall or short; second, dolichocephalic and fair; third, dolichocephalic and dark. This last group may be further subdivided into some three types: the first, platycephalic, with a disharmonic face; the next, dolichopsic, with a high head; the last, somewhat rarely met with and characterised by prognathism, a low and retreating forehead, black hair, and narrow face. The dolichocephalic brunettes are nearly allied to the Cro-Magnon type, while those who are prognathous, and who have the long narrow face, are perhaps distant relatives of the men of Canstadt and Spy, possibly also they may be distantly allied to the swarthy inhabitants of the south Algerian oasis.

Bulletins de la Société d'Anthropologie de Paris, tome v. (4e serie), No. 1, January; No. 2, February.—In a paper on the various forms of the teeth of different races, Dr. F. Regnault says that the canines of the lower races of man differ from those of the higher races, in that the crown of the tooth is larger in comparison with the neck, and that, like those of the apes, they terminate in a sharp point, which is usually much worn. M. Emile Schmit, in a paper on the "Boves" of Champagne, describes two of these curious subterranean chambers, excavated in the chalk, and approached by low narrow passages of some length. A paper by M. Zaborowski, on ten crania from Rochefort, is continued from the January to the February number. M. Zaborowski argues in favour of the primitive ethnical identity of the blondes, wherever they are found in a state of purity, whether in the Caucasus, in England, or in Charente-Inférieure.—M. Zaborowski also contributes a paper on the circumcision of boys and the excision of girls as initiation ceremonies. He traces the origin of the custom in Asia and Europe to the influence of ancient Egypt.—M. de Saporta describes certain popular medical practices in Provence. In cases of delirium or meningitis, if the warm body of a recently killed pigeon is not available, they have recourse to a fried egg, which is placed, burning hot, on the forehead of the patient. M. de Saporta does not think that any supernatural virtue is attached to these practices.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 31.—"On the Effect of Magnetisation upon the Dimensions of Iron Rings in Directions perpendicular to the Magnetisation, and upon the Volume of the Rings." By Shelford Bidwell, F.R.S.

A recent communication (*Roy. Soc. Proc.* vol. lv. p. 228) to the Society contained an account of some experiments relating to the effects of magnetisation upon the dimensions of two iron rings, one of which was annealed and the other hardened. The rings had the form of short cylinders about 6 cm. in diameter, 3 cm. in height, and 0·4 cm. in thickness. The experiments in question were concerned with the circumferential variations which took place along the lines of magnetisation; those to be here described deal with the concomitant variations in the height of the cylinders (width of the rings) transversely to the magnetisation. On the assumption that variations similar to the latter occur at the same time in the thickness of the metal, it is possible to deduce the changes in the volume of the ring which attend magnetisation.

Fig. 1, from a photograph, shows how the rings were prepared for the experiments. Four brass rods were hard-soldered to the iron, two of them being in a line with a diameter, while the other two were attached to the edges, opposite to one another, and parallel to the axis of the ring. The ring was inserted in a wooden case, also shown, through holes in which the four brass rods projected. Insulated wire for carrying the magnetising current was wound over the wooden jacket.

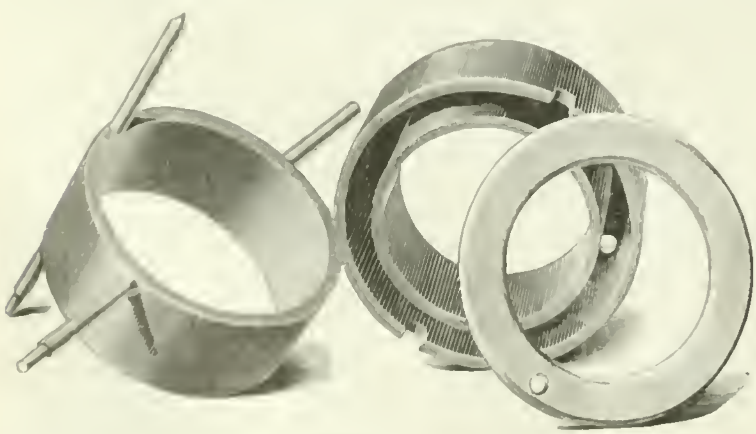


FIG. 1.

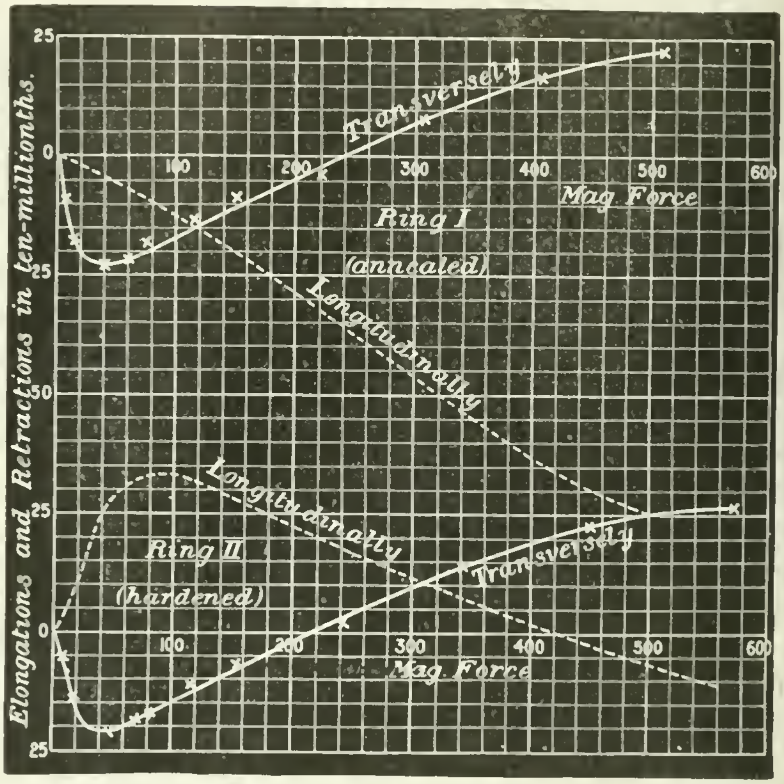

FIG. 2.—The curves marked "longitudinally" relate to circumferential changes, *along* the lines of magnetisation. Those marked "transversely" relate to changes in the width, *perpendicularly* to the magnetisation.

For the new experiments the ring was placed in a horizontal position, one of the edge rods resting upon a brass socket on the adjustable base of the instrument, and the other, which had a chisel-shaped end (not shown in the figure), actuating the lever. To counterbalance the weight of the ring a horizontal arm, carrying a sliding weight, was fixed to the lower rod.

The annealed ring will, as before, be distinguished as Ring I. and the hardened one as Ring II.

The changes observed in the widths of the two rings (transversely to the magnetisation) are indicated in the curves of Fig. 2. It will be seen that they are quite similar in the two cases, little or no effect being produced by annealing. Under gradually ascending forces both rings first become narrower, then recover their original width, and ultimately become wider than when unmagnetised.

As was shown in my last paper, the effects along the lines of magnetisation are very different in the two rings. The annealed ring (Ring I.) begins to contract circumferentially with the smallest forces, and continues to contract with the large ones; while the hardened ring expands with small forces and contracts with large ones. These effects are indicated in the figure by the dotted curves.

By combining the results of the old and of the new experiments we can ascertain the nature of the changes produced by magnetisation in the volumes of the rings. These are indicated in Fig. 3, which shows that the volume of the annealed ring is rather suddenly diminished by a small magnetising force, passes a minimum under a force of about 50 units, and then slowly increases, until, with a force of 500 units, it is about 30 ten-millionths less than at starting. The unannealed ring also at

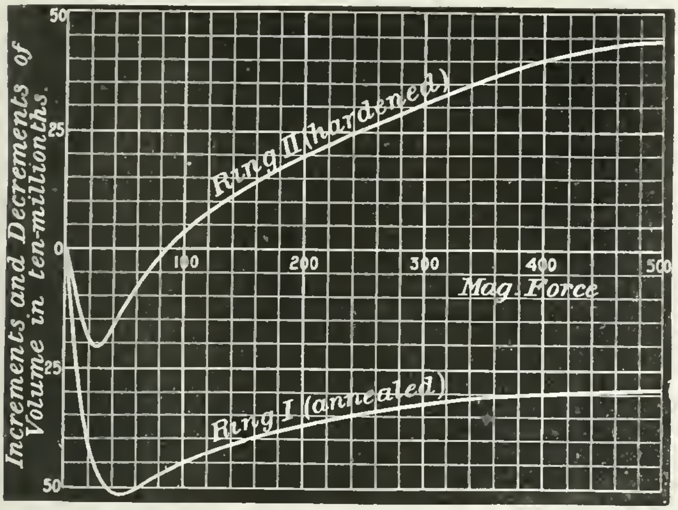

FIG. 3.

first suffers diminution, but its original volume is recovered with a force of about 90 and with higher values is increased.

The behaviour of this latter ring may be regarded as probably similar to that of the great majority of rods and rings, the annealed ring used in these experiments being the only specimen of iron that has yet been found to contract along the lines of magnetisation with the smallest forces that produced any effect at all.

EDINBURGH.

Royal Society, May 28.—Prof. James Geikie, Vice-President, in the chair.—Dr. Ramsey Traquair described some fossils from Forfarshire.—Dr. James Buchanan Young read a paper on the chemical and bacteriological examination of soil, with special reference to the soil of graveyards. He discussed the results of a series of experiments which he had made on samples of virgin soils, pure agricultural soils, and soils which had been, and were being, used for purposes of inhumation. From these results as judged by the amount of organic carbon and nitrogen present in the various samples, it would appear that soil which has been used for burial, does not materially differ as regards the amount of organic matter it contains from pure good agricultural soil. This fact goes far to support the idea that inhumation properly conducted in suitable and well-drained soils can cause no risk to the public health. The results of the bacteriological examination of the various soils goes to corroborate the results arrived at by chemical means. No pathogenic organisms were found in graveyard soils; and, although the number of bacteria present was greater than at similar depths in virgin soil, the number found was by no means so great as one might have expected. There was, moreover, a very marked and sudden fall in the number of micro-organisms in the soil below the layer containing the coffins. So that, as Reimers has pointed out, the "ground-water region" is practically free from bacteria. The broad results of the chemical examination of the samples is well seen in the annexed table. The results are stated in parts per hundred.

	Carbon.	Nitrogen.
Virgin soils	0·265	0·0257
Pure agricultural soils ...	0·842	0·0936
Soils used for inhumation	0·870	0·1073

—A paper, by Dr. J. G. Gilchrist, on the pallial complex of *Dolabella*, was read.—Dr. James Walker communicated an account of hydrolysis in some aqueous solutions.

June 4.—The Hon. Lord M'Laren, Vice-President, in the chair.—Prof. Tait read a note on the application of Van der Waal's equation to the compression of ordinary liquids.—Prof. Geikie read a note, by Messrs. G. Sharman and E. T. Newton, on fossils from Seymour Island, collected by a recent Dundee expedition to the Antarctic Seas. Nine specimens had been found in a district farther south than districts previously explored. All represented existing genera of wide distribution, but the fossils indicated more genial climatic conditions than those now existing.—Prof. D'Arcy Thompson read a paper on certain difficulties in the study of classical zoology.

June 18.—Sir W. Turner, Vice-President, in the chair.—Prof. Copeland read a paper on the path of the meteor of May 18, 1894. This was a large meteor seen in daylight, and first observed somewhere between the island of Mull and the north end of Jura. It was last seen in the north-west district of Yorkshire. Observers judged it to be moving slowly, but calculation showed that it moved over 190 miles in about fifteen seconds.—Prof. Tait read a paper on the elastic equations of the ether in æolotropic dielectrics. He has not yet discussed the question of the stability of the condition of the ether indicated by his equations.—Dr. John Murray gave a comparison of the extra-tropical marine fauna of the northern and southern hemispheres. The similarity of the Arctic and Antarctic marine fauna, and the difference of both from the fauna of intermediate waters, indicate, according to Dr. Murray, a not very remote geological time at which a universal fauna—implying uniformity of temperature—existed. He believes that in Mesozoic times forms of life were driven from the poles towards the tropics, while the fauna which was able to remain under the altered polar conditions gave rise to the present polar fauna.—Prof. Tait gave some illustrations of the range of application of Van der Waal's equation, contrasting the results got from the equation with observed results regarding the compression of liquids.—Dr. C. G. Knott and Mr. A. Shand read a paper on magnetic induction in nickel tubes. Three nickel tubes were compared, as regards their magnetic properties, with a nickel bar. All were cut from the same rod, were of the same length (44 cm.), and the same external diameter (4·2 cm.), but differed in diameter of bore. As with the iron and steel tubes formerly described (*Proc.* R.S.E., 1893), a tendency was shown, in low fields, for the magnetic movements to approximate to the same value. But the tendency was not so well marked. The explanation seems to be that, because of the comparatively low susceptibility of nickel in low fields, the "diamagnetising factor" (so called by Dr. Du Bois) is not of the same paramount importance as in the case of iron or steel. A simple calculation showed that this factor was approximately proportional to the area of section of the metal wall of the tube.

July 2.—The Hon. Lord M'Laren, Vice-President, in the chair.—A paper, by Prof. Cayley, on co-ordinates *versus* quaternions, was communicated.—Prof. Tait read a paper on the intrinsic nature of the quaternion method.—Dr. C. G. Knott and Mr. A. Shand communicated a preliminary note on volume changes which accompany magnetism in nickel tubes. The three tubes, referred to the authors in their previous paper on magnetic induction in nickel, were employed. In high fields the internal volumes were markedly diminished in all three. The greatest measured change in volume was 2·4 cubic millimetres; this was in the tube of thinnest wall in field 600. The greatest cubical dilatation was $-2{\cdot}3(10)^{-5}$, which was got in the tube of narrowest bore in field 600. The cubical dilatation, though negative in high fields, was positive in moderate fields, the change of sign occurring in a field which was lower as the wall of the tube was thinner. With the tubes of widest and intermediate bore, the cubical dilatation was negative in very low fields, each having critical fields for which the dilatation was zero. The tube of narrowest bore did not show this double change of sign. As was perhaps to be expected, the volume changes in the nickel tubes were distinctly greater than the like changes in the iron or steel tubes formerly investigated.—Dr. Gustave Mann communicated a paper on histological changes produced in nerve cells by their functional activity. Experiments on rabbits and dogs have shown that the nuclei and cells were larger in stimulated, than in non-stimulated ganglia. In the stimulated ganglia the lymph spaces practically disappear, while they are quite evident in the non-stimulated ganglia.

Paris.

Academy of Sciences, August 20.—M. Lœwy in the chair.—Electricity considered as a vortical movement, by M. Ch. V. Zenger. The author shows that an electrical discharge produces a whirling movement in the gas through which it is discharged, which may be said to be a cyclone on a small scale, so completely are the phenomena of cyclones reproduced. The particles appear to describe a trajectory which may be represented by a screw of variable pitch traced on a conical surface.—New experiments permitting the comparison of the delivery of liquids, gases, and vapour from the same orifices, by M. H. Parenty. (1) The coefficients of delivery of gases are precisely equivalent to those of the submerged delivery of liquids. (2) These coefficients are not sensibly varied when the pressure and the back-pressure are modified in various ways; they are independent of the temperature and the atmospheric pressure. (3) There exists, for liquids, no analogous phenomena to the regularity of delivery of gases. The delivery of liquids is exactly and always the ordinate of a parabola, of which the loss of charge is the abscissa.—On the periodicity of the absorption rays of isotropic substances, by M. G. Moreau. The author concludes a mathematical investigation of this question as follows: In an isotropic absorbent, there should be two possible kinds of waves of propagation. The one gives bands by anomalous dispersion (they may be reduced to very fine and black rays by regular dispersion), the other gives less intense rays, but they are periodic and more numerous. They would form a kind of double refraction which observation does not seem to have indicated.—On the action of the halogen hydracids on formaldehyde in presence of alcohols, by M. Louis Henry. A claim for priority as against M. C. Fabre.—Action of camphoric anhydride on benzene in presence of aluminic chloride, by MM. E. Burcker and C. Stabil. Two substances besides the principal product, phenylcamphoric acid, have been isolated, namely, phenylcamphoric anhydride, $C_{16}H_{18}O_2$, and a diphenyl compound represented by the formula

$$PhCO\ .\ CPh\begin{matrix} \diagup CO\ .\ CH_2 \diagdown \\ \diagdown CH_2\ .\ CH_2 \diagup \end{matrix}CH\ .\ C_3H_7.$$

—The extraction of free acids from bees-wax, by M. T. Maire.—Influence of lesions of tissues on their aptitude for fixing dissolved substances, by MM. A. Charrin and P. Carnot. It is shown that dissolved substances tend to accumulate in unhealthy or injured tissues.—On some antitoxic properties of the blood of the terrestrial salamander (*Salamandra maculosa*) against curare, by MM. C. Phisalix and Ch. Contejean. The salamander requires eighty times as much curare as the frog for poisoning to take place. The immunity of the salamander may be due to the presence in its blood of some substance which neutralises the effect of this poison. In support of this hypothesis, it is found that a mixture of salamander-blood and curare in proper proportions does not act on the frog. This substance has a physiological action conferring immunity against curare, and not a direct chemical action on the latter, for the inoculation of frogs with salamander-blood twenty-four hours before the injection of curare enables the frogs to withstand a much larger dose than when the salamander-blood has been mixed with curare previous to injection.—On the budding of Diplosomidæ and Didemnidæ, by M. Maurice Caullery.—Researches on the respiration and assimilation of the Muscineæ, by M. B. Jonsson. There are great differences among the Muscineæ in regard to the intensity of respiration and chlorophyllian assimilation. For example, the different species disengage in the dark very different quantities of carbon dioxide per gramme of dry weight. The proportion of water present in the plants is an important cause of variation, the greater this proportion the more intense are the gaseous exchanges. Specimens taken from a very damp place give off more gas than specimens of the same species taken from a dry location. The reddish coloration of many mosses, very marked when the plants have been developed in the light, diminishes considerably the intensity of respiration and assimilation.—On the perithecæ of the "Rot blanc" of the vine (*Charrinia diplodiella*), by MM. P. Viala and L. Ravaz.—On the chemical constitution of the atmosphere, by M. T. L. Phipson.

New South Wales.

Linnean Society, June 27.—Prof. David, President, in the chair.—Description of five new fishes from the Australasian region, by J. Douglas Ogilby. Of the species described, *Gillichthys mirabilis* and *Clinus whiteleggei* were from the coast of New South Wales, *Ophioclinus de visi* from Queensland, *Petroscirtes icelii* from Lord Howe Island, and *Eleotris huttoni* from New Zealand.—The land molluscan fauna of British New Guinea, by C. Hedley. Two new species, *Sitala anthropophagorum* and *Otopoma macgregoriæ*, were described and figured. It was considered that Mousson's genus *Trochonanina* should be merged into *Sitala*. Anatomical details of several species not before dissected were added.—Studies in Australian entomology. No. vii. New genera and species of *Carabidæ*, by Thomas G. Sloane. Three genera—*Notolestus* (type, *Abax sulcipennis*, Macl.), *Setalimorpha* (Feronini), and *Lestianthus* (Helluonini)—and thirty-six species were described as new.—Wood moths: with some account of their life-histories, chiefly compiled from the notes of Mr. R. Thornton of Newcastle, by W. W. Froggatt. This paper gave a general account of the habits and food-plants of several species of *Eudoxyla* and *Charagia*, and of *Leto Stacyi*.—Botanical notes from the Technological Museum, Part ii., by J. H. Maiden and R. T. Baker. The notes included (1) a list of additional localities of New South Wales plants, (2) new varieties of New South Wales plants, (3) Queensland species new for New South Wales, (4) remarks on naturalised species in the colony, and (5) descriptions of unrecorded fruits.—Notes on plants collected on a trip to the Don Dorrigo Forest Reserve, by J. H. Maiden. The author traced the southern extension of plants hitherto recorded from the Clarence River and further north, and the northern extension of plants hitherto not recorded further north than the Macleay River, Blue Mountains, &c. He also described a number of well-marked varieties of certain species, and added notes on imperfectly-described or little-known plants.

THURSDAY, SEPTEMBER 6, 1894.

A NEO-LAMARCKIAN THEORY OF EVOLUTION.

A Theory of Development and Heredity. By Henry B. Orr, Ph.D., Professor at the Tulane University of Louisiana. (New York and London: Macmillan and Co., 1893.)

THE appearance of a new work on the causes of evolution, by an American biologist, raised the hope that more solid arguments would be forthcoming in favour of the conclusions accepted by so many well-known writers and workers on the other side of the Atlantic. This hope was doomed to disappointment, the evidence adduced being even more slender than usual, and the conclusions even more rash.

According to a view which has been recently put forward by Lamarckian writers, the facts of adaptation are explained by the supposition that organisms possess such a constitution that they are compelled, by the incidence of external forces, to react adaptively, viz. by the production of useful variations. This view appears to be supported by the author (chapter i.), although no evidence is brought forward in favour of it. The hypothesis in question seems to be little more than the old "internal developmental force," or "innate tendency towards perfection," in a modern dress. Furthermore, a little consideration of the essential nature of adaptations proves the futility of any such attempt at explanation. The ultimate objects of adaptations are to obtain food, to escape enemies, or to subserve reproduction. In the vast majority of cases adaptations are relative to the condition of other individuals of the same and other species—a condition which is and has been continually changing. But the environment with which the organism is in continual contact, and which is presumably supposed to bear a pre-eminent part in working these useful variations, is the inorganic environment. So that stimuli provided by one form of environment are looked upon as the direct causes of adaptations which are essentially related to another and very different environment. It would be necessary, in order to make the suggestion valid, to prove that the changes in the organic environment which render some adjustment of adaptation necessary, are invariably accompanied by corresponding changes in those forces (chiefly inorganic) by which it is believed that the adjustment is effected.

In discussing "the limits of natural selection," the following supposition is believed to constitute an insuperable objection to Weismann's theory of heredity, viz. "the supposition that the germ-plasm may exist in the body and still be no more affected by the changes which pass over the body than if it were enclosed in an hermetically sealed vial." It is well known that in all his later writings Weismann has abandoned the hypothesis of a germ-plasm endowed with an almost resistless stability. But the admission of the converse supposition, that the germ-plasm is profoundly affected by the external forces which also affect the body, is very far from the admission that acquired characters are transmitted; and it is this latter, and nothing less, which is required as a foundation for the Lamarckian hypotheses, as, indeed, the author freely admits. In order to prove that the one proposition involves the other, it would be necessary to show that an external force producing a certain effect on the body must produce, upon a totally different thing—the germ-plasm—not, indeed, the same effect, but its precursor.

Considering "the many cases of wholesale destruction of animals—for instance, the killing of countless fishes by a sudden change in the temperature of the ocean, the killing of birds and insects by cold and storms of wind and rain, and the killing of myriads of organisms of all kinds by circumstances over which they have no control, and from which no mere individual variations could save them," the author is led "to doubt that natural selection acts with such mathematical accuracy in accumulating slight individual variations." It is difficult to understand the grounds upon which the non-operation of natural selection in certain kinds of destruction is held to cast doubts upon the efficiency of its action when it does come into operation. Furthermore, it is easy to point to results which are consistent with the view that natural selection may act "with mathematical accuracy" even in the class of cases brought forward. The peculiar condition of the wings of insects living in islands in stormy zones, and a power of resisting temperature related to the needs which follow from the geographical distribution of plants and animals, may be cited as examples.

The author quotes with approval Prof. Cope's contention that "the useful additions which have constituted certain genera, families, orders, &c., what they are," were produced as a direct consequence of needs, and were not formed first and selected afterwards, inasmuch as "it would be incredible that a blind or undirected variation should not fail, in a vast majority of instances, to produce a single case of the beautiful adaptation to means and ends which we see so abundantly around us. The amount of attempt, failure, and consequent destruction would be preposterously large, and in nowise consistent with the facts of teleology as we behold them."

This antithesis suggests that it is believed that "the useful additions" were fully formed as complete organs or parts before they were selected. According to the theory of natural selection, however, such "additions" have been led by selection from the very first—from the time when the parent organ or part first began to be used for a new purpose (for such is almost invariably the origin of the last "addition")—right back to the remote period when the original ancestor of a long succession of organs and parts came into being. But even accepting Prof. Cope's antithesis, surely, when we consider the slow succession of forms throughout geological time, and the amount of extinction which took place in every generation, we may accept his conclusion as to the amount of "attempt, failure, and consequent destruction," and reply that on this very account the Lamarckian explanation is extremely improbable, inasmuch as it would imply a direct and rapid evolution, whereas we know that evolution has been slow and interrupted.

Unnecessary confusion has been introduced into the discussion of instincts by the inclusion under this term of the clearest results of education and experience, containing nothing in common with true instinctive actions. Thus we read on p. 21:—"That the Kea-bird of New Zealand has learned to dig the kidney-fat out of living sheep since the introduction of sheep into that country, is another wonderful instance of change of instinct hardly to be accounted for by means of natural selection, but rather as the result of intelligent experience."

Speaking of instinct, he maintains "this seems to be a well-defined case of the inheritance of acquired characters. We cannot deny that the idea or knowledge has been acquired, neither can we deny that it has been inherited." And yet many instinctive actions of the greatest complexity and interest take place under conditions which preclude the possibility of the acquisition of any idea or knowledge. Thus many insects before pupation take the most elaborate precautions, which tend to prevent their detection by enemies they have never seen and never will see in the helpless stage they are about to enter. If knowledge cannot have had any part in the origin of such marvellous instincts, it is unnecessary to suppose that it is an element in the rise of any truly instinctive action.

In considering the source of organic energy in chapter ii., the author supposes that by the law of conservation of energy all the forces of the environment which act upon an organism must be transferred into some form of energy within it, accounting for "all changes in shape and all changes in the method of activity." In order to help to understand how this may occur, he instances a number of photochemical changes taking place in inorganic bodies. But the law of conservation of energy demands nothing of the kind. The forces which fall upon the organism must indeed persist, but not necessarily in any form which can be made use of by the organism; or they may, and indeed frequently do, serve to expend part of the store of potential energy derived by the organism from other forces. Thus the effect of any external force (*e.g.* light, heat, sound, &c.) upon a peripheral end organ is only conveyed to the brain by the expenditure of potential energy derived from food. The animal may benefit by the information received, but the transmission itself is a loss, and not a gain to the store of force at its disposal.

When, in chapter iii., the author considers in further detail the action of environing forces, many instances are brought forward, in which it is clear that some *necessary condition* of development, such as food or heat, is interpreted as a *cause* of development. It is surprising that the author did not think of applying his conclusion that "food is one of the stimulating forces which guide and determine the developmental reactions of the organism" to the vegetable world; where an endless variety of forms depend upon a food supply which is, when compared with that of animals, remarkably uniform.

The naive manner in which conclusions are drawn is surprising in an author who is evidently a trained biologist, and is accustomed to the indirect and excessively complex relation of causes to effects met with in organic nature. Thus, on p. 47 we are told that "pigment increases in quantity or brilliancy as we approach the equator, where the light is most intense. There is thus a direct ratio between the amount of light and amount of pigment"; and again on p. 49: "The plain facts lead to the conclusion that pigment is caused by light acting upon the tissues, and where there is no light there can be no pigment." It is interesting to compare these bald statements with the evidence produced by Dr. A. R. Wallace, that there is no proportionate increase in quantity or brilliancy of colour—either animal or vegetable—in tropical as compared with temperate countries; but that such increase as there is, is merely proportionate to the increase in variety and number of forms of life. But apart from this deliberate conviction of one whose opinion on such a subject is entitled to so much consideration, the mode of development of pigment in animals is entirely opposed to the author's conclusions. The bright colours of insect-imagines are developed in an earlier stage, during which they are comparatively screened from light, and when in the final stage the colours are exposed, they undergo no change in the direction of increasing brilliancy. Even such changes as the darkening of the freshly exposed pupal cuticle long assumed to be photochemical—have been shown by the writer to be independent of light, and almost certainly due to oxidation.

Equally rash and ill-considered is the conclusion, in the same chapter, that the colours of desert animals and of those living among the sea-weed of the Gulf Stream are due to a direct photochemical influence of the respective environments, and that the whiteness of Arctic animals "may be primarily due to the small amount of light in those regions." In reaching this last conclusion the author relies upon the supposed fact that *all* classes of animals are similarly coloured, forgetting that when, as in the raven &c., a white appearance is not needed for attack or defence, it is not attained.

In considering the action of the nervous system, in chapter iv., it is "safely" concluded that "the energy of the forces, acting from without, persists within the living matter as nervous activity and change of nervous condition." It has been already pointed out that such persistence is frequently attended by a loss rather than a gain to the energy at the command of the organism. The author has thought it worth while to translate long passages from Detmer, and does not appear to be aware that the conclusions he quotes have been refuted by Weismann, and are even rejected by botanists who do not agree with the views of the latter.

In chapter v. it is contended that development has been dependent on association and repetition. It is forgotten that many essential actions are performed but once in the life of the individual (*e.g.* cocoon-spinning), or are as perfectly performed the first time as on subsequent occasions (*e.g.* web-spinning of spiders, sucking of mammals). The author freely admits that such a theory of development demands the transmission of acquired characters, and it is therefore remarkable that his discussion in chapter vii. of this question—the foundation of every conclusion he brings forward—should be so brief, and his reasons for accepting such transmission so unconvincing.

In chapter ix. the author attempts to illustrate in the approved Neo-Lamarckian manner the moulding of limbs and the skeleton generally as the result of the forces to which they are exposed during the life of the individual. In the explanation of the remarkable lengthening of the fore-part of the giraffe we meet with a suggestion which is, I believe, new in the history of Lamarckian speculation. In stretching for food it is contended that the animal "must have constantly raised itself off its fore-feet, and as it dropped must have received a shock that made itself felt from the hoofs through the legs and vertical neck to the head. In the hind-legs the shock would not be felt. . . . The principle of increased growth in the direction of the shock resulting from superabundant repair of the momentary compression, explains how the giraffe acquired the phenomenal length of the bones of its fore-leg and neck; and the absence of the shock in the hind-quarters shows why they remained undeveloped and absurdly disproportionate to the rest of the body." (pp. 164–165.) It is unnecessary to take the trouble to refute the details of the various suggestions brought forward by the upholders of the Lamarckian hypothesis: they refute each other. One of them explains a lengthened neck as the result of extension, another as the result of compression; while neither give any approach to a proof that such an effect is likely to result from the antagonistic forces which they respectively invoke.

CELESTIAL PHOTOGRAPHS.

A Selection of Photographs of Stars, Star Clusters and Nebulæ, together with information concerning the Instruments and the Methods employed in the Pursuit of Celestial Photography. By Isaac Roberts, D.Sc., F.R.S., &c. (London: The Universal Press, 1894.)

THIS handsome collection of celestial photographs is a remarkable example of what can be done single-handed in a new line of research. Taking up celestial photography more than ten years ago, Dr. Roberts has devoted himself entirely to it, and has been rewarded with an amount of success that must be to him a source of intense satisfaction.

This success, however, has not been obtained by merely exposing plates in the telescope and watching the images come out in the developing dish. The work that Dr. Roberts set himself to do was planned at the outset in a thorough manner, and has been carried out apparently without regard to either labour or expense; even to the extent of the removal of the observatory near Liverpool, to a better position, selected after a most exhaustive discussion of weather conditions in the south of England.

In the introduction of his book Dr. Roberts tells us that a reflector of twenty inches aperture was the instrument decided upon, in consultation with Sir Howard Grubb, as the most likely to give the best results. An instrument of this size, arranged for exposing the plate without the use of a plane or prism, was made and mounted by Sir Howard Grubb in 1885. With this instrument all the celestial photographs have been taken.

The first arrangements do not appear to have been quite satisfactory, so that the telescope had in great part to be reconstructed; but even then the star images were found, on trial, to be elongated, though this defect seems to have been remedied later on, if one may judge by the remarkable absence of any deformation of image in some of the very long exposure photographs.

The question of the utility of the photographic chart is discussed, and the fact mentioned that Dr. Roberts had already, in 1885, begun a photographic chart of the northern heavens, and made some progress, when the International Congress for the Photographic Chart of the Heavens took up this work. The use of the paper copies of celestial photographs might, it is suggested, be (1) the detection of changes in the structure of nebulæ; (2) the detection, on a large scale, of movements amongst the stars; (3) determinations of variations in stellar magnitudes; (4) relative distribution of stars in space; (5) detection of new stars and disappearance of others.

In cases, however, where measurements to a second of arc are required to be made, then the original negatives must be used for the purpose; and in this we quite agree with Dr. Roberts. It would have been well worth while to picture, in this connection, the instance given by Dr. Roberts of his comparison of a chart of the heavens, made in 1863 by D'Arrest, showing 212 stars, with a photograph of the same region taken in 1890, which showed that considerable changes had taken place among the stars in this small area of the sky (comprised within one degree of declination and half a degree of right ascension) during the interval of twenty-six years between the epochs of the charts.

The relative advantages of refractors and reflectors as photo-instruments, and the requirements and adjustments of a reflector for celestial photography are discussed; and the ideal instrument for photographing the sun, moon, and planets is given as a refractor of six or eight inches aperture and very great focal length; but for the delineation of faint stars and faint nebulosity, Dr. Roberts gives a preference to the silver-on-glass reflector, and he would choose an instrument of twenty-seven inches clear aperture and eleven feet three inches focal length, the mirror being figured, and every part of the mechanism made in the most perfect manner possible, and with a guiding telescope with an objective ten inches in aperture. To anyone contemplating the erection of an instrument for celestial photography, these hints—the results of many years' experience—should be of great value.

The other chapters, on the collimation of the mirror, the essentials of a photo-telescope, method of testing the stability of a photo-instrument, and photographic plates, their exposures and developments, will be read with great interest by all photo-astronomers.

The chapter on the collimation of the mirror gives an account of the method employed to check the guiding telescope, and is perhaps the only point on which something might be said in the way of criticism of Dr. Roberts' method. It is difficult to see why the method described should not be varied so as to be always available, and so dispense with the guiding telescope; a matter of no slight importance in the case of such an instrument as Dr. Roberts has suggested, the ten-inch objective of which would cost as much or more than the mirror. We believe Sir Howard Grubb has already suggested some such method.

We should have very much liked further information about the instrument, the supports of the mirror and the plate-holder, and other details, but these are perhaps rather in the province of the telescope-maker than the photo-astronomer. A photograph of the double telescope, however, gives a very good idea of the general arrangements, and there is also a photograph of the observatory.

Of the forty-nine celestial objects reproduced on paper, four are star charts, twenty-two are clusters of stars, and twenty-three are nebulæ. The earlier and most important photographs in this collection have already been published in various ways, and many of the others exhibited at the meetings of the Royal Astronomical Society; for Dr. Roberts, with proper scientific spirit, has always been ready to place any of them at the disposal of astronomers: but they lose nothing of their great interest by being seen in the collected form.

Had Dr. Roberts' work been only to produce the first photograph, that of the great nebula in Andromeda, and had that been the only result of all his labour, he would have been amply repaid, for it is certainly not too much to say that, in this picture, photography has done more to justify its use by the astronomer than in any other case; and one can feel that the hopes that were formed by Rutherford and others in the early days of photography, and which lay dormant for so many years, have now been realised. The perfection of delineation enables the true character of this marvellous object, which remained hidden from the closest scrutiny of such a careful and competent investigator as G. P. Bond, to be at once seen and appreciated. It is difficult to imagine that such an enormous object as the Andromeda nebula must be, is not very near to us; perhaps it may be found to be the nearest celestial object of all beyond the Solar System. It is one that offers the best chance of the detection of parallax, as it seems to be projected on a crowd of stars, and there are well-defined points that might be taken as fiducial points for measurement. Apart from the great promise this nebula thus seems to give of determining parallax, there is a fair presumption that in course of time the rotation of the outer portion may perhaps be detected by observation of the positions of the two outer detached portions in relation to the neighbouring stars.

The photographs are arranged in order of right ascension, each has its position given, and many have marked fiducial stars whose position is given for 1900. The scale of enlargement is also given, so that with the help of a table of corrections of errors due to the slight alterations in scale in enlarging or printing, any point on the photograph can be determined with an accuracy sufficient at least for purposes of identification.

For some purposes, no doubt, it will be absolutely essential to have recourse to the original negatives, but, as Dr. Roberts has pointed out, there are many purposes for which these paper copies are available. In addition to the full date of each object, which is admirably done, there are various useful references to previous observations. The accuracy with which the telescope is kept pointed during a long exposure is seen by a glance at the shape of the brighter star images, as a shift, if not at once corrected, produces deformation. In nearly every photograph the stars are round, in some they seem absolutely so, which shows the perfection of the instrumental arrangements of Sir Howard Grubb, and the care with which the exposures have been made. Some of the star photographs—as, for instance, plate 43—show a perfection of image and an absence of distortion over a large field that is very satisfactory. A comparison with a plate of the same region taken by an International Chart refractor would be interesting.

In looking at the examples of spiral nebulæ, of which there are several, one cannot help thinking of Lord Rosse, and the correctness with which he delineated these objects, though his views at the time were not generally accepted by astronomers. These most interesting nebulæ will repay further study, perhaps, more than any other.

Some of the cluster photographs are too much enlarged for the ordinary distance at which one reads a book, but the proper effect can be obtained by looking at them about three feet away. All the photographs are about as good as it is possible to take with an instrument of the size used by Dr. Roberts, and the present dry plates; better photographs can only be obtained by the use of a larger telescope, or by means of dry plates that will, with the same or greater sensitiveness, give a finer grain. This is shown by a comparison of the photograph of the cluster M. 5, taken by Dr. Roberts, with one taken with a larger telescope of a similar kind. Dr. Roberts states (p. 91) that "the cluster is enclosed in dense nebulosity about the centre, the nebulosity hides the stars, even on the negative"; but an inspection of the photographs by a larger instrument shows that the stars are quite distinct, though the exposure was very much longer, a result that might fairly be expected.

A comparison of photographs of this object, taken at different dates, shows that many of the stars of this cluster are variables, and of course it is just possible that there may be variability in the central portions.

Excellent as are the paper reproductions of these photographs, they cannot give all the beautiful detail to be seen on the original negative of a nebula. If change be taking place, it is more than likely that it may be seen in the finer detail first, in which case the original negative must be seen. This points to the absolute necessity of preserving the negative where it shall be available in after years. We hope that all valuable originals will find their way eventually to the keeping of the Royal Astronomical Society, which now undertakes this important duty.

This volume shows that Dr. Roberts has spared neither himself nor his purse in fulfilling the task he set himself to do, more than ten years ago. By the great labour and devotion he has shown for many years in carrying out his carefully considered plans, he has set a model for others to follow in taking up a research of this kind, of which there are so many in astronomy, that from the nature of the case can only be well done by those who, like him, undertake it solely as a labour of love.

A. A. COMMON.

DEAF-MUTISM.

Deaf-Mutism. By Holger Mygind, M.D., Copenhagen. (London: F. J. Rebman, 1894.)

A FEW months ago, in noticing "The History of American Schools for the Deaf," we spoke of the treatment of deaf-mutes, and regretted the fact that we hear so little of that work in England. Before us we have another book, again of foreign origin, in which is described, exhaustively and systematically, the pathology of deaf-mutism. The materials used in its compilation are almost entirely obtained from Denmark, and, although published in England, and revised by an English specialist of note, the book may be said to have a somewhat foreign flavour. With the exception of special chapters upon the subject in Wilde's, Field's, and Toynbee's works on diseases of the ear, little is to be found in English writings, and there are no books dealing solely with deaf-mutism written by Englishmen. This may, perhaps, be accounted for by the fact that in the table of recent statistics of the distribution of deaf-mutes in various countries, England and Wales stand twentieth in a list of twenty-three, showing only fifty-one of these unfortunates per thousand inhabitants. Ireland and Scotland stand higher in the table, with seventy-seven and fifty-seven per thousand respectively. Still, even with the happily low rate of deaf-mutism in this country, it is a matter for regret that no Englishman has produced a work upon the subject.

Dr. Holger Mygind performs his task very well. To begin with, he arranges it in a systematic manner, and treats each part as exhaustively as lies in his power. Devoting his introduction to definition, literature, classification, and distribution, he gives evidence of considerable patient research. In discarding the classification of deaf-mutes according to the degree of its symptoms for that according to its etiology, he does wisely, the former being as unscientific as it is misleading. It is a pity that "Creed" should have been included under the heading "Distribution," since Dr. Mygind shows that the apparent greater frequency among certain religions is, as one would expect, really due to the relative numbers of persons professing such religions; while the well-known fact that the Jews produce a larger number of blind, idiotic, and deaf-mute individuals than the races among which they live, is due, doubtless, to the consanguineous marriages practised by the Hebrews.

Perhaps the most interesting part of the work (the whole of which cannot be otherwise to the student of pathology) is the chapter which deals with etiology and pathogenesis, and in which such conditions as climate, water, hygiene, heredity, and the like are discussed. With regard to heredity, Dr. Mygind brings forward a series of facts (the collection of which must have caused considerable labour) referring to the appearance of deaf-mutism and other pathological conditions among the relatives of deaf-mutes, and from these facts endeavours to formulate some definite laws concerning the heredity of deaf-mutism. These laws, it is stated, are difficult of interpretation, and seem in many respects to differ from those which relate to other pathological conditions and diseases, a fact to be accounted for by the number and variety of the causes of deaf-mutism, and consequently of the causes of each individual case. The matter is further complicated by the presence of factors, equally important, which tend to neutralise the transmission of morbid tendencies. It appears that deaf-mutism is, in many instances, the combined result of the transmission of various influences which fall into two groups—those which originate in ear diseases, and those which originate in nervous diseases in the family.

The material from which the chapter on morbid anatomy is based is formed from the reports of some 139 autopsies, the principal of which are collected in an appendix. The morbid changes in the ear are classified under the heads of external ear, middle ear, and labyrinth. From the evidence here collected, it seems that the pathological conditions differ rather in extent and intensity than in quality from those generally found in ear diseases, and, from appearances alone, it is in many cases impossible to decide whether the changes are of fœtal or post-fœtal origin. Dr. Mygind sums up the question of pathology in these words: "Deaf-mutism is, therefore, from an anatomical point of view, in most cases to be considered as a result of an abnormality of the labyrinth."

We congratulate Dr. Mygind upon the successful completion of a task which must have been at once laborious and interesting. To the pathologist, whether general or special, the work cannot fail to be a source of interest, and it is to be hoped that the work done by the author in thus bringing together so much that is known upon the subject will be productive of good.

P. Macleod Yearsley.

OUR BOOK SHELF.

A Text-book of Physiological Chemistry. By O. Hammarsten, Professor of Medical and Physiological Chemistry in the University of Upsala. Authorised translation from the second Swedish and from the Author's enlarged and revised German edition, by J. A. Mandel, Assistant to the Chair of Chemistry, Bellevue Hospital Medical College, New York. (New York: John Wiley and Sons, 1893.)

Prof. Hammarsten is so highly esteemed for his work and views on the more specially chemical side of physiology, that a text-book from his pen was looked for with keen anticipation. Unfortunately a knowledge of the Swedish language is not as yet an accomplishment possessed by more than a favoured few, however essential it may become in the future, so that when his text-book first appeared its contents were largely inaccessible to the majority of would-be readers. As a consequence of this, Prof. Hammarsten was asked by numerous colleagues to provide a German version of the first Swedish edition. Unable to comply with this earlier request, he yielded to a strongly renewed similar proposal after the appearance of the second Swedish edition, and in 1890 he published the work in German, translating it himself. In its German dress the text-book is so well known and approved that detailed criticism or renewed commendation is now scarcely necessary. Written "to supply students and physicians with a condensed and as far as possible objective representation of the principal results of physiologico-chemical research, and also with the principal features of physiologico-chemical methods of work," the book was not regarded by its author as "complete or detailed" from the point of view of the specialist. Clear, yet concise, and dealing not only with the well-known facts and methods of physiological chemistry, but also with the more important points of pathologico-chemical interest, this work is peculiarly suited for the student while going through a course of laboratory instruction. From this point of view the present English version should be widely welcomed. The translation has been made without additions or changes from the author's German edition and the original Swedish. Judged by a comparison with the German, the translator must be congratulated on the way he has done his work. While adhering very closely and literally to the original, the translation reads well and is free from the awkward and often clumsy expressions which frequently result from attempts to render German phrases too closely into English equivalents.

After a short introduction (chapter i.), treating in a general way of some of the more important chemical processes and agents which have to be dealt with in the living body, the next twelve chapters give an account of proteids, the animal cell, blood, chyle, lymph transudations and exudations, the liver, digestion, connective tissues, muscle, brain and nerves, organs of generation, milk, the skin and its secretions. Chapter xiv., the longest and one of the most important in the book, is on urine. Here, from the practical importance of the subject, the treatment is more elaborate than in the preceding chapters, more especially as regards details of analytical methods and urinary analysis. Here also, as in the other chapters, the analytico-chemical parts are distinguished from the rest of the text by special type, an excellent plan which facilitates the work of those who may wish merely to learn what is most definitely known of the substances and processes of the animal body. The last chapter contains a concise but clear account of the more important facts of the exchange of material (Stoffwechsel) or metabolism, and of its relationship to various foods and to the conditions of starvation, exercise, rest, &c. Some useful tables of the composition of various foods are placed at the end of this chapter, and, after the index, which is full and carefully made, a plate is given of the more common and important absorption-spectra.

Electricity, Electrometer, Magnetism and Electrolysis. By G. Chrystal, M.A., LL.D. and W. N. Shaw, M.A., F.R.S. (London: A. and C. Black, 1894.)

THE present cheap reprint of these articles from the Encyclopædia Britannica should meet with a hearty welcome from all students of electricity and magnetism, and more especially from those who are desirous of extending their acquaintance with the science beyond the limits of ordinary elementary text-books. Such students generally find a difficulty in selecting a work from which to read the higher parts of the subject. Maxwell's treatise is too mathematical for the majority of students; one work is, perhaps, too technical in character, while another deals too exclusively with practical measurements. The division of the subject after the first stages into mathematical and technical branches is certainly a natural one, and corresponds in some measure with the requirements of students. It does not, however, lighten the labours of those who wish to obtain a grasp of general theory and experiment without being cumbered with the details of machines on the one hand, or degenerating into pure mathematics on the other. For such students the articles of Prof. Chrystal and Mr. Shaw help to fill a gap left behind by the existing text-books. The historical, experimental, and mathematical portions are nicely balanced, and together form an epitome of the whole subject, which is made more valuable by the addition of references to original papers and standard works. The student will find it both a guide and a key to his reading, and by looking up its references he may pursue the subject to any desired degree of detail.

In the interval which has elapsed since the first publication of the articles, knowledge has been accumulated, and it is a matter for regret that the circumstances of the present issue do not permit of the articles being brought up to date. The absence of all reference to the work of Hertz in electricity, and of Ewing in magnetism, is attributable to this cause; while Mr. Shaw's Reports to the British Association show that much work has been done in connection with electrolysis since his article was written. Similarly in Electro-metallurgy—an article which, by the way, is not specified on the title-page—considerable progress has to be reported.

Apart from these additions, there is one point in Prof. Chrystal's article which might be improved, namely, the definition of the statical unit of electricity (p. 21). It ought to be stated that the force exerted on the conductors carrying the charges is measured *in vacuo*. Indeed, it would be better to introduce the idea of specific inductive capacity at this point, and so avoid a certain amount of confusion between electric induction and electric force in the following pages. The same remarks apply to the unit of magnetism (art. "Magnetism," p. 227). But although it is easy to criticise past writings in the light of present knowledge, we venture to think that the articles before us will stand a far more severe test than many works written at a later date.

JAMES L. HOWARD.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Velocity of the Constantinople Earthquake-Pulsations of July 10, 1894.

ACCORDING to the accounts so far published, it would appear that the epicentrum of this earthquake was situated under the Sea of Marmora, at a short distance from San Stefano; but, for the purpose of this paper, no very sensible error will be introduced by assuming it to coincide with Constantinople itself.

To ascertain the time at the origin, I applied to M. Coumbary, director of the Meteorological Observatory at Constantinople, and to Mr. W. H. Wrench, H.M. Consul-General in that city. M. Coumbary informs me that the first great shock was felt at 12h. 24m. p.m. Constantinople mean time (or 10h. 28m. a.m. Greenwich mean time); its direction was from south-west to north-east, and its duration eight to ten seconds. A second shock, lasting three seconds, followed immediately; and a third, of one second duration, at 12h. 31m. A number of slight shocks succeeded these, but I have received no certain record of them from distant stations. Mr. Wrench kindly made inquiries of several watchmakers in the city. Two regulating clocks were stopped by the principal shock, one at 12h. 20½m., the other at 12h. 21¾m.; both, according to their owners, having previously indicated correct local time.

The earthquake was felt at Bucharest, and it was also registered by a horizontal pendulum at Nicolaiew, and by magnetic instruments at Pola, Potsdam, Wilhelmshaven, Utrecht, Parc Saint-Maur, and Kew. In the following summary the times are reduced to Greenwich mean time:—

Bucharest (Dr. S. C. Hepites).—A very slight shock was felt at 10h. 30m. 11s. a.m., of intensity 3 (Rossi Forel scale), direction from east to west. Two pendulums, placed on north-south walls at the Meteorological Institute, were stopped.

Nicolaiew (Prof. S. Kortazzi).—The curve traced by the horizontal pendulum was suddenly broken at 10h. 30m. 36s. a.m.; the pendulum itself was thrown out of position, and was found afterwards leaning against one of the side-supports.

Pola (Dr. S. Muller).—The declination curve shows two disturbances, at 10h. 36m. 37s. and 10h. 41m. 37s. a.m. The movements indicated on the bifilar and Lloyd's balance curves are very slight.

Potsdam (Dr. Eschenhagen).—First shock at 10h. 34m. 44s. a.m., amplitude ½′; second shock at 10h. 36m. 24s., amplitude 9–10′; third shock (slight) at 10h. 41m. 14s.; all three registered on the declination curve.

Wilhelmshaven (Dr. C. Börgen).—The needles of two instruments (declination and Lloyd's balance) oscillated so strongly that the light-point for some time made no impression on the paper. Declination: from 10h. 37m. 55s. to 10h. 43m. 25s. a.m., gap in the curve, oscillations perceptible till 10h. 49m. 55s.; the needle then became steady, but oscillations were again visible from 10h. 52m. 25s. to 10h. 56m. 25s. Bifilar: magnet in oscillation from 10h. 38m. 55s. to 10h. 44m. 55s. Lloyd's balance: from 10h. 38m. 25s. to 10h. 47m. 55s., gap in the curve, then till 10h. 54m. 25s. oscillations traceable.

Utrecht (M. M. Snellen).—The magnetic curves show a disturbance beginning at 10h. 37m. a.m., reaching a maximum at 10h. 41m., and followed by a second maximum at 10h. 52m. 46s.

Parc Saint-Maur (M. Moureaux).—The pulsations are registered on the magnetic curves at 10h. 40m. a.m. They are most marked on the bifilar curve, and much less appreciable on the vertical force curve. The declination curve shows a second movement seven or eight minutes after the first. The gravity-barometer curve indicates a slight depression of the mercury at the moment of the principal shock. The two copper bars, with bifilar suspension, orientated north-south and east-west, were undisturbed by the shock.[1]

Kew (Mr. C. Chree).—There is a very slight movement on both the horizontal force and declination curves, from 10h. 41m. to 10h. 46m., that on the former being the more conspicuous. The vertical force curve shows no disturbance.

In the following table are given the velocities of the earthquake-pulsations obtained from the different records. The epoch used in each case is the beginning of the pulsations, and the initial time that given by M. Coumbary.

Place.	Distance from epi-centrum in km.	Time-interval in secs.	Velocity in km. per sec.
Bucharest	416	131	3·18
Nicolaiew	707	156	4·53
Pola	1303	517	2·52
Potsdam	1742	504	3·46
Wilhelmshaven (Declination)	2097	595	3·52
,, (Bifilar)	,,	655	3·20
,, (Lloyd's balance)	,,	625	3·36
Utrecht	2185	540	4·05
Parc Saint-Maur	2240	720	3·11
Kew	2518	780	3·23

The average velocity of the pulsations of the principal earthquake obtained from the above ten records is 3·42 ± ·12 km. per sec.[2] A more reliable estimate will probably be obtained by omitting the records from Nicolaiew and Utrecht; the former because the horizontal pendulum is far more sensitive than the magnetographs, and the latter because the time given is that of the beginning of the small pulsations. The remaining records (of the beginning of the large pulsations) give for the average velocity 3·20 ± ·07 km. per.sec.

This value agrees very closely with that obtained for the pulsations of the Greek earthquake of April 27, 1894, namely 3·21 ± ·07 km. per second (Report of the B.A. Earth Tremor Committee, 1894), and also with several values determined by Dr. von Rebeur-Paschwitz. It hardly differs, again, from the average velocity between Constantinople and Bucharest, showing that the pulsations and the vibrations which constitute the shock, even if they were independent, travelled at about the same rate.

There is some doubt as to the identity of the second group of pulsations recorded on some of the curves with one another or with one of the earthquakes at Constantinople. Those at Wilhelmshaven and Utrecht seem to follow by too long an interval to be due to the third shock at 10h. 35m. a.m. G.M.T. It is not impossible, however, that the second group at Pola, Potsdam, and Parc Saint-Maur may be connected with this earthquake. If this be the case, the velocity of the pulsations to these places would be 3·28, 4·79, and 2·99 km. per second, respectively, and the average of the three 3·69 km. per second.

CHARLES DAVISON.

King Edward's High School, Birmingham.

[1] It has been inferred, from the steadiness of the copper bars, that the movement of the needles is of magnetic and not of mechanical origin (see *Comptes Rendus*, vol. cxix. 1894, pp. 251-252, and NATURE, vol. l. 1894, p. 394). But is not the centre of gravity of the copper bar equidistant from the two points of support, and that of the declination needle nearer the south support (in order that the needle may rest horizontally)? And, if so, might not the movement be of mechanical origin? (See *Geol. Mag.* vol. ii. 1885, pp. 210-211).

[2] With the initial times as given by the two stopped clocks mentioned by Mr. Wrench, the corresponding values of the velocity would be 2·30 and 2·56 km. per sec.

Photo-electric Phenomena.

A SHORT time ago, a report was given in NATURE (vol. xlix. p. 226) of modern researches respecting the photo-electric discharge of negatively electrified bodies. But no mention was made of our investigations on the same subject, although they were published in a series of articles, from 1889 to 1894, in *Wiedemann's Annalen* and in the *Wiener Berichte*. As the results of these researches seem to be unknown to English physicists, we enumerate them here in brief, in the hope that they will prove of some interest.

Well-cleaned plates of aluminium, magnesium, and pure or amalgamated zinc are, when negatively electrified, discharged in a few seconds by the light of the sun and the cloudless sky. The active rays extend from the blue part of the spectrum to the farthest ultra-violet, so that the active rays are almost completely absorbed by transmission through glass. Hence a well-amalgamated ball of zinc connected with Exner's aluminium-leaf electroscope may be used as a photometric apparatus to settle the amount of ultra-violet radiation emitted by the sun and the sky which reaches the earth's surface. Measurements of this kind were made by us in 1890, during June in Wolfenbüttel, and during July on the top of the Sonnblick. The discharging power of sunlight at a level of 3100 metres (*i.e.* on the Sonnblick) was found to be twice as great as at a level of 80 metres (Wolfenbüttel), corresponding to the greater proportion of blue and ultra-violet rays. These results are in conformity with Langley's well-known researches on the absorption of the blue sunlight by the atmosphere.

The more electro-positive a metal is, the larger the wave-length of light capable of producing a photo-electric discharge. Photo-electric cells of high sensibility were therefore made by using cathodes of metallic sodium, potassium, and rubidium, arranged in a glass bulb, and dipping in an atmosphere of rarefied hydrogen. The leakage of negative electricity from a sodium or potassium surface is produced even by the light of a candle at six or seven metres distance from the cell, and rubidium-cells are sensible to the weak light sent out from a red-hot glass-rod.

The photoelectric discharge by the action of ordinary daylight is also shown in a clear way by some *non-metallic* bodies, *e.g.* by the phosphorescent combinations of calcium with sulphur, and by the dark-coloured kinds of fluorite. Other minerals show traces of the same phenomenon. It is, therefore, probable that the sunlight and the daylight cause the negative electricity of the earth's surface to be partly dissipated into the air. If this theory were correct, it would give a foundation to the explanation of the daily and yearly variation of atmospheric electricity. For three years we have together made measurements respecting the ultra-violet radiation of the sun and the amount of atmospheric potential at the same time, and the results agree with this supposition.

By using the liquid alloy of potassium and sodium, which, in an atmosphere of rarefied hydrogen, shows a reflecting surface, we are able to study the influence of polarised light upon the photo-electric discharge. The maximum intensity of the photo-electric current is observed when the plane of polarisation is perpendicular to that of incidence.

The photo-electric discharge is sensitive to exterior magnetic influences in a similar way to the luminous discharge in a Geissler's tube. In a strong magnetic field it almost entirely ceases.

Electrical vibrations set up by the Hertz vibrator pass through a Geissler tube provided with an alkaline metal electrode far easier in daylight than in darkness. With a sensitive arrangement the weakest traces of light are sufficient to start the luminous discharge.

In one case the disruptive electrical discharge *ceases* when light is applied. If the sparks of an influence machine are allowed to pass between a brass ball as anode, and the cleaned surface of an amalgamated zinc disc as cathode, they *disappear* in the presence of magnesium light. And if the distance between ball and plate be enlarged, the magnesium light will also hinder the formation of positive electrical brushes.

[*Cf. Wiedemann's Annalen*, Bd. 38, p. 40; 38, p. 497; 39, p. 332; 41, p. 161; 41, p. 166; 42, p. 564; 43, p. 225; 44, p. 722; 46, p. 281; 48, p. 625; 52, p. 433; and *Wiener Berichte*, Bd. 101, p. 703. March 1892.]

J. ELSTER.
H. GEITEL.

Wolfenbüttel, August 12.

A Remarkable Meteor.

ON the evening of August 26 (Sunday) I saw what was to me an unprecedented sight: a brilliant and curious "meteor" fell near Gloucester. Starting from a point a little to the west of κ "Draco," at 10h. 19m., falling in the direction shown in Fig. 1, through about an angle of 40°; when it reached point X,

FIG. 1.

it appeared to melt, and its path from X to Y was marked by a most brilliant stream of light, equalling in intensity a magnesium flame.

This luminous streak from X to Y remained stationary and brilliant for nearly two minutes; then the lower extremity gradually curled around, forming the letter J, as shown in Fig. 2; the ends gradually converged until they met, forming a somewhat irregular band, and travelling in the path indicated by the arrow in Fig. 2.

As it traversed the heavens it seemed like a phosphorescent or nebulous cloud, finally assuming the shape shown in Fig. 2;

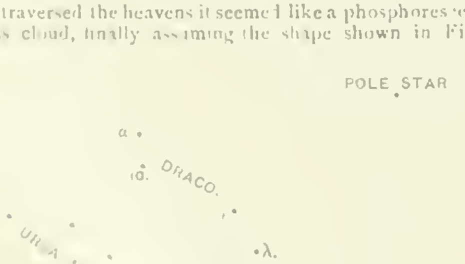

FIG. 2.

between κ and λ "Draco," then gradually becoming fainter and fainter, until at 10h. 41m. just twenty-two minutes after the "meteor" fell it became invisible, at a point as much to the eastward of κ "Draco" as the "meteor" had started from the westward of it. I should like to know if any of your readers have seen a similar phenomenon, or if it is of common occurrence.

JOHN W. EARLE.

Gloucester, August 27.

A New Rhynchobdellid.

IT seems hard to believe that a leech, common and abundant and possessing a chitinous dorsal scute, should have hitherto escaped notice. But Jackson, in his edition of the "Forms of Animal Life," does not refer to such a structure, nor does Lang, and I do not find notice of it in more recent literature. In the hope that I am not adding a needless synonym, I give a short description of the animal, of which a detailed account is in preparation.

(*Glossiphonia?*) *scutifera*, n. sp. Sub-cartilaginous, semi-transparent, greenish grey above, paler beneath; obscurely striated above, with a row of dark spots on either side of the middle line. Body widest about 40th annulus, tapering thence abruptly to the disc and gradually to the head, which is narrowest, and not marked off from the succeeding annuli. Annuli 64, ganglia 22. Length in full extension about 1 inch, at rest 3-8ths of an inch. Eyes two in centre of head. Genital apertures behind 21st and 23rd annuli. The 9th annulus is broader than its neighbours, and carries on the hinder part of its richly glandular dorsum a chitinous plate slightly elongated transversely, covering about an eighth of the width of the annulus; in young specimens the margins are overlapped by the integument. Anus dorsal.

This species is meanwhile referred to Glossiphonia, to which it bears a general resemblance.

JOHN YOUNG.

Glasgow University, August 28.

The Bleaching of Beeswax.

CAN any of your correspondents inform me how to bleach beeswax chemically, satisfactorily, and at a moderate cost?

August 28.

J. S. D.

SUNSHINE AND WATER-MICROBES.

THE bactericidal action of light is perhaps of most general hygienic significance in connection with the fate of micro-organisms in water, and there is ample field open for investigation in this direction, which so far has been but little explored. It is, therefore, with especial interest that we note Prof. Buchner's important contribution to this subject in the *Archiv fur Hygiene.* The title of the paper ("Ueber den Einfluss des Lichtes auf Bacterien und uber die Selbstreinigung der Flusse") already indicates that the practical aspect of the question has been considered, and indeed several experiments have been planned and carried out with the object of ascertaining what is the part played by sunshine in the alleged bacterial purification which takes place in river-water during its flow.

In the first series of experiments samples of boiled tap-water were inoculated with three drops of broth-cultures of the typhoid bacillus, *B. coli communis* and *B. pyocyaneus* respectively. The typhoid bacilli, even in diffused daylight, were reduced in numbers from 7400 per c.c. to start with, to 5000 at the end of one day, whilst on the second day none whatever were found. The *B. coli communis* sample had only 220 left on the third day, out of 22,000 at the commencement of the experiment, and was sterile on the fourth day; the *B. pyocyaneus* was, however, hardly affected at all during four days' exposure to diffused light.

The direct rays of the sun, however, were far more destructive. Thus about 30 c.c. of a sample of typhoid-infected water, placed in glass dishes and exposed to sunshine, contained no typhoid organisms at the end of six hours, and similar results were obtained with the *B. pyocyaneus*.

In all these experiments the perfectly admissible objection could be urged that the diminution in the numbers present might, at any rate in part, be attributed to a process of starvation in consequence of the absence of food-material, inasmuch as a marked decrease was also observed in those samples kept in the dark. To meet this objection, in the next series unsterile water was used, and to a litre and a half as much as 1 c.c. of the broth-culture of the particular organism was added, thus affording ample provision, both in light and darkness, for the support of the bacteria under observation. Instead of a decrease taking place in the samples kept in the dark, the numbers rose; on the other hand, in the samples placed in the sunshine, three hours' exposure in the case of the typhoid, colon, and pyocyaneus bacilli brought about their entire destruction, thus placing beyond doubt the direct bactericidal action which had taken place during insolation.

The amount of water used being small, no indication was given, in these experiments, of the *depth* to which the bactericidal action of the sun's rays could extend. Fol and Saracen ("Sur la pénétration de la lumière du jour dans les eaux du lac de Genève," *Comptes Rendus*, 1884) have shown by the exposure of gelatine-bromide plates that daylight penetrates to a depth of 170 metres in the water of the Lake of Geneva, the degree of light at this depth being about equal to that which we find during a bright but moonless night, whilst at a depth of 120 metres the strength of light is still considerable. These investigators also made the curious observation that in the experiments they conducted, the light penetrated far deeper into the water in September, during cloudy weather, than in the month of August with a perfectly clear sky. Thus not only does the power of light vary at different depths and, doubtless, in different waters, but it is also influenced by the time of year; and what, therefore, may be correct of a given water under certain circumstances, may not necessarily apply to it on another occasion, and hence a good deal of uncertainty attaches to the exact degree of light capable of transmission in any particular mass of water.

Prof. Buchner has endeavoured to ascertain at what depth in the water of the Starnberger Lake, near Munich, light ceases to have any *bactericidal* action. For this purpose he used his well-known process (described in the *Centralblatt für Bakteriologie*, vol. xii. August 1892) of exposing partially protected agar-agar dish cultures. This ingenious method consists in covering over parts of a glass dish containing agar-agar, in which certain varieties of bacteria have been evenly distributed, with variously-shaped strips of black paper or lead, so that the light is screened from these particular portions of the surface. In this manner the bacteria immediately beneath the covered part of the culture-medium are protected from the antiseptic action of light, whilst the rest of the agar-agar and its contents is freely exposed; the result of which is that, in the shaded part of the dish the colonies make their appearance, but in the remainder, having been subjected to the action of light, no bacterial growths, or only very feeble ones, are visible. This is beautifully exhibited in a few days' time by the shape of the black letters or other figures being sharply delineated by the abundant growths which have taken place beneath them from the blank remainder of the dish where nothing is visible, no colonies having developed.

Recently infected agar-agar dishes, partially screened with a leaden cross, were lowered to particular depths in the Starnberger Lake. The day selected was very fine and sunny, and the exposure was continued for 4½ hours, the temperature of the water being 15° R. The site was the starting-place of the steamers, and the water was not quite clear, this being doubtless due to the disturbance caused by the plying to and fro of the vessels.

It would have been more striking, perhaps, if Prof. Buchner had used only one variety of organism throughout, as then all chance of characteristic individual differences disturbing the progressive results would have been obliterated.

The following table shows the results obtained:—

Depth of the dish in the water.	Particular organism employed.	Development of the colonies.	
		In the shaded portion of the dish.	In the exposed part of the dish
0·1 m.	Cholera	Very strong	None
1·1 m.	*B. pyocyaneus*	,,	,,
1·6 m.	Typhoid	,,	,,
2·6 m.	*B. pyocyaneus*	Decidedly stronger than in exposed portion	Fairly strong
3·1 m.	Typhoid	Slightly stronger than in exposed portion	Strong

At a depth of 1·6 m. the bactericidal action of the sun's rays, as shown by this method, is equal to that produced outside the water; but at 2·6 m., however, the action is much less apparent, and in fact is only just perceptible. Thus, as has been suggested elsewhere,[1] the antiseptic potency of the sun's rays ceases a long time before the light becomes affected by the depth of water it has to traverse.

These experiments are of particular interest and importance, because they show very clearly that the agency of light in purifying water cannot be regarded as of much importance. So much stress has recently in Germany been laid upon the self-purification of river-water, that the advisability of permitting the sewage of cities of the magnitude of Cologne to pass untreated into the Rhine, has been publicly discussed on the assumption that in its subsequent flow all objectionable matters will disappear, one of the agencies cited as materially assisting in this magic destruction being sunlight. It is, however, sufficiently apparent that the action of light can only affect a very small fraction of the whole mass of water, for we know that bacteria exist in large numbers at depths very considerably below those which insolation can embrace, whilst there are only a few months in the year, at any rate in our northern climes, when the sun's action is sufficiently strong or prolonged to produce any appreciable effect even in the upper layers of the water.

Prof. Buchner concludes his paper with some investigations carried out by his assistants on the River Isar, 10 km. above Munich. These experiments were made to ascertain if any increase from the number of organisms present during the daytime takes place in the night, as in the absence of light might reasonably be anticipated. Dr. Minck and Dr. Neumayer, therefore, undertook on a September night to abstract samples from the river at ¼ m. below the surface at intervals of from 1–2 hours from 6 o'clock in the evening until 6 o'clock the next morning. The temperature of the water during this time only varied between 9°–10° R., and the samples were examined immediately after collection. The results are recorded in the following table:—

Time of taking sample.	Number of microbes in about 20 drops of water.
6¼ evening	160
8¼ ,,	5[2]
11 ,,	8[2]
12 ,,	107
1¾ morning	380
3 ,,	460
4 ,,	520
5 ,,	510
6¼ ,,	250

It would be interesting to have further confirmation of the results here given, other factors having doubtless assisted besides the absence or presence of light; but the arduous nature of the experiments will doubtless greatly militate against such a series being sufficiently often made to permit of any definite conclusions being arrived

[1] "Bacterial Life and Light," *Longman's Magazine*, September, 1893.
[2] No explanation is offered for these abnormally low figures.

at. In this connection, it may also be noted that in the year 1886 the Thames water at Hampton contained twenty times as many microbes in the winter as were found in the summer months. Here again the consideration of other agencies also tending to influence the bacterial condition of the river water cannot be excluded, but sunshine undoubtedly assisted in the banishment of the microbes. G. C. Frankland.

NOTES.

The Municipal Council of Paris has opened competitions for the best means of suppressing or diminishing the smoke of cities, and of purifying water. To the author of the best memoir on the former subject, the sum of ten thousand francs will be given, and two other prizes will be awarded of five thousand and two thousand francs respectively. The memoirs must be sent in before November 1. Prizes varying from one thousand to three thousand francs will be awarded for the processes of water purification which give the best results. Papers relating to this must reach the Council before September 15.

The death is announced of Dr. Karl Neumann, Professor of Chemistry in Zurich Polytechnic School, at the age of forty-three.

We learn from the *Athenæum* that Father Epping, S.J., died on August 22. He was one of the highest authorities on Assyrian astronomy and chronology, on which subject he published, in conjunction with Father Strassmaier, a valuable treatise some years ago.

The tenth International Congress of Orientalists was opened at Geneva on Tuesday. Fourteen Governments, and ninety-seven Universities or learned societies, have sent delegates to the meeting.

The International Congress of Hygiene and Demography is now being held at Budapest. We hope to give a report of the proceedings after the meeting has ended.

The Association Géodésique Internationale met at Innsbruck yesterday. M. Faye, M. Bouquet de la Grye, and M. Tisserand were delegated by the Paris Academy of Sciences to attend the meeting.

The International Meteorological Committee held its meeting, as arranged, at Upsala, August 20-24. M. Wild, the president, was unfortunately prevented from attending, owing to indisposition. M. Mascart was elected president for the meeting, and Mr. Scott, as usual, secretary; the other members present were Prof. v. Bezold (Berlin), Dr. Billwiller (Zürich), Mr. W. G. Davis (Cordoba), Dr. Hann (Vienna), M. Hepites (Bucharest), Dr. Hildebrandsson (Upsala), Prof. Mohn (Christiania), Dr. Paulsen (Copenhagen), M. Snellen (Utrecht), and Prof. Tacchini (Rome); the absentees were, in addition to the president, Admiral de Brito Capello (Lisbon), owing to health, and Messrs. Eliot (Simla), Ellery (Melbourne), and Harrington (Washington), owing to distance. The principal points dealt with at the meeting were as follows:—(1) The establishment of an International Meteorological Bureau was recognised as impracticable. (2) It was resolved to publish in the report of the meeting a *résumé* of the measures adopted in all countries to communicate to agriculturists meteorological results likely to be useful to them. (3) The acceleration of meteorological telegrams. It was decided to address the International Telegraphic Bureau at Berne on this subject. (4) The scintillation of stars as an indication of weather. A paper by M. C. Dufour will be reproduced in the report. (5) The study of clouds. This was the *pièce de résistance* at the meeting. The Cloud Committee, appointed at Munich in 1891, held a meeting at the same time as the International Meteorological Committee, and presented a report dealing with definitions for the ten classes (Hildebrandsson and Abercromby) adopted at Munich, and with instructions for cloud observations. They also proposed to prepare and issue an authoritative cloud atlas. This report was carefully discussed and, after modification, adopted. The members of the Cloud Committee who were present at the meeting, were Prof. Hildebrandsson, Dr. Hann, Prof. Mohn, Mr. A. L. Rotch (Blue Hill Observatory), M. Teisserenc de Bort. In addition, the following gentlemen were admitted, but without voting power: Prof. v. Bezold, Dr. Billwiller, and Mr. Davis (of the International Meteorological Committee), and Prof. Broounof (Kieff), Dr. Fineman and Dr. Hagström (Upsala), Prof. Riggenbach (Basle), Prof. Sprung (Potsdam), and M. Philip Weilbach (Copenhagen). (6) The subject of the treatment of the wet bulb below the freezing point was discussed, and the use of Ekholm's formula was recommended *ad interim*. (7) It was decided to arrange for a conference of the same character as that at Munich in 1891, which was not an official congress, to be held in Paris in September 1896. M. Mascart and Mr. Scott were requested to make the necessary preparations, such as the arrangement of the programme, &c.

The great pine forest region in the States of Minnesota and Wisconsin has been devastated by fire. There had been no rain in the district for nine weeks, and the trees had therefore become very dry and inflammable. Forest fires occurred in the early part of last week, but their advance was checked. On Friday, however, several fires broke out almost simultaneously, and the flames spread with alarming rapidity. Many towns and villages were entirely destroyed, and it is estimated that nearly one thousand lives were lost.

A recent number of the official organ of the National Department of Hygiene in Buenos Ayres, a copy of which has been sent to us, calls attention to a hygienic exhibition which is to be held in that city at the close of this month. The authorities hope that it may render important service in helping to establish a permanent museum of practical hygiene, besides stimulating public interest in sanitary questions generally. The journal also contains many useful notices of original work published in various foreign papers.

The current numbers of the *British Medical Journal* and the *Lancet* should be obtained by everyone desirous of entering the medical profession. They are almost entirely devoted to descriptions of the universities, corporations, and colleges which grant the degrees and diplomas required by a medical practitioner. Prospective students will find our contemporaries complete guides to the medical calling. They will also find that to succeed in this noble profession it is necessary that a man "should be imbued with a love of humanity and a love of science, and should be indifferent to the worship of the god of the modern world—the golden calf. No man whose aim is to make a fortune should dream of entering the medical profession. Let him learn the grocery business or the drapery business; he will not only fail in medicine, but will help to degrade it." These remarks are applicable to students of most branches of science.

Some years ago, an observatory was established on the Saint-Jacques tower in Paris, under the direction of M. J. Jaubert. The institution is of a private nature, but it is furnished with good instruments, and has from time to time issued useful bulletins. An interesting report upon the atmosphere of Paris is published in the supplement of *La Nature* of August 25, based on the observations made between July 1, 1891, and December 31, 1893, which shows very clearly the influence exerted on meteorological elements by a large mass of houses. M. Jaubert had compared the observations at his own observatory with those at the official observatory at Parc Saint-Maur, in the suburbs of Paris. The tables show that the variations of pressure between the two places are very small, but that temperature, especially towards the evening, is from 3 to 4° F. higher in the city, while the maxima and minima occur some hour or two later than in the country. The amount of cloud has this peculiarity, that during the evening the sky is clearer over Paris than in the suburbs. All other elements, rainfall, wind, &c., have been compared, and some interesting details as to visibility are also given. We published some time since (vol. xlix. p. 460) a similar comparison with reference to the temperature of Berlin. Such statistics are of great practical value, especially to persons living near large towns.

AMONG some of the old German legends concerning the weather, the recent meteorological conditions experienced in Göttingen and its neighbourhood have turned nearly everyone's mind to that very old one called the "seven sleepers," or "Die Siebenschläfer" That such a belief should still be held to these old legends is not to be wondered at, even in these days of forecasts, &c., for were they not to a great extent founded on real, although roughly observed, facts which had been noticed over the space of many years, and at last become legendised? The legend of the Siebenschläfer runs as follows:—Seven Christian youths, Maximianus, Malchus, Serapion, Dionysius, Johannes, Martinianus, and Konstantinus, in the reign of King Decius, 251, fled to the mountains because they would not follow the Jewish religion. In a mountain called Kalion, near Ephesus, they found a large cave, into which they entered, slept, and ultimately became shut in. It was not till the year 446, under the reign of Theodosius, that this cave was accidentally opened, and the seven sleepers woke up from their long sleep of nearly 200 years, Bishop Martin and the king being both witnesses to this wonder. The Christians died eventually surrounded with glory and honour. The saying which has come down to us to-day, and which, curiously enough, connects these holy men with the weather, is that, if it should rain on June 27, we must expect rain for the following seven weeks; this is for the Roman Church. In the Greek Church this day is held on August 4, while the "Acta Sanctorum" name July 27 for its remembrance. It may be of interest, however, to see whether the application of this old legend to the weather recently experienced holds good. Taking the Roman Church Calendar as our reckoning, and commencing on June 27, the seven weeks would then terminate on August 14. Unfortunately rain did not happen to fall on the 27th at the place in question, but records show that both the day before and after it was experienced. On the 29th and 30th also no rain fell, but with the exception of July 6, 29, and 30, rain has fallen daily until August 14. Thus from June 27 to August 14, both days inclusive, a period of 49 days, only six days were recorded without rain, but rain did *not* actually fall on the 27th. One infers from the legend that at the end of this period fine weather should be the order of the day, that is to say, if according to the "Sieben Brüdern" it did not rain on July 10. Unfortunately or not, as the case may be, 1·5mm. on 200 square cm of rain were recorded, which means, according to the latter legend, that it must rain for seven weeks after this date. At the time of writing, August 24 (7 p.m. Central European time), it has rained daily since the 14th, so that the "Sieben Brüdern" seems as if it will be verified. The meteorological records referred to above we owe to Herr A. Spörhase, meteorological observer at the Physical Institute, Göttingen.

AT a recent meeting of the Société Française de Physique, M. Bouty read a paper on the capacity of the capillary electrometer. The author supposes that the two quantities of mercury are brought to a difference of potential e, and that the surface of the mercury in the capillary is brought back to the zero by increasing the pressure, and that a quantity of electricity dQ is then supplied without changing the pressure. The capacity of the apparatus, under these conditions, consists, according to Lippmann's theory, of two parts, one term proportional to the square of $\frac{dA}{de}$ where A is the surface tension and represents the quantity of electricity absorbed or produced by the change in the form of the small surface of mercury, and has the preponderating influence when e is nearly zero. The other term which is proportional to $-\frac{d^2A}{de^2}$ is only of importance when A is near its maximum. In order to measure the capacity C which is equal to $\frac{dQ}{de}$ the author measures separately the corresponding values of δQ and δe within such limits that proportionality exists between these quantities. He produces a constant quantity of electricity (δQ) by means of a piezo-electric piece of quartz, and discharges it into the electrometer, whose capacity may be considered as infinite compared to that of the quartz. He then determines by means of a derivation on the circuit of the charging battery the increase δe of the electromotive force necessary to reproduce the same shift in the mercury as was produced by δQ. In every case the observed values agreed with those deduced by means of Lippmann's theory.

M. W. SPRING, who about fifteen years ago proved the possibility of welding metallic bodies by simple pressure at temperatures far below their fusing point, publishes an interesting extension of his researches in the *Bulletin de l'Académie Royale de Belgique*. He was led to the conclusion that at a certain temperature, where a metal is to all appearances a perfect solid, a certain proportion of the molecules attain a rate of vibration corresponding to the liquid state, and that these molecules, by softening the body, make it capable of welding and of producing alloys with other metals. The metals were put in the shape of cylinders bounded by plane surfaces, upon the purity of which great care was bestowed. They were then mounted in a stirrup, and pressed together by means of a hand-screw. In this state they were placed in a heating oven, and kept at a constant temperature between 200° and 400° for from three to twelve hours. The most perfect joints were produced with gold, lead, and tin, and the worst with bismuth and antimony. Two cylinders thus welded together could be put in a lathe, one of them only being held in the chuck, while the other was being worked upon by a cutting tool, without coming apart. They could be separated with the aid of pincers, but then a rough breakage was produced which did not coincide with the original plane of separation. It appears that the more crystalline the bodies are the less do they exhibit this phenomenon of incipient liquefaction, which begins to show in the case of platinum, for instance, at 1600° below its fusing-point. That such a liquefaction or softening actually takes place was proved by cutting a delicate spiral 0·2 mm. deep on the end surface of a piece of copper weighing 130 grammes, and placing it upon a sheet of mica. After keeping it at 400° for eight hours, the spiral had entirely disappeared, and the surface looked as if just fused before the blowpipe. Where two metals were employed, alloys were formed, which, in the case of lead and tin, were fusible and flowed out at 180°. By placing a perforated disc of mica between the two, the outflow could be prevented, but the alloy formed at the centre and the metals were hollowed out in the proportion of their degrees of liquefaction. In a lead-antimony couple, the hole in the lead was 8 mm. or 9 mm., and that in the antimony 2 mm. The most striking and novel experiments, however, were those showing the evaporation of metals, or rather their sublimation, at temperatures between 300° and 400°. This was also shown by inserting a disc of mica, say, between a zinc and copper couple at 360°. When air was carefully kept away from the surfaces, the copper was tinted a golden yellow over the area of the hole in the mica, the exact colour of tombac, and a brown layer was produced on the zinc, which chemical analysis proved to contain copper. Similar results were obtained with cadmium, the thickness of the mica being 0·8 mm.

WE have received a copy of the *Jahres-Bericht des Vereins fur Naturkunde of Mannheim*, in which a brief account is given of the proceedings of the Society during the years 1889–93 inclusive. It appears that in spite of the population of Mannheim having doubled itself during the past eighteen years, the Society has not increased in numbers. That it should have maintained a bare existence must be considered very creditable to the energy of its members, for we read that Mannheim, as perhaps no other commercial or industrial centre, possesses so few attractions in the shape of social or scientific intercourse that the inhabitants as soon as they can retire from work leave the city to settle elsewhere. A similar nemesis unfortunately overtakes some of our local naturalist societies, and Mannheim cannot claim the unique position ascribed to it by the president of its Naturkunde Verein! The greater part of the pamphlet is occupied by an elaborate paper, by Dr. Migula, entitled "Methode und Aufgabe der biologischen Wasseruntersuchung." The endeavour is made to build up a bacteriological standard of purity for water, not according to the number of microbes, but from an estimation of the particular varieties present in a given sample of water. We are not surprised to find Dr. Migula willing to resign this herculean task to others to work out.

MR. W. A. SANFORD read before the Somerset Archæological and Natural History Society, at its late meeting at Langport, a paper in which he announced his discovery, in the Rhætic beds at Wedmore, of a large Dinosaur. The animal appears to have been carnivorous, and, though very much larger, to have resembled *Megalosaurus Bucklandi* of the Stonesfield slate. The remains at present available for study are about twelve vertebræ, a large portion of the pelvis, some portions of the mandible, some teeth, a nearly complete femur, parts of a tibia and of both fibulæ, some phalanges, including a perfect claw-bone, and fragments of ribs and of other small bones, and other larger fragments that may be placed. The bones are accompanied by fossils of Triassic date, which render their geological position a matter of nearly absolute certainty. The results of a complete and close examination of the bones will be of considerable interest.

IN addition to a preliminary note on some new species of fish, belonging to the genera *Cyprinodon* and *Atherinichthys*, from the Mexican Seas, by Dr. F. Steindachner, the June number of the *Proceedings* of the Imperial Academy of Science of Vienna (1894, No. xv. pp. 147–154) contains a communication from Prof. Weisner upon the results of a physiological investigation upon some interesting points in the germination of the mistletoe and its European and tropical allies (*Viscum* and *Loranthus*). The author finds a considerable difference between the seeds of the European and tropical forms as regards their reaction to light and moisture, and as to the existence or duration of a "resting period." These differences and peculiarities, however, he is in all cases able to interpret as specific adaptations to differences in the natural conditions of life. The viscid envelope of the seeds in all the parasitic species is undoubtedly an adaptation for ensuring the attachment of the seed to the bark of its host; but Prof. Weisner regards its great development in the common mistletoe (*Viscum album*) as also serving to retard the process of germination. There is practically no resting period in the case of the tropical species, and in them the viscid pericarp is developed in much smaller quantity; and the seeds of our own *Viscum album* germinate most readily when freed from their mucilaginous investment. It is to be hoped that Prof. Weisner will publish before long a fuller account of his interesting researches, and that he will also incorporate some statements as to the effects of temperature upon the germination of the same seeds.

IN an elaborate paper "Étude expérimentale sur le charbon symptomatique" (*Annales de l'Institut Pasteur*), Dr. Duenschmann describes some extremely interesting and suggestive experiments which he has made on the effect of associating a virulent with a non-virulent micro-organism in animal inoculations. For this purpose the well-known bacillus *prodigiosus* was introduced into guinea-pigs along with the bacterium *Chauvæi*, the exciting cause of symptomatic anthrax. Under ordinary circumstances the latter microbe will kill guinea-pigs in eighteen hours, but, strange to say, its lethal action is delayed for four days, when it is associated with the *B. prodigiosus*. M. Roger already found that the rabbit, an animal not easily susceptible to symptomatic anthrax, may be readily infected if cultures of the *B. prodigiosus* are introduced along with the *B. Chauvæi*, and similar observations in the case of other disease microbes, associated with this harmless bacillus, have been made by others. Dr. Duenschmann, however, has carried his investigations still further, and has found that the *B. prodigiosus*, usually regarded as an innocent saprophyte, will, if used in sufficient quantities, kill guinea-pigs when introduced into the peritoneum. The chief interest of Dr. Duenschmann's experiments lies in the contribution which they afford to the important subject of the *associated* action of micro-organisms. The bacteriological study of disease has so far been mainly carried on with single varieties of microbes; but it must not be forgotten that in nature infection with a pure culture, or one variety of organism, is the exception and not the rule, and that in working with mixtures of micro-organisms we may obtain much important assistance in understanding the intricate and puzzling course run by so many diseases.

THE annual report of the Russian Geographical Society for the year 1893 is so full, that only in a publication specially devoted to geography would it be desirable even to enumerate the headings of its varied contents. All we can do is to mention the parts which possess general interest. Such are the remarks of M. Obrucheff on the Eastern Gobi between Urga and Pekin, which has the characters of a steppe, but not of a desert, as it receives a regular amount of rain in the summer, and is covered then with grass, while true deserts are found in small limited portions only of its vast area. M. Obrucheff's find of a skull of a rhinoceros, probably *Tichorhinus*, in the lake deposits of the Ordos, in latitude 38° N., is also worth mentioning. E. G. Fritsche's measurements of the magnetic elements in the neighbourhood of Moscow, where an anomalous distribution had been observed, show that the anomaly is due to the presence, at a depth which is estimated at ten kilometres, of large iron masses. M. Komaroff's measurements of the movement of the Zerafshan glacier and the exploration of its former much greater extension, as also his levellings in the Transcaspian territory in the region which is supposed to have been the *Area Palus* of the ancients, promise to yield very interesting results. The yearly reports of both the East and the West Siberian Branches of the Geographical Society are also full of geographical information. In East Siberia, M. Prein has explored the vegetation of the Olkhon Island in Lake Baikal, which offers great interest for its curious mixture of species characteristic of the steppes with purely forest species, and which also contains a number of varieties, either unknown or intermediary between different formerly known varieties. In West Siberia, we notice the steady work of the Meteorological Committee which opened last year, in connection with the Central Meteorological Observatory, eight stations in different parts of the territory; M. Siyazoff's work on the flora of the Ishim Steppes, and its comparison with the flora of Tyumen, at the eastern slope of the Urals; M. Katanaeff's larger work on the Kirghiz Steppes; and Slovtsoff's, on the Pelym region and on the Siberian cedar—all published in the memoirs of the West Siberian branch—are also of interest.

A report, showing the distribution and production of some of the most important minerals worked in India, has been issued by the Department of Revenue and Agriculture of the Indian Government.

The principles of the manufacture of steel are ably described in "Fabrication de la Fonte," by M. E. de Billy, the volume being the latest addition to the Aide-Mémoire series published jointly by Gauthier-Villars and Masson.

The fifth part of Kerner and Oliver's "Natural History of Plants" (Blackie) has been published. Its contents refer to metabolism and the transport of materials, and to the growth and construction of plants.

We have received a paper "On the Analytical Treatment of Alternating Currents," read by Prof. A. Macfarlane before the International Electrical Congress held at Chicago a year ago, and reprinted from the Congress' *Proceedings*.

All regulations referring to the registration and inspection of classes held in connection with the City and Guilds of London Institute are given in the "Programme of Technological Examinations" just published for the Institute by Messrs. Whittaker and Co.

Under the title "Peregrinazioni Psicologiche," U. Hoepli, of Milan, has published a collection of psychological papers by Dr. Tito Vignoli, Professor of Anthropology in the R. Accademia Scienze e Lettere di Milano, and Director of the Museo Civico di Storia Naturale.

The September number of *The Country Month by Month*, by Mrs. Owen and Prof. Boulger, appears to us to be better than some that have preceded it. The poet-naturalist will find the authors' descriptions of autumnal plant and bird life greatly to his liking. Some parts of the book are really very fine. Messrs. Bliss, Sands, and Foster are the publishers.

The Manchester Microscopical Society, with a membership of 245, ranks high among provincial scientific societies. Several interesting papers are printed in the *Transactions* of the Society for 1893. Among these we note the address of the president, Prof. F. E. Weiss, on recent researches and speculations on the structure of protoplasm; a paper on modern views of the plant cell, by Mr. Thomas Hick; and one on the organic forms of silica, by Mr. W. Blackburn. A useful summary of information on the plans of growth and the forms of Foraminifera is contributed by Mr. E. Halkyard; and a survey of typical examples of some common microscopic fungi is given by Mr. A. T. Gillanders. These papers show that interest in the Society is still maintained.

The Meteorological Sub-Committee of the Croydon Microscopical and Natural History Club is doing good work by the collection of rainfall statistics; its report for 1893 contains daily and monthly values for sixty-three stations in the counties of Kent and Surrey. The Hon. Sec., Mr. F. C. Bayard, points out that the smallness of the total rainfall during the year is very remarkable. The average yearly fall for Greenwich for seventy-five years (1816–90) is 25·11 inches; but in the year 1893 there was a deficiency of 5·02 inches, which quantity nearly represents the deficiency of the district dealt with by the Club. Most of this deficiency, viz. 4·77 inches, occurred during the first six months of the year.

The additions to the Zoological Society's Gardens during the past week include a Diana Monkey (*Cercopithecus diana*) from West Africa, presented by Mr. Darent McDonald; a Pinche Monkey (*Midas œdipus*) from New Granada, presented by Lieut. W. N. Gordon, R.A.; a Puma (*Felis concolor*) from Argentina, presented by Mr. Ponsonby Ogle; a Stone Curlew (*Œdicnemus scolopax*), British, presented by Colonel H. W. Fielden; two Poe Honeyeaters (*Prosthemadera novæ-zealandiæ*), from New Zealand, presented by Mr. Reginald Moorhouse; an Elephantine Tortoise (*Testudo elephantina*) from the Seychelles, presented by Mr. Arthur Gladstone; two Hawks-billed Turtle (*Chelone imbricata*) from the East Indies, presented by Captain E. Fleetham; a black-headed Lemur (*Lemur brunneus*) from Madagascar, five Meyer's Parrots (*Pœocephalus meyeri*) from East Africa; two Brown-throated Conures (*Conurus æruginosus*) from South America, deposited; two Javan Wild Swine (*Sus vittatus*) from Java, presented by Mr. E. J. Kerkhoven.

OUR ASTRONOMICAL COLUMN.

Recent Observations of Mars.—Mr. John Ritchie, jun., has kindly sent us a cutting from the Boston *Commonwealth* containing some observations of Mars, made at the Lowell Observatory, Arizona, since those recorded in our issue of August 16. The staff of the observatory includes Mr. Percival Lowell, Prof. W. H. Pickering, and Mr. E. A. Douglass. Mr. Lowell himself communicated the following observations to the *Commonwealth*: July 5. Both Pickering and Douglass observed that the terminator was flattened in a certain place. Light from the Sabaeus Sinus was found to be polarised. July 19. Douglass observed a protuberance on the terminator, and a notch. The height of the former was estimated at 0″·1, which suggests an elevation of about five-eighths of a mile. July 20. The notch seen by Douglass was confirmed by Pickering. July 21. Douglass saw two notches which were afterwards confirmed by Pickering. July 23. Other notches on the terminator observed by Douglass. July 26. A large protuberance observed by Pickering. The light from the larger "lakes" found to be unpolarised, even when near the limb of the planet. (Mr. Ritchie points out that the projection seen by Pickering was in all probability the one seen by Javelle at Nice, on July 28.) The first observation of a canal, Eumenides, was made on June 6 by Pickering. The same channel was seen by the other observers on June 7, and appeared persistently on June 9. During the whole of June and July the snow-cap diminished in size. On July 10, a minute patch of white, in the position of the former star-like points, was seen as a difficult object, entirely detached from the snow-cap. On July 18, Pickering reported that the cap had materially diminished, and that the canals were coming out more clearly. He had some views of clouds and glimpses of some of his "lakes." Early in August he reported that he had seen seventeen of these lakes, two of them new. By the end of June the canal Ganges was seen twice, and both times single. July 29, a light grey tint was seen on an extended region. Some canals were well developed, no duplication visible. July 30, early in the evening, with the seeing 4 and 3 on a scale of 10, Pickering thought he saw Ganges double. Later in the evening, when the seeing had improved to 8 and 9, it was evident that such was not the case. The apparent double was a canal from Fons Juvente and a north branch of Tithonus. The latter observations have an interest, since the canal Ganges has been reported as having been seen double at the Lick Observatory.

A circular just distributed by the Centralstelle für Astronomische Telegramme, Kiel, states that a telegram, of which the following is a translation, was received from Teramo on August 31:—"Greenish-white spot on the northern cap of Mars. Length thirty to forty degrees. *Nix borea* apparently covers *Mare acidalium*. Cerulli."

THE MASS OF JUPITER.—It was more than twenty years ago, Prof. Simon Newcomb reminds us in the *Astronomische Nachrichten* No. 3249, that he called attention to the great value of observations on the minor planet Polyhymnia for determining the mass of Jupiter. Prof. G. C. Comstock's computations of the special perturbations of the elements of the former planet from the date of discovery in 1854, together with the observations made during the opposition of 1888, have enabled Prof. Newcomb to make this determination. The result obtained shows that the mass of Jupiter is $\frac{1}{1047 \cdot 34}$ part the mass of the sun. Other determinations of Jupiter's mass are shown in the following table, and also the weights assigned to them by Prof. Newcomb, who proposes to regard the weighted mean as definitive, and to use that mass in his work on the planetary theories.

	Jupiter's Mass.	Weight of Determination.
All observations on the satellites ...	1047·82	... 1
Action on Faye's Comet (Möller) ...	1047·79	... 1
Action on Themis (Krueger) ...	1047·54	... 5
Action on Saturn (Hill)	1047·38	... 7
Action on Polyhymnia	1047·34	... 20
Action on Winnecke's Comet (v. Haerdtl)	1047·17	... 10
Weighted mean	1047·35	± 0·065

It is pointed out that in the interests of the astronomy of the future, it is very desirable to apply Gill's heliometer method to the continuous observation of a selected number of minor planets.

AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

THE forty-third annual meeting of the American Association for the Advancement of Science was held at Brooklyn, N.Y., from August, 16–22.

The marvel is that no meeting had previously been held in that great city. Overshadowed as it is by the greater metropolis of New York, its next neighbour, many strangers fail to realise that Brooklyn is one of the great cities of the world. By a recent act of the legislature its area has been doubled, and its population now exceeds one million, making it the fourth city in America; until the last census it was the third, but Chicago has now outstripped it.

Not merely as a portion of the metropolis of America, but also in those features which are distinctively peculiar to itself, Brooklyn offers unrivalled attractions to men of science. The massive bridge which spans the East River, connecting it with New York, is a world-renowned triumph of engineering. The United States Navy Yard attracts the attention of those who study applied science, and eleven thousand manufacturing establishments provide valuable object-lessons.

The city is also notable for educational institutions of the best character, including the Pratt Institution, the Packer, the Polytechnic, the Long Island Medical College, the Hoogland Biological Laboratory, a large and well-equipped High School for each sex, and several Roman Catholic Seminaries.

A marked feature of recent meetings of the Association has been the increasing number of affiliated societies which hold meetings in connection with the general Association. Two new accessions bring the number of these already up to nine, and next year the American Botanical Society will still further swell the list, which now includes the American Mathematical Society, the Society for Promoting Engineering Education, the Society for the Promotion of Agricultural Science, the American Microscopical Society, the Geological Society of America, the Association of Economic Entomologists, the American Chemical Society, the Association of State Weather Services, and the American Forestry Association.

The citizens of Brooklyn entered into the arrangements with an evident determination to do everything to insure the success of the meeting. The reception at the Academy of Music and the Art Building, on the opening evening, was perfect in all its details. The excursions were of unusual number and variety, and included features of exceptional scientific interest, such as dredging expeditions by the steamer *Fish Hawk*, furnished by the United States Government. Special mention is also due to the elegant excursion to West End, and entertainment furnished by Mrs. Herrman, a patron of the Association, and of the sterling silver badges of her own design given as souvenirs.

The weather continued cool and comfortable throughout, so that all the external conditions were as favourable as possible. Teleologists even found evidence of providence and prevision in the unusual circumstance that nine century plants bloomed together to welcome the coming Association.

The attendance of members was well above the average of recent years, and if to the registry of the general Association be added the names of specialists attending the affiliated societies, it will raise the total to an aggregate comparing favourably with the largest meetings, notwithstanding that the depression of business and the fear of detention by railroad strikes exerted a deterrent influence.

Three evenings were occupied with popular scientific lectures. Paul du Chaillu spoke on the Vikings, their civilisation and expeditions; Edward D. Cope, on the relation of human structure and physiognomy to those of the other mammalia; and B. E. Fernow, on the battle of the forest.

The annual address of the retiring president, Prof. William Harkness, was on the magnitude of the solar system. An exhaustive account was given of the various methods of measuring the sun's distance. Many of Prof. Harkness' hearers were surprised to learn that but little accuracy has been attained for many years. He states as his conclusion after comparing all the corrected results of these various methods, that the sun's distance is 92,797,000 miles with a probable error of 59,700, and the diameter of the solar system, measured by that of its outermost member, the planet Neptune, 5,578,400,000 miles.

The address of Vice-President George C. Comstock, on binary stars, was of interest, as will be seen from the following extracts. After a general review of the subject, he said that the orbits of forty-two binary stars based on motion of over 80° have been computed. The shortest are δ Equulei and κ Pegasi, each less than twelve years.

ζ Cancri presents a curious study. Two stars less than a second apart revolve in an ellipse; a third star 6″ distant revolves in loops, suggesting an invisible companion. Four binaries have been discovered by the spectroscope: β Aurigæ, revolving in a period of four days; α Virginis, four days; ζ Ursæ Majoris, 105 days; and Algol, three days.

The masses of the visual and of spectroscopic binaries are derived by totally different methods, but both classes of bodies indicate that the sun is an undersized star, a result that is confirmed by other and independent lines of investigation. The small range of values presented by the masses of the stars is remarkable, and points to an unexplained uniformity of size in the heavenly bodies, the average component of a double star having a mass somewhat greater than the mass of the earth.

If binary stars are classified with respect to their type of spectrum, it will be found that on the average the distance of a star possessing a Sirian spectrum is about three times as great as that of a star possessing a solar spectrum, and it will further be found that although stars of the Sirian type are, on the whole, more numerous than solar stars, binaries of solar type outnumber their Sirian fellows three to one.

Four-fifths of the binaries, with periods of less than two hundred years, have orbits smaller than Neptune, while the fastest have orbits between Jupiter and Saturn.

A combination of measured amounts of light with elements of orbit is mass-brightness, or "candle-power per ton" (Young). γ Leonis has more than 1000 times the mass-brightness of 61 Cygni—probably. Confining ourselves to those with well-determined orbits, we find at extremes of the list ϕ Ursæ Majoris, with a mass-brightness fifty-times that of 70 Ophiuchi. The mass-brightness of the sun is probably not much greater than that of 70 Ophiuchi.

It has long been known that if the components of a double star are of approximately equal brilliancy, they are of the same colour, and if of unequal brilliancy the colour of the fainter companion lies nearer to the violet end of the spectrum than does the colour of the brighter one. The spectra of the stars furnish a partial explanation of their difference in colour by showing, in at least some cases, that the stars possess spectra of different types, the fainter companion having a Sirian, and the brighter one a solar spectrum.

Few researches upon double stars exceed in theoretical interest the mathematical investigations of Mr. See with regard to the mode of development of these bodies. As early as 1878, Doberck had shown, from a statistical comparison of double star obits, that, in general, the longer the period of revolution of the compounds the larger and more eccentric are their orbits. That the orbits would be larger might be expected as a consequence of the law of gravitation, but it required a special investigation based upon the theory of tidal friction, as developed by Prof. G. H. Darwin, to show that the increasing eccentricities are also a necessary consequence of the same law. The conclusions of Mr. See may be briefly summarised as follows:—If we suppose the components of a double star to be composed of a plastic material, they will produce in each other bodily tides whose effect will be to push the stars asunder, and at the same time to increase the eccentricity of their orbits. This increase of eccentricity will not continue indefinitely, but in the later stages of developments will give way to a diminution of the eccentricities, which will ultimately produce circular orbits. But since the energy of the star is being constantly wasted by radiation, it will, in the later stages of its career, be reduced to invisibility, and during the period of its existence as a luminous body its history will present a continuous increase in the size and eccentricity of its orbit. It is of interest to note in this connection that the two orbits of spectroscopic binaries which have been computed, present eccentricities very much less than that of the average double star orbit, while the dimensions of their orbits are so small as to suggest an early stage in the development of the systems.

Prof. Wm. A. Rogers year by year brings to the Association either new and more refined apparatus, or the result of delicate experiments with the perfected apparatus already at his command. This year he presided over the Section of Physics, and read an elaborate address on obscure heat as an agent in producing the expansion of metals under air contact.

Vice-President Thomas H. Norton addressed the Chemical Section, on the battle with fire; Mansfield Merriman, the Engineering Section, on paradoxes in the resistance of materials; Samuel Calvin, the Geol gical Section, on some points in geological history illustrated in North-eastern Iona, exhibiting and using American chalk obtained from the Niobrora beds; Lucien M. Underwood, the Botanical Section, on the evolution of the Hepaticæ, a subject to which he has devoted especial attention, and on which he is probably the foremost authority; Franz Boas, the Anthropological Section, on human faculty as determined by race; and Henry Farquhar, the Economic Section, on a stable monetary standard.

One hundred and seventy-eight papers were read before the Sections, the largest number being before the Section of Anthropology.

It was decided to visit San Francisco next year if suitable rail rates can be secured, and the date of meeting recommended is June or early in July. Definite action, however, was deferred, owing to the expense of crossing the continent, so that time may be taken to apply for special rates of fare.

The following officers for the ensuing year were recommended by the nominating committee, approved by the council, and elected by the Association:—

President, E. W. Morley, Cleveland. Vice-presidents: Mathematics and Astronomy—E. S. Holden, Lick Observatory. Physics—W. Le C. Stevens, Troy, N.Y. Chemistry—William McMurtrie, Brooklyn, N Y. Mechanical Science and Engineering—William Kent, Passaic, N.J. Geology and Geography—Jed. Hotchkiss, Staunton, Va. Zoology—D. S. Jordan, Palo Alto, Cal. Botany—J. C. Arthur, Lafayette, Ind. Anthropology—F. H. Cushing, Washington, D.C. Economic Science and Statistics—B. E. Fernow, Washington, D.C.; permanent secretary, F. W. Putnam, Cambridge, Mass.; general secretary, James Lewis Howe, Louisville, Ky.; secretary of the council, Charles R. Barnes, Morrison, Wis. Secretaries of the Sections: Mathematics and Astronomy—E. H. Moore, Chicago, Ill.; Physics—E. Merritt, Ithaca, N.Y.; Chemistry—William P. Mason, Troy, N.Y.; Mechanical Science and Engineering—H. S. Jacoby, Ithaca, N.Y. Geology and Geography—J. Perrin Smith, Palo Alto, Cal. Zoology—S. A. Forbes, Champaign, Ill. Botany—B. T. Galloway, Washington, D.C. Anthropology—Mrs. Anita Newcombe McGee, Washington, D.C. Economic Science and Statistics—E. A. Ross, Palo Alto, Cal. Treasurer, R. S. Woodward, New York.

WM. H. HALE.

THE IRON AND STEEL INSTITUTE.

THE summer meeting of the Iron and Steel Institute has been held this year, for the second time in the history of the Institute, in Belgium, the former meeting in that country having taken place at Liège just twenty-one years ago.

This year's meeting commenced on Monday, August 20, and continued until the following Friday. The President of the Institute, Mr. E. Windsor Richards, presided throughout. The proceedings commenced on the evening of the first day by a reception of members at the beautiful and historic Hôtel de Ville at Brussels, the civic authorities being the hosts. The proceedings were of an exceptionally successful character. On the following morning, Tuesday the 21st ult., the first sitting for the reading of papers was held. The following is a list of the contributions submitted:—

(1) "On the Use of Caustic Lime in the Blast-Furnace," by Sir Lowthian Bell.

(2) "On the History of Crucible Steel," by R. A. Hadfield.

(3) "On the Coal-mining Industry of Belgium," by A. Briart, President of the Society of Engineers, Hainaut.

(4) "On the Iron and Steel Industries of Belgium," by A. Gillon, President of the Society of Engineers, Liège.

(5) "On the Influence of Aluminium upon the Carbon in Ferro-Carbon Alloys," by T. W. Hogg, of the Newburn Steel Works.

(6) "On the Manufacture of Open Hearth Steel," by J. A. Lencauchez, Paris.

(7) "On Colour Gauges for Carbon Determinatioo," by W. G. McMillan.

(8) "On Electrical Power in Belgian Iron Works," by D. Selby Bigge.

(9) "On the Manufacture of Coke," by the late R. de Soldenhoff.

(10) "On the Iron Ores of the Mediterranean Seaboard," by Arthur P. Wilson.

The papers of Mr. Hadfield and the late M. de Soldenhoff were taken as read.

The members were received in the Burse des Métaux, where the sittings were held, by M. Gillon and M. Briart, on behalf of the reception committee, and the usual complimentary speeches having been made, business was commenced by the reading of M. Gillon's paper. The title sufficiently indicates the scope of this contribution, and it is evident that an abstract such as, in any case, we could give here would be quite inadequate to so large a subject. The same remark applies to M. Briart's paper, which followed. Both contributions are of considerable interest from an industrial point of view: the first because the Belgians are such keen and successful competitors of our own iron and steel manufacturers in some branches of the industry, and the second from the fact that the coal-mining practice of the Belgians is of a very advanced character. Coal is won in Belgium often under conditions of extreme difficulty, such indeed as would cause despair to mining engineers in our own more favoured land, though doubtless we should rise to the occasion were the necessity put upon us. The natural obstacles which the Belgian engineers are forced to meet have necessitated the highest skill in mining practice, and we cannot but look with admiration at the patience, ingenuity, and skill displayed in the working of many collieries of the country. Sir Lowthian Bell's paper followed. The controversy regarding the respective merits of using caustic lime or raw limestone in the blast furnace is one of much antiquity, and though Sir Lowthian's paper did not perhaps do very much in itself to determine the dispute, it may be said that the paper and the discussion together served to determine the lines upon which the controversy should be carried on. The author said that in the older type of blast furnace it was a desirable thing to calcine the limestone separately, but with the higher furnaces now in vogue there was, on the balance, practically no advantage. In the discussion which followed, Mr. Charles Wood said that when iron ore and limestone were calcined together there was a distinct gain. We gathered from Sir Lowthian's reply to the discussion that he had not tried the plan Mr. Wood referred to—and which the latter had been following for twenty-five years—but that he would make further experiments on those lines. Perhaps the most striking feature in connection with this paper and discussion is its illustration of the value of societies of the nature of the Iron and Steel Institute. Here we have one practical detail which cheapens the cost of iron-making—at least, that is the opinion of a very competent ironmaster—in use for years, and it might have remained unknown to the majority of manufacturers had not the fact been elicited in this discussion. If Mr. Wood be right in his contention, he will doubtless receive confirmation from Sir Lowthian Bell at a subsequent meeting.

Mr. Hogg's paper followed, and in it were given the results of a large number of experiments, from which the author concluded that in the purer classes of iron the tendency of carbon to be retained in a combined state is prevented by the addition of 1 per cent. of aluminium, but curiously enough every increase above that percentage has an opposite tendency. It was also stated that the more rapidly cooled ferro-carbon alloys containing aluminium also contain a larger proportion of graphite. A short discussion followed the reading of this paper, and the meeting was then adjourned until the next day.

On the members reassembling on the following day, Wednesday, August 22, Mr. Selby Bigge's paper was first read. The author gave some interesting particulars of the progress that has been made in Belgium in using electricity as a means of distributing power in factories and workshops. The question has become one of commercial expediency, and the author boldly attacks it from this point of view, stating that his "whole contention in advocating electricity as the right and proper agent of operating new works, and as a means whereby old works can be remodelled, may be summarised by the one word 'economy.'" As an instance in point, he quoted the National Arms Factory at Herstal, near Liège. These works were recently founded to execute, in the first instance, an order for 200,000 rifles, the production being guaranteed at 250 rifles every twelve working hours. The Compagnie Internationale d'Electricite supplied the electric power installation, laying down thirteen motors, ranging between 16 and 37 horse-power, and giving a total of 260 horse-power. For the former size of motors they guaranteed a commercial efficiency of 87 per cent., and for the latter 89 per cent. The total power of the motors (260 horse-power) would therefore be obtained by 296·9 initial horse-power. There was a large amount of electric lighting to be done also, so that an engine and dynamo of 500 horse-power was installed. The ratio between the electric energy available and the energy transmitted to the shaft by the engine was guaranteed to be 90 per cent. The electric motors drive the line shafting of the machines, and the efficiency of transmission—that is to say, the ratio between the power available and the effective horse-power developed by the steam engine—is given by the product of three efficiencies, as follows:

90 per cent. for the dynamo, 98 per cent. for the conductors, and 87 per cent. for the motors = 76·6 per cent. The installation has now been running for three years without being the cause of cessation of work for a single minute.

It is a very difficult matter to form comparisons between the respective efficiencies of different methods of power distribution, and it may be pointed out that in the Herstal case the electric system does not appear to its greatest advantage, as the motors drive line shafting in place of being attached directly to the machines. There is no doubt, however, that a very strong case can be made out for electricity, and electrical engineers may look forward with confidence to a large extension of their field of activity in regard to power distribution.

The paper of M. Lencauchez dealt with a novel description of open hearth furnace in which jets of air and gas appear to be blown on the bath of molten metal to assist oxidation. The device did not receive much commendation in the discussion which followed the reading of the paper, but in the absence of illustrations referred to by the author, it was very difficult for those who had not had the advantage of seeing the furnace to follow the description.

The paper of Mr. McMillan, on colour gauges, was read in brief abstract, and Mr. Wilson's paper was also considerably curtailed in delivery, the time of the meeting having expired.

There were several excursions in connection with the meeting. The first, on the Tuesday afternoon, was to the Antwerp Exhibition, and on Wednesday evening members were received by the King of the Belgians, at the Royal Palace in Brussels. This was the chief feature of the meeting, the King receiving his guests in person, and apparently thoroughly enjoying the many conversations he had with the English metallurgists and engineers present. On the Thursday and Friday of the meeting, visits were paid to steel works, collieries, glass works, and engineering establishments. The last excursion on the list was to the important works known as the Société Cockerill at Seraing, near Liège. These works date from the beginning of the century, having been founded by a British subject, we believe a Scotchman. At present 5500 workmen are employed. According to particulars given to members in the shape of a handbill, there are five blast furnaces, an open steel plant, a basic steel plant, 250 coke ovens, 40 puddling, 15 reheating furnaces, 10 rolling mills, 3 foundries, 9 winding engines, 5 pumping engines, 4 blowing engines, 28 engines for rolling mills, 204 machine tools, 14 locomotives, and 184 steam boilers supplying 17,000 horse-power. The Company has also a shipbuilding establishment at Hoboken.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

THE meeting of the Association this year was a memorable one for physiology, since this subject was for the first time placed by the Council on an independent footing. This action of the Council has been amply justified by the success of the new Section I, there being a very representative attendance of English and continental physiologists, and great wealth of material for their consideration. The number of papers was so large that even when the sittings were extended to the final Wednesday morning, the business of the Section could only be got through with difficulty, and the opinion of all concerned was emphatic as to the high quality and great interest of many of the communications. In addition to the sectional meetings, advantage was taken of the presence of so many physiologists to dovetail a meeting of the Physiological Society into the proceedings; this was held on Saturday afternoon, when several interesting communications were made, and the meeting was followed by the dinner of the Society in Magdalen College, under the presidency of Prof. Burdon Sanderson.

The following summary will furnish a general account of some of the chief points in the many varied papers read before this Section:—

Thursday, August 9.—The proceedings opened with a communication by Mr. M. S. Pembrey, on the reaction of animals to changes of external temperature. The observed reaction was that of the production of heat, this being estimated by the amount of CO_2 discharged from the animal. Experiments upon the mouse were described, which showed that in proportion as the external temperature was lowered, the CO_2 output of the animal was rapidly increased (in one minute the increase amounted to 60 per cent. when the temperature fell from 33° to 17 C.), and concurrently with this increase the animal's muscular activity became far more vigorous. Experiments made upon the developing chick showed that up to the twenty-first day the effect of external cold was to decrease the CO_2 output, the chick in this stage behaving like a cold-blooded animal, but that a comparatively sudden change took place from this day onwards, the chick reacting like the warm-blooded animal previously referred to. This change in reaction is probably related to the development of the neuro-muscular mechanisms, and is undoubtedly influenced by the activity of the animal. Observations made upon newly-hatched pigeons showed that these birds, being more or less helpless when hatched, react for the first few days like cold-blooded animals, the output of CO_2 decreasing with a fall in the external temperature; it is probably for this reason that these young birds are kept warm by the parent until their muscular activity is more developed. The influence of the muscular activity upon the production of heat was further shown by details of observations made upon mice after section of the spinal cord, as well as during anæsthesia; in both cases the muscular paralysis was accompanied by a change in the reaction, which now resembled that of a cold-blooded animal.

Mr. Harris described the results of an investigation into the muscular rhythm of voluntary tetanus in man. The muscle thrill during contraction was ascertained by recording the continuous contraction in a great variety of ways, as well as by ascertaining through a suitable telephone and microphone the muscle note. The observations confirmed in the main those of Schafer and of Griffith, and indicated that the thrill was due to a muscle vibration, the rate of which varied from 10 to 15 in the second, with an average of about 12 or 13 vibrations.

Prof. Allen gave a short demonstration of mirror writing.

Prof. McKendrick showed a phonograph, and demonstrated some of its effects to the audience. He explained the working of the instrument and the means by which he was now endeavouring to adapt it for such physiological investigations as those connected with the nature of the vowel and consonant sounds, and those in which it was desirable to obtain a permanent record of the cardiac and respiratory sounds. He then showed a new model, constructed by himself, to illustrate a possible mode in which the essential structures of the basilar membrane of the cochlea might be supposed to respond to compound tones. The model consisted of a glass box containing two cavities separated by a horizontal membrane and filled with liquid, the box communicating with the exterior by two apertures covered by membrane analogous to the fenestræ ovalis and rotunda. Two pistons rested by their bases on the horizontal membrane, and could be arranged of such size and weight that their periods of vibration should be as 1 : 2. In this scheme it was shown that in accordance with the rate of vibration communicated to the liquid the two pistons responded in variable amounts, thus analysing the wave in the liquid.

Prof. Gaule showed microscopic specimens and slides illustrating the remarkable changes observed by himself as following the section in the rabbit of the inferior cervical sympathetic ganglion or its branches. After a definite lesion these changes were found to be localised in particular muscles and special parts of the nervous system. Thus he found that after section of one branch of the ganglion the observed changes occurred in the rami communicantes, the lower cervical spinal cord, the anterior roots of the brachial plexus, and the biceps muscle of the forelimb. He considered that the changes indicated trophic disturbances in the affected parts due to the lesion, and showed muscles in which the substance had suffered at various points the alteration in question.

Prof. Haycraft described an extensive research which he had made upon the development of the kidney, and showed a large number of micro-photographs to illustrate his remarks. The examination of continuous series of sections through this organ in different stages of its early growth, had convinced him that both the glomerular and tubular portions of the gland substance were formed as ingrowths from the same epithelium, viz. that lining the genito urinary canal. The view thus advanced as to the development of the kidney makes it analogous to that of other glands in opposition to former opinions.

Friday.—The Section commenced with the opening address of its President, Prof. Schäfer. This was followed by a communication by Prof. Heger, on the unequal diffusion of poisons into the organs of the body. In this paper an account was given of some of the chief means by which the organism was continually struggling against toxic substances, the principal objects to be effected being either the elimination of the unaltered poison, its neutralisation, or its destruction. The neutralisation might be either a true chemical combination, as in the case of CO_2, or a physical localisation in some special organs which could endure this excess, and so remove it from the rest of the organism. Thus morphine, if given in a series of increasing doses, accumulated in the liver, spleen, and marrow of the bones. In the case of microbic poisoning, Prof. Heger, whilst admitting that the constant multiplication of the microbes necessitated the destruction of the poison by phagocytosis, &c., pointed out that some such process of neutralisation as that just referred to was not only a possible but a probable antecedent to this destruction. Thus the liver cells and their secretion or extract appeared to have exceptional antitoxic properties. Experiments were quoted which showed the extent to which the frog's liver could not only retain and digest such poisons as hyoscyamine, but actually utilise the products derived from them as a food supply for the organ.

Mr. Hurst explained a new hypothesis as to the mode in which he conceived the organ of Corti and adjacent structures might be supposed to be affected by such alterations of pressure in the endolymph as must be produced by sound waves.

Prof. Schäfer showed photographs to illustrate a research made by Dr. Oliver and himself as to the functions of the suprarenal bodies. The photographs were chiefly those of tracings indicating the blood pressure, the heart beats, and the volume of the blood-vessels in such localised parts as a limb or the kidney. The injection of suprarenal extract was seen to cause a great rise of blood pressure, due not to any modification in the heart beat, but to the constriction of the blood-vessels, this constriction being dependent upon the integrity of the central nervous system.

Prof. Rutherford showed the result of an extensive series of observations in which the reaction time was measured for sight, hearing, and touch. The stimulus for the ear was the response of a telephone to a current, that for the eye the movement of an electro-magnetic signal, and that for the touch an induction current sent through the skin; the stimulus in all cases being made by the closure of a circuit. The response of the individual was the break of a current sent through a suitable electro-magnetic recording arrangement. By means of the pendulum a large series of records were obtained, in which as the initial starting-point occurred always at one place, and the different observations were arranged in series beneath one another, a comparison between different reaction times was rendered very conspicuous. He found that with eight intelligent men of ages varying from 19 to 62, the time for sight varied from $\frac{16}{100}$ to $\frac{42}{100}$ second, for hearing, $\frac{14}{100}$ to $\frac{19}{100}$, for touch, $\frac{14}{100}$ to $\frac{19}{100}$. The shortest reaction times were obtained when the response was that of the hand on the same side of the body as the ear or cheek which was stimulated.

Mr. D'Arcy Power showed a series of preparations of the conjunctival and vaginal mucous membranes taken from rabbits and guinea-pigs which had been subjected to mechanical and chemical irritation. Many of the epithelial cells presented appearances which were identical with those described as being parasitic when they were met with in cancer. The changes in the epithelium were summarised as a general vacuolation of cells; various forms of intracellular œdema; epithelial "pearls," collections of leucocytes, and the spaces left after these leucocytes had migrated. The series of preparations shown on the present occasion indicated that many squamous epithelial cells had the power of phagocytosis, for in no other way could the remarkable intracellular appearances be explained; cells were shown containing a leucocyte, and others containing a microcyte. Partial necrosis of the cell also took place as a result of irritation, and there was an invasion of large eosinophile cells into the conjunctival epithelium.

Saturday.—Prof. Hermann gave a most interesting communication upon the production of vowel and consonant sounds. His investigations were made by means of the phonograph, the excursions of the stylus being magnified, for which purpose a small mirror was attached to this part, and the character of its movement recorded by photographing the reflection in the mirror of a beam of light. Observations were also made in which a special telephone was introduced, thus rendering the excursions still larger. Numerous photographic records of various vowel and consonant sounds were exhibited, and each was seen to produce its own characteristic tracing. A matter of much theoretical interest in connection with the previous work of Helmholtz and others, was the character of the tracing when the same vowel sound was sounded in notes of different intensity but of similar pitch, or *vice versâ*.

Prof. Fredericq showed a new aerotonometer and gas pipette, which he had made in order to investigate the causation of the gaseous interchange between the blood and air of the lungs. By means of this apparatus the tension of the gases in these two media had been ascertained, and the results were laid before the Section. These furnished, in the author's opinion, material for criticising the view advanced by Prof. Bohr, that, as the Oxygen tension in the circulating blood often exceeded, whilst the CO_2 tension fell short of, that in the pulmonary air, the interchange could not be brought about in accordance solely with the laws of diffusion, but must be largely modified by the special vital activity of the lung epithelium. Prof. Fredericq's observations led him to believe that the data upon which Bohr's conclusions were founded, might be more or less incomplete owing to the time allowed for the contact between the blood and the air of the aerotonometer being too short in Bohr's apparatus for the correct determination of the tension of the O and CO_2 in that liquid. Fredericq's apparatus allowed of a long time, two hours, for the determination, and he had never obtained as low a tension of CO_2, nor as high a tension of O, in the blood as

Loewy had found. He therefore concluded that the diffusion hypothesis was adequate to account for the interchange. Dr. Haldane, replying to the above, pointed out that the criticism did not affect those experiments of Bohr's in which the ærotonometer CO_2 tension, although made initially higher than that in the pulmonary air, yet fell in the course of an experiment to a value much below the latter.

Mr. L. Cobbett and Mr. Melsome brought before the Section the results of an investigation on the production of local immunity through a localised specific inflammatory condition. It appeared from the authors' experiments that an attack of erysipelas localised to the ear of the rabbit conferred upon that organ an immunity against subsequent inoculation by the erysipelas organism so long as there was any indication of the inflammatory thickening occasioned by the first attack, and that the only consequence of this subsequent inoculation was a localised non-specific inflammation. The authors regarded this inflammation as the reaction of the affected tissues against the specific poison of the disease, since the absence of the specific *streptococci* indicated that this secondary effect was not due to the invasion of the tissues by the microbes. This view was confirmed by the fact that it was found possible to obtain similar inflammatory effects when the organisms themselves having been destroyed by heat the concentrated filtered culture was injected into the ear. Finally, since the parts which had previously suffered from erysipelas reacted more quickly and vigorously to the subsequent injection of the poison, it seemed probable that this non-specific inflammation was due to some adaptation of the tissues enabling them to respond with greater vigour, and thus more effectively, so that, as Metchnikoff and others have affirmed, the inflammatory process is from one aspect a truly protective one.

Mr. Lorrain Smith and Mr. Trevithick brought forward a research in many respects similar to the foregoing, but with one important difference, since the initial protective inflammatory process was brought about by a simple irritant. A sterilised liquid containing fine glass particles was injected into one pleural cavity of the rabbit and guinea-pig. The injection was followed by hyperæmia of the lung and by inflammatory exudation into the pleural cavity and the subjacent pulmonary alveoli. The subsequent injection of the *Bacillus pyocyaneus* was found to be inoperative as long as the injection was limited to the parts which were the seat of this primary inflammatory process; thus the inflammatory region was rendered immune, the localised immunity produced by the glass lasting as long as twenty-eight days.

Dr. Mann showed a series of microscopic specimens and microphotographs in which changes could be observed in various nerve cells as the result of their functional activity. The cells in question were those of the spinal cord, cerebellum, &c., particularly those associated with the functional activity of the retina, whilst the chief alterations were in the size and chromatin distribution of the cell nuclei. By bandaging one eye of an animal and then exposing it to light, Dr. Mann was able to distinguish an alteration in the size and staining of the cells upon the two sides in the following situations: the outer nuclear layer of the retina, the pyramidal cells of the occipital cortex, and the cells of the external geniculate body. The changes were most conspicuously shown both in the specimens and in the photographs.

At the meeting of the Physiological Society, held on Saturday afternoon, the following communications were made:—Dr. L. Hill showed the effect of gravity in altering the mammalian blood pressure, as illustrated by the remarkable rise in carotid pressure which occurs when the animal is changed from a horizontal to a vertical position with the head down, and the corresponding fall when the animal is similarly placed with the head up. Mr Kent showed an organism which he believed might turn out to be the specific organism of vaccinia. Dr. Pavy showed a sugar of low reducing power which was obtained from the urine of an animal after the administration of large quantities of dextrose. Dr. Mott showed microphotographs of the medulla, cord, &c., after section of the gracile and cuneate nuclei of the monkey on one side of the medulla. The sections showed the degenerated arcuate fibres sweeping over to the opposite side of the medulla, and the degeneration in the fillet of the opposite side above the lesion. A remarkable point in connection with the changes was that the degenerated fibres could be traced up to the optic thalamus, but no farther, there being none in the internal capsule. He also showed microphotographs taken from sections of a cord in which a longitudinal section had been made in the lumbar region, the section being in the middle line. The sections showed degenerated fibres in both antero-lateral columns.

Monday.—Dr. Starling gave an account of the experiments which led him to believe that the flow of lymph from the thoracic duct was dependent upon the amount of the blood-pressure in the liver capillaries, and hence that the old mechanical theory of lymph formation was correct as regards this source of the lymph flow. He showed that obstruction of the inferior vena cava must raise the pressure in the portal capillaries, and that a similar result follows obstruction of the abdominal aorta. The flow of lymph which Heidenhain observed after these operations was not therefore necessarily due to secretory activity, but must occur in consequence of the pressure even if the permeability of the portal capillary walls remained unaltered. Similarly the injection of a large quantity of saline into the circulation (hydræmia) caused an increased flow in consequence of the purely mechanical rise of pressure in the liver capillaries, this rise being ascertained by taking simultaneous tracings of the blood pressure in the portal vein and the inferior vena cava. Many lymphagogues act by causing hydræmia, and in these the flow of lymph must be directly caused by the increase in the portal capillary pressure. That the lymph under these circumstances comes from the liver is shown by the absence of the flow from the thoracic duct when the lymphatics of the liver are ligatured. Some lymphagogues, the action of which was especially noted by Heidenhain (such as crayfish muscle extract), stimulate the flow of lymph without giving any evidence of increased pressure in the portal capillaries. The effect of these lymphagogues disappears after long continued obstruction of the aorta, and on this ground, since the liver lymph still flows, the author concludes that lymphagogues of this class act on other lymph sources than the liver, and probably in the main upon those present in the intestines.

Dr. Lazarus Barlow followed with some experiments upon the flow of lymph from the hind limbs. He found no increase in the flow when considerable though incomplete venous obstruction was maintained for one hour, whilst the specific gravity of the blood, muscles, and skin showed no evidence of any increased exudation. Such increased flow and exudation occurred, however, when, after thus damming up the katabolic products, the tissues under observation were supplied with blood through actively dilated arterioles. The dilatation, when caused by section of the sciatic nerve, led to no such increased exudation: hence he concluded that the demands of the tissue are an effective factor in lymph formation. When the arteries are actively dilated, the amount of exudation varies directly as that of the venous pressure; so that lymph formation, though not a purely mechanical process, is nevertheless simpler than a pure secretion, such, for instance, as exists in the salivary glands.

Messrs. Bayliss and Starling communicated the results of an experimental inquiry into the innervation of the portal vein. The method consisted in reading the pressure in the portal end of the cut splenic vein, which thus formed a side branch of the portal system. They found that the pressure rose when certain definite anterior roots were stimulated, these extending in the lower dorsal region from about the seventh to the tenth dorsal nerves; these, therefore, contain vaso-constrictor nerves for the portal system.

Mr. Bayliss gave a further communication upon vaso-dilator nerves. He showed that the fall of blood pressure which follows the excitation of the central end of the depressor nerve was accompanied by vaso-dilatation, this being evidenced in the case of the kidney by the simultaneous expansion of that organ, and in the case of the lower limbs by their increase of volume as indicated by the plethysmograph. As the vaso-constrictors leave the spinal cord by the lower lumbar roots, the section of the cord in the dorso-lumbar region will cut off the vaso-constrictors, and since, under these circumstances, the stimulation of the depressor still causes an increase in the volume of the limb, he was led to conclude (*a*) that the dilatation was really due to the increased activity of vaso-dilator centres, and not to the diminished activity of vaso-constrictor centres; (*b*) that the anterior roots by which the vaso-dilator nerves of the lower limbs leave the cord, extend higher into the dorsal region than is the case with the constrictor nerves. Corroborative experiments were carried out in which the cord was left intact, whilst the sympathetic, in which the vaso-dilators run, was divided. Under these circumstances no increase in the volume of the limb accompanied the depressor excitation because the dilator supply was cut off.

Prof. Waymouth Reid gave an account of the alteration in the mucous membrane of the lateral pouches of the pigeon's crop, which were associated with the breeding season of the bird, and resulted in the formation of masses of fat-holding material constituting the so-called *pigeon's milk*. The secretion of this material is in its histological features analogous to the formation of sebum in the sebaceous glands, the fat being contained in cells which are cast off in masses from the mucous surface. The material is used for feeding the young pigeon, and when analysed is found to contain from 7 to 9 per cent of fat and 12 to 15 per cent. of proteids, the chief of which is a nucleo-albumin; unlike true milk it contains no sugar, but among its proteids is a caseinogen which clots with rennet with or without the addition of calcic chloride.

Prof. Dubois read a paper on the production of heat in hybernating animals, and brought forward the results of experiments made on the marmot in order to ascertain what circumstances influence the change which takes place at the end of hybernation. Section of the cord at the level of the fourth cervical nerve interferes with the waking from winter sleep, the delay thus caused being only partially due to the muscular paralysis and consequent inability to produce heat, since it appears that the integrity of the sympathetic system is an essential factor in the process. Further experiments seemed to indicate that the nervous control of the circulation was necessary for the waking up, and that the most important part of the circulation was that through the liver, which under the conditions produced by the section was inadequate for the supply of that organ. In consequence of this inadequate circulation the author believed that the proper functions of the liver were very much interfered with, and that in the normal animal these functions were at the moment of waking very actively carried on, particularly those by which glycogen is converted into sugar.

Prof. Haycraft showed some micro-photographs of collodion casts of muscle fibres in which the transverse striæ of the fibres were displayed. This communication was followed by one from Prof. Rutherford, who exhibited on the screen micro-photographs of muscle fibres both at rest and in contraction. 14, Aug

Tuesday.—A combined meeting of the Physical and Physiological Sections was held in the large theatre of the museum, when Prof. Lodge showed a number of experiments upon the reflection, polarisation, and refraction of Hertz waves, using as a detector for the presence of the propagated electrical disturbance an extremely sensitive cohesion tube. This contained fine particles in imperfect contact, and consequently offering considerable resistance to the passage of an electric current. The surging in the particles of an electric disturbance causes a better contact to be established, and the resistance consequently to be enormously diminished. Prof. Lodge followed this demonstration with a suggestion as to the mode in which it was possible to conceive of a reaction of the retinal structures to light vibrations. If we assume that the retinal elements constitute an imperfect conductor, and that a constant electromotive source is present in the retinal tissues, then it is not improbable that the light waves would cause a sudden diminution in the resistance of the elements, and allow the passage of a previously masked current; this current might excite the nerve-endings, and thus start the necessary nerve impulses. He pointed out that the coherer was acted on not only by the sudden commencement, but also by the sudden cessation, of the Hertz waves, and drew attention to Hering's view that white and black are both positive sensations, and both caused by retinal excitation. He stated that as regards colour, mathematicians only demanded a triple starting-point, and that since in Hering's theory three such independent factors were postulated, no objections to this theory could be raised on that score. The Young-Helmholtz theory seemed to him difficult to reconcile with the facts described by physiologists and observed by himself.

A discussion followed, in which several physiologists took part, the general tendency of the tone being that the suggestion must be capable of being applied to all living electromotive structures which display electrical changes when called into activity. It was also pointed out that the histological appearances were not at any rate opposed to Prof. Lodge's suggestion.

Prof. Osborn described a modification of Golgi's method used by Mr. Strong, of New York, and showed beautiful photographs of nerve cells from various parts of the central nervous system treated in this way.

Dr. Haldane brought before the Section the evidence which had led him to the conclusion that in the recent colliery explosion in South Wales, and probably in most previous ones, the cause of death by suffocation was the deficiency of oxygen in the mine due to its displacement by the products of the explosion, *i.e.* after-damp. Suffocation by deficiency of oxygen occurs when the respired air contains less than 8 per cent. of O; it is ushered in by an extremely sudden attack of muscular paralysis, so that there is but little warning of the danger when air is inspired deficient in O, and little chance of escape owing to the muscular failure. Suffocation through excess of CO_2 is quite different, as it is preceded by gradual respiratory distress in which the neuro-muscular system is aroused to greater activity. In addition to the deficiency of O, the poisonous "after-damp" contains often at least two noxious gases in fatal percentage, these being CO and H_2S. The most effective method of fighting one's way through after-damp seemed therefore to be one which aimed at restoring to the inspired air an adequate quantity of oxygen, and this the author thought might be effectually done by suitable portable cylinders of this gas.

Mr. W. G. Smith brought forward some observations illustrating some of the mental conditions which influence the association of ideas, *i.e.* memory. Experiments were made as to the effect upon such association of contemporaneous nervous activities other than those which presumably were more or less directly involved. Thus the power of recollecting a given arrangement of letters which had been exposed before the eye for ten seconds was found to be modified by the person under observation having to carry out simultaneously any one of the following among other operations during the period of exposure: tapping rhythmically on the table with the forefinger; speaking a simple syllable over and over again; carrying out a simple sum in addition in an audible voice. In all cases the effect was to confuse the recollection, the degree of confusion being greatest in the last two described instances.

Wednesday Morning.—Profs. Gotch and Lodge demonstrated the method employed by them in order to study the physiological effects produced by rapidly alternating currents of high intensity. They first showed that a nerve muscle preparation from the frog, if held in the neighbourhood of a friction machine to the poles of which were attached Leyden jars, responded by a single contraction whenever a spark passed between the knobs of the machine. Since there was no connection, except an air one, between the preparation and the machine, it was evident that the response was due to the preparation being in the line of force which spreads out from the knobs, and that when the spark passed, the sudden equalisation of these effects must be accompanied by a surging to and fro in the exposed nerve; the sudden character of this excites the tissue. They then showed the following experiment:—

A looped circuit was arranged connecting the two Leyden jars together, but leaving them attached to the friction machine; the end of the loop was connected to the earth, this being essential to avoid all static effects. Two wires were joined, one to each side of the loop, and the ends placed so as to embrace the exposed nerve of a nerve muscle preparation midway between the central end and the muscle. The upper end of the nerve was now brought into contact by means of other separate electrodes with an induction apparatus, and was excited every four seconds by a minimal excitation. On working the friction machine, and passing the strong rapidly-oscillating currents of the Leyden jars through the preparation, it was observed that only when the spark of the friction machine was extremely intense did the preparation respond by a contraction to these rapidly alternating currents, and that the sole effect of rather feebler alternating currents was to so alter the nerve that it ceased for a brief period to transmit the nerve impulse evolved by the constant rhythmical stimulus at the central end. The passage of these currents thus seems to produce a temporary paralysis of the nerve without causing excitation, acting thus like pressure or cold.

Prof. Engelmann described a new kymograph and polyrheotome, and exhibited tracings obtained with the instrument, which showed the great accuracy of the apparatus. The recording surface was driven by means of a weight which was so contrived as to ensure that in each experiment the same velocity should be reached before the weight ceased to act, and the subsequent revolution rendered practically uniform.

Mr. G. J. Burch showed a series of photographs of the excursions of a very sensitive capillary electrometer when projected on to a rapidly travelling plate and actuated by speaking into a telephone placed in the circuit. The excursions formed the basis for calculations of the E.M.F. of such telephone currents as are produced by the sounds of ordinary conversation: this varied from ·05 to ·1 of a volt, but with louder sounds might be sufficient to produce electrolysis. Photographs were shown which demonstrated that the instrument used could respond to changes of potential difference when these occurred one after another at a rate of nearly 3000 double vibrations in one second. The effect of the sounds of certain vowels and consonants were shown, such as *ah*, *ee*, *z*, and . In each case the fundamental tone of the voice and some of its harmonics combined to give a characteristic electrometer excursion with higher rapid vibrations superimposed upon it. These in the case of *z* were just visible under a lens, and appeared to have a rate of 3000 in one second. Photographs were also shown of the characteristic excursion caused by the pronunciation of the words, "Pop, pop," and "Dod, dod," the difference between the labial and the dental being well marked. Finally another series of photographs was exhibited which demonstrated that when electrolysis occurs in the electrometer, and the evolution of the gas recorded on the travelling photographic plate, this evolution is seen to take place without any measurable delay the instant the electrolysing current commenced.

BRITISH ASSOCIATION CONFERENCES OF THE DELEGATES OF THE CORRESPONDING SOCIETIES.

THE meetings of the Conference of Delegates were held at the New Examination Schools. Forty-two societies nominated delegates to represent them at the Conference.

FIRST CONFERENCE, AUGUST 9.

The Corresponding Societies' Committee was represented by Prof. R. Meldola (chairman), Prof. T. G. Bonney, Sir John Evans, Sir Douglas Galton, Dr. Garson, Mr. Hopkinson, Mr. Cuthbert Peek, Sir Rawson Rawson, Mr. Symons, Mr. Topley, Mr. Whitaker, and Mr. T. V. Holmes (secretary).

The Chairman remarked that this was their tenth Conference. Hitherto the reports of these Conferences had always been a year behind, as regards their publication in the British Association volume; the report of the Conference held at Edinburgh in 1892, for example, appearing in the volume giving an account of the proceedings at Nottingham in 1893. Steps had been taken to prevent this delay in future. They had also taken a new departure in announcing beforehand that some special subject would be discussed at the Conference. On that occasion they had been fortunate enough to secure the attendance of Mr. Cuthbert Peek to open a discussion on Local Museums.

Mr. Cuthbert Peek dealt with the subject under the following headings:—

(1) Methods of registration and cataloguing.

(2) The protection of specimens from injury and dust.

(3) The circulation of specimens and type collections for educational purposes.

(4) Central referees for nomenclature and classification.

(5) The most satisfactory methods of making museums attractive.

(6) Museum lectures and demonstrations.

(7) The relations between museums and County Councils.

(1) For small museums he thought a card catalogue was the best. Sectional letters should distinguish the various classes of objects. Each specimen, when received, should have a number under the letter of the section assigned to it, painted on the specimen. It was a good thing to have the dimensions of the specimen, with a rough outline of it, on the back of the card.

(2) Every closed case was acted upon by changes in the pressure of the atmosphere, so that it drew in and gave out air and dust with every change of pressure. It was desirable to admit air into each case by means of an opening filled with cotton-wool, or some similar material, so that the air entering might be filtered.

(3) At Liverpool a system had been elaborated by which type collections were prepared and circulated among a large number of schools. Each collection contained some special class of objects, such as food products, woods, &c. Those wishing to organise a plan of this kind should consult a paper by Mr. J. Chard, in the Report of the Museums' Association for 1890.

(4) The average curator of a small museum was often in difficulties as to the correct names of certain specimens. An organisation of specialists who would, for a small fee, allow specimens to be forwarded to them for identification, would be of the greatest use.

(5) While there were many well-arranged and attractive museums, there were others dusty, with labels illegible or invisible, which were almost unvisited and unknown. The English as well as the Latin names of specimens should be given. Much might be done to exhibit the variations of structure in creatures of different families or genera. Thus, in the Natural History Museum, South Kensington, there had recently been placed the skeletons of a man and of a horse, both in the attitude of running, so that the relations of the two, bone for bone, could be distinctly seen. The surgical, ordinary, and veterinary names of the bones were added.

(6) It was extremely difficult to make a museum demonstration useful to more than about a dozen persons. One experienced demonstrator had suggested that a lecture should be given in an ordinary lecture-room, illustrated by specimens, &c., to the whole of a large gathering, and a case-demonstration afterwards to the few seeking further information. The demonstrator should be placed on a temporary stand, so that he might see, and be seen by, his audience.

(7) It had always appeared to him that demonstrations in museums should take a very prominent part in technical instruction, and he had been surprised that so little aid had been given by County Councils to museums. Having sent out a circular to County Council Technical Education Committees, he had found that local museums and free libraries had been assisted in only nine cases. From some counties no information had yet been received, but it would appear from the answers received that there was no insuperable obstacle to the application of money intended for technical education to the development of museums.

In conclusion, Mr. Peek drew attention to the magnificent museum founded at Oxford by General Pitt-Rivers, the arrangement of which was unique.

The Chairman thought they were greatly indebted to Mr. Peek, and invited discussion.

Sir John Evans said that Mr. Peek had left but little for any one to add. He approved of the card catalogue, but thought that the American system of having a perforated card through which a wire passed might perhaps be preferable. He would be glad to know the best way of keeping a cabinet free from dust. He had tried a lining of cotton wool, but did not think the result perfectly satisfactory. As regards referees for nomenclature and classification, he would suggest the keepers of the various departments of the British Museum, who would always give prompt and valuable assistance.

The Rev. O. P. Cambridge, having a large collection in spirits of wine, had found that the best place for the labels was inside the glass jars, not outside. The writing should be with a pencil.

Sir Rawson Rawson had not always found pencil-marks indelible; and the Rev. O. P. Cambridge added that the pencil should be neither very hard nor very soft.

Dr. Garson could corroborate what had been said as to the advantages of using pencils in spirit preparations. Mr. Gray remarked that variation in the aspect of a museum constituted a most important element of attraction. The circulation of specimens tended, in itself, to make a museum attractive.

Mr. T. W. Shore hoped that Conference might do something towards obtaining aid for museums from County Councils. It was clear that grants could be made by County Councils to defray the expense of lectures and demonstrations in museums.

Mr. Sowerbutts remarked that though County Councils might be subject to the Government auditor, boroughs were not; and Mr. Kenward said that at Birmingham the Corporation had established a museum and art gallery without any help from the County Council.

Mr. T. V. Holmes had in his hands a letter from Mr. W. Cole, secretary to the Essex Field Club, who was most intimately acquainted with technical education as it existed in Essex. Mr. Cole's experience had given him a very low notion of the efficacy of mere lecturing. A lecturer brought specimens with him, but with the departure of the lecturer the specimens also departed. What was wanted was (Mr. Cole thought) a permanent central museum continually sending forth loan collections to the remoter districts, the collections being allowed to remain a certain time after the lectures illustrated by them had been given. He did not think County Councils should have the entire control of museums, as that would greatly diminish the interest taken in them by the naturalists and field clubs to whom they usually owed their existence. But a grant from the County Council would give a permanence to a museum which would immensely increase its efficiency in every way.

After some discussion, in which Dr. Brett, Sir Douglas Galton, Mr. Gray, Sir John Evans, Mr. Cushing and Mr. Whitaker took part, the following resolution was proposed by Sir Douglas Galton, and seconded by Dr. Brett :—

"That in the opinion of this Conference it is desirable that local natural history societies, and those in charge of local museums, should place themselves in communication with the Technical Instruction Committee of the county or borough in which they are placed, with the view of obtaining pecuniary grants towards extending technical knowledge by means of lectures or by demonstrations in museums."

Mr. Coates stated that at Perth they were building a large addition to their museum, and had obtained a grant from the County Council on condition that they provided specimens suitable for agricultural teaching.

Mr. Elworthy said that a difficulty felt by many had not been touched upon. They needed the services of an expert who would visit a museum and pronounce with authority, "this is rubbish," in the case of worthless specimens. A secretary would seldom venture to get rid of rubbish on his own responsibility.

Sir John Evans thought the opinion of the secretary should be deemed sufficient.

The Chairman then put the resolution to the meeting, and it was unanimously adopted. On asking if any delegates had any other remarks to make,

Mr. Seward, of Cardiff, was anxious to know, if possible, what things bought for a museum in order to make it more useful and attractive to the poorer classes might be legally purchased under the Act.

Sir John Evans said that it seemed to him that the last resource in these cases was the Science and Art Department at South Kensington.

The Chairman thought the Conference could not possibly attempt to decide the point raised by Mr. Seward. He felt sure that all present were most grateful to Mr. Peek for having opened this discussion on museums, which, he believed, would lead to most useful results.

SECOND CONFERENCE, AUGUST 14.

The Corresponding Societies' Committee was represented by Prof. R. Meldola (chairman), Dr. Garson, Mr. Hopkinson, Sir Rawson Rawson, Mr. Symons, Rev. Canon Tristram, Mr. Whitaker, and Mr. T. V. Holmes (secretary).

The Chairman hoped that delegates would do their best to further the resolution passed at their last meeting, with regard to local museums.

SECTION A.

Meteorological Photography.—Mr. Clayden stated that a sufficient collection of photographs had been received, except that he would be glad of photographs of lightning showing anything abnormal. Sometimes he read of the remarkable effects of a whirlwind in some district when it was too late to obtain photographs of its results. In such cases he would be glad if the secretary of some local society could get photographs taken at once, and send them to him before it was too late. In reply to Sir Rawson Rawson, he said that he had seen the photographs of storms and lightning exhibited by the Royal Society, and believed he had many of them.

Mr. Symons remarked that much help could be given by local societies if they were to send reports in.

Earth-tremors.—Mr. Davison said that in the last report of the Earth-tremors Committee there was a description of a bifilar pendulum invented by Mr. Horace Darwin. It had also been described in NATURE for July 12. It was especially desirable that instruments for registering earth-tremors should be placed along the course of great lines of fault (dislocations of the strata).

Mr. Horace Darwin then explained the construction of his bifilar pendulum for registering earth-tremors. It was not, he said, affected by the rapid, complicated movements which took place during an earthquake, nor by the slight tremors caused by passing carts or trains. But extremely slight movements of the kind which would make a factory chimney lean to one side would be registered.

Mr. Symons, as chairman of the Earth-tremors Committee, explained how the work of the Committee had grown, and in what respect it needed additional help. A series of pulsations which had been recorded by an instrument placed at the bottom of one of the deepest mines in the district of Newcastle-on-Tyne had been traced to two causes—the gradual settlement of the ground in consequence of the removal of the coal, and the beating of the waves on the coast. They had since been looking for traces of earthquake tremors. Mr. Davison on one occasion watched his instrument for some time, as he found pulsations were taking place. They turned out to have been produced by the earthquake then going on in Greece. They wanted information as to the changes going on in connection with the faults in geological strata, and, if possible, to get records of the alterations in the earth's crust caused by tidal waves. The work was then going on at Birmingham under Mr. Davison, but they were anxious to have instruments established in other parts of the British Isles. In answer to Mr. Tiddeman, Mr. Symons said that an instrument could be placed on the floor of a cellar. Mr. Horace Darwin had kindly undertaken to explain its mechanism at the close of the Conference.

The Chairman hoped that some of the corresponding societies would have something to report on this question next year.

SECTION B.

Pollution of Air in Towns.—Dr. G. H. Bailey said that for three or four years they had been engaged in Manchester, in connection with the Manchester Field Naturalists, in examining the air of towns. The amount of pollution and the amount of the death-rate varied together. They had almost perfected a method for determining the amount of sulphur compounds in the air, and one for measuring the amount of sunlight in towns. Their work had been chronicled in the *Journal* of the Manchester Field Naturalists for 1893.

Mr. Slater made a few remarks on the effects of smoke on plants, and the Chairman added that cryptogams and lichens were once common on trees in Epping Forest. London had now approached too near for them to flourish.

SECTION C.

Mr. Whitaker (representing Section C) said that he would first refer to coast-erosion. The final report on this subject would be made, he hoped, next year. The subject would then be handed over to the local societies, and those which had coast borders could continue the work by recording changes on six in maps. As regards the Committee on the Circulation of Underground Waters, its final report would also be made next year. In this case, also, the local societies could continue the investigation. It had been suggested that the twenty reports should have their contents arranged topographically, and that if then published, as a volume of 250 to 300 pages, many local societies might be glad to purchase it.

Erratic Blocks.—Mr. Murdoch regretted that the labours of the Erratic Blocks Committee were confined to England and Ireland. The work in Scotland had not been so nearly finished as was commonly supposed. Mr. Gray said that in Ireland they had issued their first Report on Erratic Blocks.

Prof. J. F. Blake stated that he was engaged in examining the microzoa of clays, especially of Jurassic clays, and would be glad if members of the corresponding societies could send him samples. He would gladly report to senders on the general character of these clays and their microzoa. He might take that opportunity of telling the delegates that unless he could obtain more support for the *Annals of British Geology* he could no longer afford to publish it.

Mr. Whitaker hoped that Mr. Blake's remarks would prevent the cessation of that most useful work.

Geological Photographs.—Mr. Jeffs said that the committee had received 1055 photographs, and had passed a resolution recommending the Council of the British Association, whose property the collection was, to deposit it in the Museum of Practical Geology, Jermyn Street, London.

SECTION E.

Mr. Sowerbutts said that the Manchester Geographical Society had come to the conclusion that geography would never be taught satisfactorily in primary schools unless it was made a compulsory subject. Progress had been made in some primary schools by the institution of school-museums. It was a singular fact that at an examination in geography of the primary schools of Cheshire, Lancashire, and Yorkshire, the girls had won all the prizes in Yorkshire, and the boys in Lancashire. His Society had for the last two or three years published an analysis of the chief geographical papers which had appeared in English and foreign journals.

SECTION H.

Ethnographical Survey.—Mr. Brabrook remarked that during the past year their list of suitable villages had been considerably increased, and now numbered 367. At Ipswich a sub-committee had been formed to assist them, and at Liverpool the keeper of the museum had given most valuable help. In Wales their sub-committee had met and had done good work, and the same remark might be made of Ireland. In Scotland they had a promise of assistance from the Glasgow Archæological Society. They had been told that their instructions about photographing were too minute, but they had been drawn up by Mr. Francis Galton with reference to his system of composite photographs, and any departure from them would make the application of that system comparatively difficult.

Mr. Sowerbutts stated that old people in his district objected to be photographed and measured.

Dr. Garson said that as regards photographs it was not necessary to get all the appliances Mr. Galton had mentioned. It was desirable to have a seat which could be raised or lowered like a piano-stool, so that each person might have his head in the same place, whatever his height might be. It was well, also, to have chalk lines on the floor at right angles to each other, the sitter being directed to look along either one line or the other. They did not want measurements of people more than fifty years old.

Mr. Brabrook added that a set of instruments for measurements might be had for £1 6*s.*, and a more expensive set for £3 3*s.* And Dr. Garson remarked that the cheaper set was quite good enough.

A vote of thanks to the chairman closed the proceedings.

SCIENTIFIC SERIALS.

Proceedings of the Edinburgh Mathematical Society, vol. xii. (Williams and Norgate, 1894)—The geometrography of Euclid's problems, by Dr. J. S. Mackay, is a modification of M. E. Lemoine's La Géométrographie ou l'art des constructions Géométriques (the subject of two memoirs read at the Oran (1888) and Pau (1892) meetings of the French Association for the Advancement of the Sciences), and an application of it to the problems in the first six books of Euclid's "Elements." The restrictions are those of Euclid, viz. that the constructions should be effected by means of the straight-edge and compasses only. It is an interesting introduction of M. Lemoine's methods to English readers. The same author contributes formulæ connected with the radii of the incircle and the excircles of a triangle. This is on the lines of the work we recently noticed by the same writer (vol. i. *Edin. Math. Soc. Proceedings*). It is founded upon a table given in the *Lady's and Gentleman's Diary* for 1871. Nearly all of the eighty formulæ are assigned to the authors who first published them: possibly those unassigned are due to Dr. Mackay himself. M. Paul Aubert, in his "Coordonnées Tangentielles," applies them to the discussion of a number of general problems relating to surfaces of the second order.—Dr. Sprague writes on the geometrical interpretation of i^i; his investigation was suggested by a result given in Hayward's "Vector Algebra and Trigonometry."—Mr. G. A. Gibson, in a proof of the uniform convergence of the Fourier Series, with notes on the differentiation of the series, discusses a point which has not, apparently, been considered in the English text-books.—In addition to the above papers there are several short notes: Prof. Crum Brown gives an abstract of a paper (to appear) in the *Transactions* of the Royal Society of Edinburgh, on the division of a parallelepiped into tetrahedra; notes on factoring, J. W. Butters; on a problem in tangency, G. E. Crawford; on certain maxima and minima, G. Duthie; on solutions of certain differential equations, F. H. Jackson; on E. Carpenter's proof of Taylor's theorem, R. F. Muirhead; notes on the number of numbers less than a given number and prime to it, and on the pedal triangle, Prof. Steggall; five notes, viz. two circular notes, geometrical note (ii.), two triplets of circum-hyperbolas, three parabolas connected with a plane triangle, and notes on an orthocentric triangle, R. Tucker; and a note, by W. Wallace, on a third mode of section of the straight line. Of the other communications that were made to the Society during the session the titles only are given. A list of members and of the presents made to the library close the volume, which contains a good deal of matter of interest to mathematical teachers.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 7.—"On the Recurrent Images following Visual Impressions." By Shelford Bidwell, F.R.S.

The earliest recorded observation of a certain curious phenomenon associated with optical after-images is that of Prof. C. A. Young, who published a note on the subject in the year 1872, and proposed that the phenomena should be called "recurrent vision." (*Phil. Mag.* vol. xliii. 1872, p. 343). He noticed that when a powerful Leyden jar discharge took place in a darkened room, any conspicuous object was seen twice at least, with an interval of a little less than a quarter of a second; often it was seen a third time, and sometimes even a fourth.

A few months later an account of two experiments on the same subject was published by Mr. A. S. Davis. (*Phil. Mag.* vol. xliv. 1872, p. 526). In the first, a piece of charcoal, one end of which was red-hot, was waved about so as to describe an ellipse or circle a few inches in diameter. A blue image of the burning end was seen following the charcoal at a short distance behind it, the space between the charcoal and its image being absolutely dark. The other experiment was made with a piece of apparatus resembling a photographic instantaneous shutter. The shutter was interposed between the observer's eye and the sky, and was covered with pieces of coloured glass, through which momentary flashes of light were allowed to pass. It was found that each flash was, after a short interval, generally succeeded by a recurrent image, the colour of which was nearly complementary to that of the glass.

In 1885 the author called attention to a very simple and effective method of exhibiting a recurrent image (NATURE, vol. xxxii. 1885, p. 30). If an ordinary vacuum tube, illuminated by an induction coil discharge, is made to rotate slowly upon a horizontal axis fixed at right angles to the middle of the tube, the tube is seen to be followed at a distance of a few degrees by a ghost-like image of itself, the ghost exactly imitating the original in form, but having a uniform steel grey colour. In the same paper the following observation is noted:—"The vacuum tube being at rest in a feebly lighted room, I concentrated my gaze upon a certain small portion of it while the discharge was passing. The current was then interrupted, and the luminous image was almost instantly replaced by a corresponding image which appeared to be intensely black upon a less dark background. After a period, which I estimated at from a quarter to half a second, the black image again became luminous; this luminous impression lasted but for a small fraction of a second, and the series of phenomena terminated with its disappearance . . . . It was also found desirable to make the preliminary illumination as short as possible, a single flash being generally sufficient to produce the phenomena." The following comment was added:—"The series of phenomena seem to be due to an affection of the optic nerve which is of an oscillatory character. Abnormal darkness follows as a reaction after the luminosity, and again after abnormal darkness there is a rebound into feebler luminosity."

The subject has recently attracted much attention in connection with the experiments of M. Aug. Charpentier. The account of them given by M. Charpentier in a paper on "Retinal Oscillations"[1] is briefly as follows:—If a black disk having a white sector is illuminated by a strong light, and slowly turned round while the observer's eye is fixed upon its

[1] "Oscillations rétiniennes," *Comptes Rendus*, vol. cxiii. 1891, p. 147. See also "Réaction oscillatoire de la Rétine," *Arch. de Physiologie*, 1892, p. 541.

centre, there appears upon the white sector, near to its leading edge, a well-defined dark band, which is separated from the black ground of the disk by a similar white band. The angular extension of the dark band increases with the speed of rotation, so that it always takes the same time to pass over a fixed point on the retina; it begins about one-sixty-fifth or one-seventieth of a second after the first passage of the white, and lasts sensibly the same time. He goes on:—"The dark band is in fact only a kind of reaction of the retina after the luminous excitation, a reaction which can be demonstrated in a totally different manner. I have found that if an instantaneous luminous excitation is produced in complete darkness the sensation appears to be reduplicated; shortly after its first generation it seems to disappear, and then manifest itself again. This is the case, for example, when a single discharge from a Ruhmkorff coil is passed through a Crookes or Geissler vacuum tube, or simply, but less obviously, through the air. . . . . There is, then, in this last experiment, as in the first, a negative reaction of the retina under the influence of excitation. . . . . It would be difficult, and in any case premature, to indicate the cause of this phenomenon, but it may fairly be characterised as the result of a retinal oscillation set up under the influence of the beginning of the luminous excitation."

The present paper deals partly with the colours of recurrent images under different conditions, and partly with the reaction attending the early stages of a luminous impression as noticed by Charpentier.

In the observation of the recurrent images set up by the action of light of different colours, the author began, like Mr. Davis, by using coloured glasses.

A metal disk, about 8 cm. in diameter, was arranged so as to rotate slowly and steadily about its centre in front of the condenser of a projection lantern. Near the edge of the disk was a circular aperture about 0·5 cm. in diameter, the image of which was focussed upon a distant screen. A plate of coloured glass was placed before the projecting lens, and thus was obtained a small coloured disk of light, which described a circular path upon the screen. The coloured disk was, in most cases, seen to be followed at an interval of a few degrees by a ghost of the same size and shape, but of feebler luminosity, and of a hue which varied more or less with the colour of the glass employed. With white electric light the colour of the ghost was violet.

This method of experimenting was, however, found to be unsuited for the purpose in view, and it is mentioned only on account of the facility which it affords for exhibiting the phenomenon to a large number of persons. To obtain results of any value, it was necessary to employ the simple colours of the spectrum.

In the arrangement finally adopted, light from a selected portion of a spectrum was projected upon a small mirror, to the back of which was attached a horizontal arm, not quite perpendicular to the mirror: the arm was rotated by clockwork, and the reflected beam of light was received upon a white screen, forming a coloured disk about 1·5 cm. in diameter, which revolved in a circular path having a diameter of 30 cm.

When the mirror turned once in 1½ seconds the ghost or recurrent image appeared about 50° behind the coloured disk, the corresponding time interval being one-fifth of a second. The ghost appeared to be circular in form, its diameter being generally rather less than that of the original. The colours of the recurrent images, as specified below, have all been observed by several persons, and, except as to those at the extreme limits of visibility, all the observations were in agreement.

Spectrum colours.	Recurrent colours.
Extreme violet... ...	No perceptible image.
Middle violet	A pale image, variously described as grey, yellow, and greenish-yellow.
Dark blue	Feeble violet.
Light blue	Brighter violet.
Middle green	Bright violet. The image is more conspicuous with green light than with any other.
Greenish-yellow ...	Blue.
Orange-yellow... ...	Bluish-green.
Orange	Dark bluish-green.
Orange-red	Very dark bluish-green.
Red	No image at all, however bright the red was made.

A complete small spectrum, revolving parallel to itself in a circle about 1 metre in diameter, was followed by a ghost which corresponded to the portion of the spectrum comprised between the orange and the beginning of the violet. The *whole* of this ghost was of a violet hue: no trace whatever of yellow or greenish-yellow could be detected at the more refrangible end, nor of blue or bluish-green at the other.

From other experiments it appeared probable that the blue and bluish-green recurrent colours apparently observed when the yellow and orange portions of the spectrum are tested separately are due merely to an effect of mental judgment, and not to any cause of a physiological nature.

Four independent facts are consistent with the conclusion that luminous recurrent images are due to a reaction of the *violet* nerve fibres only.

(*a*) With white light the recurrent colour is violet.

(*b*) In the recurrent image of the complete spectrum no colour but violet can be detected.

(*c*) A pure red light, however intense, gives no recurrent image. (It is generally supposed by the supporters of the Young-Helmholtz theory that red light has no action upon the violet nerve-fibres.)

(*d*) The apparently blue colour of the ghost of simple spectrum yellow is just as well produced by a compound yellow consisting of green and red, the latter of which is inert when tested separately.

The path of the revolving spot of light is generally marked by a phosphorescent track, which, when the rate of revolution is not less than one turn in 1½ seconds, often forms a complete circle. The trail is due to the usually feeble continuation of the after-image, of which the bright initial stage constitutes the recurrent image.

In the experiment next to be described, the Charpentier effect and the recurrent image are made to exhibit themselves simultaneously.

Two blackened zinc disks, 15 cm. in diameter, from each of which two opposite quadrants were cut out, were mounted in contact with each other on a horizontal axis, driven by clockwork, and making one turn in 1½ seconds. By slipping the disks over one another round their centres, opposite open sectors might be obtained, of any aperture from 0° to 90°. The apparatus was set up opposite a box containing a 32-candle power incandescent lamp, with a variable resistance in the circuit, the side of the box between the lamp and the disks being covered with a sheet of ground glass.

The sectors being in the first place opened as widely as possible, Charpentier's dark band was easily seen upon the illuminated background.

The sectors were then gradually closed up, until the posterior edge of the dark band approximately coincided with that of the sector. When this was accomplished, it was found that the arc of the open sector was equal to about $\frac{1}{52}$ part of the whole circumference. The dark reaction, therefore, ceased in ($\frac{1}{52}$ of 1½ seconds =) $\frac{1}{35}$ second after the first impact of the light upon the eye.

For more readily demonstrating the succeeding phenomena, it was found convenient to again open the sectors a little, so that they covered an angle of about 10° or 12°. Resuming the observation, it was seen that the posterior edge of the open sector was bordered by a luminous fringe due to persistence. A little beyond the termination of the fringe there appeared an intensely black radial band, estimated to cover a space of from 3° to 4°, and distinguishable even upon the black ground of the metal disk, though it is shown far more conspicuously upon a translucent disk made of stout writing-paper with a sector cut out. Lastly, after another interval of perhaps 35° or 40°, came the luminous recurrent image, which, with the yellowish light of the incandescent lamp, appeared to be of a blue colour.

This method of observation revealed one other point of interest, which seems hitherto to have escaped notice, though it is evident enough with a Charpentier disk, when once attention has been directed to it. The average illumination of the bright band intervening between the dark band and the leading edge of the sector is much more intense than that of the other portion of the sector. Moreover, it is not uniform, but increases, gradually at first, and very rapidly at last, from the leading edge up to the dark band. In fact when the light used is not strong, the luminous margin of the bright band is a far more conspicuous object than the dark band itself: it appears to glow almost like a white-hot wire.

Charpentier states that, under favourable conditions, he has been able to detect the existence of a second, and even of a third, dark band of greatly diminished intensity, though he adds that the observation is a very difficult one. What is probably the same effect in a different form can, however, be shown quite easily in the following manner :—

In a blackened zinc disk 15 cm. in diameter, there were cut two opposite radial slits, about 0·5 mm. in width. The disk was rotated at the rate of one turn per second in front of a sheet of ground glass, behind which was an incandescent lamp. The glass was covered with opaque paper, in which a circular opening was made of slightly less diameter than the disk. The disk was placed opposite this opening, and no light reached the eye except such as passed through the two slits. When the disk was observed from a distance of about $1\frac{1}{2}$ metres, the eye being fixed upon its centre, each slit appeared to give four (or possibly five) luminous images, arranged like the ribs of a partly opened fan. The images were distinctly separated by dark intervals near the circumference, but overlapped one another towards the centre. The leading image was naturally the brightest, each consecutive image being considerably weaker than its precursor. All had the same tone of colour, namely, that of the yellowish-light given by the electric lamp. The usual blue recurrent image could also be seen following the images of the radial slits, at an angle of about 80°.

It appears, then, that when the retina is exposed to the action of light for a limited time, the complete order of visual phenomena is as follows :—

(1) Immediately upon the impact of the light there is experienced a sensation of luminosity, the intensity of which increases for about one-sixtieth of a second : more rapidly towards the end of that period than at first.

(2) Then ensues a sudden reaction, lasting also for about one-sixtieth of a second, in virtue of which the retina becomes partially insensible to renewed or continued luminous impressions. These two effects may be repeated in a diminished degree, as often as three or four times.

(3) The stage of fluctuation is succeeded by a sensation of steady luminosity, the intensity of which is, however, considerably below the mean of that experienced during the first one-sixtieth of a second.

(4) After the external light has been shut off, a sensation of diminishing luminosity continues for a short time, and is succeeded by a brief interval of darkness.

(5) Then follows a sudden and clearly-defined sensation of what may be called abnormal darkness—darker than common darkness—which lasts for about one-sixtieth of a second, and is followed by another interval of ordinary darkness.

(6) Finally, in about a fifth of a second after the extinction of the external light, there occurs another transient impression of luminosity, generally violet coloured, after which the uniformity of the darkness remains undisturbed.

No account has been taken of the comparatively feeble after-image, to which the phosphorescent trail before referred to is due, and which may last for two seconds or more.

In an addendum to the paper reference is made to the recent experiments of Dr. Carl Hess ("Pfluger's Archiv fur Physiologie," vol. xlix. p. 190).

PARIS.

Academy of Sciences, August 27.—M. Lœwy in the chair.—On the variations of the apparent signs of lines and angles, in direct vision and in vision by movements of the eyes and head, by M. Ch. Henry. Formulæ and tables are given embodying the results of the consideration of a great number of cases and enabling apparent sizes to be calculated.—On the transformation of *équations canoniques* in the problem of three bodies, by M. Paul Vernier.—On the possibility of replacing the indeterminate problem given by the generalisation of Pascal's theorem by a determinate problem, by M. Paul Serret.—Researches on the movements of the solar atmosphere, by M. H. Deslandres. An examination of many photographs of spectra of the sun reveals interesting phenomena in connection with a bright line occurring within the wide dark lines H and K of calcium. This line may be resolved into two bright lines enclosing a dark line; the bright lines correspond to the lower layers of the chromosphere, while the dark line belongs to the higher layers. These bright lines often show dissymmetry, sometimes one and sometimes the other becoming the narrower. Spectra of the faculæ do not usually show this dissymmetry, but it is a common condition over the remainder of the surface, and is more pronounced near the equator than in the neighbourhood of the poles. Near spots the observed dissymmetry is often in the opposite direction on opposite sides, and the narrowing of the line is sometimes irregular. These phenomena can be explained on the hypothesis of a continual circulation of the sun's atmosphere, but it is worth noting that a less marked dissymmetry has been obtained in the calcium spectrum produced by the induction spark. Resemblances are pointed out between these phenomena and those observed in the spectrum of Nova Aurigæ.—A remarkable thunderstorm, by M. Ch. V. Zenger.

BACTERIA IN WATER.

Micro-Organisms in Water; their Significance, Identification, and Removal. By Prof. Percy Frankland and Mrs. Percy Frankland. (London: Longmans, Green, and Co., 1894.)

On perusing this volume, there can be left no doubt in the mind of anyone who has paid attention to the enormous progress in the knowledge of micro-organisms in water, that the authors have succeeded in producing a work which testifies to a full and accurate survey of the subject, and to a large amount of original observations carried out by the modern approved methods. For these reasons we venture to say that this volume will occupy the position of a valuable text-book and standard work on the subject of micro-organisms in water. The views which the authors, in common with modern sanitarians, hold as to the relative value of the chemical and biological examination of potable waters, deserves special attention on behalf of some distinguished chemists, on whose mind the whole progress of bacteriological science seems to have as yet made but little impression; in this connection we quote, from p. 117, chapter v., the authors' statement which, being those of a distinguished chemist, it is to be hoped will have the desired effect:—"If water which is known to have received sewage matters (and the *entire* exclusion of such from supplies drawn from rivers is practically impossible) is to be supplied for dietetic use, and if this water, as is so often the case, is not objectionable on account of the absolute quantity of organic matter, as revealed by chemical analysis, which it contains, but only of the suspicious origin of a part of this organic matter, then it is evident that in the purification of such water the point to be taken primarily into consideration is how the organic life it contains can be reduced to a minimum." The authors might have further added that the chemical analysis only of such waters is for sanitary purposes of little practical use, since a water may contain less than the recognised amount of organic matter, and yet be dangerous for drinking purposes on account of the presence in it of some undesired pathogenic microbes. The amount of organic matter and the presence of these latter in water need not, and in some cases (*e.g.* the well-known outbreak of typhoid fever at Caterham) do not bear a constant or a definite relation to one another. As a more recent illustration of this kind, the well-known instance of the cholera in Hamburg and Altona in 1892 may be quoted.
