As is well known, Hamburg and Altona (p. 152) "are dependent upon the river Elbe for their water supply, but whereas in the case of Hamburg the intake is situated *above* the city, the supply for Altona is abstracted below Hamburg after it has received the sewage of a population of close upon 800,000 persons. The Hamburg water was therefore, to start with, relatively pure when compared with that destined for the use of Altona. But what was the fate of these two towns as regards cholera? Situated side by side, absolutely contiguous in fact, with nothing in their surroundings or in the nature of their population to especially distinguish them, in the one (Hamburg) cholera swept away thousands, whilst in the other (Altona) the scourge was scarcely felt." . . . "The Hamburg water, to start with, was relatively pure when compared with the foul liquid abstracted from the Elbe by Altona; but whereas in the one case the water was submitted to careful filtration through sand before delivery, in Hamburg the Elbe was distributed in its raw condition as taken from the river." Here we have water coming originally from the same source, which was yet widely different in biological respects for the two sets of consumers:—

(*a*) Hamburg water, chemically comparatively pure.

(*b*) Altona water, chemically foul, owing to great sewage pollution; yet the Hamburg water proved deadly because rich in cholera germs, while the Altona water, from which most of these germs had been removed by careful filtration, but chemically still impure, did little harm.

Prof. Percy Frankland, when before the Royal Commission on Metropolitan Water Supply, seemed to have resented a statement made by myself before that Commission as to the comparatively small value that sanitarians attribute to a purely chemical analysis of water; inasmuch as he (Prof. Frankland) quoted the very water of Hamburg as proving the importance of chemical analysis. He said that the Hamburg water which he had examined for the editor of the *British Medical Journal*, would already, on chemical grounds, have been condemned as unwholesome water. But he was immediately after this answer confronted with the information not then known to him (Prof. Frankland), given to him by one of the Commissioners, viz. that the population of Altona drank with comparative immunity the same water, only chemically more polluted, the difference between the two waters being that the Hamburg water was consumed unfiltered, while the Altona water was filtered before delivery. From what we have quoted above, it is satisfactory to find that Prof. P. Frankland, in common with others, does not attribute great value to chemical analysis alone.

The subject of preparation of culture media for bacterioscopic water-analysis, and of the methods of isolation of micro-organisms from water, are treated in a fairly exhaustive manner in chapter i. We miss, however, the description of the methods of making agar plates, probably because the authors as a rule used only gelatine plates. Chapter ii. gives a detailed description of the methods of staining bacteria. It is not quite clear where, in the examination of micro-organisms in water, the staining of sections of tubercle, leprous, and other pathological tissues comes in; at any rate, if quoted, it might as well have been quoted more perfectly. Chapter iii. deals with the examination of water for micro-organisms; chapter iv. with the bacterial contents of various waters, of rivers, lakes, wells, springs, sea-water, ice, hail, rain, &c.; chapter v. with the purification of water for drinking purposes by the various filters in use on large and small scales, sterilisation by heat, subsidence, chemical treatment, &c.; and chapter vi. on the multiplication of the micro-organisms in water. All these subjects are treated in great detail, both on account of the large amount of bibliography, as also on account of a considerable amount of work contributed by the authors themselves. There are, however, two subjects on which it is necessary to make some comment. The first refers to a passage on p. 119: they say: "In the year 1885 Koch's gelatine process of water examination was first introduced into this country by one of us."

I am quite sure that Prof. P. Frankland hereby quite unintentionally omitted to state the fact that Dr. Angus Smith (*The Sanitary Record*, 1883) was the first to apply the gelatine test for showing the relative number and the different characters of the colonies of the microbes present in water.

The second point refers to the factors which determine the efficient character of sand filters. From p. 119 to p. 142 we have a detailed account, with numerous tables, of the results of the bacteriological examination of London waters "by one of us," yet no mention is made and no indication is given of one of the most important factors (*cæteris paribus*) in efficient sand filtration, viz. the formation in the superficial layers of the filter bed of a slime (Schlamm); it is precisely after the formation of this "slime" that the filter becomes efficient, it is inefficient before the "slime" is formed. The authors have had abundant indications as to the importance of this "slime"; they quote on p. 158 researches by Piefke, who demonstrated already in 1887 that (p. 159) "it is the slime deposit on the sand which constitutes the real filtering material in the water-works' filter." Further indication of the importance of this "slime" was given to the authors by Prof. Lankester's extremely valuable evidence before the Royal Commission on Metropolitan Water Supply, November 1892, and lastly by Koch's paper on water filtration in the *Zeitschr. f. Hygiene und Infektions*, vol. xiv. Koch clearly shows that the sooner this slime is formed—water which initially contains a greater amount of impurity would form it sooner than water initially pure—the sooner the filtration becomes efficient; further, that on renewal (by scraping) of the surface of the filter this protective slime is removed, and therefore the filter for the time becomes inefficient; then the influence of frost on this slimy layer, and a variety of other important points connected with this slime. All these and others are of the utmost importance as regards the real understanding of the working of sand filters; *e.g.* the exact nature of the slime, the conditions affecting its formation, the differences of its formation in the filter-beds of the various London Water Companies, and at various periods, &c. All these points require elucidation, and one must regret that the authors have missed a valuable opportunity to treat of these in the book; since the researches "by one of us" made of the London waters in 1886, which are quoted in full in the work, no real progress appears to have been made. One thing, however, is brought out by the observations not only of Fraenkel and of Piefke, but of all that have worked on the question of purification of drinking-water by filtration, and that is (p. 157) that "even under the most favourable conditions of working the sand filters do not form a complete obstacle to the passage of micro-organisms."

Chapter vii., on the detection of pathogenic bacteria in water, gives an extensive bibliography and the most reliable methods for the detection of bacteria, the typhoid bacilli, and Koch's comma bacillus receiving a not undeservedly large share of attention. With regard to the differentiation of bacillus coli and typhoid bacillus by the presence or absence of gas-bubbles in gelatine cultures, the authors state (p. 269): "This distinction has been shown by one of us to be available in an extremely simple form for the differentiation of the two organisms," viz. the bacillus coli forming gas-bubbles in gelatine shake cultures already after twenty-four hours' incubation at ordinary temperature, while the bacillus of typhoid does not do so. I am able to confirm this, and to state that this characteristic formation of gas-bubbles by bacillus coli in gelatine shake cultures has been known and practised in my laboratory for more than two years, and is described by me in the Reports of the Medical Officer for the Local Government Board, 1892–1893; also in the *Journal of Pathology and Bacteriology* November 1893; and in the *Centralblatt für Backt. und Parasit.* vol. xv. Nos. 8 and 9.

There is one further subject to be mentioned, viz. on p. 272 and p. 273. The authors in using Parietti's method, in order to detect the typhoid bacillus in water, recommend adding to the cultivating medium "1 to 10 drops of the water under investigation"; if, as is almost invariably the case, the typhoid bacillus is present in the water in a highly diluted state, *i.e.* few examples in a large bulk of water, how the authors can under these conditions hope to recover the typhoid bacillus by using 1 to 10 drops of the water, is difficult to see. True, later on, on p. 285, an important addition *in small print* is made in the shape of a note at the end of chapter vii., to the effect that in "examining water for the typhoid bacillus it is advisable to pass a considerable volume, 250 c.c. or upwards" (this sounds rather different from 1 to 10 drops) "through a sterile porcelain or infusorial earth filter, and then to transfer this deposit on the surface of the cylinder by means of a sterile brush into a small quantity of sterile water"; this is then used for cultivation. This is the identical method which was used by me with success in the summer of 1893 in detecting the typhoid bacillus in the Worthing water, and soon after in the water from a polluted well in Rotherham.[1]

For the means by which Koch's cholera vibrio can be differentiated from other vibrios that have been hitherto found in water, the authors (on p. 270) mention Koch's conclusion that the absence of indol reaction, as well as the absence of any pathogenic effects on guinea-pigs, sufficiently distinguish the non-cholera vibrio from Koch's comma bacillus. This conclusion is definitely contradicted by a number of more recent observations made by independent workers, amongst them notably R. Pfeiffer (*Archiv. f. Hyg. und Infekt.* vol. xvii.).

Chapter viii. treats of the vitality of particular pathogenic bacteria in different waters; a large amount of bibliography with tabulated results by the various authors are given *in extenso*. Turning to the vitality of the typhoid bacillus, we find one observer (p. 290), Braem, gives the vitality of this bacillus in distilled water 188

[1] A similar remark may be made to a passage on p. 2[illegible]3. The authors in describing the detection of anthrax spores in water, state—"A method has been devised by one of us (1[illegible]3) suitable for the detection of anthrax spores when present along with other micro-organisms in water." This consists in killing by heat the non-spore-bearing forms, while the spores, being more resisting, survive. This method "one of us" might have found described in Klein's "Micro-organism and Disease," 3rd edition, 1886, p. 1[illegible]6.

days; Hochstetter, on the other hand, not exceeding five days; Meade Boulton, from two to three and ten to fourteen days; Wolffhügel and Riedel, thirty-two days. Similarly as regards the vitality of Koch's cholera vibrio in distilled water, Percy Frankland states that none were discoverable on the second day (the vibrio was initially in a weakened condition); Hochstetter, twenty-four hours to seven days; Nicati and Rietch, more than twenty days; Slater, five hours; Strauss and Dubarry, fourteen days. These differences are extremely perplexing and materially interfere with the value of the statements. As all these observers used distilled water, the differences as to the vitality must be due to the microbes themselves; the readiest explanation is this, that the different observers used the microbes in different states of resistance. It is perfectly well known that a variety of conditions, such as the nature of the nutritive medium in which the organisms had been growing, the age and the pedigree of the culture used, determine the resistance and vitality; unless, therefore, in all cases the best and most favourable cultures are used, the observations are of small value, and the authors justly (see pp. 331 and 334) lay stress on similar points.

One conclusion proceeds with clearness from the recorded observations, viz. that (p. 261) "a number of bacteria, possessing pathogenic properties of the most pronounced character, have been detected in natural waters from time to time," and it is therefore not quite correct to assume, as is generally done, that typhoid and cholera are the only diseases whose germs are distributed by water, nor is it justifiable to limit our attention to these two species only, because the whole subject of the identification of specific bacteria in water is practically still in its initial phase.

Chapter ix. and last, on the action of light on micro-organisms, is extremely well written and gives a detailed account of this important and ever-widening field of research; the history of the whole subject and the very valuable results obtained by the authors (or rather "by one of us"[1]) are described in a thorough and readable manner. It is to be regretted that the beautiful and well-known researches of Prof. Marshall Ward on the fundamental difference of action of the red and blue part of the spectrum should have been passed over.

In an appendix a valuable and up-to-date systematic description is given of the micro-organisms that have been hitherto found in water, by which their identification is greatly facilitated. We only wish the authors had not ventured to classify them into pathogenic and non-pathogenic bacteria, the former indicated by being printed in red letters, the latter in black. The authors do not accurately define, for obvious reasons, what is and what is not a pathogenic micro-organism, but give a list of "those microbes which have been found to be pathogenic to man or animals." The classification in the appendix is both incorrect and misleading. It is incorrect because a great many of the microbes mentioned here as non-pathogenic, produce disease and death in the guinea-pig if injected in sufficiently large doses into the peritoneal cavity; it is misleading because microbes are mentioned here as pathogenic, *e.g.* the *Bacillus coli*, the *Proteus vulgaris*, the *Proteus mirabilis*, which have no greater claim to such a designation than the *Bacillus prodigiosus* or the *Bacillus subtilis*; for it has been conclusively established, by a number of independent observers, that these latter act in the same way pathogenetically when injected into the guinea-pig's peritoneum as the *Bacillus coli*, the vibrio of Koch, or the bacillus of typhoid fever.

In conclusion, we have no hesitation in saying that, short of the omissions that we have pointed out, the book will take a prominent place amongst the standard works on micro-organisms in water. E. Klein.

[1] This expression occurs over thirty times.

RITTER'S "ASIA," RUSSIAN ADDENDA.

East Siberia. Part i., *being the Sayan Highlands in the Government of Irkutsk, in the South of the great Siberian Highway, up to the South-western Extremity of Lake Baikal.* By P. P. Semenoff, I. D. Chersky, and G. G. von Petz. (St. Petersburg, 1894.)

This volume belongs to the great undertaking of the Russian Geographical Society, which was begun many years ago with the intention of publishing addenda to those parts of Ritter's "Asia" which deal with regions of the great continent belonging to Russia, or touching its frontiers. The large number of geographical researches which have been made since the year 1832, when Ritter's great work had been published, and the difficulty of treating them with the same details as Ritter had treated the scanty information available sixty years ago, have resulted in many delays in the appearance of the promised volumes, and even this last one comes out as the work of three different persons—P. P. Semenoff taking it up when Chersky had met with an untimely death in the far north of Siberia. But in the hands of P. P. Semenoff, the volume we now have before us bears no traces of an incomplete posthumous publication. On the contrary, it is a well-finished work, worthy to take one of the first places among the several excellent volumes of "Russian Addenda" previously published.

Not only the great lines of Ritter's classical work and its spirit could be fully maintained, but the many explorations which have been made in this region during the last sixty years, have only confirmed the correctness of the conceptions of the great geographer. The Sayan mountains appear, indeed, as a huge border-wall of the great massive upheaval of North-west Mongolia, and as a part of the immense border-ridges which fringe the high plateau of East Central Asia. And in the Alpine regions beyond it there is no trace of the chains which Humboldt wanted to run along the parallels, and the meridians. There is, in the Tunka, the Kitoi, and the Byelaya Alps, simply a succession of chains running roughly parallel to the border-ridge.

In the huge border-ridge lies the 11,500 feet high Munku Sardyk, the highest mountain of East Siberia, which till lately was supposed to be the only one snow-clad peak in that part of Asia. Its glaciers and its summit had already been visited and described by Radde in 1856, but the present volume contains also the most interesting observations of Captain Bobyr, who has re-visited the peak, and from whom we learn that four more peaks rise above the snow-line in the same part of the

Sayans. One of them, situated further west and named Peak Middendorff, gives origin to mighty glaciers, visited by M. Yachevsky. The same expedition has fully confirmed the fact which was much contested five-and-twenty years ago, namely, that the highlands lying in the south of the Sayans are a plateau, 3000 to 4000 feet high, belonging to the great plateau of East Asia.

However, much remains to be done to explore the border-wall of this plateau, for, apart from the exploration of the Munku Sardyk and the plateau in the south of it, by Captain Bobyr, little has been added to what was known thirty years ago from the rapid excursions of Radde, Polyakoff, and the writer of these lines. The ridge offers, however, a good deal of interest in more than one aspect. It gave rise, probably, in the early Quatenary period, to mighty flows of lava, which spread down the valleys of its northern slope, reaching the valley of the Irkut; and, in the valley of one of the tributaries of the Upper Oka, the Junbulak, two small craters of ejection, 400 feet high, were described in 1864. Unhappily, these formations, so interesting in the very heart of Asia, at an altitude of about 6200 feet, have not been revisited since, and all we know about them is what could be gathered during a rapid excursion.

The beautiful valley of the Irkut, between the Sayans in the south, and the wild stony wall of the Tunka Alps in the north, is described next, and a masterly perusal of the available documents gives a very lively picture of that broad valley, covered with lacustrine deposits, and, about the Tunka village, with sheets of lava. But with the mountains in the north of this valley one enters again in a field nearly quite unbroken by the explorer. Happily enough, Chersky has crossed it in at least one direction, and some of the most interesting parts of the present volume are those given to the description of these mountains, among which the Munku Sagan Khardyk—snow-clad, as its very name shows—reaches to the unsuspected height of nearly 10,000 feet. The description is the more interesting, as it is based upon Chersky's unpublished MS. notes, and it is sufficiently detailed to give a good idea of that part of the immense Alpine region stretching in the north of the Irkut. Further west, the footpath which leads to the long since abandoned graphite mines of Mount Alibert, and which has been followed by several geographers, as also further east, this grand mountain region, rising to 7000 and up to 9000 feet above the sea-level, continues to remain totally unknown. Even the river valleys of the Kitoi and the Byelaya are only mapped in their lower courses.

The 1500 to 2000 feet high plains which lie in the north of this Alpine region, and which will soon be intersected by the great Siberian railway, come next. These fertile plains are well explored by this time, and their climate, soil, and flora are fully described; especially the flora, for which we have the excellent works of MM. Agapitoff, Prein, and J. Freyn (plants gathered by Ferd. Karo), so that we not only possess lists of plants, but know their distribution and subdivision into vegetable "formations," the whole making a capital addition to the classical work of Turchaninoff.

And, finally, the volume contains a full geographical and statistical description of the regions occupied by both the Russian and the Buryate settlements on the high plains along and on both sides of the present Siberian highway.

In the appendix the description of the Nizhneudinsk caves, explored by Chersky, is especially interesting for the naturalist; the more so as Chersky's report had only been published in Russian, in the little-known publications of the East Siberian Geographical Society, and his collection of bones was destroyed during the great Irkutsk conflagration. These caves, situated in limestones 700 feet above the level of the Uda River, and attaining a total length of 1525 feet, contain immense quantities of relics of all sorts of mammals, 17 feet thick at certain places. Moreover, in consequence of the low temperature which prevails in the caves, the bones of the animals are sometimes found with perfectly well-preserved pieces of cartilages, muscles, and skin attached to them. The species discovered by Chersky were:—*Vespertilio borealis* and another still living species of bat; *Sorex vulgaris*; *Canis Nischneudinensis*, a species of wild dog, analogous to, but separate from, the *Canis alpinus*, which may still exist in the mountains of the above Alpine region; the Arctic fox (*Canis lagopus*) and the common fox (*C. vulpes*): the common bear, the *Gulo borealis*, and the sable; a species of *Spermophilus*, different from both the *S. Eversmanii* and the *S. Perryi* which exist in north-east Siberia (its samples have perished during the Irkutsk conflagration); several *Arvicolæ*; the lemming, probably *Myodes obensis*, various soft parts of the head and fore-feet being well preserved with the bones; *Lepus variabilis*, *Lagomys hyperboreus*, *Cervus tarandus*, and *Antilope saiga* (named *Antilope borealis* by Chersky); an undetermined species of *Capra*, the horse, and, what was most striking, a piece of the skin of a rhinoceros. This find was so extraordinary that Chersky hesitated to consider it as a rhinoceros skin, and mentioned it in his report as *Sus?* And so it appears also in Count Uvaroff's "Anthropology." But this piece had happily been sent to St. Petersburg before the conflagration took place, and on nearer examination it at once was recognised as having belonged to a rhinoceros, on account of its characteristic oval pits filled with clusters of seven to ten, and even thirty-three hairs in each cluster. The mixed fauna of the caves proves that they have been filled with animal remains since the Glacial period, and possibly it also points out (through the *Saiga* remains) to a relatively warm post-Glacial period. It is evident, at any rate, that a new exploration of the Nizhneudinsk caves would prove of great utility for post-Glacial palæontology.

The foregoing rapid sketch gives an idea of the interesting contents of this volume. The very name of P. P. Semenoff is itself a guarantee for a thoroughly scientific and good all-round use having been made of all the available materials, without falling into the lengths and repetitions which one would readily excuse in a work of this kind, if they existed. The whole is a lively description of the region, with a view to the grand lines of structure, combined with minutest accuracy in even small details. It would certainly be a great regret if this volume, like the preceding ones of the Russian addenda to Ritter's "Asia" (Amur, East Turkestan, West Sayans) were to remain accessible to Russian geographers only.

P. K.

ELEMENTS OF COMETARY ORBITS.

Verzeichniss der Elemente der bisher berechneten Cometenbahnen. By Prof. Dr. J. G. Galle. (Leipzig: Wilhelm Engelmann, 1894.)

THE volume which we have before us contains, as its title indicates, a list of the orbits of all those comets which have up to the present time been calculated. As our readers may already be aware, this is not the first "Verzeichniss" with which Prof. Galle has presented us, for one has only to refer to the second edition of "Olber's Methode zür Berechnung der Cometenbahnen," by Encke, where will be found a collection of the orbits of comets which had appeared up to the year 1847. In the following or third edition, which came out in 1864, the list was expanded, revised, and brought up to date. The present "Verzeichniss" has, however, assumed larger proportions than its predecessors, containing as it does over 300 pages, and so is published as a separate work.

In the introduction the author sums up in a few words the chief points about the numerous lists of cometary orbits which have been published from time to time, referring chiefly to the different ways in which they have been arranged and compiled.

Several changes from preceding lists have been adopted in the book before us, and we will chiefly restrict ourselves to a brief statement of the same. It may be mentioned here that the order of the elements of the same comet has been so chosen that the less accurate elements precede those which have been considered more correct, so that the last elements in every case are those which approach nearest to the truth.

Two important alterations concern the removal of the distinction between direct and retrograde moving comets, and the way of representing the inclinations of orbits from $0°$ to $180°$. Instead of the Longitude of Perihelion (π) being adopted, Prof. Galle employs the angle between the node and the perihelion point, that is, he introduces an angle ω, which equals the Longitude of Perihelion minus the node, so the relation may be represented by $\omega = \pi - \Omega$. The arc ω has been termed the "Argument of Perihelion," and is somewhat analogous to the "Argument of Latitude" ($u = v + \pi - \Omega$), so that ω is the Argument of Latitude for $v = 0$, or is Perihelion point.

To pass from the "Argument of Perihelion" ω, to the "Longitude of Perihelion" π, without distinguishing between direct and retrograde movement, the simple relation $\pi = \Omega + \omega$ is used. On the other band, if, after the old style in the case of retrograde moving comets, the Longitude of Perihelion is denoted by the difference $\Omega - \omega$ and represents this by π', and if also i' denotes the value of the inclination in this case only as far as $90°$, then the relation for the reduction is as follows:

$$\pi + \pi' = 2\Omega. \quad i + i' = 180°.$$

Following the columns dealing with the position of Perihelion, the Node, and the Inclination, are others giving the logarithms of the Perihelion distance, and the eccentricity, concluding with the names of the computers of each of the orbits and the references in every case.

In addition to the above, we have no less than 160 pages of remarks and literature references, which will be found invaluable by those searching for special information about any particular comet. Perhaps a brief note will best serve to give the reader some idea of the style in which the author has brought together the information. The subjoined note, picked out at random, is typical of the method followed.

No. 356. 1883 II. Discovered 1884. January 7, by Ross in Elsternwick, at Melbourne, observed only for a few days in the southern hemisphere and in Madras, by Ellery in Melbourne until February 4, still approaching February 7 and February 19. At first visible with the naked eye, then afterwards dimmed quickly and difficult to observe—*A.N.* cviii., cix. *M.N.* xliv., xlv. *Observatory* vii. NATURE xxix.—*Tebbutt's* elements are computed from the observations made on January 19, 23, 28. *Tennant's* from those of January 17, 26, 30. *Bryant's* from three normal positions January 19, 25, February 2. *Ellery's* from those of January 12, 18, 28. Oppenheim's from those of January 12, 18, 28, 29, February 4. Three computed ellipses, one by Tennant and the other two by Bryant, in *M.N.* xlv. and xlvii., have been omitted, so also an approximate orbit by Hind in NATURE xxix.—All the above-mentioned orbits are referred to the M.E. 1884, 0.

As a rule the notes are much longer than the above, some, such as those which relate to comets 1880 I., 1881 III., 1882 I., 1882 II., 1889 V., &c., extending over a page or more.

In the compilation of this work, the thoroughness with which it has been done is a striking feature throughout, and Prof. Galle deserves the thanks of all astronomers for the completion of this volume. The information is brought up to the beginning of this year, thus making the book, besides the best, the most recent of all other lists.

W. J. L.

OUR BOOK SHELF.

Primary Geography. By A. E. Frye. Pp. 128. (Boston U.S.A.: Ginn and Co., 1894.)

WE have never seen a class-book of geography more profusely and admirably illustrated than the one under review. Our only regret is that the book, being written for schools in the United States, possesses the eccentric or reformed orthography that obtains there. This, in conjunction with the fact that the British Isles are dismissed in less than a page of text, renders the volume unsuitable for use in our schools. We hasten to remark, however, that the author has not merely concerned himself with the interests of the United States, as a brief statement of the various sections in his work will show.

The book opens with what is called "Home Geography," which section deals with elementary facts of physical geography observable at any place. The earth is next studied from an astronomical point of view; and then follow descriptions of the slopes of the earth. After describing the surface features of the different continents, the author passes to an account of the peoples of the earth, and then to meteorological phenomena. This is followed by sections on plants and animals, and finally commercial geography is treated, the continents being taken in succession. The book has so many excellent points that we can only mention a few of them. One is that the text on people refers to child-life, and must therefore appeal to children more than references to cheek-bones and the texture of hair. Plants and animals are studied in their relations to climate and physical features, and thus a clear idea as to the causes affecting distribution is obtained. Another good point is that each of the great divisions of the earth's surface is shown in its relation to the whole; in other words, the earth is the unit throughout the book. But it is in the matter of illustrations that the work excels all others of its kind. The hundreds of pictures and maps are really works of art, and the author does not claim too much when he expresses the thought that they are superior to those in any similar school book. They are true to nature, most of them having been engraved from photographs; they well illustrate and supplement the text, and they present typical forms. Only in two or three cases can any fault be found. In some of the relief maps showing hemispheres of the earth, the parts of continents extending beyond the hemispheres are, as it were, lifted from the other side, and drawn in outside the containing circle. We are sure that this will lead to misconception, for children will get the idea that the continents are surfaces lying on the earth instead of portions of the earth itself above sea-level. But this is a small matter, and one easily remedied. The book is both attractive and instructive; it reflects great credit upon the author for his originality, and upon the publishers for their enterprise. We should be glad to see a similar work produced on this side of the Atlantic.

Theoretical Mechanics. Vol. i., *Solids.* Vol. ii., *Fluids.* By J. Edward Taylor, M.A., B.Sc. (London: Longmans, Green, and Co., 1894.)

When Solomon delivered himself of the sage remark that "there is no new thing under the sun," his prophetic eye may have been looking up the corridors of time, and seen the "soul-destroying text-books" (as Dr. Armstrong terms examinational literature) of the present day. It is only rarely that a text-book writer goes beyond his brief. He designs his book to meet the requirements of a particular examination, and feels that he has performed his task successfully if future questions set by the examiners are more or less anticipated in the text. Such a writer has little scope for originality. If he departs much from the lines laid down in the examiners' syllabuses, his production fails in its object, and if he keeps the contents within the examiners' bounds, he incurs the censure of the reviewer. Thus it is that text-books are often mere summaries, and that there is a family likeness between those covering the same ground.

The volumes which Mr. Taylor has put together cannot, by the greatest stretch of imagination, be termed interesting. They are little more than collections of exercises and examples. We do not, however, raise any objection to this. Theoretical mechanics, like arithmetic, can only be learned by steadily working at exercises, and of these there is an abundance. The examples are also numerous, and they are so clear that the most obtuse student cannot fail to understand them. There is nothing remarkable about the illustrations except their familiarity. Most of them are very old, and many have done duty time after time.

The Animal as a Machine and a Prime Motor, and the Laws of Energetics. By R. H. Thurston. Pp. 97. (New York: John Wiley and Sons. London: Kegan Paul and Co., 1894.)

Prof. Thurston, the head of Sibley College, Cornell University, ranks very high among American engineers. He is well known as the author of several widely-used text-books and of numerous important papers on engineering matters. The volume just published runs into less than one hundred pages; but in that space, energy and its transformations, and the relations between matter, force, and energy are skilfully described. The chapter which deals with the animal as a prime motor will be found attractive from many points of view, and should be read by all who have to do with the muscular work of men and animals. Among the many matters with which it is concerned are the processes of vital machines, the efficiency of the animal system, effective methods of application of power, intensity of muscular effort, dietaries, and the draught of vehicles. To a large extent the book is made up of reprints from magazines, and selections from various works; nevertheless, it contains many original and valuable points, and will add to the author's already high reputation.

The Aborigines of Western Australia. By Albert F. Calvert. Pp. 55. (London: Simpkin, Marshall, Hamilton, Kent, and Co., 1894.)

Captain William Dampier, the first Englishman known to have made the acquaintance of the Australian natives, referred to them as "The poor winking people of New Holland . . . the miserablest people in the world." Mr. Calvert, who has had a little experience with the natives, looks upon their imperfections with a more lenient eye than the plain-spoken buccaneer, who visited Western Australia in 1688. He gives descriptions of a few of their habits and rites, the information being drawn in some cases from journals in the British Museum, while in others it is based upon his own recollections. Their marriage laws are curious. Children of either sex always take their mother's family name, but a man may not marry a woman of his own family name. Interesting descriptions are given of aboriginal funeral ceremonies, and these, with one or two other matters of interest to anthropologists, render the book worth reading, if a little discretion is used.

LETTERS TO THE EDITOR.

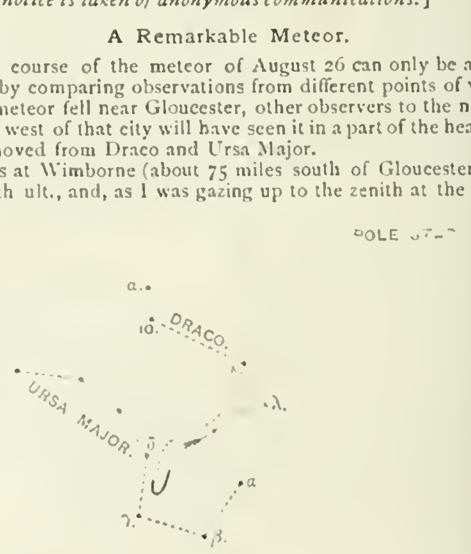
A Remarkable Meteor.

The course of the meteor of August 26 can only be ascertained by comparing observations from different points of view. If the meteor fell near Gloucester, other observers to the north, east, or west of that city will have seen it in a part of the heavens far removed from Draco and Ursa Major.

I was at Wimborne (about 75 miles south of Gloucester) on the 26th ult., and, as I was gazing up to the zenith at the time



This figure accompanied Mr. Earle's letter last week. To it a × has been added to show the position of nebulous remains of meteor as seen from Wimborne.

the meteor fell, I missed its descent, but attracted by the vivid glow, I was just in time to catch sight of a brilliant light, which seemed to me two or three times as bright as Venus at its brightest. Any elongated trail disappeared quickly, but a nebular light remained at the lowest point reached by the meteor, which assumed a vague oval shape and imperceptibly faded away. For four minutes the nebular light was easily watched; then I ceased to note the time, and after two or three minutes more I failed to distinguish it.

The position of the nebulous remains of the meteor appeared to me vertically beneath β Ursæ Majoris, at a distance from it rather more than one-third the distance of α from β. I did not notice any motion, but if the apparent upward movement of the nebulous light were due to a north-north-west current of air drifting the light incandescent ash of the meteor to the south-south-west, the motion would be imperceptible to a distant observer who was nearly in the same line up or down the direction of the wind. EDWARD F. LINTON.

Bournemouth, September 8.

IN case it may prove of interest, I write to say that I noticed the meteor mentioned in your last number by Mr. John Earle, as having been seen on the night of August 26. I was walking in the country that evening, and not long after 10 p.m. I saw the landscape lighted up as by a vivid flash of lightning from behind me—my back being towards the north at the time. On turning round, I just caught sight of the meteor as it disappeared, leaving a bright track behind it, about two degrees of arc in length. This track, as seen from where I stood, lay half-way, or nearly so, between the last star in the tail of Ursa Major and Alpha Canum Venaticorum, and in a line connecting the above two stars. It lasted several minutes, as far as I could judge, gradually fading away, and curled up at the lower end, after the manner described by Mr. Earle; but I did not detect any change of position. It seemed to remain about half-way between the end of the tail of Ursa Major and Alpha Canum Venaticorum all the time it was visible to me. I regret that, not having matches with me, I was unable to read my watch and take the exact time of the phenomenon. T. B CARTWRIGHT.

Brackley House, Brackley, September 7,

THE meteor of August 26, referred to by Mr. Earle, was seen at Northwich by me, and noted as remarkable owing to the long continuance of the brilliant light in the sky. We had had thunder and lightning in the afternoon, but the clouds had cleared away, and the stars were visible through a faint haze. On entering my garden shortly after 10 p.m., I saw a most brilliant flash of what I took to be lightning. Not hearing any thunder, I looked to see from whence the flash had proceeded. I then saw, almost in the zenith, but a little to the west, a brilliant streak of light. This remained nearly stationary for perhaps half a minute, and then one end bent till the light assumed the shape of the letter J, or, according to a note made at the time, the shape of a hockey stick. Whilst this was taking place there was a manifest movement of the whole, as I thought, towards the west. In the space of two or three minutes the light faded away. The whole time, from the brilliant flash till the fading away of the phosphorescent light, could not have been more than three minutes. Perhaps the slight haze hid the light here sooner than at Gloucester.

Northwich, September 9. THOS. WARD.

Drought at Antigua.

[MR. THISELTON-DYER has kindly sent us the following interesting note received by him from the Superintendent of Agriculture, St. John's, Antigua.—ED. NATURE.]

We are suffering from a terrible drought here. I thought you might like to look at the accompanying average prepared for H.E. the Administrator. The *Bryophyllum calycinum* weeds are drying up, and in some parts the Opuntias are dying! No single fall of under 1 inch is of any use to us.

	Jan.	Feb.	March.	April.	May.	June.	July.

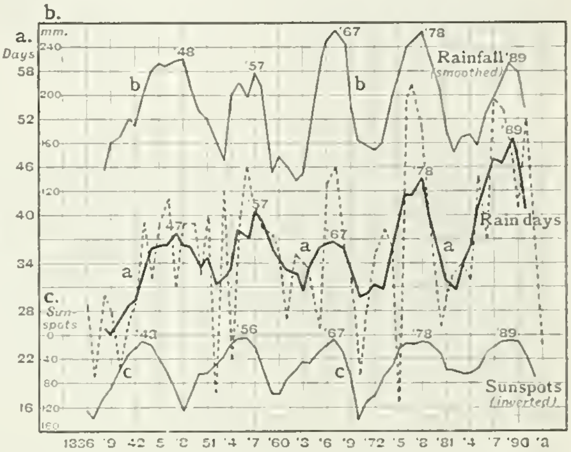
1893 „ „ „ „ 6·73 „ „ „
1894 promises to be worse than any

Antigua, West Indies, August 13. C. A. BARBER.

On Spring Rains in Geneva.

THE variation of rain at Geneva Observatory in spring (March to May), through a long series of years, appears to have been subject to a certain periodicity, to which it might be well to draw attention, even if its (considerable) similarity to that of the sun-spot curve should prove to be merely of a fortuitous nature. In the accompanying diagram, I have dealt with both rainfall and rain days (rain *hours* would have been better than rain *days*, but these extend back only to 1861). The dotted-line curve shows the actual variation in the annual number of rain days, and the continuous curve with it is the result of smoothing with averages of five. Above is a similarly smoothed curve of the spring rainfall, which is very similar (the actual variations are not given). Below is the *inverted* sun-spot curve.



The letters a, b, c, connect the curves with their respective vertical scales on the left. It will be seen that, the sun-spot *minima* occurring in 1843, 1856, 1867, 1878, and 1889, we have in the smoothed rain curves, *maxima* in 1847 or 1848 (but note that the curves rise nearly as high in 1844), in 1857, in 1867, in 1878, and in 1889. In the case of the sun-spot *maxima* (the earlier at least) there seems to be more "lag."

It would be interesting to know what happens in other parts of Europe in this respect. The Paris curve is, I think, like the Geneva one; but Bremen and Berlin present some important differences. A. B. M.

Interesting Marine Animals.

TWO rare and interesting animals, which we have had alive and under observation for a week past in the aquarium of the Port Erin Biological Station, are probably worthy of record in the pages of NATURE. The one is the yellow variety (?) of *Sarcodictyon* (*Rhizoxenia catenata*. This was first found by Forbes and Goodsir in the Hebrides, and has been described since by myself from specimens dredged in Loch Fyne in 1883. We have now found it here, off the west side of the Calf Island, in 25 fathoms, and have at present several colonies alive with the polypes expanded. The commoner red form of *Sarcodictyon* is rarely seen expanded, and I do not know that the yellow one has ever been seen in this condition. The polypes are of a beautiful transparent white, and glisten in the light like frosted silver.

The other interesting animal is the Polynoid worm *Panthalis oerstedi*. We dredge in the deep water near here large muddy sausage-like tubes, which sometimes contain *Panthalis*, but are frequently empty. Some doubt has been felt, however, as to whether the *Panthalis* really builds the tubes, and it is therefore satisfactory to have had the matter definitely settled by the formation of a new tube before our eyes by a living *Panthalis* in the aquarium during the last few days. Mr. Arnold Watson, of Sheffield, who has been studying the formation of Polychæte tubes for some years, after examining our preserved specimens, became anxious to settle the *Panthalis* question, and came here on my suggestion to get living material. I was fortunately able to take a steamer to the ground on the 25th inst., and amongst the tubes brought up in the dredge, from over 50 fathoms, one contained a fine living *Panthalis* which was successfully transferred to a small tank provided with a supply of the fine mud in which the animal lives. This worm has been kept under the closest observation by Mr. Watson and his son during the whole daytime and part of the night for the past week, and their care and enthusiasm have been rewarded by the collection of a number of drawings, photographs, and notes of the appearance and movements of the animal. During that time the *Panthalis* has deserted its old tube, and has formed a new one in the mud, fortunately using the glass of the tank for part of one side, so that the processes of scooping out the mud and of putting on the lining of mucous threads, and the various movements of the animal, have been readily enough seen—if one does not mind the inconvenience of lying for hours in a cramped position on the damp concrete floor of the aquarium room. The worm, and Mr. Watson, are still alive and at work, and we may expect a detailed account of their mutual labours from the latter when his observations are completed. W. A. Herdman.

Port Erin, August 31.

Symmetry of "Aurelia aurita."

During the last few months I have seen countless thousands of living specimens of *Aurelia aurita*, and have paid special attention to abnormal varieties. I have found not only such as have throughout the five-fold symmetry, seen by Mr. Unthank at Brightlingsea, as named in Nature for August 22, but have with me on the *Glimpse* specimens stained and mounted as lantern slides having entire three-fold and entire six-fold symmetry, and one in which it is partially two-fold. I think it may be said that in Suffolk and Essex, a few such abnormal varieties occur per thousand of the normal. An imperfect four-fold symmetry is much more common. H. C. Sorby.

Yacht *Glimpse*, Burnham, Essex, August 31.

MARS AS HE NOW APPEARS.

Statistics are looked upon, as a rule, as hateful things, but nevertheless it would be interesting to know how many people out of the millions who walk this globe will turn at this period a telescope, however small it may be, in the direction of the planet Mars, which is shining so brilliantly in our eastern heavens. Times there were, no doubt, as for instance in the early Babylonian and Egyptian civilisation, when Mars was more generally the subject of scrutiny than to-day, but then the appearance of this intermittent and gradually brightening object made far different impressions on the minds of those early observers. Early it was that the peculiar coloured rays cast by his shining surface on this earth were first remarked. He was known to the Greeks and Hebrews as the fiery planet, and in Sanskrit he was referred to as like "burning coal."

To-day, however, the case is quite different. Many there are who may happen to notice an object more brilliant than usual in the heavens, and make some brief allusion to the fact, and trouble himself or herself no more about it, but it is to the increasing few that his appearance is of the greatest interest. To those who have once made use of even a small telescope to observe the planets, the fact that the nearest, and, it may be added, the most interesting, of them, namely Mars, is approaching us day by day, will be certain to raise a strong desire to catch another glimpse of his disc under such favourable conditions.

So much has been written about the markings of his surface, which represent huge areas of water and land, to say nothing of the most curious network of canals, that reference only to the very recent work on them will here be dealt with.

A few brief remarks, before proceeding, as to the position of the planet in the heavens, and to the approaching opposition.

Firstly, as to position. At the present time Mars is moving easterly in the heavens, situated at the southernmost corner of the constellation of Aries. By September 15 he will have reached his most eastern point, and from that time he will turn in his loop, and continue his apparent journey in the westward direction, passing into the neighbouring constellation of the Fish.

The following table will perhaps be useful to those who have not the data at hand. The times referred to are Greenwich mean time.

Date.		R.A. Noon.	Decln. Noon	Diam.	Rises.	Transit.	Sets.

Nov. 7	...	1 25 29	7 51	22·8	3 29	10 16	16 55

The fact of Mars being the first superior planet reckoning from the sun, his opposition, or in other words, the position in which he is to be found in his orbit when on the same side of the sun as the earth, with all three bodies in a straight line, affords us a good opportunity for studying his surface features. Owing, however, to the non-concentricity of planetary orbits, his distance from the earth at these times is always varying, and this explains why some oppositions are more favourable for observation than others. The nearest approach of Mars to the earth may be approximately given as 35,000,000 miles, his distance at the coming opposition exceeding this number by about 5,500,000 miles.

In consequence of these varying distances, the apparent size of his disc is undergoing changes; thus the conditions at each succeeding opposition are rarely the same.

That the coming opposition is a very favourable one, can be seen from the table given below, and that it will be more favourable than that of 1892 for observers on the northern hemisphere is due to the planet's more northern declination at this period, bringing him above the mists which spoil good seeing near the horizon.

Let us turn our attention now to the observations that have been made up to the present time, and see what has as yet been learnt from a study of the Martian surface. The work to which we are now about to refer hails from the Lowell Observatory, Flagstaff, Arizona, and the observations have been and are continually being made by its founder, Mr. Percival Lowell, who has set his observatory on this spot for the single purpose of carefully studying the surface of Mars during this period of opposition. The old saying that the early bird gets the first worm, can be applied with some force to Mr. Lowell, for he has been rewarded with ample satisfaction for commencing his observations at such an early date. Indeed, perhaps the great value of this series of observations which he is making will be in its very length, for is he not, from a study of his own observations, watching attentively the various stages of a vast aquatic display which becomes more and more distinct the nearer the earth is approached, and therefore must be continually and for a long period observed?

At the commencement of the observations (May 31) the planet was 98,000,000 miles away, and his south pole was directed towards the earth at about 23½°, reaching a maximum dip of 24° on June 22, the disc appearing gibbous to the extent of about one-sixth.

Such being the conditions of seeing, one could look on the planet, so to speak, rotating under one, watching the snowy pole whirling, as a boy might look at his colour-striped top. The observations were thus limited more or less to the southern hemisphere, but occasional glimpses carried one up as far as latitude 40° north. The regions most referred to in the observations were the Syrtis Major, all the region of the north pole, that about Solis Lacus, Lacus Phœnicis, and that a little more north of Mare Sirenum and Mare Cimmerium.

The rapid diminishing of the huge snow-cap, which at this period of the planet's summer has been taking place very rapidly, has perhaps been the most prominent feature of this series of observations. Mr. Lowell has noticed a decrease in its diameter of about 7° in as few as fifteen or sixteen days, by no means a small diminution considering the length of the period.

A further very prominent feature of this polar cap is the apparently perfectly elliptical outer edge, which means that the boundary is in reality circular. The narrow dark streak girdling it, and of nearly a uniform breadth, is "clearly water at the edge of the melting snow, a polar sea in short."

On the snow-cap itself, in the region of the great bay situated south, Hellas and Chersonesus, several extremely brilliant parts have been observed, the appearance and behaviour of which have led to the conclusion that we are here dealing with mountains. These at present are accounted for by supposing that the rotation of the planet brings them into such positions that the sun's light can be reflected by them in the direction of the earth, just as a beam of sunlight can be thrown by means of an ordinary mirror. What has led us to believe them to be mountains is the constancy of the positions in which they are, for not only have they been several times observed at this period of opposition, but Mitchell in 1845, in a drawing made at Cincinnati on August 30, and Green in 1877, have both recorded them and in the same position.

Another marking on this polar cap, referred to as "the great rift," seems to be a very conspicuous object. The best time for observing it is when it is, so to speak, end on, or on the central meridian of the planetary disc. Mr. Lowell has likened it to "a huge cart-track coming down to one over the snow," and he has estimated its size as 220 miles broad and 1200 miles in length.

An observation, which is of more importance than one is at first likely to admit, is that concerning the *indefinite* characters of all the markings between the sharp boundary of the snow-cap and the *definite* characters of the continental coast-line. The coast-line was "most salient and clear cut on the western side of the Hour-Glass Sea (Syrtis Major or Mer du Sablier). To the eastward the coast lay in general direction straight, approaching the pole as it stretched eastward. It was indented by numerous bays, but destitute of those comet-tail peninsulas so generally observed connecting it to the chain of islands south. All of these islands, Hellas, Ausonia, and the rest, were vague, without definite contours, and lapsed imperceptibly into the surrounding seas. Even in colour they were less decided than, though of much the same tint, as the continental areas."

With such facts before us, it is hard to believe that we are not observers of a great inundation, which obliterates, or nearly so for a time, all landmarks lying anywhere in the region 20° or more south of the equator. The source of this flood would of course be the rapidly melting snow, and the great volume of water now liberated from the solid form, and forming at the boundary of the cap the dark narrow belt, would be ample to account for the disappearance of islands, blurring of coastlines, and suchlike phenomena. Certain are we that these landmarks are *there*, and the only justifiable cause of their dimness of outline and colour is the hypothesis of their partial and sometimes total submersion.

An observation of great interest may be mentioned here, as it deals directly with the great variation of surface markings we have referred to above. The most conspicuous object on the planet's surface at the present time is the large black gulf bounding the melting snow, and situated due south of the Hour-Glass Sea, or Syrtis Minor. This, as Mr. Lowell has previously described it, is clearly water at the edge of the melting snow, or, in other words, a polar sea. On June 4 the polariscope was brought to bear on this gulf by Prof. Pickering, with the result that it was declared to be water, just as the canal in the same region, running north from it, was concluded to be of this substance. This observation simply verified what had previously been thought to be the case from its general appearance and colour; but another examination, at a later date, represented the matter in quite a different light. On July 9 "no trace of the polarisation in the dark spot could be detected," and a more minute examination of the colour of this region showed it to be of a "rich chocolate-brown tint, differing entirely in colour from the bluish-grey regions to the north of it." This reads somewhat different from Lowell's observation on July 9: "Bay a deep blue, looks just as deep water does." Prof. Pickering is of opinion that as the colour of the grey regions does not, he thinks, represent water, he is led to conclude, as far as his observations at present go, that the "permanent water area on Mars, if it exists at all, is extremely limited in its dimensions." This favours to a considerable extent the hypothesis of an inundation.

Let us consider for a moment the observations relating to the appearance of the channels at this time. These, at this season of the Martian southern hemisphere, are generally not so easy of observation, but Mr. Lowell has been able to make out several of them. Those most generally seen were Cerberus to the north of Mare Cimmerium (on June 9 glimpsed as double), Eumenides, Gigas, Titan, Gorgon and Sirenius, all of which lie just to the north of the Mare Sirenum, and at a later date he has seen some in the region of the Lake of the Sun (Solis Lacus), namely Phasis, Eumenides, and Agathodæmon. These channels, including one or two others which we have not mentioned in the above list, have, we may say, the greatest southern latitude, or lie nearest to the south pole, a fact which may or may not be insignificant.

Of course the great inclination of the pole of Mars towards us, renders those on the northern hemisphere more difficult of observation, so that our information is to a great extent restricted. Nevertheless, one is inclined, from Mr. Lowell's drawings, to look upon the channels simply as the watercourses caused by the inundation of the sea on to the land, commencing naturally at the lowest levels, and of course at the water's edge. Out of the nine drawings which he gives, illustrating the positions of the canals observed, eight of them show the majority of the canals in connection with the southern seas, while there is only one instance of a channel not so connected, and that a very short one. This is as it should be if the channels are, so to speak, overflow courses, and accounts also for the invisibility, or at any rate the difficulty of observation of the channels, as a whole, about this time. As the polar cap ceases to melt, the channels should then be at their fullest, and therefore easily visible. The absence of cloud on the planetary surface about this time shows that the aqueous circulation is almost totally brought about by this flood season.

Whatever may be the cause of these channels and their duplicity at times, cannot be dwelt on here: but that they are the results of a great inundation, seems to be the conclusion which is most compatible with recent observation.

A further fact which has recently attracted particular attention is the frequent observation of bright projections on the terminator of the planet's disc. It may be here simply mentioned that the observations as yet seem to point to the presence of high mountains as the cause of these bright markings.

A discussion of this question will be dealt with, however, in a future article, which will contain a detailed account of the work up to the present time.

Such, then, are some of the facts which have been brought before us by the Arizona observations. Observations at other observatories, such as that of Juvisy, &c., are also at hand, but the weather seems to have been hard on these eager watchers, so the observations are very few. The surface of Mars is still a puzzle to be unravelled, and there are many who are employed in the fascinating work of solving it. One may repeat, what has often been stated before, that in the study of planetary details, the aperture or the size of object-glass is not the most important function for good observations. A keen and patient observer sitting at the eye-piece of a comparatively small equatorially-mounted telescope, if he makes his observations carefully and with due regard to atmospheric conditions for good seeing, can do more useful and valuable work than one who has a large aperture at his disposal, and employs it indifferently. For Martian detail, Mr. Lowell puts the observer first, then the atmosphere, and lastly, the instrument, as the order of weights to be given as factors of a good observation. W. J. LOCKYER.

Note. In my article on "The Discs of Jupiter's Satellites," which appeared in a previous number of this journal (August 2, p. 320), the table, giving the measurements of the position angle of the 1st satellite, requires a slight alteration, owing to a printer's error in that number of *Astronomy and Astrophysics* from which the table was taken. In the column indicating the initials of the observers, the following measures, 1, 3, 5, 7, 9, 11, ought to be attributed to Prof. Pickering, and the rest to Mr. Douglas. This alteration makes no change in the text necessary, as it was only stated that there was "a mean personal correction of about 7°·1," which, in the light of the revised column, still holds good. The correction, with one exception, simply reverses the names of the observers in each case. W. J. L.

THE ARCHOPLASM AND ATTRACTION SPHERE.

PLATNER in 1886, when dealing with the spermatocytes of helix, showed that the great "nebenkern" in these elements was derived after each division from a coalescence of the spindle-fibres. At the same time he pointed out in the interior of the structure bright refractive points answering in every way to what was then known about the centrosomes. Some time afterwards F. Hermann, in an exquisite description of the karyokinetic process in the spermatocytes of salamander, successfully homologised the great "archoplasm" (as he termed the nebenkern of these cells), on the one hand with Platner's nebenkern, and with the sphere-attractive and archoplasm of Van Beneden and Boheri on the other. I subsequently drew attention to the fact that this archoplasm in the salamander arose by a collection of the spindle-fibres precisely in the same manner as that of helix, *i.e.* these structures (attraction-spheres) in widely separated groups present precisely similar constituents, and arise in a precisely similar way.

The clear appreciation of the mutual equivalence of these bodies is of considerable value, as it paves a way towards the systematic splitting up of a whole group of structures present in reproductive cells, which had all previously been loosely grouped under the head of nebenkerns. Nevertheless, if we accept it, a certain difficulty arises, to which I referred briefly at the time, and to which Dr. Neves has since called my attention in an interesting letter from Kiel:—If the archoplasm of the spermatocytes with its inner constituents is the homologue *in toto* of the attraction-sphere when at rest (Fig. 3), or during the initial phases of mitosis, what is to be said of it in the later phases of this process?

In the attraction-sphere as first described and ordinarily understood in ascaris, the centrosomes, with their light-surrounding zone, occupy the middle of an extended archoplasm which divides with the centrosomes during the course of the mitotic change, but in the case of salamander the archoplasm remains undivided as a rule: and its whole mass is used up in the construction of the spindle, the centrosomes appearing at the apices of the figure related to a radiation of the non-archoplasmic and external protoplasm. Now when the karyokinesis is completed, and the daughter nuclei formed, the centrosomes can be found at the remote sides of the nuclei (as in Fig. 4, *c*, one-half of a dividing spermatocyte of a rat), but the two new archoplasmic masses are being regenerated on each side of the division plane (as in the rat, Fig. 4, *b*). These masses become completely formed, but in consequence of their position are destitute of centrosomes, which must acquire a secondary connection with them; so that at this phase the sphere is divided into two parts in each cell, that which attracts (centrosomes) being at one side of the nucleus, that which is regarded as primarily attractive (the archoplasmic portion of the kytoplasm) on the other. In salamander these anomalous conditions eventually become righted by the centrosomes wandering round the nuclei into the archoplasm.

Turning, however, to a still higher type of vertebrates, the Mammalia, a short time ago I found in the spermatocytes of various forms, besides other and well-known accessory bodies, a great lightly staining nebenkern (archoplasm), which can be determined as arising during the spermatogenesis by a coalescence of the spindle-fibres (Figs. 1, 2, *a*), so that we must regard this body as having the same value as the nebenkern in Amphibia, in Helix, in Echinoderms, or that it is the archoplasmic portion of the attraction-sphere; but at no time, either at rest or during active mitosis, does it contain within its mass the centrosomes! In the resting spermatocytes of the rat (Fig. 2) these bodies lie quite outside the archoplasm (Fig. 2, *c*), they become duplicated, and enter into the formation of a spindle without any connection with the archoplasm (Fig. 1, *c*), which passes further away, and ultimately degenerates (Fig. 1, *a*). The spindle-fibres are constructed anew out of the kyto- and superficial nuclear-plasm, and the mass of substance thus utilised is collected on either side the division plane as the archoplasmic bodies of the daughter cells.

The archoplasm, then, has no permanent existence in these cells, and is of no immediate consequence in the formation of the spindle. The fact, however, that the transitory body formed in mammals from each new crop of spindle-fibres, after each division (Fig. 4) rapidly dissolves and reincorporates itself into the surrounding kytoplasm, is distinctly favourable to the view now gaining ground, that the spindle has a kytoplasmic origin.

From all this it will be seen that we cannot regard the archoplasmic portion of the sphere as a permanent organ of the cell any more than the ripples wind produces are the permanent features of the surface of a pond.

On the other hand, all the more recent investigations concerning normal or karyokinetic propagation of cells, whenever sufficient pains have been taken to insure good results, show that the centrosomes retain their individuality through every change. Couple with these facts the discovery by Dr. Field of the entry of the centrosomes into the spermatozoa of the echinoderms, and a quite similar state of things I have found to occur in mammals, and there seems much evidence that the centrosomes, unlike the other constituents of the sphere, retain their individuality during successive mitoses, and are incorporated as an essential constituent of the spermatozoa.

Further, the well-known observations of Fol, and more recently those of Fick, show clearly that these bodies assume their old functions as dominants of the attractive process in the initial steps of fertilisation. Their identity through successive generations being thus maintained, the

Fig. 4.

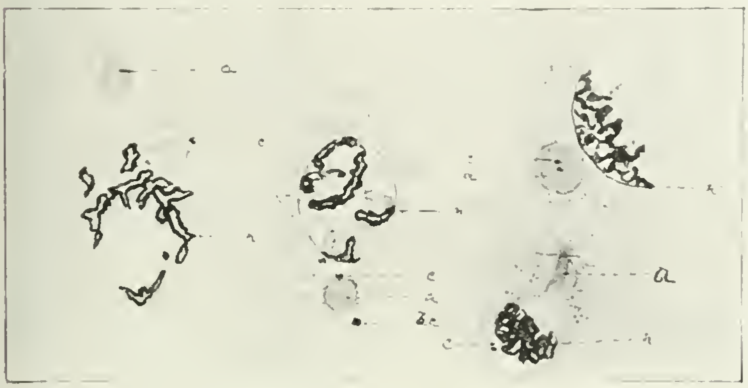

Fig. 1. Fig. 2. Fig. 3.

important functions they perform in the division process itself necessitates our regarding them, with Van Beneden, as organs of the cell, although, when viewed in such a light, they will have to be disrobed of their more conspicuous radial and archoplasmic vestments. With respect to these latter, in whatever degree they may be present, it seems an unavoidable conclusion that they can only be regarded as the effect produced by the inconstant action of polarity or whatever power is exercised by the centrosomes on the surrounding kytoplasm.

J. E. S. Moore.

HERMANN VON HELMHOLTZ.

Honoured and mourned by all, Prof. von Helmholtz, one of the most brilliant men who have devoted their lives to science, passed away at Charlottenburg, on Sunday last. Shortly before his death, the Empress Frederick sent a telegram of inquiry as to his condition, and upon hearing of his decease messages of sympathy were sent to the sorrowing relatives by the Emperor and herself. This fact is a significant indication of the regard in which the representatives of science are held in Germany.

Hermann Ludwig Ferdinand Helmholtz was born August 31, 1821, at Potsdam, where his father, Ferdinand Helmholtz, was Professor in the Gymnasium, his mother, Caroline Penn, being of an English family. While but a schoolboy he developed a love for science, and studied all the books on physics which his father's library contained. They were very old-fashioned; phlogiston still held sway, and electricity had not grown beyond the voltaic pile. When the class was reading Cicero or Virgil, he was finding the paths of the rays in a telescope, or developing optical theorems not usually met with in text-books. At that time there was little possibility of making a living out of physics, so, acting on the advice of his father, Helmholtz took up the study of medicine. He entered the Army Medical School, the Friedrich Wilhelms Institut, and while there came under the influence of a profound teacher—Johannes Müller. He eventually became a military surgeon, and continued in that position till the end of 1848, when he was appointed Assistant of the Anatomical Museum of Berlin, and Teacher of Anatomy at the Academy of Arts.

In 1847, that is, during his career as an army surgeon, Helmholtz's essay, "Ueber die Erhaltung der Kraft," was published. In this, the principle of the conservation of energy was developed. About Joule's researches on the same subject, he knew at that time but little, and nothing at all of those of Robert Mayer. He was led to write the essay by an examination of Stahl's theory, adopted by most physiologists, which accorded to every living body the nature of a *perpetuum mobile*. The essay contained the results of a critical investigation of the question whether any relations existed between the various kinds of natural forces for perpetual motion to be possible. It was written for the benefit of physiologists, but, to Helmholtz's surprise, the physicists took up the doctrine of the conservation of energy, which some of these were inclined to treat as a fantastic speculation. Jacobi, the mathematician, recognised the connection between the line of thought in the essay, and the principles investigated by Daniell, Bernouilli, d'Alembert, and other mathematicians of last century, and soon the members of the then young Physical Society of Berlin accepted Helmholtz's results. It is unnecessary for us to dwell upon the marvellous influence that these results have had upon physical science during the last half-century. The principle of the conservation of energy has long passed through the debatable stage, and some of the greatest discoveries in thermodynamics and other branches of modern physics have been deduced from it.

In 1849 Helmholtz went to Königsberg as a Professor of General Pathology and Physiology; seven years later he accepted a similar position at Bonn University. While at the former University he designed the ophthalmoscope for the diagnosis of diseases of the inner parts of the eye—a discovery which shows the great importance to the physiologist and physician of a thorough knowledge of physical principles. The year 1859 saw him occupying the chair of Anatomy and Physiology at Heidelberg; and in 1871 he was appointed Professor of Natural Philosophy in the University of Berlin, a post which he held until his death.

The two great works of Helmholtz on "Physiological Optics" and on the "Sensations of Tone," are splendid examples of the application of methods of analysis to the two kinds of sensation which furnish the largest proportion of the raw material for thought. In the first of these works, the colour-sensation is investigated, and shown to depend upon three variables or elementary sensations. The study of the eye and vision is made to illustrate the conditions of sensation and voluntary motion. In the work on the "Sensation of Tone as a Physiological Basis for the Theory of Music," the conditions under which our senses are trained are illustrated in a yet clearer manner. His researches threw a flood of light upon what may be termed the mechanical, physical, physiological, and psychological processes involved in seeing and hearing.

No good end would be served by enumerating Helmholtz's contributions to knowledge. The versatility of his genius is well known among all workers in the realm of nature. Mathematics, physics, physiology, and psychology are but a few of the branches of knowledge which have been enriched by his investigations. His acquaintance with science was not only extensive but thorough, and, as Clerk Maxwell said in these columns in 1877 (vol. xv. p. 389), the thoroughness was that which of itself demands the mastery of many sciences, and in doing so makes its mark on each. He solved problems with which great mathematicians, since the time of Euler, had occupied themselves in vain. Questions as to vortex motion and the discontinuity of motion in liquids, and the vibrations of sound at the open ends of organ pipes, belong to this class of subjects elucidated by him. In his numerous papers on thermodynamics, he reduced to an intelligible and systematic form the labours and intricate investigations of several independent theorists, so as to compare them with each other and with experiment. Other subjects investigated by him are electrodynamics, stereoscopic vision, galvanic polarisation, the theory of anomalous dispersion, the origin and meaning of geometrical axioms, the mechanical conditions governing the movements of the atmosphere, the production of waves, &c. But even the circle of natural and physical sciences does not embrace all the subjects which he benefited by his keen insight and strenuous energy. He was an acute logician and an accomplished metaphysician. His investigations on perception and observation of the senses led him to study the theory of cognition. The principal conclusion he came to after an examination of the subject, was that the impressions of the senses are only signs for the constitution of the external world, the interpretation of which must be learned by experience.

In 1891, when Helmholtz reached his seventieth birthday, the event was made the occasion of an international celebration. In honour of the anniversary, a marble bust was prepared, and numerous marks of respect were bestowed upon him by his admirers, both in and out of his own country. The German Emperor raised him to the highest rank in the Civil Service; the Kings of Sweden and of Italy, the Grand Duke of Baden, and the President of the French Republic conferred Grand Crosses upon him; many academies, not only of science, but also of the fine arts, faculties, and learned societies representing all parts of the world, sent him diplomas and richly illuminated addresses, expressing their recognition of his scientific labours, and their thanks for his work. His native town, Potsdam, conferred its freedom upon him, and countless individuals sent their congratulations. It was on the occasion of this jubilee that Helmholtz delivered the autobiographical sketch published in the second volume of his "Scientific Lectures," and which has furnished us with some of the particulars contained in the foregoing. He was made a Foreign Member of the Royal Society in 1860, and received the Copley Medal in 1873. He was also one of the Associés Étrangers of the Paris Academy of Sciences, and a correspondent of most important scientific academies and societies all over the world.

Science has had few investigators who have furthered her interests more than Helmholtz. He was constantly exploring new fields of research, or bringing his keen intellect to bear upon old ones. With his contributions he helped to raise science to a higher level. And, while he did as much as anyone to render scientific discoveries understandable to the whole intellectual world, he always recognised that he was in the service of something that should be held everlastingly sacred, a feeling which kept him from playing to the gallery either in his popular works or in his lectures. Many years ago, it was written—

"A wise man instructeth his people, and the fruits of his understanding fail not."

"A wise man shall inherit glory among his people, and his name shall be perpetual."

To no one could these words be more appropriately applied than to the eminent investigator whose loss we now deplore.

NOTES.

We note with deep regret that Prof. H. K. Brugsch, the distinguished philologist and Egyptologist, died on Sunday last, at the age of sixty-seven.

The Deputy-Mastership of the Mint, vacated by the resignation of Sir C. Fremantle, K.C.B., will be filled at once by the appointment of a distinguished official, Mr. Horace Seymour, Deputy-Chairman of the Board of Customs. If the post had been destined for a scientific man, it would doubtless have been given to Prof. Roberts-Austen, C.B., but his acceptance of it would have involved his resignation of his chair at the Royal College of Science. The due discharge of the duties of the Deputy-Mastership would, moreover, have left him far less opportunity for research than he has in his present office at the Mint, which he has made such an important one for science. Sir Charles Fremantle has always encouraged original research in his Department, and we wish him much happiness in his well-earned retirement.

The death of the Comte de Paris recalls the fact that he was a Fellow of the Royal Society. He was elected by ballot on April 27, 1865, and signed the charter book on May 18 of the same year. Under the statutes which were then in force, any foreign sovereign prince or the son of a sovereign prince could be proposed for immediate ballot if he wished to enter the Society. In the case of the Comte de Paris it was found that, according to the strict letter of the statutes, the head and representative of a Royal house might be inadmissible by privileged election, whilst members of the same family of inferior rank were entitled to it. Although he was the hereditary representative of the then late King of the French, yet inasmuch as his father had not been a "sovereign prince," the Society was precluded from extending the courtesy of election, and therefore took steps to amend the statute, and upon being advised that Court usage would accord, introduced words establishing the privilege to "any foreign prince who is received by her Majesty as Imperial Highness, or Royal Highness." It was under such an amended statute that the unanimous election of the Comte de Paris occurred.

The death of Prof. Josiah Parsons Cooke, LL.D., which took place in Boston, Massachusetts, on Tuesday, is, says the *Times*, not simply a loss to Harvard University, where he has laboured for more than forty-four years, but to the scientific world at large. His work on "The New Chemistry" is well known and highly esteemed, and has been translated into nearly every language of Europe. Born in 1827, he graduated from Harvard in 1848. In the following year he became tutor in mathematics, afterwards instructor in chemistry, and in 1850 Erving Professor of Chemistry and Mineralogy at Harvard. Under his direction the course in chemistry was greatly developed. He was the first in America to introduce laboratory instruction into the undergraduate course. In addition to his duties at Harvard, it was his practice to give courses of popular lectures on chemistry in the cities of Baltimore, Brooklyn, Washington, Lowell, and Worcester, besides his regular lectures at the Lowell Institute in Boston. As director of the chemical laboratory at Harvard he has published numerous contributions to chemical science, most of which have been collected and published in a volume entitled "Chemical and Physical Researches." In 1872 he was elected an honorary Fellow of the Chemical Society, sharing that distinction with only one other American; and in 1882 he was granted the degree of LL.D. by Cambridge University.

The death is announced of Sir Edward Augustus Inglefield, K.C.B., F.R.S., at the age of seventy-four. The following particulars as to his scientific work are extracted from an obituary notice in the *Times*:—After seeing a large amount of active service, and earning for himself a high reputation, he was appointed to the command of the yacht *Isabel* in a private expedition which was sent in search of Sir John Franklin to Smith's and Jones's Sound—an experience which partly suggested the interesting story he published under the title of "A Summer Search for Sir John Franklin." Although it failed in its main object, his plucky mission on that occasion enabled him to record the discovery of an open polar sea and a coastline 800 miles in length, while he also had the pleasure of carrying mails to the Government Arctic Expedition at Beechey Island. For these services he received the gold medal of the Royal Geographical Society of London, the large silver medal of Paris, and a much-treasured diamond snuff-box from the Emperor of the French. He was at the same time elected a Fellow of the Royal Society. His first Arctic experience brought him a second like command in 1853, when he went out by order of the Admiralty with three ships, especially despatched to the relief of Sir Edward Belcher's expedition. One of the three vessels was crushed in the ice, and foundered, but he was able to bring home an officer bearing the news of the discovery of the North-West passage. In the following year he received the command of another expedition, consisting of the *Phœnix*, the *Talbot*, and a transport with stores, sent out to afford further relief to Sir Edward Belcher, and this time he brought back the officers and crews of five ships which were abandoned in the ice. For these services he was awarded the Arctic medal, and the honour was signally confirmed by the Queen in 1887, when he was knighted on the occasion of the celebration of the completion of the fiftieth year of her Majesty's reign. To his skill and daring as a seaman Sir Edward Inglefield added a technical ingenuity which has bequeathed to naval engineering the hydraulic steering apparatus fitted in the *Achilles* and the *Minotaur*, the screw-turning engine of the *Monarch*, and the anchor bearing his name, which was supplied to the *Dreadnought*, *Sans Pareil*, *Renown*, *Inflexible*, and other ships. He was a graceful writer and a vigorous speaker, and, beside the book recounting his Arctic researches, was the author of pamphlets on "Maritime Warfare," "Naval Tactics," and "Terrestrial Magnetism."

THE thirty-ninth exhibition of the Royal Photographic Society will open to the public on Monday, September 24. The exhibition will be held, as on former occasions, in the Gallery of the Royal Society of Painters in Water Colours, at 5A Pall Mall East, and will remain open until November 14.

THE Royal Commission appointed last year to inquire into the mode of identification of habitual criminals having reported favourably on the Bertillon system, the Commissioners of Prisons have decided to adopt the anthropometrical system of measurement of criminals. The system will be worked in connection with the present system of identification. From various prisons officers have been already ordered to attend at her Majesty's Prison, Pentonville, to receive instructions from Dr. Garson.

REUTER reports that the members of the Arctic excursion party, organised by Dr. Cook, and noted in NATURE of August 30 (p. 429), have returned to North Sydney, Cape Breton, in the Gloucester fishing schooner *Rigel*. The steamer *Miranda*, by which the party travelled, grounded and sprang a leak on the coast of Greenland. After they had remained on the disabled vessel for some time, the party were taken off by the *Rigel*. The *Miranda* was floated and taken in tow, but foundered on her way home.

A MONUMENT, erected in honour of Armand de Quatrefages, was unveiled at Vallerangue, his native town, at the end of last month. M. Darboux presided over the distinguished company that took part in the ceremony. The scientific labours of the renowned investigator were extolled by MM. Milne-Edwards, Hamy, Geoffroy Saint Hilaire, and Brongniart. Prof. Hamy referred to Quatrefages as the creator of the science of anthropology. The monument is five metres in height, and consists of a bronze bust of the deceased on a stone pedestal, having on its principal face a figure holding in one hand a scientific work, while the other is presenting a crown to the eminent naturalist.

WE learn from the New York *Nation* that the Marine Biological Laboratory at Wood's Holl, Mass., has concluded its seventh summer session, the most successsful in its history. The number of students and investigators in attendance was 133, representing seventy colleges and high schools. Courses of instruction in zoology and botany were offered, a new building for the accommodation of the students in the latter course having been erected. The important part played by the Laboratory in the development of the biological sciences in this country is evidenced by the fact that no less than fifty-eight of those in attendance were carrying on research in zoology, botany, or physiology, and that several important investigations were completed during the summer. A number of the lectures delivered at the Laboratory during the session will as in former years, be published in book form.

MR. H. GARNETT informs us that while boating with a friend on the River Avon, just above Evesham, on August 11, he had a good view of a white swallow flying amongst a flock of others very near the ground. Its companions were apparently persecuting it. Finally it flew across the river close over the observers' heads, and this view was sufficient to convince them that it was the common swallow, and not one of the martins. Curiously, it was not a snow-white, but apparently a very pale uniform cream colour. In connection with Mr. Garnett's observation, it is worth remark that the current number of *Science Gossip* contains a note on a white variety of the common sparrow, shot at Ripley on August 13; and Mr. E. W. Atkinson, writing to the *Zoologist*, says that he recently saw a white swallow at Harswell, in the East Riding of Yorkshire.

OF all the sciences, meteorology is probably the farthest from perfection. Many dabble in it, but few seriously attempt to reduce the abundance of observations to law and order. One of the reasons for this state of things is that, so far as we can remember, none of our educational institutions include systematic courses of meteorology in their curricula. There is practically no field for professional meteorologists, and therefore no training-school exists. For the sake of the science we are glad to note, however, that the Board of Regents of the University of California has decided to establish a course in meteorology in that University. Through the course of study and investigation which the students of meteorology will prosecute at the University, valuable additions to knowledge may be expected.

M. DE FONVIELLE calls our attention to one of Roger Bacon's essays, published in 1618, in which some of the possibilities of steam are vaguely foreshadowed, and aerial navigation is declared to be a thing of the future. We quote from a translation with which he has furnished us, and which reads like Mother Shipton's prophecies. "Instruments may be made for navigating without any men pulling the oars, with a single man governing, and going quicker than if they were full of pulling men. Waggons also can be made so that without any horse they should be moved with such a velocity that it is impossible to measure it. . . . It is possible also to devise instruments for flying, such that a man being in the centre if revolving something by which artificial wings are made to beat the air in the fashion of the birds. . . . It is also possible to devise instruments which will permit persons to walk on the bottom of the sea. . . . All these things have been done in old times and in our times, except the instrument for flying, which I have not seen, and I have not known any man who saw it done."

THE portion of Lord Salisbury's address which refers to the periodic law was not delivered in exactly the same form that it was printed in the official copy. A correspondent of the *Chemical News* points out that in the printed report (see NATURE, August 9, p. 340) the following passage occurs:—"In the last few years the same enigma has been approached from another point of view by Prof. Mendeléeff. The periodic law which he has discovered reflects on him all the honour that can be earned by ingenious, laborious, and successful research." Before the address was delivered, Lord Salisbury became aware of the claim of Newlands as the first discoverer of the periodic law, and the words actually spoken in the Sheldonian Theatre were:—"In the last few years the same enigma has been approached from another point of view by our own countryman Newlands and by Prof. Mendeléeff. The periodic law which they have discovered, &c." Unfortunately, the address was already printed and distributed to the press before the alteration was made. The claim of Mr. Newlands is secured to him by the award of the Davy Medal in 1887 by the Council of the Royal Society.

WRITING from Table Cape, Tasmania, Mr. H. S. Dove says that a fine aurora was witnessed there early on the morning of July 21, from about 12.30 until a few minutes after 1. The whole of the western, southern, and a good deal of the eastern heavens was illuminated by a strong red glow, paling to a delicate pink at the edges. The glow was brightest about half-way between the horizon and zenith, but was discernible over the whole space between those two boundaries, and when it paled and faded in the west would spread and become very vivid towards the east. The broad vertical white stripes which usually accompany these auroræ were also noticeable, but the most uncommon feature of the phenomenon was the presence of brilliant white flashes which shot upwards in rapid succession, spreading out into a fan-shape as they rose, and instantly disappearing. These were principally seen about the Southern Cross, where the vertical stripes were also brightest, the region about that constellation appearing to be the centre of a great electrical disturbance. A low bank of clouds lay along the horizon under the aurora, and a stream of white fleecy clouds sailed up from about west-north-west, but preserved almost a straight line on the edge next the phenomenon, as if something in the highly electrical state of the atmosphere there prevented their spreading in that direction. A note concerning the same aurora appeared in our issue of August 30.

A NEW department of the Pasteur Institute in Paris has recently been established, having for its special object the experimental study of means of defence against destructive insects. The new section—Station expérimentale de l'Institut Pasteur—as it is called, has (says the *Revue Scientifique*) been placed under the superintendence of M. Metchnikoff, with M. J. Danysz as assistant. The department will be concerned with the following points: (1) The collection and cultivation of all the pathogenic microbes of insects and animals destructive to crops; (2) the study of the conditions of development of these microbes in animals and on various media; (3) the direction of field-experiments; (4) the superintendence and control of practical applications of the results of laboratory work. The best means of applying these results will be discussed by a *Comité d'étude* consisting of naturalists, agriculturists, and some specialists in mycology, bacteriology, and agriculture, such as MM. Brocchi, Costantin, Grandeau, Millardet, Sauvageot, Schribeaux, A. Giard, J. Kunckel d'Herculis, A. Laboulbène, P. Marchal, and E. L. Ragonot, of the Société entomologique of France. A *Bulletin* will be published, containing notes and communications to the station and the committee, and the proceedings of meetings. It is also proposed to give monographs of destructive insects and pathogenic microbes; statistics concerning the damage done by harmful animals; and critical notes on all publications referring to these matters. In connection with the Laboratoire de Parasitologie of the Bourse de Commerce and the entomological station of Paris, the new section of the Pasteur Institute will render excellent service to French agriculture.

WE have received from the *Deutsche Seewarte* its report for the year 1893; it is issued as an appendix to the *Annalen der Hydrographie*, from which useful publication we have frequently had occasion to quote. The report shows that much good work is being done, but to which we can now only briefly refer. In the department of maritime meterology, great activity is shown in the collection and utilisation of observations made on board ships of both services, the number of co-operators during the year amounting to 430 for the mercantile marine alone. The results are published in tables for one-degree squares of the North Atlantic, in the daily synoptic charts issued in connection with the Danish Meteorological Institute, and in the preparation of atlases for different oceans, the one now in hand being for the Pacific. Similar activity is also shown in the department for weather prediction, and the daily weather reports issued by it are among the most complete that are published; they contain full particulars of the weather twice or thrice daily, at about 100 stations all over Europe, in addition to the usual weather charts and summary of existing conditions.

IN a paper read before the Asiatic Society of Bengal, Dr. R. Havelock Charles calls attention to the incomparability of nasal indices derived from measurements of the living head with those deduced from observation of dry skulls. The author carefully measured the nasal diameters of sixty-two "subjects," of various castes, and then having removed the integuments, &c., and cleared the naso-frontal suture and anterior nasal aperture, he again measured the diameters. The results are certainly somewhat startling. The height of the nose taken on the undissected head is almost invariably less than the long diameter of the nose measured on the skull of the same head, the difference amounting, in one case, to as much as 16 mm. The higher the caste the greater the discrepancy, but it may be reckoned to be upon an average about 4 mm. in the higher races. The transverse diameter of the anterior nasal aperture, taken on the skull, is less than the breadth of the nose taken on the head of the same subject. The difference is usually 7 mm., and in the lower castes it may be as much as 9 mm. or even 11 mm. Also, other things being equal, the older the individual the greater is the difference between these measurements. Hence, we see that the nasal index deduced from observations on the skull must always be lower than the index calculated from measurements taken upon the head; and, therefore, the *skull* nasal index will place a race upon a higher platform than the *head* nasal index.

THE *Rendiconti del Reale Istituto Lombardo* contain a paper by Profs. Bartoli and Stracciati on the effect of a thin veil of cloud or mist upon the intensity of solar radiation. This effect was brought out in a striking manner by choosing from among some thousand pyrheliometer observations made at Catania and at Casa del Bosco, on Etna (4725 feet above sea-level), those which corresponded to the same altitude of the sun and to approximately the same hygrometric state of the atmosphere. It was found that a stratum of cirrus clouds interposed in the path of the sun's rays was capable of intercepting up to 30 per cent. of the radiant energy. When the sky was of a light blue colour, but quite cloudless, the absorption was greater than in the case of a deep azure sky. The ratio of the amounts of heat transmitted ranged from 77 per cent. with an altitude of 10° above the horizon, to 96 per cent. at 50°. The effect of a slight mist equally distributed in every direction was somewhat undefined, since the ratio of the absorptions does not appear to vary regularly with the thickness of the stratum of air. In one pair of cases, with the sun at 45° 15′, the quantity of heat received during one second by 1 square cm. of the pyrheliometer surface was 0·0237 with a deep blue sky, and 0·0201 with a slight mist. With the sun at 9° 42′ the figures were 0·0161 and 0·0093 respectively. In general, the ratio varied between 58 and 92 per cent.

AT the Adelaide meeting of the Australasian Association for the Advancement of Science, the committee appointed to collect evidence as to glacial action in Australasia, in Tertiary or post-Tertiary time, presented their report. The conclusions arrived at are as follows :—At the time of their greatest extension the ancient glaciers of New Zealand were larger and descended lower the further they were south. The terminal moraines in North-West Nelson go to 2700 feet above the present sea-level ; Lake Rotoiti, in South Nelson, to 2000 feet ; Lake Sumner, probably a glacier lake, is 1700 feet above the sea. In South Canterbury the terminal moraines are 1000 feet, and in South Otago only 600 feet above the present sea-level. In Westland and in the West Coast Sounds the glaciers advanced to below the present sea-level. The glacier of Boulder River was four, and that of Lake Rotoiti about twelve miles in length ; the glacier at the head of the Waiau-ua or Dillon, fourteen miles ; that of the Rakaia, fifty-five miles ; the Wanaka glacier, sixty ; that of Wakatipu, eighty ; and that of Te Anau, sixty-five miles in length. There is, therefore, a considerable difference in relative proportion between the ancient glaciers and their present representatives. At present they reach their maximum in South Canterbury, and get smaller both to the north and to the south ; while in ancient times their maximum was in Central Otago. The committee had little biological evidence to report upon, but what there is indicates that the ocean round New Zealand has not been much colder than at present ever since the Miocene period.

THE Glasgow and West of Scotland Technical College has issued its Calendar for the session 1894-95. Another Calendar just received refers to the Mining School at Houghton, Michigan, and contains information concerning the institution and its courses of instruction.

THE current number of the *Quarterly Journal of the Royal Meteorological Society* contains a portrait of Luke Howard, the author of the system of cloud nomenclature in general use, together with a biographical notice of him. The papers in the *Journal* include one by Mr. W. H. Dines, on the duration and lateral extent of gusts of wind, and the measurement of their intensity ; and another, by the same author, on the relation between the mean quarterly temperature and the death-rate. The calculation of photographic cloud measurements is described by Dr. G. K. Olsson, and Mr. Inwards' address on phenomena of the upper air, delivered before the Society in April last, is printed in full.

A CALENDAR of the Evening Classes to be held at the People's Palace, Mile End Road, during the Session 1894-95, has been sent to us. Under the direction of Mr. J. L. S. Hatton, the number of these classes has been largely increased. In addition to the usual scientific and technological subjects, instruction is offered in astronomy, brass-work, bookbinding, instrument making, differential and integral calculus, determinants, trilinear co-ordinates and advanced co-ordinate geometry of three dimensions, and practical physics. The Drapers' Company have voted the sum of £5000 for the erection of new engineering workshops, and several new laboratories have been constructed. More than 8000 class-tickets were issued last session, and there is every prospect of this number being increased during the coming one.

To the current number of *Science Progress*, Prof. W. Halliburton, F.R.S., contributes a paper in which he emphasises the importance of further study of blood coagulation and the poisonous proteids secreted by snakes. Mr. A. C. Seward shows that algæ have a much greater claim to the attention of geologists as possible agents of rock construction than has generally been admitted. Fossil algæ is also the subject of a paper by Mr. George Murray. Dr. George A. Buckmaster describes the biological characters of *Bacillus typhosus* (Eberth) and *Bacterium coli commune* (Escherich). In a paper on ancient volcanic rocks, Mr. Alfred Harker compares the views of continental petrologists, who hold that there is a fundamental distinction between the "older" (that is, pre-Tertiary) volcanic rocks and the "younger" (Tertiary and Recent), with the conviction of English students, that the supposed differences are due to the fact that the former are, as a rule, more affected than the latter by the changes which come with lapse of time. Mr. E. H. Griffiths writes on the measurement of temperature, and shows that mercury thermometers are hardly comparable in point of accuracy with the platinum thermometer.

AN account of the striking changes which the great lava lake in Kilauea has undergone this year, appears in the *Hawaiian Gazette* for July 24, a copy of which the Hon. Rollo Russell has sent us. The lava steadily rose after the last great breakdown of the floor of the crater in March 1891, when an area of 2500 feet long, by 2000 feet wide, fell more than five hundred feet in one night. Towards the end of last year, the rising and overflowing of the lake filled the pit thus produced. Since that time the activity of the lake has been intense, as many as twenty-three overflows of liquid lava having taken place in a single day, and the walls surrounding the lake have been rapidly raised by continual overflows. Accurate measurements of the lake were made by Mr. F. E. Dodge, of the Survey Department, in August 1892 and March 1894. From his observations it appears that in August 1892 the outer rim surrounding the lake was 282 feet below the level of the Volcano House. The surface of the lake was 240 feet below this line. In March, 1894, the surface of the lake was 207 feet above this line, making a rise of 447 feet in nineteen months. But the most interesting observations relate to the breaking down of the lake, witnessed by a number of persons in July last. On July 11 the lava began to sink steadily, falling at the rate of about twenty feet an hour. This subsidence caused the banks to give way. We quote from the *Gazette* :—"From about noon until eight in the evening there was scarcely a moment when the crash of the falling banks was not going on. As the level of the lake sank, the greater and greater height of the banks caused a constantly increasing commotion in the lake as the banks struck the surface of the molten lava in their fall. A number of times a section of the bank from 200 to 500 feet long, 150 to 200 feet high, and 20 to 30 feet thick, would split off from the adjoining rocks, and with a tremendous roar, amid a blinding cloud of steam and dust, fall with an appalling down-plunge into the boiling lake, causing great waves to dash into the air, and a mighty 'ground swell' to sweep across the lake, dashing against the opposite cliffs like storm waves upon a lee shore. Most of the falling rocks were immediately swallowed up by the lake, but when one of the great downfalls referred to occurred, it would not immediately sink, but would float off across the lake, a great floating island of rock. At about three o'clock an island of this character was formed estimated to be about 125 feet long, 25 feet wide, and rising 10 to 15 feet above the surface of the lake. Shortly after, another great fall took place, the rock plunging out of sight beneath the lava. Within a few moments, however, a portion of it approximately 30 feet in diameter, rose up to an elevation of from 5 to 10 feet above the surface of the lake, the molten lava streaming from its surface, quickly cooling, and looking like a great rose-coloured robe, changing to black. These two islands, in the course of an hour, floated out to the centre, and then to the opposite bank. At eight in the evening they had changed their appearance but slightly, but the next morning they had disappeared." It was observed that, as the falls occurred, the exposed surface, sometimes more than 100 feet across, was left red-hot. Sometimes a great mass would fall forward like a wall; at others it would simply collapse and slide down, and again enormous boulders, as big as a house, singly and in groups, would break from their fastenings, and, all aglow, leap far out into the lake. It is believed that this is the first break-down of Kilauea that has taken place in the presence of observers, those prior to 1868 being before the establishment of the Volcano House, and those of 1868, 1886, and 1891, and several minor ones, all having occurred at night when no one was present.

THE additions to the Zoological Society's Gardens during the past week include a Slender Loris (*Loris gracilis*) from Ceylon, presented by Miss Grace Thomson; two Wild Swine (*Sus* sp.?) from Turkish Arabia, presented by Mr. F. G. Beville, H.B.M. Consul; three Agoutis (*Dasyprocta* sp.?) and two Orange-winged Amazons (*Chrysotis amazonica*) from the Island of Tobago, presented by the Hon. W. Low; a Raven (*Corvus corax*), European, presented by Mr. Ogilvie Grant; a Green Turtle (*Chelone viridis*) from the West Indies, presented by Mr. E. Leach; a Japanese Teal (*Querquedula formosa*) from North-eastern Asia, purchased; a collection of Marine Fishes, purchased; two Shamas (*Cittocincla macrura*) from India, received in exchange; a Brazilian Blue Grosbeak (*Guiraca cyanea*), and a Red-headed Marsh Bird (*Agelaeus ruficapillus*) from Brazil, received in exchange; and a Diana Monkey (*Cercopithecus diana*) from West Africa, deposited.

OUR ASTRONOMICAL COLUMN.

THE HARVEST MOON.—This year's Harvest Moon will be exceptionally conspicuous. On the day of full moon, September 14, the ascending node of our satellite's orbit will be only 1° 35' from the vernal equinox. The inclination of the orbit to the horizon will therefore be very nearly the same as if the node were exactly at the equinox. Owing to this, the moon is longer above the horizon than she is at other times of the year. On the average, the moon rises fifty-one minutes later every night; but for a few evenings before and after the coming full moon, the average interval is only about ten minutes.

ECLIPSE OF THE MOON.—A partial eclipse of the moon, partly visible at Greenwich, will occur early on Saturday morning. The first contact with the penumbra takes place at two o'clock in the morning, the first contact with the shadow at 3h. 36m., and the middle of the eclipse happens at 4h. 32m. The last contact with the shadow will occur at 5h. 27m. As the moon sets shortly after, the last contact with the penumbra will not be observable. Taking the moon's apparent diameter as equal to 1, the magnitude of the eclipse = 0·225.

M. TISSERAND ON SATELLITE ORBITS.—M. Tisserand's recent investigations on the satellite of Neptune have already been referred to in these columns (vol. xlix. p. 543). He has shown that the equatorial protuberance of Neptune causes the direction of the major axis of the orbit of the satellite to change, and that the reaction of the satellite itself modifies the position of the plane of the planet's equator. As the mass of the satellite is comparatively small, the latter effect can be neglected for a considerable period of time. But when the difference of mass between a primary and its companion is not great, the case is altered. In the *Bulletin Astronomique* for August, M. Tisserand investigates the various conditions affecting the secular displacements of the equator of a planet and the satellite-orbit. He cites the Algol system as a case in which the two members—that is, the luminous star and the dark companion revolving round it—have comparable masses. The distance separating the pair is also commensurate with their dimensions. Under these conditions, the variations of the equator, and those of the orbit of the satellite, can be treated at the same time. The secular inequalities undergone by the equator and the orbit doubtless cause the proportion of the bright star's disc eclipsed by the dark companion to vary with the lapse of ages. A secular change in the range of variability must result from this. Observations extending over a long interval of time should also show changes in the periods of variables like Algol. M. Tisserand considers cases of this kind and develops the formulæ relating to them. The discussion of the formulæ is reserved for a future communication.

THE DISTRIBUTION OF NEBULÆ AND STAR-CLUSTERS.—Mr. Sidney Waters has mapped the positions of the nebulæ and star-clusters—7840, in all—contained in the New General Catalogue, and two excellent lithographed charts, given in the number of *Monthly Notices*, R.A.S., just issued (vol. liv. No. 8), show the results of his labours. The Milky Way is drawn upon the charts, the portion for the northern heavens being taken from Dr. Boeddicker's fine maps, while that in the southern heavens is copied from the *Uranometria Argentina*. Mr. Waters designed the maps with two objects. First, to study the distribution of nebulæ and clusters of stars, and, secondly, to guide astronomers engaged upon the observation of nebulæ to fields of research. Clusters are shown upon the charts by means of red crosses, resolvable nebulæ by red dots, and irresolvable ones by black dots. The distribution of these objects is thus taken in at a glance. Whether, in the light of recent research, it was desirable to continue to recognise this difference between nebulæ is a matter of opinion; one point in favour of the distinction is that it was followed in similar maps drawn by Mr. Waters and laid before the Royal Astronomical Society in 1873, so that the two sets are easily comparable. The present charts show very clearly the peculiarities of the distribution of clusters and nebulæ. Referring to the former, Mr. Waters says: "It is striking to note the fidelity with which they follow not only the main track of the Milky Way but also its convolutions and streams. They appear in many parts to seek out the denser regions, and to avoid with an equal persistence the dark spaces." As to nebulæ, we read (and the maps bear out the remarks): "A proportionate scattering of resolvable nebulæ follow the others throughout the charts, showing that they are probably intermixed, and that the resolvability of many of them must not necessarily be regarded as a criterion of their distance. The remarkable avoidance of the nebulæ of the galaxy, although in some points reaching up to and encroaching upon its edges, is equally significant with the coincidence of the clusters with its main track." It is pointed out that the exceeding nearness to one another of very many of the nebulæ suggests the probability of physical connection analogous to that of double stars, hence long-continued observations may lead to the detection of similar orbital motions. Other fields of research are suggested by the charts, and by exploring them new light will certainly be thrown upon the structure of the sidereal universe.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

A GENERAL account of the recent meeting of the American Association for the Advancement of Science was contributed to our last issue by Dr. W. H. Hale. We are now able to give a few extracts from presidential addresses, together with descriptions of some of the papers read before the different sections.

In the course of his reply to the address of welcome to

Brooklyn, Dr. Daniel G. Brinton, the President, thus expounded the aims of the Association.

"The influence of our Association is in the highest and best sense of the word educational. Its discussions are aimed to present the correct methods of scientific investigation and to be guided by the true spirit of scientific inquiry.

"The goal which we endeavour to attain is scientific truth, the one test of which is that it will bear untrammelled and unlimited investigation. Such truth must be not only verified, but always verifiable. It must welcome every test, it must recoil from no criticism, higher or lower, from no analysis and no scepticism. It challenges them all. It asks for no aid from faith; it appeals to no authority; it relies on the dictum of no master.

"The evidence, and the only evidence, to which it appeals or which it admits is that which it is in the power of every one to judge, that which is furnished directly by the senses. It deals with the actual world about us, its objective realities and present activities, and does not relegate the inquirer to dusty precedents or the mouldy maxims of commentators. The only conditions that it enjoins are that the imperfections of the senses shall be corrected as far as possible, and that their observations shall be interpreted by the laws of logical induction.

"Scientific truth has likewise this trait of its own: it is absolutely open to the world; it is as free as air, as visible as light. There is no such thing about it as an inner secret, a mysterious gnosis, shared by the favoured few, the select *illuminati*, concealed from the vulgar horde or masked to them under ambiguous terms. Wherever you find mystery, concealment, occultism, you may be sure that the spirit of science does not dwell, and what is more, that it would be an unwelcome intruder. Such pretensions belong to pseudo-science, to science falsely so called, shutting itself out of the light because it is afraid of the light.

"Again, that spirit of science which we cultivate and represent is at once modest in its own claims and liberal to the claims of others. The first lesson which every sound student learns is to follow his facts and not to lead them. New facts teach him new conclusions. His opinions of to-day must be modified by the learning of the morrow. He is at all times ready and willing to abandon a position when further investigation shows that it is probably incorrectly taken. He is in this the reverse of the opinionated man, the hobby rider and the dogmatist. The despair of a scientific assemblage is the member with a pet theory, with a fixed idea, which he is bound to obtrude and defend in the face of facts. Yet even towards him we are called upon to exercise our toleration and our charity, for the history of learning has repeatedly shown that from just such wayward enthusiasts solid knowledge has derived some of its richest contributions.

"All this prying into the objective, external aspect of things, this minute, painstaking study of phenomena, this reiterated revision and rejection of results, are with the single aim of discovering those absolute laws of motion and life and mind which are ubiquitous and eternal, which bear unimpeachable witness to the unity and the simplicity of the plan of the universe, and which reveal with sun-clear distinctness that unchangeable order which presides over all natural processes.

"This is the mission of science—noble, inspiring, consolatory, lifting the mind above the gross contacts of life, presenting aims which are at once practical, humanitarian, and spiritually elevating."

Mathematics and Astronomy.

The address of the vice-president of Section A (all the sectional presidents are termed vice-presidents) was summarised in our last number. In this section Prof. George E. Hale gave an interesting paper on "Some Attempts to Photograph the Solar Corona without an Eclipse."

C. W. Hough presented a method of control of the equatorial driving clock, based on a description published in the Transactions of the Albany Institute in 1871.

W. R. Warner, on "Requisites for Governing the Motion of Equatorial Telescopes," told of the differing resistance produced by weather, oil, or the lack of it, &c., which a driving clock must overcome in order to run accurately.

Prof. Doolittle exhibited a large diagram showing the results of the recent latitude determinations at the Sayre Observatory, of South Bethlehem, Pa. The Chandler theory and these observations differ so much that one can hardly be called an approximation of the other. Prof. Doolittle finds a diminution in the mean value of the latitude which is entirely unaccounted for.

Physics.

The subject of the presidential address to this section was "Obscure Heat as an Agent in producing Expansion in Metals under Air Contact." The address contained the results of a study of the forces under which the expansion and contraction of metals take place, under the conditions in which they are used in every-day experience. Among the papers communicated to the section was one by Miss Mary Noyes, on the influence of heat and electricity upon Young's modulus for a piano wire. It appears that the effect of heat is to make the modulus less. Magnetism has no effect. The passage of a current of electricity through the wire causes the modulus to diminish more than can be accounted for by the heating effect.

W. Hallock, of Columbia College, who has photographed sensitive flames, exhibited specimens.

Dr. Bedell presented a paper by Prof. Nichols and Miss Crehore, of Cornell University, giving studies of the lime-light. They have examined the light from the lime cylinder of the Drummond light, by means of a spectro-photometer.

In a paper upon aluminium violins, Mr. Springer discussed their merits. He said that soundboards made of aluminium differed from those made from other metals, and were analogous to those of wood. They did not produce secondary tones which were not in harmony with the prime tones. There were many difficultities to be overcome in the manufacture of violins from aluminium. The material could not be soldered satisfactorily, and had to be rivetted. As uneven thicknesses could not be secured for the belly and back, it was necessary to rib and arch the metal. In conclusion, he said: "My experiments incline me to believe that the real cause of the superiority of old wooden instruments over new ones is not so much in the elasticity of the wood or in the composition of the varnish, but in the peculiar warping of the wood to a higher arch, a buckling caused by the position of the F holes and sound-post. I have never seen a good old instrument which was not thus warped. Moreover, I believe if a new wooden instrument were immediately so constructed, while good at first, would deteriorate because further arching would produce rigidity and consequent veiling of tone. Time has no such effect on aluminium violins, as they remain practically unaltered; one which has been used daily for the last two years shows no signs of crystallisation. A perfect instrument would consequently retain all of its good qualities, and could easily be duplicated."

Two papers of considerable interest were read, one by A. McAdie, on some peculiar lightning flashes, and the other on a phonographic method of recording the change in alternating electric current, by C. J. Rollesson.

Mr. McAdie said that in the month of June, 1894, there were one hundred persons killed by lightning in the United States. It is, therefore, important to get accurate knowledge about lightning discharges, especially in reference to the length and form of the path of lightning, so as to discover its energy. Mr. McAdie has three cameras pointed at the top of the Washington Monument, in the city of Washington; one at the Capitol, a second at Fort Myer, and the third at the Weather Bureau. He wishes to obtain three simultaneous photographs of a lightning discharge, but though he has watched since May, he has not been successful.

Mr. Rollesson said that two operations were necessary to produce the alternating current curve by the aid of the phonograph: first, a record of the curve must be produced on the wax cylinder of the phonograph; second, the record produced in the second operation must be magnified by means of a suitable multiplying arrangement. The method described was especially adapted for the study of harmonics in the alternating current.

Chemistry.

The subject of Prof. T. H. Norton's address was "The Battle with Fire, or the Contributions of Chemistry to the Problem of Preventing Conflagration." We hope to be able to print this address in full in a future issue.

Among the papers read before the section was one upon observations regarding certain European water supplies, by William P. Mason. It was shown that the difference in the death-rate of various towns and cities in Europe, caused by improvement in the water supplies, varied from 2 to 13 per cent. "Fallacies of Post-mortem Tests for Morphine" was the title of a paper by David L. Davoll. Other papers before this section were on the behaviour of allylmalonic, allylacetic, and æthylidenpropionic acids when boiled with caustic soda solutions, John G. Spenzer; camphoric acid, W. A. Noyes; double halides of antimony and potassium, Charles H. Herty; some peculiar forms of iron, T. H. Norton; on the existence of ortho-silicic acid, T. H. Norton; volatility of certain salts, T. H. Norton; a new formula for specific and molecular refraction, W. F. Edwards; action of nitric acid upon the chlorides of zinc, bismuth, and cadmium, O. C. Johnson; and a convenient milk sampling tube, M. A. Scovell.

Mechanical Science and Engineering.

Dr. Mansfield Merriman delivered an address before Section D, on "the resistance of materials under impact." He pointed out that the science of the resistance of materials, as taught in text-books and used in the daily practice of every engineer, was mainly that of static conditions where external force is resisted by internal stress. The question of resistance to the impact of falling bodies, likely to occur in machinery, on bridges, and to a certain degree also in buildings, is recognised as important, but it is seldom reduced to computation or made the occasion of careful experiment. Even the fundamental principles and laws regarding it seem often not clearly understood. Dr. Merriman's address was an attempt to set forth the present state of knowledge concerning impact, and to reconcile some of the apparent paradoxes that often arise in the discussion and application of its principles.

The first paper before the section was on the crank curve, by J. H. Kinealy, secretary of the section. In this paper a simple graphical method was given for determining the velocity of the piston of a steam engine for a given positon of the crank. The next paper was on preliminary experiments on a new air pyrometer for measuring temperatures as high as the melting point of steel, by D. S. Jacobus. Experiments made at the Stearns Institute show that three pyrometers gave concordant results in measuring extremely high temperatures.

Another paper, by Prof Jacobus, was on improvements in methods of testing automatic fire sprinkler heads. Automatic fire heads for extinguishing fires have now come into common use. In these a valve is opened automatically in case of fire, by the melting of a fusible solder piece, and the water from this valve puts out the fire. The method of making tests on such heads was described in detail. A paper, by Prof J. E. Denton, was read on the ratio of the expansion of steam in multiple expansion marine engines for maximum economy in East River steamers. This was followed by a paper by Samuel Marsden, on experiments on the transverse strength of long-leaf yellow pine. The results of numerous experiments were presented. The last paper was by Elmo G. Harris, on the air lift pump.

Geology and Geography.

The president of this section, Samuel Calvin, took for his subject "Niobrara Chalk." The Niobrara stage of the Upper Cretaceous is well represented along the Missouri, from the mouth of the Niobrara River to the mouth of the Big Sioux. East of the Sioux, beds of the same stage are found at various points in Iowa as far eastward as Auburn in Sac country, while fossils distributed through the drift indicate the former existence of cretaceous strata at points many miles farther east than any locality where they are not known to occur in place. The general distribution of the Niobrara deposits covers an area reaching from Western Iowa to the Rocky Mountains, while north and south it stretches from Texas to Manitoba, and probably northward to the Arctic Ocean. The address was limited, however, to a description of some of the characteristics of the Niobrara chalk exhibited in the somewhat restricted region lying between the mouth of the river from which the formation takes its name, and the most eastern exposure of the beds at present known, near Auburn, Iowa.

Major J. W. Powell read a paper on the water resources of the United States. Mr. Powell said that the ultimate development of the United States rested largely upon the most thorough utilisation of the water resources. This was conspicuously true of the vast arid and sub-humid regions extending from the great plains to the Pacific coast. There the almost boundless extent of fertile land could not be utilised for agriculture without the artificial application of water. In all cases, whether in arid or in humid regions, the proper solution of the problem rested upon the correct knowledge of the distribution and fluctuation of the available water. This study had been begun by the United States Geological Survey, and was now being carried on.

Prof. W. J. McGee read a paper by F. H. Newell, on the Geological Atlas Folio issued by the United States Geological Survey. These folios are the final maps of the survey showing the topography, geology, and the mines of the areas covered by the sheets. Accompanying the maps are the descriptions of the same in popular rather than technical language, for the benefit of the people. The folios have involved a great expense, and represent probably the finest specimens of geological lithography that are known.

Mr. Joseph H. Hunt described briefly the minerals from Paterson, Upper Montclaire, N.J., and the Palisades, and exhibited excellent specimens, some of which showed in a beautiful manner the process of alteration of one mineral into another.

Dr. W. H. Dale, in a paper, entitled "Notes on the Atlantic Miocene," showed that the vast deposits of phosphate rock of South Carolina, which have yielded millions of dollars, are of Miocene age, like those of Florida.

Prof. Spencer read an interesting paper upon the age of Niagara Falls. He said that the first conjecture as to the age of Niagara Falls was made by Andrew Ellicott in 1790, who supposed the Falls to be 55,000 years old. About 1841 Lyall estimated the age of the Falls as 35,000 years. According to Prof. Spencer, the evolution of the Falls was as follows: A little stream draining the Erie basin only fell about 200 feet over the brow of the Niagara escarpment, and in magnitude was just about the size of the American Falls. This stream was not over one-fourth the present volume of the great cataract, and, consequently, was able to excavate the gorge at a much lower rate than at present. During this early history of the river the waters of the three upper lakes emptied through the Huron basin by way of the Ottawa River. The height of the Falls has advanced several times, and, owing to this change and the variation in the discharge of the water, retreat of the Falls has varied greatly during changing episodes. The computations of the age have been based upon these changing conditions of elevation and downfall of the river. The first episode, as before stated, represented a small river, with a total fall of 200 feet. This lasted about 11,000 years. Then fell another episode, where the height of the Falls was increased from 200 to 400 feet, succeeded by the entire drainage of all the upper Great Lakes. At the same time there were series of three cascades, the lower gaining on the upper, until finally they were all united in one great cataract, much higher than that of the present time. Subsequently the waters were raised at the head of Lake Ontario so as to bring about the present conditions after a lapse of 17,000 years from the end of the first episode. The last or modern episode has lasted 3000 years under nearly the present conditions. Thus we see that the age of the Falls is about 31,000 years, with another 1000 years added for an earlier condition not given. It is now 8000 years since Lake Huron emptied into Lake Erie for the first time. The land has risen about the outlet of Lake Erie, and if the present rate continues, in 5000 or 6000 years the waters of the four upper lakes will be turned into the Mississippi River drainage at Chicago.

Zoology and Botany.

Among the papers read before the section of Zoology were the question of spider bites, L. O. Howard; the pulmonary structures of the Ophidia, Edward D. Cope; photographing fishes and other aquatic animals under water by means of a vertical camera, Simon H. Gage; a migration of cockroaches, L. O. Howard; sexual characters in Scolytidæ, A. D. Hopkins; notes on the genus *Perigoninus*, Sars, Charles W. Hargett; the transformations of the lake and of the sea lamprey, S. H. Gage; on the above-ground buildings of the seventeenth year Cicada, J. A. Lintner.

Prof. L. O. Howard described an extraordinary migration of Croton bugs or German cockroaches, witnessed by him on the streets of Washington on a very dark day last summer. He found that the migrating army, which was composed of many thousands of individuals, consisted almost entirely of females carrying egg-sacs.

At a joint meeting of the sections of Botany and Zoology, Dr. Manly Miles read a paper on the limits of biological experiments. Among other things the speaker pointed out the futility of most feeding experiments. During the discussion which followed, Prof. Edward Cope remarked: "If Weissmann had been a better botanist he would never have promulgated his theory of the isolation of the germ plasm."

Prof. L. H. Bailey discussed the relation of the age of type to variability. He called attention to the wide range in variability of cultivated types, some of which, he said, vary so much and so quickly that specific types may be lost, yet the difference was not due to age or period, nor to geography or diversity of cultivation. Continuing, he said:

"Variability under cultivation must be ascribed to some original elasticity of the species, and this elasticity or flexibility is no doubt intimately associated with the phylogeny of the type. The common notion that man can modify any plant in given directions is not true. The newer the type the more readily does it vary. All this establishes an intimate relationship between development under cultivation and evolution under natural conditions. They are not two, but one, and the agriculture (*sic*) of man is but an extension of the agriculture of nature."

Prof. Bailey also read a paper on the struggle for existence under cultivation, and during the course of his remarks he said—

"It is commonly supposed that struggle for existence ceases under cultivation, and that man's endeavours and nature's are two. Here we have statistics. There are enough seeds in the United States to stock the world. It is observed that in cultivation there is less waste than in nature. Struggle is more intense than in nature. Not more than one in twenty or more which actually germinate are allowed to mature. But it is a struggle of few against few, rather than a struggle of few against many. This struggle, therefore, instead of fixing the specific type in a warfare against outsiders, sets up a divergence among individuals of the species itself. This, to my mind, is one of the reasons for the rapid development of garden plants."

Other papers read before the joint meeting were:—The numerical intensity of faunas, L. P. Gratacap; the growth of radishes as affected by the size and weight of the seed, B. T. Galloway; the work of the Indiana Biological Survey, A. W. Butler; the movement of gases in rhizomes, Katherine E. Golden; some interesting conditions in wood resulting from the attacks of insects and woodpeckers, A. D. Hopkins.

A paper on evidence as to the former existence of large trees on Nantucket Island, by Dr. Burt G. Wilder, was read before the section of Botany.

Dr. Byron D. Halstead, in a paper upon a root rot of beets, before the section of Botany, described a new disease of those plants.

Major J. Hotchkiss showed specimens of wood cut from trees that had been marked by surveyors 107 years ago. The presence of the injury was still manifest upon the surface of the trees. The growth per year was about one-twentieth of an inch.

Dr. E. F. Smith read a paper on watermelon disease in the south. Other papers read were:—The sugar maples of Central Michigan, W. J. Beal; some affinities among Cactaceæ, John M. Coulter; simplification and degeneration, Charles E. Bessey; regulatory growth of mechanical tissue, Frederick C. Newcombe; further studies in the relationship and arrangement of the flowering plants, Charles E. Bessey.

Anthropology.

Dr. Franz Boaz's address to this section was on human faculty as determined by race. He traced the history of civilisation from its dawn in the far East until now, showing how ideas and inventions were carried from one nation to another. He referred to the civilisations in ancient Peru and Central America, and showed that the general advancement was the same as in Asia and Europe. The only difference was one of time. One reached a certain stage 3000 or 4000 years earlier than the other. But this difference was insignificant compared with the age of the human race. Man had existed for a period to be measured by geological standards only. He showed that, in the past, nations brought into contact with civilisation easily assimilated it, and now they dwindled away before its approach. This was due to the fact that formerly races did not differ so widely as at present, and now disease devastated regions newly opened to white people. The conditions for assimilation in ancient Europe were much more favourable than in countries where primitive people now came in contact with civilisation. This conclusion was confirmed by other facts from the history of civilisation—Northern Africa and in China.

Dr. Boaz remarked: "Several races have developed a civilisation of a similar type to the one from which our own had its origin. A number of favourable conditions facilitated the rapid spread of this civilisation in Europe. Among these common physical appearances, contiguity of habitat and moderate differences in the modes of manufacture were the most potent. When, later on, civilisation began to spread over other continents the races with which the modern civilisation came into contact were not equally favourably situated. In short, historical factors appear to have been much more potent in leading races to civilisation than their faculty, and it follows that achievements of races do not warrant us to assume that one race is more highly gifted than another."

He also said: "After going over the field of anatomical differences, between races, so far as they have a bearing upon our question, our conclusion is that there are differences between the physical characters of races which make it probable that there may be differences of faculty. No unquestionable fact, however, has been found yet which would prove beyond a doubt that it will be impossible for certain races to attain a higher civilisation."

Dr. Boaz expressed the opinion that the probable effect of civilisation upon an evolution of human faculty has been much over-estimated. The psychical changes which are the immediate consequence of civilisation may be considerable. They are changes due to the influence of environment. It is doubtful, however, if any progressive changes or such as are transmitted by heredity have taken place. The number of generations subjected to this influence seems altogether too small. Besides, the tendency of human multiplication is such that the most highly cultured families tend to disappear, while others, who have been less subjected to the influences regulating the life of the most cultured classes, take their place. Therefore, it is much less likely that advance is hereditary than that it is transmitted by means of education.

In conclusion Dr. Boaz said: "The average faculty of the white race is found to the same degree in a large proportion of individuals of all other races, and although it is probable that some of these races may not produce as large a proportion of great men as our own race, there is no reason to suppose that they are unable to reach the level of civilisation represented by the bulk of our own people."

In the Anthropological Section, Dr. Daniel G. Brinton read a paper entitled "Variations in the human skeleton and their causes." The speaker called attention to a number of peculiarities in the human skeleton which had attracted the notice of anatomists, and which had frequently been interpreted as signs of reversion to an ape-like ancestry. He said that most of these variations can be explained by mechanical function, or excess or deficiency of nutrition; and when they can be so explained, this is the only interpretation they should receive. They could no longer be offered as evidence of the theory of evolution, nor considered as criteria or marks of the human races.

Mr. M. H. Saville read a paper on a comparative study of the Glyphs of Copan and Quirigua, in which he presented his conclusions on the hieroglyph "pax." In the discussion of Mr. Saville's paper, Dr. Brinton presented his conclusions, which he announced for the first time, based upon studies of vases in the museum of Pennsylvania, that the symbol pax was a representation of the sacred drum of the Aztecs, and that the hieroglyph stood in the codices for paxahs, "It is finished."

"Iroquois migration" was the subject of a brief paper by the Rev. Dr. Beauchamp, who said that one at least of the three great divisions of the Iroquois family had its centre near the south-western border of Lake Erie.

Mr. Frank Hamilton Cushing, ethnologist for the Bureau of American Ethnology at Washington, read a paper entitled "Salt in Savagery." He referred tot he universal liking for salt among the Indians of North America. The Zuni Indians believed that the first salt came from the sun. According to Indian mythology, there is a salt goddess who is the daughter of the ocean. Mr. Cushing related her genealogy, and then proceeded to discuss the influence of salt upon the culture of the Indians in the south-west. He stated that he believed that nothing led the cliff-dwellers down from their inaccessible dwellings to live in villages more than their desire for salt. Men's dispersion over the world, said Mr. Cushing, is largely influenced by salt. Coming down from his arboreal retreat, where he lived on nuts and fruit, he found the seashore and acquired a taste for a substance now universally used.

Mr. R. G. Haliburton read a paper on the dwarf races of the New World.

Rev. W. H. Beauchamp described the southern visit of the Eskimo, in which he declared that evidence of Eskimo contact with the Indians of Northern New York were to be found in certain stone knives found among them, specimens of which he exhibited.

Mr. Dorsey read a paper by William Sturtevant, in which Mr. Sturtevant described three ears of corn from prehistoric grains from localities in Peru, collected by Mr. Dorsey, the especial point of interest being that from a grave of undoubted antiquity in Iquique was found a kind of corn which was commonly supposed to be of a recent cultivated variety. Mr. Dorsey called attention to the great importance of collecting and preserving all varieties of corn from all prehistoric sources as a means of determining the original habitat of the maize, as well as furnishing an index of civilisation.

THE DISPLACEMENTS OF THE ROTATIONAL AXIS OF THE EARTH.[1]

DISPLACEMENTS of the rotational axis of the earth with reference to fixed directions in space have been observed since the earliest ages of astronomical measurement; for such displacements, visible in wanderings of the pole of the apparent diurnal rotation of the celestial sphere among the constellations of fixed stars, exist in such enormous amplitudes, that in their main features they could be detected by the aid of very simple apparatus and observations.

The true law and explanation of these wanderings of the pole remained, nevertheless, a deep mystery till Copernicus lifted the veil by showing that they were only the celestial image of real displacements of the rotational axis of the earth in space, and until Newton came and, combining his discovery of universal gravitation with his deduction of the ellipsoidal figure of the earth, proved that these displacements are due to the actions of the moon and the sun on the earth.

The mathematicians of the eighteenth century completed this explanation by profound researches embracing the full theory of free rotation of a solid system of masses, under the action of various disturbing influences, not only those acting from outwards on the rotating body (as in the case of the sun's and the moon's attractions on the earth), but also those depending upon the condition or changes within the rotating system itself.

Among several interesting results, these investigations pointed out an essential difference between the development of the disturbed rotation in the first and in the second case.

Upon the supposition, corresponding to the real terrestrial conditions of the problem, namely, that all the disturbing influences are relatively small in comparison with the amount of energy represented by the primary rotation of the earth itself, the following distinctions were demonstrated.

Exterior disturbing influences will mainly produce displacements of the axis in space, and corresponding wanderings of the pole among the stars, whilst the simultaneous displacements of the axis in the earth itself, in consequence of the particular conditions of their evolution, remain insensible.

On the contrary, interior conditions and disturbing influences, as those contained in the configurations of the masses, or in changes of the distribution of the masses composing the rotating system, will mainly produce displacements of the rotational axis in the rotating body itself, whilst in this case the simultaneous displacements of this axis in space and the corresponding variations of the position of the pole among the stars remain insensible.

Very soon after these deductions had been made from the theory, astronomers began to inquire if also effects of the latter type, that is to say, displacements of the rotational axis in the earth, really existed.

According to the theory, such displacements ought even then to exist when the distribution of the masses composing the earth is not in the slightest degree variable.

It is sufficient for producing such displacements that the position of the rotational axis of the earth is actually not in perfect coincidence with one of its principal axes of inertia, known as the principal axis.

The slightest deviation of the rotational axis from the principal axis has the consequence that the pole of the rotational axis begins and continues to describe a small circle around the pole of the principal axis.

The velocity of this movement depends upon the law of the figure and of the distribution of the masses composing the earth, and the best numerical data for this dependence had given the result that the displacement in question would probably have a period of nearly ten months.

Now all such displacements, possibly measurable with reference to fixed directions in the earth, and insensible with reference to fixed directions in space, could be found in the most favourable way by measuring as exactly and continuously as possible the distance of the pole from the zenith of the observer's station; in other words, by repeated determinations of the geographical latitudes. But, notwithstanding very long and refined determinations of the geographical latitudes at some of the principal observatories, beginning shortly before the middle of the present century, only very uncertain and discordant traces of the phenomena in question were found.

The reason for this want of success is now very clear. Astronomers had limited their researches too narrowly to the last-mentioned type, namely, to the supposed regular ten-monthly periodical movement of the pole of the rotational axis around the pole of the principal axis. Too easily it had been admitted that all the existing variations of the distribution of terrestrial masses were by far too small for altering sensibly the position of this principal axis itself.

It was Lord Kelvin, at the Glasgow meeting of the British Association (1874), who at first drew the attention of the scientific world to the consideration of the great natural transports of masses of air and water and various masses by the water, going on continuously and periodically in the form of currents and circulations of different kind, as well in the atmosphere as in oceans and rivers, for instance the enormous periodical sediments of snow and ice. He showed that these very considerable variations of the distribution of masses on the earth could not only produce sensible displacements of the principal axis of inertia, but that such displacements of this axis could have an amplifying effect on the total amount of displacements of the rotational axis.

For if the principal axis were itself not in a constant position, the theoretically required movement of the rotational axis around the principal axis would become a very complicated movement, differing entirely from the simple form which to that epoch had appeared in the researches of astronomers.

This epicyclic character of the movement of the pole of the rotational axis could considerably modify not only the length of the period, but also the whole geometrical character and amplitude of the curve in such a way, that in longer periods epochs of very small variations of latitude could alternate with epochs of considerably increased variations of latitudes. Possibly, as a further consequence of this complication of the displacements of the two axes, and as a consequence of the still existing plastic state of certain parts of the earth, as well as by the damping effects of the fluid parts, even *progressive*—though very slow and unsteady progressive—displacements of the rotational axis in the earth could still result.

The field of this research was thus decisively cleared by the veritably releasing ideas of Lord Kelvin. Finally, about four years ago, by the co-operation of some observatories with the International Geodetic Union, clear evidence was obtained, and in the last three years, with the aid of an expedition sent by the International Union to Honolulu, decisive proofs of such displacements have been found. I consider it a special honour and pleasure to be enabled to submit some of the newest results of this international co-operation to a meeting of the same Association which, twenty years ago, had been witness of the almost prophetic assertions of one of its most illustrious members regarding the real conditions of this important phenomenon.

I have prepared a diagram (Fig. 1, p. 489) showing these newest results. You see in this diagram a representation of the wanderings of the pole of the rotational axis of the earth on the surface of the latter during the last twenty months, from October 1892 to May 1894.

This sketch is founded on nearly 6000 single determinations of latitude made in the Observatory of Kasan (Eastern Russia), Strassburg (Elsass), and Bethlehem (Pennsylvania). The observations are condensed in twenty monthly mean results,

[1] A paper read by Prof. W. Foerster, Director of the Royal Observatory of Berlin, before the British Association.

numbered, as you see, from zero to nineteen. Every one of these resulting monthly positions of the pole indicated by the centres of the small circles is thus the mean result of about 300 single determinations.

The accompanying figure is drawn on a scale of two millimetres to one-hundredth of a second of arc, and the maximum amplitude of the curve is nearly 50-hundredths, or half a second. The amplitude of these movements of the pole on the surface of the earth is between 40 and 50 feet.

You see the general character of the movement quite in accordance with what has been mentioned concerning its complicated and somewhat spiral character. The sense of the motion is turning from west to east. The velocity is apparently very variable, and it seems as if we now approach an epoch in which the amplitude considerably diminishes. It is also evident that such

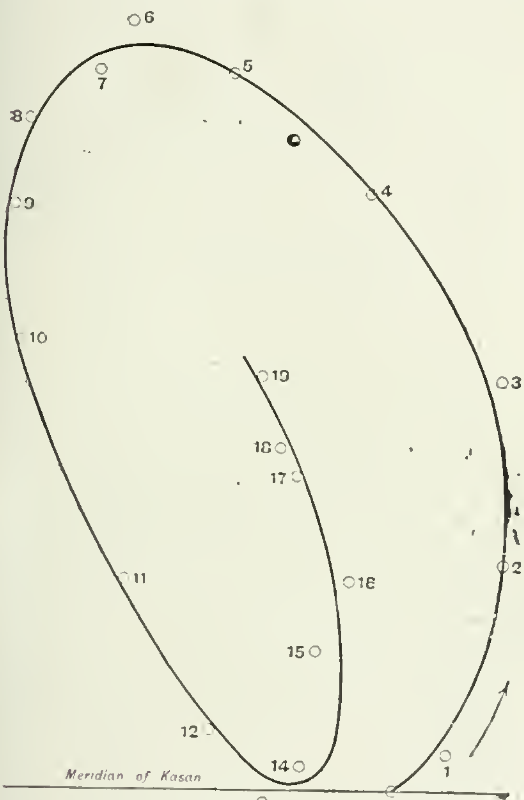

FIG. 1.—Movement of the North Pole of the rotational axis of the earth Derived from observations made at Bethlehem, Strassburg, and Kasan :—

0 = 1892 Oct 20	13 = 1893 Nov. 1.
1 = ,, Nov. 1.	14 = ,, Dec. 1.

a character of movement can very easily produce slow progressive motions, and also from this reason the whole phenomenon wants to be watched incessantly and very carefully.

The astronomers and geodetists who are now associated in the International Geodetic Union, have invited the geologists to associate with them in this common research. Such an international organisation will be also useful and almost indispensable for a great part of the work of astronomical observatories.

It is to be hoped that Great Britain will now participate in this international union, embracing all other civilised nations. Such organisations, with their clear and reasonably limited aims, involve not only real economies and refinements of mental work, combined with diminutions of material expenses, but it is hoped that they will also have a great importance as slowly growing foundations of human and terrestrial solidarity.

SCIENCE IN THE MAGAZINES.

MR. HIRAM S. MAXIM gives, in the *National*, a brief description of his experiments on flying by means of aeroplanes. His flying machine, when finished and loaded with its water, its fuel, and three men, weighed very nearly 8000 lb., and the actual horse-power developed on the screws was 363 horse-power, with a screw-thrust of rather more than 2000 lb. The total width of the machine was over 200 feet. It was found that upon running the machine at thirty miles an hour very little load remained on the lower track, and at thirty-six miles an hour the whole machine was completely lifted.

The *Fortnightly* is remarkable this month for two critical articles by Prof. Karl Pearson and Mrs. Lynn Linton, respectively. Prof. Pearson assails Lord Salisbury's address to the British Association, and moans over the fact that Lord Kelvin courteously said that throughout it " there was the spirit of the student, the spirit of the man of science." Here is his opinion on it : "We find nothing in it which shows the spirit either of student or of man of science ; it teems with fallacious conclusions, and whatever may have been intended by the author, it can only serve as an appeal to that gallery which is occupied by the reconstructed theological party." Mrs. Lynn Linton outpours the vials of her wrath upon Prof. Henry Drummond and his "Ascent of Man." "He brings his subject," says she, "which only the educated can rightly understand, down to the level of the ignorant. He strips science of her divinity, and sends her out as a cottage-maid, or rather as a young priest, of whom no one need be afraid. But he lets slip truth in this endeavour to extract milk for babes out of the meat for men ; and his rendering of synthethic philosophy is both inadequate and shallow. Whatever is true is borrowed ; whatever is false, strained, and inconclusive, is his own. His sin is the sin of plagiarism, with the additional offence of distortion in the lifting." Surely a writer never received a more terrible flagellation than this.

Brief descriptions will suffice for other articles of more or less scientific interest in the magazines received by us. Sir Robert Ball contributes to *Good Words* a paper on Galileo. The *Century* contains a continuation of Messrs. Allen and Sachtleben's account of their journey across Asia on bicycles ; and a fine picture of an aurora, observed and sketched at Godthaab on September 3, 1892, by Mr. F. W. Stokes, one of the members of the Peary Relief Expedition. Dr. Carl Lumholtz describes in *Scribner* the life and costumes of the Tarahumaris, the inhabitants of the Sierra Madre. In *Chambers's Journal* we find a diversity of instructive articles. Among the subjects scientifically treated are "British Ring-Snakes," "Dynamite," "Sweet Lavender," and "Sources of Power in Nature." Lovers of nature will find pleasure in an article entitled "In a Rock Pool," contributed by the Rev. Theodore Wood to the *Sunday Magazine*, and geographers will be interested in a description of the inhabitants of the Andaman Islands. Under the title "Spirit and Matter," Emma Marie Caillard philosophises, in the *Contemporary*, on such psychical subjects as were touched upon by Prof. Oliver Lodge in his British Association address in 1891.

SCIENTIFIC SERIALS.

Bulletin de l'Académie Royale de Belgique, No. 7.—Comparative study of the isothermals observed by M. Amagat and the isothermals calculated from M. Van der Waals's formula, by MM. P. de Heen and F. V. Dwelshauvers-Dery. A comparison of the theoretical and experimental isothermals shows that the molecules which constitute carbonic anhydride expand regularly as the temperature increases. The coefficient of mean molecular expansion, for temperatures between 30° and 258°, is sensibly equal to 0·001, a number which closely approaches the coefficient of expansion of liquids in general. To this intramolecular dilatation corresponds the internal latent heat of dissociation, made evident by the variability of the specific heat of carbonic anhydride in the gaseous state. Since Van der Waals's equation furnishes fairly accurate values for the part of the isothermals situated to the right of the minimum, one might feel tempted to introduce another constant and to force the curve to pass through a supplementary point conveniently chosen to the left of that minimum. This would give much more satisfactory results, but they would have no value with regard to the theory.—On the motion of the satellites of the planets with respect to the sun, by P. Stroobant. The author points out that the moon alone, among all the satellites, always turns the concavity of its orbit towards the sun. This concavity is less at new than at full moon, but the attraction of the sun always outweighs that exerted by the earth. The author investigates theoretically the motions of the satellites round the sun, and introduces the attractions of their planets as perturbations. In order that the trajectory may be looped, the linear velocity of the satellite must be superior to that of the planet. The satellites I., II. and the new one of Jupiter, and Mimas, Enceladus, Tethys, and Dione of Saturn are the only satellites with looped orbits. The rest of the satellites follow a sinuous curve with points of inflexion. Those of Uranus are not taken into consideration. The author expects that if the moon is considered as revolving round the sun, subject to perturbations due to the earth, the lunar theory will be simplified, and successive approximations will be more convergent.

Bulletins de la Société d'Anthropologie de Paris, tome v. 4e serie), No. 3, March 1894; No. 4, April 1894.—Meeting of February 1, 1894.—Dr. P. Mauclaire and M. Bois contributed a note on Ectrodactyly and Syndactyly, in which they describe a very remarkable case, where the right foot and both hands have the appearance of a two-pronged fork. The authors had the opportunity of dissecting this subject, and give a most interesting account of the anatomy.—M. Paul Denjoy described a religious ceremony in Annam, celebrated at the commencement of the new year in honour of ancestors.—M. Ch. Letourneau read a paper on synthetic literature of the first ages, and M. F. Gaillard contributed a note on the sculptures of Gavr Inis.—On February 15, M. E. d'Acy made a communication on flint implements from the plateaus of Picardy and Normandy.—At the meeting of March 1, M. L. Lapicque exhibited some photographs of the inhabitants of the Mergui Islands (the Selungs), and made some anthropological and ethnographical observations on those people. The Mergui archipelago is situated off the coast of Tennasserim (long. 96° 20′ E.; lat. 13° to 9° N.). It is composed of lofty islands covered with ancient forests. The islands themselves may be said to be uninhabited, but in the straits and roadsteads of the Archipelago are to be found several tribes of nomadic fishermen who live entirely on their boats, except during the wet season, from May to September, when they come ashore and build temporary habitations for themselves on the coast. They are very wild, and hold little communication with the people on the mainland. The people seem to be of Malay origin, but there is evidently a considerable admixture of foreign blood of various kinds.—On March 15, M. G. Lagneau read a paper on the mortality from tuberculosis as affected by occupation and by residence.—M. O. Lambert offered some observations with regard to a recently observed case of the presternal muscle, in which he contended that the names *rectus thoracis* and *sternalis brutorum* as applied to this muscle are misleading, and that it ought to be regarded as a survival of a connection that once existed between the panniculi of the abdomen and of the neck.—Dr. Michaut contributed an account of the prehensile foot among the Japanese and Annamites.—M. A. Ponchon gave an account of the caves of Herleville, Canton of Chaulnes (Somme); and M. Octave Vauville read a paper on the enclosures, dwellings, and common pottery of the Gallic epoch. The conclusions at which M. Vauvillé arrives are (1) that the same forms of pottery were in use at the same time in different parts of the country; (2) that the pottery, at the close of the Gallic epoch, was generally made with a wheel; and (3) that it is evident that true artists existed amongst the potters of that period.

L'Anthropologie, tome v. No. 3, May-June 1894.—In an article on the inauguration of anthropology and human anatomy at the Jardin des Plantes, M. E.-T. Hamy gives a most interesting account of the work of Marin Cureau de la Chambre and Pierre Dionis, who lectured there during the years 1635-1680. Dr. R. Collignon contributes an anthropological study of the Basque race, in the form of a summary of a work published *in extenso* in the "Memoirs of the Anthropological Society of Paris." M. Salomon Reinach continues his exposition of sculpture in Europe anterior to Greco-Roman influences.

Tome v. No. 4, July-August, 1894.—This number opens with an interesting article, by Antony Jully, on funeral rites, graves, and honours paid to the dead in Madagascar. The worship of the dead is greatly developed in the different tribes that people the isle of Madagascar, and the ceremonies connected with it and the monuments that result from it are distinctive characters of that race, composed though it is in all probability of heterogeneous elements. The dead is honoured, not because his memory is dear to his relations, but because they fear to rouse his anger by neglect, and so to suffer from his vengeance. Careful attention is paid to the orientation of the graves, which are placed to the north-east of the house and in close proximity to it.—In a short paper on the remains of Elk and Lion, found in a prehistoric station at Saint Martory (Haute-Garonne), the author explains the reasons that have induced him to include these animals, together with the reindeer, in his list.—In an article on Mycenean Crete, M. Salomon Reinach gives an account of the important discoveries lately made in that island by Mr. Arthur Evans.—M. Eugène Toulouze describes the discovery of an interment of the neolithic period at the village of Saint Mammès (Seine et Marne). The sepulchral chamber measures 1·75m. in length by 0·90m. in width, and it is bounded by walls constructed of comparatively small stones. A vase, a polished axe, an arrow-head, and three other worked flints were found associated with the human remains, which were much damaged.—Prehistoric crania of Patagonia form the subject of a valuable article by Dr. R. Verneau. According to M. Moreno, it is possible to distinguish five or six distinct types amongst the known skulls of the ancient inhabitants of Patagonia. Dr. Verneau shows that all the crania have certain characters in common, such as great capacity, prominent glabella and superciliary ridges, sub-nasal prognathism, extroversion of the mandibular angles, large chin, and much-worn teeth.

SOCIETIES AND ACADEMIES.

London.

Royal Society, June 21.—"On Some Phenomena in Vacuum-tubes." By Sir David Salomons, Bart.

This paper deals with the phenomenon known as striæ, or bands, in vacuum tubes.

As far as the author could learn from the sources of information available to him, no one had previously discovered how to produce a predetermined number of bright and dark bands in a tube having an open or free path.

After a prolonged investigation he has succeeded in producing this result, and in the present paper he describes, first, the methods by which a definite number of bright and dark bands can be produced in a vacuum-tube; and, secondly, a number of interesting phenomena which have a bearing on the production of the bands in general.

Some of the conclusions drawn from the experiments are:—

That bands may be produced with greater facility in small tubes than in large, and that they become more accentuated probably on account of the inequality of the diameter of such tubes.

That for the production of bands, the glass of the tube itself appears to play a part, since the bands are difficult to produce unless they reach to the glass of the tube.

That an exceedingly minute current produces bands which to the eye, in most instances, disappear when the current is somewhat increased, and on further increasing the current they become visible again. The author believes that in all previous investigations it has been stated that the bands cannot be produced until a considerable current is passed. He refers to investigations by Messrs. Warren de la Rue, Gassiot, and others. His experiments, however, prove the contrary. The probable reason why these statements were made is due to the fact that with the apparatus employed at that time such small currents could not be easily produced. When the minute current is increased, and the bands seem to disappear, the author thinks this is due to an optical illusion: the bands are there, but too faint to be seen, perhaps in consequence of the dark bands being so narrow that they escape observation.

That, when an electric discharge takes place in a large tube in which is placed a partition pierced with a hole, "a forcing effect" frequently appears to be produced. Any bright bands being produced at the hole in the partition may give the appearance of being pushed through to the side of the tube which has the greater length. This phenomenon is mentioned because it is apt to mask many effects, unless the current is suitably adjusted.

That it is not impossible, after the first trace of light becomes visible in a tube when passing a very minute current, that the dark bands subsequent to this stage are illusory, and that they are really the bright bands; and what appear to be the bright bands consist of overlaps which produce double the brightness of the so-called dark bands. In reality, therefore, the bright bands indicate the position of the dark bands.

That by devices bands can be produced in a large tube occupying only a small portion of the cross sectional area, at any rate so far as the eye can discern.

That, when employing Prof. Crookes' tubes for illustrating experiments on radiant matter, if suitable conditions are observed, striæ are formed in these tubes.

That, in tubes having exceedingly small electrodes, and apparently not capable of producing striæ, these can be shown to exist if very minute currents are employed.

That the tube, when made to act as a condenser, permits more current to pass.

That from the above considerations it is not unlikely that a view, which has been held, in regard to the probable origin of the bands, that they consist of a series of discharges through the tube, is true; that the nature of such discharge can be varied by suitable devices placed within the tubes, and that the examination of the nature of the discharge can be best made with very minute currents, that is to say, currents so small that, if made any less, the tube would no longer show any sign of light.

"The Asymmetrical Probability-Cure." By Dr. F. Y. Edgeworth.

"On the Absorption Spectra of Dilute Solutions." By Thos. Ewan.

In order to measure the extinction coefficients of very dilute solutions, a new spectro-photometer was devised, in which a Lummer and Brodhun photometric prism was used, and the photometric measurements made by means of Abney's rotating sector.

The absorption spectra of dilute solutions of cupric sulphate, chloride, bromide, and nitrate were found to be identical. Solutions of cupric acetate absorb, for the same amount of copper, more light than those of the other salts used. The difference tends to disappear as the solutions become more dilute, and it is increased by the addition of acetic acid.

Measurements of the absorption spectra of a series of solutions of dinitrophenol in pure water were made, from which the amounts of the substance dissociated into ions were calculated, and found to be in very satisfactory agreement with those calculated from the electrical conductivity of the solutions.

The ferric hydroxide formed by the hydrolysis of ferric chloride in aqueous solutions containing less than 0·005 gramme molecules of $Fe\,Cl_3$ per litre, was found to contain no chlorine. The hydrolysis may therefore be represented most simply by the equation $FeCl_3 + 3H_2O \rightleftarrows Fe(OH)_3 + 3HCl$. The determinations of the quantity of colloid ferric hydroxide contained in these solutions (made partly by the spectro-photometer, partly by filtration through porous earthenware) showed that the equilibrium does not take place in accordance with the law of Guldberg and Waage, but agrees much better with the modified form of the law due to Arrhenius, in which account is taken of the electrolytic dissociation of the different substances.

PARIS.

Academy of Sciences, September 3.—M. Lœwy in the chair.—The marine laboratory of the museum at Tatihou I., near Saint-Vaast-la-Hougue (Manche), by M. Edmond Perrier. A description is given of the laboratory fittings and arrangements, and the work enabled to be done by its means.—On two methods for the study of currents in open circuits and of displacement currents in dielectrics and electrolytes. An abstract of a memoir given by the author, M. de Nicolaïeff. Discs or rings of dielectrics are, in the first method, supported by bifilar suspension between the two poles of an electromagnet so that the plane of the ring is at 45° to the axis of the electromagnet, and centrally situated between the poles. The difference in the displacements caused in constant and alternating fields of the same strength is due to a secondary field set up by displacement currents caused in alternating fields. Paraffin shows an augmentation of 12 per cent. for a period of 930 per minute, and 9 per cent. for 770 per minute. In the second method, displacement currents in the rings are caused by the iron in the magnet cores. The ring is suspended perpendicular to the axis of the cores; the polar faces are able to be brought nearer to or removed farther from the parallel faces of the ring. By this method, augmentations have been obtained of 15 per cent. for yellow wax, and 8·3 per cent. for paraffin. Electrolytes in annular glass tubes behave just like perfect dielectrics, sulphuric acid giving an augmentation of deviation of 15 per cent.—Assimilability of potash by the action of nitrates in poor siliceous soils, by M. P. Pichard. It is shown that, in presence of nitrates, a part of the potash combined with silica is capable of being assimilated by various plants, and hence that it is necessary to determine the total potash present in soils as well as that portion eliminated by acids or aqua regia when estimating the agricultural value of soils.—On the construction of the circle derived from seven right lines or defined by the equation $O = \Sigma_1^7 l_1 T_1^3 = X^2 + Y^2 - R^2$, by M. Paul Serret.—On a new gravimetric method for the estimation of glucose, by M. Fernand Gaud. Cuprous oxide is obtained in much the usual manner by reduction, but care is used to carry out the reduction below 100° by using a water-bath as source of heat. The reduced suboxide is then weighed by transferring the carefully-washed precipitate to a specific gravity bottle, and filling up with boiled water and weighing. The weight p of the precipitate is given by the formula

$$p = \frac{P - V_t d}{1 - \frac{d}{\Delta}},$$

where P is the weight of the water and precipitate, V_t is the volume of the flask at the temperature of experiment t, d is the specific gravity of water at the same temperature, and Δ is the specific gravity of dry cuprous oxide 5·881. The quantities of glucose corresponding to given amounts of cuprous oxide are as follows:—10 mg. of Cu_2O = 5·413 mg. of glucose; 20 = 9·761; 30 = 14·197; 50 = 23·036; 100 = 46·221; 200 = 91·047; 300 = 138·842; 400 = 188·928.—Phenomena following from the dialysis of the cells of the beer ferment, by M. E. Onimus. Yeast secretes a dialysable substance which inverts the sugar present before new cells are produced. The medium is modified by the zymase, and then only becomes able to support the production of new cells.—On the Constantinople earthquake of July 10, 1894, by M. D. Eginitis. The method of Dutton and Hayden gives the focus at a depth of 34 km. The speed with which the shock travelled to various places is as follows:—Paris, 3 km.; Pavlovsk, 3·5 km.; and Bucharest, 3·6 km. per second.

BERLIN.

Physiological Society, July 6.—Prof. Munk, President, in the chair.—Dr. J. Munk had tested the results of his experiments on fasting man by further new experiments on dogs, with the special object of investigating the excretion of chlorine, phosphorus, lime and magnesia, which he had found to be increased in man during hunger. During ten days of fasting he found all four of the above substances, but especially phosphorus and lime, in largely increased quantities in the urine, as compared with days of normal dieting. The fæces also during hunger, which closely resembled meconium both in appearance and composition, contained an increased amount of phosphorus, lime, and magnesia. By calculating, from the amount of nitrogen excreted, the amount of body-proteid metabolised during hunger, he found that only a portion of the excreted phosphorus could have come from the proteid; the remainder must have resulted from the metabolism of some constituent of the body rich in phosphorus and lime. The ratio of these to each other corresponded to a metabolism of bone-substance amounting to about 39 grms. in ten days of hunger. Dr. Munk further reported on experiments on dogs, in which he at one time administered a given amount of meat all at once, and at another time the same amount of meat distributed over three meals. In the latter case the excretion of nitrogen in the urine was greater than in the former, indicating a less perfect utilising of the proteid. This result on dogs is, however, not applicable to man, in whose case the conditions are different, and in whom, as shown by Ranke's older experiments, a given amount of food is more completely utilised if taken in separate portions than if eaten all at once.—Dr. Engel gave an account of his observations on the blood-corpuscles of incubated hens'-eggs, leading to results essentially the same as those obtained from mammalian embryos. In birds the red and white corpuscles and platelets take their origin from nucleated red cells. These views were supported by photographs and microscopic preparations, which were, however, regarded by Dr. Benda as not excluding the possibility that the appearances they presented were purely artificial.

July 20.—Prof. du Bois Reymond, President, in the chair.—Mr. W. T. Porter, of Boston, spoke on spinal respiratory tracts, and gave an account of the following interesting experiments:—On unilateral section of the cord at the level of the nucleus of the phrenic, the movement of the diaphragm on the same side ceases or becomes very weak, whereas it continues unaltered on the other side. If now the phrenic nerve on the uninjured side be cut through, the diaphragm on this side becomes relaxed, while at the same time, on the other side with the unilateral section, the movements of the diaphragm begin again and are continued quite normally. Prof. Koenig had been able, in conjunction with Miss Koettgen, to investigate the absorption of light by visual-purple from a freshly extirpated human eye. A portion of the solution was examined in an unaltered condition, and the remainder after it had been converted into visual-yellow by the action of green light. The curves of the transmission of light for a solution of visual-purple were found to be identical with the luminosity curves of the totally colour-blind, and of bi- and tri-chromatic eyes where the intensity of light is so small that colours cannot be perceived. The curve for a solution of visual-yellow was the same as the luminosity curve of a red-green colour-blind eye. From the above, Prof. Koenig deduced the probability that visual-purple serves for the perception of undefined colourless grey, while visual-yellow serves for the perception of blue. Since both visual-purple and, hence also, visual-yellow are absent from the fovea centralis, this part of the retina should be colour-blind for blue. The speaker brought forward a series of facts in support of this view, and a discussion followed.

July 27.—Prof. du Bois Reymond, President, in the chair.—Prof. Koenig first spoke about an "experimentum crucis" as to his theory of the significance of visual-purple which had been suggested during the discussion at the end of the last meeting, and declared it to be irrelevant. Dr. Greef described the neuroglia cells of the retina and chiasma of the optic nerve as prepared by Golgi's method, and which were called spider-cells, owing to their small elongated bodies and long slender processes. A comparison of these cells in different classes of vertebrate animals had shown that they are most numerous in man, and possess the longest and slenderest processes, while they are less numerous and have shorter and thicker processes the lower one goes in the vertebrate scale. The function of the cells appears to be to isolate the individual nerve-fibres. Prof. Kossel had further investigated the products of the decomposition of nucleic acid, and obtained a much simpler chemical composition for thymin, based on its elementary analysis, than in his previous researches. He had also discovered a new base, which he called "cytosin," and whose reactions he described in detail. Prof. Kossel further described a new and simpler method for determining urea in urine, consisting in a modification of Bunsen's well-known method, and which had proved itself trustworthy as applied to solutions of urea of known composition. Dr. Krüger had isolated a new base of the xanthin group from human urine, which, while it differed materially in its reactions from the xanthin bodies, but showed much resemblance to guanin, he had named epiguanin. Dr. Lilienfeld gave an account of his further researches on diglycocollamide esters. By combining diglycocollamide with leucic acid, as also with tyrosinic and asparaginic acids, he obtained various substances which all gave proteid reactions. One of the compounds so closely resembled ordinary peptone, both in appearance and in all its reactions, that he had provisionally given it the name of synthetised peptone. He reserves for himself the further investigation of this interesting group of synthetic products.

NEW SOUTH WALES.

Linnean Society, July 25.—Prof. David, President, in the chair.—The following papers were read:—(1) Observations on the femoral gland of *Ornithorhynchus* and its secretions, together with an experimental inquiry concerning its toxic action, by C. J. Martin and F. Tidswell. The gland is a compound racemous variety with large alveoli possessing a wide lumen, and somewhat recalling the appearance of a mammary gland. The alveoli communicate with ducts which eventually join at the hilus of the gland to form the duct leading to the spur. The gland is surrounded by a capsule of fibrous tissue, exterior to which is a thin layer of smooth muscle fibre. A marked difference in the minute structure of the gland was noted in animals killed in June and those in April respectively, the former showing the appearance characteristic of an actively secreting gland, whereas the latter suggested that of a mammary gland when it had undergone retrogressive morphosis. Examination of the poison showed it to consist principally of albuminous bodies, and the introduction of these into rabbits produced very marked poisonous results. When injected under the skin, local swelling, and great general depression and rise of temperature followed, but in three days the animal was well again. When the poison was introduced directly into the vascular system, small quantities (1/8 grain) caused death in under half an hour. Larger doses so introduced produced almost immediate death, by producing nearly universal clotting of the blood whilst travelling in the blood-vessels. Such clotting naturally soon put an end to all circulation. In summing up, the authors compared the action of Platypus poison with that of the venom of Australian snakes, supposing the latter to be diluted 5000 times.—Notes on Australian "shipworms," by C. Hedley. A large species of "shipworm" or "cobra" from South Australia, perhaps the largest yet discovered, was described and figured under the title of *Teredo edax*. The type of *T. antarctica*, Hutton, from New Zealand was also figured to demonstrate that the supposed recognition of this species from the coast of Queensland was erroneous.—On five interesting shields from Northern Queensland, by R. Etheridge, jun.—Additional notes on the Palæontology of Queensland. Part i. Palæozoic, by the same.

THE PRINCIPLES OF PURE MATHEMATICS.

Grundzüge der Geometrie von mehreren Dimensionen und mehreren Arten gradliniger Einheiten in elementarer Form entwickelt. Von Guiseppe Veronese, Professor an der königl. Universität zu Padua. xlvi. + 710 pp. Leipzig: Teubner, 1894.)

THE work before us is an authorised German translation, by Lieutenant Adolf Schepp, of Wiesbaden, of Prof. Veronese's treatise on the Foundations of Geometry, first published at Padua in 1891; and the translator tells us in his short preface that the author has communicated to him the corrections and improvements of his work that have occurred to him since its publication in Italian. To give such an account of the contents of a book, so important, so original, and, it may be added, so controversial, as would serve to render its purpose and method generally intelligible, and at the same time to subject it to adequate criticism, would require a memoir rather than a review. We shall therefore endeavour only to give such a description as will recommend it to the attention of all who are interested in the logical basis of Pure Mathematics.

The Preface of thirty-four pages gives a general view of the author's system; the Introduction of 222 pages is devoted to the logical establishment of the notions of Number and Continuous Quantity; after that the First Part deals with the Straight Line, the Plane, and Space of Three Dimensions; the Second Part is occupied with the theory of Space of four or n Dimensions. The treatise ends with an interesting historical and critical discussion of the most important previous works on the same subject, and some notes elucidatory of special principles. A full table of contents is given, and a list of authors quoted; but it would have added much to the value of the book as a work of reference if a good alphabetical index of subjects had been included. The remainder of the present notice will be confined to the Introduction, the specially geometrical parts of the book being reserved for another occasion.

The thorough revision to which, in this century, the underlying principles of mathematical reasoning have been subjected is not less remarkable than the great advances made in the ulterior developments of these principles. Crelle has said that for those who probe the depths, equally with those who build in the heights of mathematical thought, there ever remain unexplored mysteries. Among those who have probed the depths, the investigators, namely, who have occupied themselves with the notions of number and quantity, the continuum of real numbers, the infinitely great and the infinitely small, there has been much divergence of opinion as to the logical grounding of the subject. Such discussions appear to be foreign to the taste of our English writers. With us Arithmetic is an affair of sums to be done by rules; Algebra is arrived at by noting the laws of operation with the numbers of Arithmetic, and giving to them the power of holding generally. We are too used to the process humorously described by Clifford [1]—"In the science of number while five-sevenths of fourteen has a meaning, namely, ten, five-sevenths of twelve is nonsense. Let us then treat it as if it were sense, and see what comes of it." This method, which Clifford held to be "logically false and educationally mischievous," is not that adopted by continental writers, and in particular it is not the method of Prof. Veronese. For him it is necessary so to define the abstract notions—number, quantity, and so on—that the laws of operation with them may be logically well-grounded upon the definitions. Let us see how he sets about the notion of (positive integral) number.

Readers of Clifford's lecture just now quoted will remember that the *crux* of Arithmetical theory lies in the proof of the statement that the number of things in a group is independent of the order in which they are counted; and the difficulty of proving it is not diminished by the facts, firstly, that everyone is firmly convinced of its truth, and secondly, that the whole system of Arithmetic is the work of the human mind, and therefore the theorem must somehow be implicitly included in the definitions when these are given with sufficient clearness. Prof. Veronese, like Kronecker,[1] appears to regard the ordinal number as logically preceding the cardinal number; in other words, he makes the idea of a group of things arranged in an order more elementary than the idea of the number obtained by counting the things in the group. Kronecker, going out from this notion, rapidly arrived at the required result, but our author is not satisfied with his reasoning. His own process is much more leisurely. He starts from the notions of unity and multiplicity (Einheit and Mehrheit) and explains the operations of uniting (Vereinigung) the objects of a series into a group, and of separation (Zerlegung) of a group into objects by successively taking away (Wegnehmen) object after object from the group. He defines an ordered group, and explains the unique correspondence of elements in two such groups. It is only after all this that he is prepared to define a number as an ordered group of units arranged to correspond uniquely and in the same order to the objects in an ordered group of objects. This definition is found to be a sufficient ground for the definition of counting, for proving the crucial proposition above referred to, and for the establishment of the commutative law of addition and the remaining laws of operation with positive integral numbers.

To establish the notion of Quantity and the extended conception of Number, with which Algebra has made us familiar, it is necessary, as many writers (including Du Bois Reymond) have pointed out, to frame an account of the Fundamental Form, or, as we may call it, the *Locus in quo* of real Quantity. A numerical fraction implies a something divisible into equal parts, and a part of it containing a certain number of these parts. A square root implies an exact measurement of a side of a square which has a given area. These examples show that we do tacitly or expressly assume a *somewhat* capable of exact division into parts in arbitrary ways corresponding to various mathematical ideas. This *somewhat* is the Fundamental Form (Grundform), and it has been frequently figured as a geometrical straight line, as by Du

[1] "Lectures and Essays," vol. i. p. 356.

[1] "Ueber den Zahlbegriff." *Crelle*, Bd. ci. 1887.

Bois Reymond in his Algemenie Functionentheorie. According to Prof. Veronese it is more proper to give an independent abstract account of the Fundamental Form, partly because the properties of the straight line are afterwards to be determined in accordance with abstract definitions. He therefore takes as a guide the rectilinear continuum of intuition, of whose properties he gives an analysis, and then proceeds in an abstract manner. He defines a Form as anything whose marks are part, whole, order, and kind of position. Thus a line regarded as consisting of segments limited by points in a certain order having positions on the line is a Form, a song regarded as consisting of certain words pronounced in a certain order and each in a certain musical pitch is a Form. He explains how one Form may be determined by other Forms, and how the identity of two Forms may be inferred from the identity of the Forms that severally determine them. To avoid the circular reasoning that must ensue, unless some Forms are known to be identical there arises the necessity for introducing the Fundamental Form as a standard which serves for the determination of all others. He describes successively a system of one dimension as a form given by a series of elements whose order, from a certain element, is a mark of the form, a homogeneous system of one dimension, and a system of one dimension identical in the positions of its parts. Such a form is chosen as Fundamental Form. The operations of uniting segments of the Form and of separating united segments are described, and shown to obey the Laws of Algebra for addition and subtraction. The relations of segments as multiples or factors of other segments lead to the laws of multiplication and division, and to the description of the Scale founded upon any segment as unit. The Range of the Scale (Gebiet der Scala) is the part of the Fundamental Form arrived at by continual repetition of the segment chosen as unit.

The author is now prepared to introduce the conceptions of the infinitely great and the infinitely small. He assumes that there is an element of the Fundamental Form which lies outside the Range of the Scale founded on any segment as unit. This assumption is apparently free from any contradiction. Such an element being chosen, the segment limited by it, and any element within the range of the scale, is infinitely great in reference to the unit of the scale; had this segment been chosen as unit, the original unit would have been infinitely small. From the nature of the Fundamental Form, as a homogeneous system identical in the position of its parts, follows the necessity of assuming any number of orders of infinite segments and any number of orders of infinitesimal segments.

To every segment corresponds a numerical symbol, just as in particular the natural numbers correspond to the segments which are exact multiples of that one chosen as unit. The ordinary Laws of Algebra holding for the segments hold in like manner for the numbers thus introduced. To the infinitely great and infinitely small segments of different orders correspond infinitely great and infinitely small numbers of different orders. It is proved that the numbers thus arrived at are not identical with Cantor's "Transfinite numbers" (*Acta Mathematica*, Bd. II). After the introduction of these numbers, and the establishment of the laws of operation with them, come the hypotheses of continuity of the Fundamental Form, an idea here treated in a very instructive manner, the proof of the existence of Limits so elaborately discussed by Du Bois Reymond, the notions of commensurable and incommensurable segments, and the theory of Proportion, the last being especially interesting. A chapter is added for the sake of completeness, in which the properties of real, positive and negative, rational and irrational, numbers are established on the basis of principles already discussed.

It is a cardinal feature of the author's account of the theory of Quantity to dispense with the so-called Axiom V of Archimedes, according to which it is inherent in the notion of quantity that when one quantity a is greater than another b, there exists a number n such that nb is greater than a. This axiom has been found by other writers, as Stolz, extremely useful in establishing the properties and relations of finite quantities, but appears to involve difficulties in connection with the infinitely great and the infinitely small. At the expense of greater length of explanation, Prof. Veronese has freed the theory from the axiom and the involved difficulties. His own exposition is generally clear, though his doctrine of "commensurable numbers of the second kind" (pp. 182 and 213) is not without obscurity. Could not an example have been given?

Enough has been said to show that Prof. Veronese's book treats of a great deal besides the Foundations of Geometry—his Introduction might, in fact, well be entitled the Foundations of Mathematics. He tells us that although some parts of it will be useful in Geometry, much has been worked out simply for its own sake. We may well be grateful to him for the patience and trouble that he has expended in clearing up the Logic of the operations that most of us, without a thought of underlying difficulties, cheerfully perform with confidence and success. He has none of the charm of style to be found in the writings of Clifford or Kronecker. Rigorous he is, thoroughly common-sense, careful almost to tediousness, and extremely leisurely. For the elucidation of the very difficult subject he has chosen, these qualities are perhaps the greatest of merits, yet we fear that they will not render his writings acceptable to readers unprepared for a considerable sacrifice of time.

TEXT-BOOKS ON ORGANIC CHEMISTRY.

Organic Chemistry. Part I. By W. H. Perkin, jun., Ph.D., F.R.S., and F. Stanley Kipping, Ph.D., D.Sc. (London: W. and R. Chambers, 1894.)

Lessons in Organic Chemistry. Part I. Elementary. By G. S. Turpin, M.A. (Camb.), D.Sc. (Lond.) (London: Macmillan, 1894.)

It is not surprising that "organic" chemistry should have received less attention in this country than on the continent, considering that the professors in nearly all the chief British universities have been notoriously neglectful of this department of the science, and that the highest degrees in connection with chemical science have been until recent years generally attainable without a practical acquaintance with the subject, and without evidence of capacity for research.

The influences which in Germany have led to so widespread and successful prosecution of research in organic chemistry are traceable partly to the university system, which demands the production of a piece of original work, and partly to the wonderful development in that country of the colour industry, which is now practically a German monopoly. We have, however, British chemists who have successfully devoted themselves to "organic" chemistry, and among them the names of Perkin (son as well as father) and Kipping stand out in honourable prominence. Hence a text-book issued in these conjoint names would naturally excite attention and interest.

"Our original intention," say the authors in their preface, "was to write a small text-book on organic chemistry, based on the syllabus drawn up by the Science and Art Department." Such a plan, however, was not worthy of the reputation of the writers, and they are to be congratulated upon having enlarged the scope of their work beyond this rather narrow limit.

This volume, Part I., deals with the fatty compounds, and "contains in the first place a general account of the methods most frequently employed in the separation, purification, and analysis of organic compounds, and in the determination of molecular weight. The preparation and properties of typical compounds are then described, attention being directed to those changes which come under the heading of general reactions rather than to isolated facts regarding particular substances. Questions of constitution are also discussed at some length, and in the case of the most typical compounds, the facts on which the given constitutional formula is based are specifically mentioned." From this outline it will be seen that the arrangement of the book is not essentially novel. The best feature is the discussion of the structure or constitution as expressed by the formulæ of the more important compounds, and, notwithstanding one or two statements which look rather dogmatic, this is the feature which gives it some superiority over other text-books of about the same dimensions. No reference is made in this volume to ideas of geometrical isomerism, which are prudently reserved for the second part. It is to be regretted that the authors should have allowed themselves to drop, in print, into the slovenly phraseology which is too common among all classes of chemists. For example, p. 99, cane sugar is said to be converted into "equal molecules" of dextrose and levulose. It is true that this expression is employed by writers of bigger books, but that is no justification for the continuance of a phrase which is absolutely unmeaning. On p. 204, triethylamine is said to be "a stronger base" than diethylamine; while on the opposite page, 205, tetrethylammonium hydroxide is stated to be "a stronger base" than potash or soda. If eminent chemists occupying the position of university professors are so lax, it is not to be wondered at that the poor South Kensington teacher and his pupils should be sometimes found wanting when called upon for definitions.

Chapter xiii., p. 218, opens with this statement:—

"It may be assumed as a general rule that the changes which any particular group of atoms is capable of undergoing are independent of the nature of the groups with which it is combined."

This requires for its justification something more than the example which follows, for organic chemistry is full of instances of the influence which neighbouring atoms and groups have upon the character of a given atom or group; and at the top of the very same page the authors draw attention to one of these, namely: "The influence of alkyl groups in increasing the basic character of an element." Mercury is here referred to, and the meaning is obvious to the instructed chemical reader, though the reference to the basic character of the element, coupled with the succeeding statement that mercuric oxide is a feeble base, is well calculated to confuse the mind of a learner.

Dr. Turpin's book is one of the series of science class-books adapted to the elementary stage of the South Kensington syllabus, and issued by Macmillan. Here again the arrangement runs upon well-established lines, beginning with processes of analysis, methods of estimating molecular weight, and then plunging into the successive series of hydrocarbons, alcohols, ethers, acids, and so forth. Detailed directions are given for the performance of a selection of instructive experiments, the number of which, however, being no more than twenty in the whole book, ought to be considerably increased. At the end of each chapter are some questions which will doubtless be suggestive to both pupil and teacher. These are good and useful features of the book, which it must be remembered is labelled elementary; but, oh! Dr. Turpin, where in the whole range of stereo-chemical literature did you find the "valuable hypothesis" that "the carbon atom is regarded as being similar in shape to a regular tetrahedron"? (p. 31). We certainly feel justified in protesting against the author's treatment of the "tetrahedral theory of the carbon atom," which is disposed of in about twenty lines with three shaded diagrams. It is more than doubtful whether this hypothesis should appear in an elementary book at all, but to thrust it in without reference to the sort of fact which it is intended to explain, and to state it in this crude form, cannot be too strongly condemned.

Both these little books have their good points, and both will undoubtedly be found useful by many young students; but the perusal of them and others leaves the impression that the text-book which will meet all the difficulties and provide fully for the needs of the student entering upon this ever-widening subject of organic chemistry, has yet to be written. Organic chemistry is not begun till the student has some acquaintance with inorganic and general chemistry, and if properly taught previously he ought not to require to be told how to deduce a formula from the results of analysis, or how to determine a molecular weight. The practice of reserving these matters as an introduction to organic chemistry belongs to a bygone time, and it has the disadvantage of leading many students to think that vapour density and other methods are applicable only to organic compounds. The arrangement of carbon compounds in homologous series from the outset is also confusing to the beginner, because each succeeding term of such a series is derived from distinct materials which have no apparent connection with either those which go before or those which follow after. A better plan, adopted in some of the older books, now out of date, is first to study the transformations of some one substance, such as alcohol, which lends itself to many changes, which are easily traced experimentally, and subsequently to deal with series. This leads naturally and easily to the great object of the detailed study of carbon compounds. Apart from their practical utility and the application of knowledge gained by this detailed study to the purposes of the vegetable and animal physiologist, the great aim of the organic chemist is surely to trace the relation of chemical constitution to physical properties, and so to shed light upon the wider question of the constitution of matter generally: but this is just the aspect of the study which, in most of the text-books, is kept in the background. W. A. T.

PRACTICAL PHYSICS.

Physikalisches Prakticum, mit besonderer Berücksichtigung der physikalisch-chemischen Methoden. Von Eilhard Wiedemann und Hermann Ebert. Zweite verbesserte und vermehrte Auflage. Pp. xxiv. 455. 279 Woodcuts. (Braunschweig, Viewig, 1893.)

RECENT years have seen a great development in the teaching of practical physics, and a great increase in the number of laboratories in which instruction in the elementary parts of the subject can be given to large classes of students. So much has this been the case, that now practical physics is taught in a good many of our schools, and forms one of the subjects in numerous examinations. Those who have been largely concerned in the establishment of classes for practical instruction in physics, and have had some experience in actual teaching, have often felt the need of a suitable book to put into the hands of their students, and have endeavoured, each for himself, to supply this want. This is the origin of several books on practical physics, such as Glazebrook and Shaw's manual (to take an English example), and the work before us. The authors of such books are able to employ the MS. or the proof-sheets in the instruction of their students, and thus are able to obtain a practical test of their work before sending it forth to the public, with the result that the books are generally very satisfactory for the purposes for which they are designed. The only drawback is that each book is apt to appeal only to a particular type of students, and to give descriptions of the apparatus in a particular laboratory.

The "Practical Physics" of Wiedemann and Ebert has been designed for a special class of students, viz. those who are chiefly interested in acquiring a knowledge of chemistry. Particular attention has therefore been devoted to those parts of physics which are of most use in a study of chemistry, while several parts of the subject of great interest to physicists have been either omitted or only very briefly dealt with. Thus experiments on rigid dynamics and on the magnetic properties of iron and steel are completely passed over.

The authors have not attempted to give an account of the methods of precision which may be employed in the experiments selected by them, and consequently have taken no notice of the small corrections which become of so great importance in an accurate research. In those cases where it seemed desirable that some sou[rce] of error should be brought prominently before t[he] student's notice, the experiment is so arranged that t[he] correction shall not be too small.

To each section there is an introduction wherein t[he] general laws to be employed are stated, and the quantit[ies] to be measured are sometimes defined; but, as a rule, [no] account whatever is given of the reasoning by which t[he] formulæ are arrived at. This is bound to be unsat[is]factory, and must lead the student to be continually a[sk]ing for explanations of the formulæ, unless indeed he [is] a person of little mental vigour, when he will acc[ept] formulæ without a murmur. In many instances [no] explanation or definition whatever of the quantity to [be] measured is vouchsafed to the student. For example, [he] is informed that the coefficient of viscosity of a liq[uid] can be determined by the formula

$$\eta = \frac{\pi p r^4 t}{8 V l}$$

where V is the volume of liquid which is driven thro[ugh] a fine tube of radius r and length l in time t by a pr[es]sure p, but there is absolutely no definition of [the] coefficient of viscosity, although it might have been gi[ven] in a few lines. The same complaint may be made ab[out] several other sections. The authors are surely mistak[en] in their idea that by their method the use of books [on] "the higher mathematics" may be dispensed with, a[nd] the "Prakticum" become a self-contained treatise on pr[ac]tical physics, wherein the student may find all he requi[res] without the trouble of searching through special te[xt]books. Besides, it is in every way better that the stud[ent] should endeavour to acquaint himself with the metho[ds] by which the formulæ have been deduced. He gains [in] this way a grasp of the principles of the subject which [is] hardly attainable in any other manner; and if he d[oes] learn a little mathematics, he may hope that it will [not] seriously injure his ability for chemistry.

Before dealing with the contents of the book, it may [be] well to mention some points in which the book is far l[ess] satisfactory than the authors were capable of making [it]. The first complaint is that the results of the sample [ex]periments are frequently set down without any stateme[nt] of the units in which they are expressed. For instan[ce], the modulus of rigidity of brass is found by an expe[ri]ment to be 4770 *somethings*, but what the *somethings* [are] is not stated. The student who happened to express t[he] linear magnitudes in centimetres instead of millimetr[es] would doubtless be much perplexed when he fou[nd] by his experiment the value 477,000 instead of t[he] result in the book. If, on the other hand, the value [of] the modulus had been expressed as 4770 kilogramm[es] per square millimetre, all the difficulty would have be[en] avoided. The student should be so trained to state pr[e]cisely the units in which his results are expressed, th[at] the bare statement that the modulus of rigidity is 47[70] should produce an unsatisfied feeling, in his mind, mu[ch] the same as is called up by the conundrum, Why is [a] house? In some instances where units are given, th[ey] are given wrongly, as when the velocity of sound is fou[nd] to be 331·5 *metres*, and the average velocity of hydrog[en] molecules is stated to be 1698 *metres*.

A minor defect is that one system of units is r adhered to throughout. Sometimes centimetres are employed, and sometimes millimetres. This is of no consequence, except so far as it tends to keep alive and propagate the state of confusion from which the C.G.S. system might have been expected to deliver the scientific world.

The first part of the book deals with the mechanics of solids, liquids, and gases. The usual methods of measuring lengths, &c., are described, and an account is given of experiments on the balance, on the laws of the pendulum, on elasticity, and on acoustics. The greater portion of the space is devoted to experiments with liquids and gases. The full account which is given of the methods of making measurements of a mechanical nature upon matter in these two states, should be very useful to the students for which the book is designed.

The second division, which is devoted to heat, is excellent. A large number of experiments are described, most of them of great importance to the modern chemist. In this connection may be mentioned specially the sections dealing with melting points, the effect of dissolved substances on the freezing and boiling points of liquids, and the amount of heat evolved in solution and chemical combination. A section is devoted to the determination of the mechanical equivalent of heat by the aid of what is practically a model of Joule's apparatus.

Optical measurements and observations occupy the next portion. Some simple experiments with reflecting surfaces, lenses, and prisms are given, so as to form an introduction to the subject. A few simple experiments with combinations of lenses with lenses or mirrors would have been of much use here, for students generally find difficulty with such experiments, and require some little experience before they can deal practically with the real or virtual images which are seen in mid-space, and not down the tube of a telescope. A large part of the section is devoted to spectrum analysis, and there are some excellent plates of emission and absorption spectra. A short account of the phenomena of polarisation leads up to a chapter on the rotation of the plane of polarisation by various substances, and the use of this property for saccharimetry and other purposes.

The last division of the book, which is devoted to electricity and magnetism, is somewhat abbreviated, only those parts of the subject being included which are supposed to be of interest to the chemist. Voltaic electricity practically takes up the whole of the space. The same omission of definitions, which has been already noticed, shows itself strongly here, no definition being given of either the ampere, the volt, or the ohm, while the enunciation of Ohm's Law is just what a schoolboy might be expected to put down. Although a tangent galvanometer is described, no hint is given that it is possible to calculate its "reduction factor" if the value of "H" is known, and, in fact, the electromagnetic definitions of the units seem quite kept out of sight. From a physical point of view, this division compares quite unfavourably with the three other divisions.

The volume is brought to a conclusion by a useful collection of numerical tables, physical and mathematical.

In spite of the defects which have seemed to call for notice, the book is undoubtedly a useful one, the defects being such as the teacher can very easily remove. If a third edition is called for, it is to be hoped that the authors may see their way themselves to remove them.

The book will often be of service to those teachers who are engaged in the task of conducting classes in practical physics, for it will often suggest fresh experiments to be added to those forming the regular course of the laboratory. But it must be remembered that although a demonstrator in the course of a few years may acquire a knowledge of a large number of experimental methods, yet the students who come under his care for a year or so have only time to acquire a very limited acquaintance with the subject, so that if a new experiment is added to the course, it practically displaces some old one. The course of experiments which is most suitable for students of a particular type working for a particular end, very soon settles itself by a process of selection, and then must remain practically unchanged, although there may be a gradual evolution in the employment of improved methods.

G. F. C. SEARLE.

OUR BOOK SHELF.

Object Lessons in Elementary Science. By Vincent T. Murché. Three volumes. (London: Macmillan and Co., 1894.)

WHEN a child is shown any object, he usually asks "What is it?" and then "What does it do?" If these questions are sensibly answered the child learns much about the properties of common things while he is very young, and, what is more, his faculty of observation is developed. Evidently, then, an excellent grounding for a scientific education can be obtained from object lessons. Simple objects are brought under the children's notice, and their peculiarities observed. For instance, liquids such as water, oil, wine, milk, and quicksilver are taken and used to show that they flow, break up into drops, have no shape of their own, and keep a level surface. Physical properties of solids can then be treated; but whatever the subject of the object lesson, the aim of the teacher must be to let the class come to their own conclusions upon the points illustrated. This principle of sound instruction is well exemplified by the lesson on hard and soft bodies in the first of the three volumes before us. The aim of the lesson is to enable a child to express clearly (1) what he understands by "hard" and "soft"; (2) that hardness and softness are merely relative terms; (3) how to test the hardness of a body. Such objects as an apple, a turnip, a potato, cork, chalk, wood, lead, iron, flint, steel and glass are taken, and children are asked to scratch them with the finger-nail. It is then found that some of the objects can be scratched easily, others not so easily; a third class can only be scratched with difficulty, and a fourth cannot be marked at all with the finger-nail. The experiments are afterwards repeated with a knife, and then the objects are rubbed against one another, and the results noticed. By these means the pupils learn that there are many degrees of hardness, some bodies which are commonly called hard being really soft when compared with others; *e.g.* lead is hard when compared with wood, but soft when compared with iron, and so on. To our minds, this method of teaching elementary science is admirable. It must not be supposed however, that Mr. Murché only deals with physical conditions. His excellent little volumes are also concerned with the chemistry of common things, with the mechanics of every-day life, with zoology, botany, and physiology, and with various arts and manufactures. The volumes follow a scheme of object teaching in elementary science issued by the London School Board some years ago. The author adopted this scheme for use in his school as soon as it was issued, and the experience gained since then has enabled him to produce a thoroughly practical work. We know no better work for teaching elementary science to young children. Though designed for Standards I. to VI. of Board and National schools, most of our private, and many of our public, schools would gain by introducing these object lessons into their curricula.

Précis de Météorologie Endogène. By F. Canu. (Paris: Gauthier-Villars et Fils, 1894.)

LA MÉTÉOROLOGIE ENDOGÈNE is, according to the author's definition, concerned with (1) all acoustic and dynamic phenomena produced more or less directly by variations of atmospheric pressure within the earth's crust; (2) internal manifestations of electricity and magnetism. Ritter gave this branch of knowledge its name, but it was De Rossi who reduced it to a system. M. Canu's volume is an elementary description of phenomena belonging to the physics of the earth. Among the subjects dealt with are the aurora and its connection with the sun; earth currents; subterranean noises, and circumstances affecting them; terrestrial magnetism; earthquakes and earth tremors; and causes producing the escape of fire-damp. All these phenomena are first treated descriptively, and then in relation to other phenomena. Thus, after descriptions of the height, spectroscopic features, acoustic properties, electric character, and geographical distribution of auroræ, we find brief statements of all the causes believed to influence the phenomena. This plan is followed in each chapter, and though the correlation between the phenomena described is sometimes very doubtful, in general the observations quoted deserve consideration. "Pour propager une science," says the author, "il faut avant tout la vulgariser." To accomplish this object the book has been made easily understandable to a French-reading public.

Sach- und Orts-Verzeichnis zu den mineralogischen und geologischen Arbeiten von Gerhard vom Rath. Im Auftrage der Frau vom Rath bearbeitet von W. Bruhns und K. Busz. Pp. 197. Leipzig: Engelmann, 1893.)

THIS book is a tribute by the widow of Prof. vom Rath, of Bonn, to the memory of her late husband. It had been her wish to republish his numerous memoirs in a collected edition, but the expense of reproduction of the elaborate crystal drawings with which his researches have been illustrated was found to be prohibitory; hence the tribute has taken the form of a detailed Index to his works. The plan adopted for the Index is identical with that of the useful Repertorium of the "Zeitschrift für Krystallographie und Mineralogie von P. Groth." There are two alphabetically arranged lists, the one a subject-index, the other a locality-index. The crystallographical and mineralogical part is the work of Dr. Busz, while for the petrographical and geological part Dr. Bruhns is responsible. The Index gives striking evidence of the vast range of Prof. vom Rath's studies and observations, while the high standard of excellence which characterised his work is known to all who have occasion to refer to his memoirs. By reason of the diversity of the species and subjects discussed by him, this Index will be of great advantage to students of mineralogy.

Elementi di Fisica. Vols. I. and II. By Antonio Ròiti. (Florence: Successori Le Monnier, 1891 and 1894.)

THE first volume of the third edition of this work was published in 1891, but the second volume, revised and enlarged, has only recently appeared. The two constitute an admirably-arranged work on general physics, similar in structure to Ganot's "Natural Philosophy," After an introduction on the properties of matter, Prof. Ròiti passes to the mechanics of solids, and then to the mechanics of fluids. The next section is devoted t acoustics, after which come chapters on heat and energy. These conclude the first volume; the second being concerned with radiant energy, and electricity and magnetism. There are nearly nine hundred illustrations in the complete work, but the majority of them are old friends. However, scientific judgment has been used in making the compilation, and the only matter for complaint is the absence of an index—a common defect of continental publications. In a work of science having the scope of that under review, such an omission is unpardonable.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Latitude by Ex-Meridian.

THE problem under consideration is that of finding latitude by an altitude of a heavenly body taken near the meridian, commonly called the "Ex-Meridian." The method most frequently employed by navigators is that in which a reduction is applied to the observed altitude in order to reduce it to the meridian, this reduction being either found by calculation or taken by inspection from special tables such as the "Ex-Meridian Altitude Tables," by Messrs. Brent, Walter, and Williams. In the following it is proposed to show how this reduction may be effected by the use of the Azimuth and Traverse Tables.

If l be the latitude, d the declination, and h the hour angle, the formula of reduction is

$$x = Ch^2 \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where

$$C = \frac{\cos l \cos d}{2 \sin (l-d)} \left(\frac{\sin^2 1''}{\sin 1''} \right) \text{(Godfray's "Astronomy")}.$$

Now since C may be considered constant

$$dx \text{ or } dl = 2\,Ch\,dh \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (2)$$

Again from the fundamental relation

$$\cos d \cos l \cos h = \cos z - \sin d \sin l$$

it is easily found that

$$dl = dh \cos l \tan A \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (3)$$

where A is the azimuth, and eliminating C between (1) (2) and (3) the formula is obtained in the simple form

$$x = \tfrac{1}{2}\,h \cos l \tan A$$

which expresses the reduction in minutes of arc, h being the number of minutes of arc in the hour angle.

As an example of the use of this formula, take the observation given at the beginning of the Brent Tables.

Date, November 18, D.R. latitude 51° north, hour angle 0h. 24m. 54s., declination 19° 20′ 43″ south, and altitude 19° 29′ 18″. Required the true latitude.

From Burdwood's Azimuth Tables the bearing is found to be about 6° 15′, and we have

$$x = 186'{\cdot}75 \cos 51° \tan 6° 15' = 12' 48''$$

giving a latitude 50° 57′ 11″ north.

The result found in the book is 50° 57′ 10″ north.

To find the reduction by the Traverse Table we may proceed as follows:—With 187 as distance and 51° as course, we have d lat. 117′·7; with this as d lat. and 6° 15′ as course, we have in the departure column 12′·8, which agrees with the result found above.

A difficulty attending the above method is that the Burdwood Tables do not give the azimuths of bodies having an altitude greater than 60°, and are only calculated for bodies whose declinations do not exceed the maximum declination of the sun. However, this should hardly be sufficient to condemn the method, especially as the sun is the body most frequently observed.

It may be also of interest to notice an additional use of the Brent Tables. These are constructed on formula (1), Table III. giving the value of C for every degree of latitude from 0° to 70°, and of declination from 0° to 60°. Now (2) may be written in the form

$$2h = \frac{1}{C}\frac{dl}{dh}.$$

So that if we wish to find during what time observations may be taken so that an error dh in the estimated longitude will not produce more than an error dl in the latitude, we have, if t be expressed in time,

$$t = \frac{15}{C}\frac{dl}{dh}.$$

Thus in the above example, suppose it were required to find during what time observations should be taken, so that an error of a second of time in the estimated longitude would not produce more than an error of a second of arc in the latitude, we have

$$t = \frac{15}{1 \cdot 23} = 12\text{m. } 11\text{s.}$$

In cases where the latitude and declination are of the same name and do not differ by very much, this time is very small, but when of different names in high latitudes t is considerable.

Magnetism of Rock Pinnacles.

OWING to my absence from home, I have only just seen the letters of the Rev. E. Hill, M.M.S., and James Heelis, in NATURE of August 2 and 9, on the above subject. The writers have apparently overlooked the very interesting report by Profs. Rucker and Thorpe, published in the Brit. Assoc. Report for 1889, p. 586, in which it is shown that "all the principal masses of basalt in the kingdom form centres of magnetic attraction," and that "the Malvern Hills, though composed of diorite in which magnetic polarity can barely be detected, produce deviations of twenty minutes of arc at a distance of one mile from their axis."

The mineral magnetite is an original constituent of basic igneous rocks; and, owing to the action of gravity on this heavy mineral whilst the magma which contained it was still in a fluid or plastic condition, or to some other cause, it has sometimes segregated into masses, or has become more or less concentrated, in certain parts of igneous rocks. Two very interesting papers on gabbros, in which remarkable concentrations of magnetite have been observed, have quite recently been read before the Geological Society—one by Sir Archibald Geikie and Mr. Teall, and the other by Mr. Alfred Harker—in which the concentration observed in these rocks is accounted for in different ways. Rocks in which a local concentration of magnetite has taken place must have a very powerful effect on the magnet even at a distance.

In addition to original magnetite, basic rocks, especially those of igneous origin, contain secondary magnetite, and magnetic pyrites, formed by aqueous and other agents, out of the unstable minerals of which the original rocks were built up. Serpentine, for instance, usually contains secondary magnetite formed out of the mineral olivine, one of the principal constituents of the peridotite from which serpentine was derived.

Owing to the presence of the above original and secondary minerals, small hand-specimens of ordinary igneous rocks—even those in which special segregation of magnetite has not taken place—will generally be found, when examined, to attract a magnet more or less powerfully.

A suitable instrument for testing hand-specimens may be formed by attaching a small horse-shoe magnet to one arm of a chemical balance. After the equilibrium of the balance has been restored, place the hand-specimen under the magnet and raise it carefully. The balance will dip unmistakably towards the specimen if it contains an appreciable amount of magnetite.

20 Nevern Square, S.W. C. A. MCMAHON.

Aurora.

IN Barrhead, Renfrewshire, on Friday (14th), at 9.15 p.m., I witnessed the finest aurora I have observed for years. The luminous arch extended from south-west to north-east, and shortly reached the zenith. The rapid fluctuations in the streamers were remarkable. There were no coloured bands. The moon, nearly full, was shining, rendering the appearance less vivid. In about fifteen minutes the auroral light began to wane.

Tynron, Dumfriesshire, September 18. J. SHAW.

BRIGHT PROJECTIONS ON MARS' TERMINATOR.

THE appearance of bright spots on the surface of Mars has been long familiar to observers of this planet. An idea of the ease with which they may be observed can be gathered from the following words of Schiaparelli, our highest authority on Martian questions.

"It would not be difficult to find a series of hypotheses which would explain satisfactorily the appearance of the polar and other white spots by attributing them in some way to the evaporation of the supposed seas, and to the atmosphere of the planet whose existence is indisputable. But I consider it more useful to point out that these different white spots are, of all the species of appearances on *Mars*, the easiest to observe. They require only an instrument of moderate power and a very persevering attention. The . . . . peculiarities concerning these spots show that they offer a field for the most interesting investigations, whose importance in the study of the physical constitution of Mars is obvious; and in this field useful work could be done by those observers who are not able to decipher the much more difficult details of the canals and their doubling."

Now the appearances of some of these spots in different positions on the planet's disc have been observed at times to undergo rapid changes in brightness, and it was, if we do not err, the distinguished observer just quoted who first pointed out the tendency of some of these bright regions to increase relatively in brightness as the terminator of the planet was approached.

Observations of more recent date than those just referred to, have, however, made us acquainted with other surface phenomena connected, perhaps, in some way with, but of more importance than, the bright spots, and these are the bright prominences or projections at the terminator.

It must be remembered, nevertheless, that bright projections may be of two kinds, optical and real.

The former is an effect of contrast. It may be brought about by the approach of a very bright spot to the terminator where the adjacent darkness tends to give it the appearance of a projection, or, in other words, it is the result of pure irradiation. As a somewhat parallel example may be mentioned the "drop" seen at the transits of Venus. That numbers of such spots have been seen at various times, can easily be shown by a brief examination of the records. Terby, for instance, in 1888, on several nights watched three such points, which, as they approached the western edge of the disc, became very bright, and before passing behind the planet, projected beyond the edge of the disc, as was the case with the polar cap. At Mount Hamilton, also, numerous similar observations at various times have been made.

The second kind of bright projection is that due to the physical peculiarities at the surface of the Martian globe itself, and may correspond to elevated highly illuminated regions. These were first observed at the Lick Observatory in 1890, at the Observatory at Nice, and at the Arequipa Observatory in 1892. The first prominences observed this year were seen on June 28 at Mount Hamilton, and since then have been more or less constantly observed.

To give the reader an idea of what actually is seen at the telescope when such a projection is under observation, an instance or two may not be out of place.

On July 5, 1890, at 10h. Pacific standard time, a sketch by Prof. J. E. Keeler, with the 36-inch, showed a narrow, elliptical, white spot from 1″·5 to 2″·0 long, projecting northward at a slight angle with the line of the terminator. Half an hour later the spot was within the disc, but still visible as an oval white patch on a darker background. The following day (8h. 3m.) Prof. Holden saw a projecting spot curved upwards and nearly meeting, and the smaller projecting spot some 2″ farther towards the south. The lower spot changed very considerably its shape during the time of observation, about an hour, and was observed to be always situated at the end of a long bright stripe of the surface of the planet which lies north of Deuteronilus.

A second case may be taken from the observations of Prof. Hussey and Campbell, made at the opposition of 1892, on July 11, with the Lick instrument. They record that a most striking one (prominence) was visible when the observations began at 12h. 15m., and remained constantly in view for about two hours. Its shape changed a great deal during that time. At 13h. 25m. it was unusually prominent, and its outer extremity was perceptibly bent upward toward the south polar cap. On July 13 these observations were duplicated; the southern one of the two projections presented the hooked or bent appearance most strongly at 14h. 35m., just as it was seen two nights earlier at 13h. 25m. Allowing for the longer rotation period of *Mars*, the same point on the planet was under observation on the two nights.

A somewhat indirect reference to these bright projections made by the Arequipa observers is included in the statement made by Prof. W. H. Pickering, that "clouds have on several occasions been observed to project beyond the terminator and also beyond the limit, thus confirming the observations made at the Lick Observatory."

Besides the above-mentioned observations, inserted to serve as samples of what has been seen, many more, by different observers, might be given, but they are all of the same type, and undoubtedly describe the same phenomena. One principal fact about them seems to be that although their shapes undergo distortions of all kinds, due to the different directions of the illuminating source, their mean positions seem to be at all times more or less constant.

As they appear beyond the terminator, not too far from it and within the limb, and are brilliantly illuminated, the natural conclusion to draw from this is that they must either be the tops of high mountains lighted up by the sun, or clouds at a high altitude in the Martian atmosphere, rendered bright by the same source. The latter suggestion, which, in the face of the most recent facts, does not seem to have much weight, was put forward by Prof. W. H. Pickering, and their height above the surface of Mars was measured to be at least twenty miles: more recent measures indicate that these estimates are far too high. That they may be, and most probably are, mountain tops, is the most general explanation; and Prof. Campbell,[1] whose opinion coincides with our own, says they are "due to mountain chains lying *across* the terminator of the planet, possibly covered with snow in some cases, and in others not necessarily so."

The reasoning he adopts may be summed up as follows: On July 11, 1892, the Earth was approximately 39,000,000 miles distant. With powers of 350 to 520 the equivalent distances were reduced to 110,000 and 75,000 miles respectively, distances equal to one-half and one-third of that of our Moon from us. Now if, with the *naked eye*, one can see at the terminator of our satellite bright projections at a distance of 240,000, surely projections, if any, at much lesser distances should be visible on the Martian disc.

If they be due to mountains, a small calculation has shown that they need be only of a moderate height, entirely comparable with those on the Earth and Moon. The figures computed to represent the height of the hills, satisfying the July observations, represented an altitude a little more than 1·89 miles.

A well-observed fact, which strengthens the mountain theory to a certain extent, is the presence of extremely brilliant star-like points which have appeared both on and off the snow-cap. If these are really mountain-tops, they should be visible always with suitable illumination, for when seen on a background of snow their height should enable them to catch all available light for reflection; and, secondly, when observed on darker surroundings (as when the snow serving as a background has melted), their height would still serve the same purpose, besides preserving for them their snow-capped peaks. The constancy in position of these spots shows that they are rigidly connected with the surface, and not due to the atmosphere, unless they be looked upon as stationary clouds or mists, which does not seem likely in the Martian atmosphere. Mr. Lowell this year has observed and measured some, the positions of which correspond with the measurements made by Green in 1877.

In Prof. Holden's mind the mountain theory seems to be thoroughly conclusive, for at Mount Hamilton, night after night, and even month after month, the prominences on the planet appear in the same longitudes and latitudes, insomuch that a map of some of the chains is in preparation.

The positions of these brilliant spots on the globe of Mars, just referred to, lie much nearer the South Pole than those which have appeared as projections. This shows that we must not look upon the Martian surface as very flat, but as one studded with hills and dales, if we have such indications of unevenness as we are led to believe.

It may be remarked here that at Mount Hamilton and at Nice no bright prominences have been seen outside the limb, the only observations of such a nature of which we are aware being those of Martian clouds at Arequipa, where, Prof. Pickering states, "clouds have on several occasions been observed to project beyond the terminator and also beyond the limb."

In considering the visibility of mountains at the terminator and at the limb, certain important points must, as Prof. Campbell says, be taken into account.

In the first place, to obtain the greatest "seeing effect" at the terminator, it is not so much the height of the mountain in question, but the length of its chain that is the chief function. On the other hand, a mountain at the limb is seen simply by virtue of its *height* above the general surface, the *length* of the chain in this case being entirely eliminated. It must not be forgotten, however, that we view Mars from the earth, and not from the sun. This fact, combined with the different positions of the planet's axis at the times of opposition periods, accounts for the innumerable ways under which mountain chains can be illuminated, rendering them sometimes visible and sometimes invisible, according to the conditions in vogue. For instance, in 1890 the mountainous part observed was in the region a little to the north of Tempe (lat. 40° N., long. 45°). In 1892 the projections were chiefly observed about the region of Noachis (lat. 30° and 50° S.), two small ones being remarked at 25° N. lat. At Nice projections were noticed in approximately the same position, and in addition at 30° S. lat. and 220° long. to the south of Hesperia.

Such, then, are some of the facts and deductions to which a discussion of the observations of these prominences, made up till now, has led us. There is, no

[1] "An Explanation of the Bright Projections observed on the Terminator of Mars," by W. W. Campbell. *P. Astronomical Society of the Pacific*, vol. vi. No. [illegible] p. [illegible]

doubt, much to be learnt before we can say with certainty that we are dealing with mountain ranges pure and simple; but, as Prof. Campbell says, this hypothesis is a good one to work upon. The explanation, which assumes the presence of clouds, does not, as previously hinted at, seem to be any longer tenable, for would not permanent clouds (as these must necessarily be) at a considerable height mean land at a high altitude, and therefore mountains?

Those making measures of the positions of projections on the Martian terminator may find the following method of procedure, recommended by Prof. Campbell, serviceable:—"Marth's valuable ephemeris of Mars gives the 'position angle of the greatest defect of illumination.' With the micrometer wires set to that position angle, place the fixed wire tangent to the upper limb and bisect the projection with the movable wire. Again, place the fixed wire tangent to the lower limb, and bisect the projection with the movable wire. The diameter of the planet should also be measured, without changing the position angle of the wires. Irradiation caused by the bright polar cap is liable to increase some of the distances measured, especially with small telescopes."

Before concluding this brief summary, a few words may be added with respect to a recent note which appeared in these columns (p. 319), entitled "A Strange Light on Mars." The note in question was based on a telegram issued by the International Bureau, and referred to an observation made at the Nice Observatory. The "strange light" alluded to was regarded by the writer as referring to something quite exceptional, and *not* to the well-known prominences which during 1892 were so often seen, and which during this present period of opposition have been observed and measured several weeks before the telegram was dispatched.

W. J. S. Lockyer.

NOTES.

The funeral of Prof. von Helmholtz took place on September 13, at Charlottenburg. Among the numerous tributes of admiration were magnificent wreaths from the German Emperor and the Empress Frederick, both of whom were represented at the ceremony. Most of the learned societies of the capital and many of the Universities and scientific bodies in other parts of the Empire also sent representatives. Among those present at the funeral were Baron von Marschall, the Secretary of State for Foreign Affairs, Count Eulenburg, Dr. Miquel, Dr. von Botticher, Herr von Schelling, and Herr Thielen.

We are glad to learn that the Technical Education Board have made a grant of £500 to Bedford College (for Women), to aid in the full equipment of the laboratories of that institution.

The *Lancet* states that the trustees of the late Mr. Richard Berridge have, with the consent of the Attorney-General, now handed to the British Institute of Preventive Medicine the residue of the legacy, amounting to over £20,000, for the purpose of building and endowing a laboratory for the chemical and bacteriological examination of water-supply and the investigation of processes of sewage purification. The permanent laboratory is now in course of erection on the site secured by the Institute at Chelsea, but, pending its completion, a temporary laboratory has been fitted up in order that the work may be at once proceeded with. Mr. Joseph Lunt, formerly assistant to Sir Henry Roscoe, has been appointed by the Institute to carry on this work under the director's supervision. The Institute is now, the *Lancet* understands, prepared to undertake the bacteriological and chemical examination of any samples of water which may be submitted. In addition to this, the Institute will give expert assistance in the bacteriological or pathological diagnosis of any pathological material. The demand for this kind of work has greatly increased, so much so that, although Dr. Ruffer will still retain charge of this department, a specially trained bacteriologist has been appointed to work under his direction. Particulars may be obtained by writing to the director at the temporary offices of the Institute, 101 Great Russell Street, London, W.C.

According to the *British Medical Journal*, a Clinical Research Association has been formed, under the patronage of Sir James Paget, Dr. Wilks, Mr. Jonathan Hutchinson, Sir W. H. Broadbent, Sir George Humphrey, Dr. Clifford Allbutt, and others, with the object of assisting medical practitioners in the investigation and treatment of disease by furnishing trustworthy reports upon excretions, tumours, and other morbid products. A laboratory has been fitted up, and will be under the direction of Dr. J. Galloway and Messrs. J. H. Targett and F. G. Hopkins. Further particulars of the Association can be obtained from the secretary, Mr. C. H. Wells, 5 Denman Street, S.E.

A Medical School for Women is to be established by the Russian Government at St. Petersburg. This step, which is said to be due to the influence of Prince Wolkowski, acquires additional importance from the fact that only a few years ago the Ministry of Instruction was strongly opposed to every movement favourable to the higher education of women. The fate of the new institution will, we hope, be happier than that of the one established by Prof. Gerie, which was closed in 1884.

An international Congress of Chemistry and Microscopy will be held in Vienna during the last week of the present month. Dr. E. Ludwig is the president of the committee of arrangements, and the secretary is Dr. Hans Heger, I. Kolowrating, Pestalozzigasse 6, Vienna.

We notice that in the Universal Exhibition to be held in Paris in 1900, there are to be sections devoted to hygiene, military and naval hygiene, and medicine and surgery.

Information has been received respecting an Exhibition of Industry which is to be held at Kioto from April 1 to July 31, 1895. The exhibition is the fourth of the kind organised by the Japanese Government, and will be divided into classes under the following heads:—Manufactures, Fine Arts, Agriculture, Waste Products, Education, Mines and Mining, and Machinery.

We have on several occasions referred to the great landslip at Gohna, and on July 5 printed an illustrated abstract of the report upon it by Mr. T. H. Holland. The dam, as readers of our notes for August 30 are aware, burst on August 26, and, as a consequence, very considerable destruction of property ensued. Further information respecting the occurrence has now reached England, and the *Times* of Saturday last published the following interesting details received from a correspondent:—"On August 24, at 8 o'clock in the morning, an automatic bell, placed within a foot of the top of the dam, sounded the first note of alarm. The warning was communicated throughout the whole of the threatened territory almost instantaneously by means of telegraphic messages, bonfires, rockets, the beating of drums, and other signals, and the people immediately fled, with all their cattle and personal belongings, into the hills. In this way ample warning was given and the apprehended loss of life averted. Three hours after the first signal the water reached the lowest point of the ridge, and the officials thought it expedient to block the passage through which the torrent would first escape, so that the lake should not overflow before 7 o'clock on the morning of the 25th. Warning telegrams were despatched along the valley. The weather was very unfavourable for observation, a heavy mist obscuring the landscape. Signs of collapse were visible at 8 o'clock in the evening, and shortly before midnight the dam burst. A flood 30 feet high, sweeping onward with irresistible force, reached Chamoli, half-way between Gohna and Srinagar, at half-past 12 on the 26th. At 1 in the morning there was another tremendous rush of water, which descended with an awful roar; but nothing was visible owing to the constantly thickening mist. The flood travelled at an average rate of twenty-four miles an hour all down the valley, rising in places to a height of 200 feet. At Chamoli it rose to a height of 160 feet, destroying the bazaars and the hospital. At Srinagar the devastation was even more widespread. The flood reached Hardwar at 9 o'clock on Sunday, and by noon the river had risen 12 feet. It presented a magnificent spectacle, and the view from the surrounding heights was at once grand and terrible. At Hardwar all Government buildings, with the exception of the telegraph office, were destroyed. The whole lake was discharged in about two hours."

AT the August meeting of the Calcutta Microscopical Society, the retirement of Dr. William King from the Geological Survey of India was referred to, and a brief notice of his work in India, and especially in connection with the Society, was read. We take the following information from a report in the *Englishman*:—Dr. King joined the Geological Survey in Calcutta under its first Director, Dr. T. Oldham, in March 1857. In May of that year, a memorable month in Indian history for its connection with the mutiny of the Native Army, he went to Madras with the first survey party for that Presidency, under Mr. H. F. Blanford. Dr. King continued in Southern India for over twenty-five years, with only occasional visits to headquarters in Calcutta; and during that period he took part in the surveys of, or himself surveyed, the districts of the Coromandel and part of the Northern Sircars, working chiefly at the Crystalline, Transition, Vindhian, Gondwana, and Cretaceous formations of Peninsular India. In 1870 he became Superintendent of the Madras Survey Party, and the latter years of his work in Madras were spent in connecting the coastal Gondwanas of Nellore and the Godaveri District with the coal-bearing division of the series in the Central Provinces, by the Godaveri Valley and Western Hyderabad. After this Dr. King's labours lay in the Central Provinces, where in his progress over the Mandla and Bhundara districts, and eventually over the whole of Chatti-garh, he connected most of the rock formations of Southern India with those of the Central Provinces and Central India, up to the western frontiers of Chota Nagpur. In 1887 he became Director of the Geological Survey of India. During the period of his directorship the geology of the north-west frontier (particularly in Beluchistan and in the Salt Range) and of Burma, was considerably advanced in respect to the extent of area mapped, and its correlation with European and Europo-Asian geology. The mineral development of those regions in the way of coal, oil, and tin was also greatly advanced during the same period. Dr. King is the author of four memoirs on the geology of districts in the Madras Presidency, and of more than twenty reviews on the geology, or mineral condition, of other tracts. Dr. Simpson has been appointed President of the Microscopical Society of Calcutta, in the place of Dr. King.

THE Pilot Chart of the North Atlantic Ocean for September shows the remarkable drift of the derelict *Fannie E. Wolston*. On October 16, 1891, the vessel became a derelict not far distant from Cape Hatteras, and on June 13, 1892, was reported in 39° west longitude, from which position, after a number of irregular gyrations, she drifted back to about longitude 75° west by th[e] end of January last, and on August 6 was again sighted i[n] latitude 34° N. and 67° W. This vessel has thus been a derelic[t] for over 1000 days, during which time she has drifted abo[ut] 8600 miles. The American Hydrographer points out that th[e] dangerous character of these derelicts is illustrated by the fa[ct] that during a period of seven years there have been forty-fiv[e] collisions with them, which caused the total loss of nine vessels[.] The United States Government has employed the steamshi[p] *San Francisco* in destroying these obstructions, and durin[g] the above period sixty-nine have been burnt, and one blown u[p] by torpedoes. The efficacy of destroying derelicts by fire i[s] thus illustrated.

THE Italian Meteorological Office has published part 1 of [it]s *Annali* for the year 1893, showing the work done in variou[s] departments of the service. Special studies of the behaviour o[f] thunderstorms are carried on in the interest of agriculture, wit[h] the view of establishing for each province, and for each week o[f] the year, the mean number of storms, distinguishing thos[e] which were accompanied with rain or hail, attention also bein[g] paid to the size of the hailstones. A list of all hailstorm[s] which have occurred during a period of fifteen years is bein[g] prepared. The volume contains several discussions of earth[-] quake shocks, especially those which occurred in Zante, in 1893[.] A new seismograph has been erected at the Collegio Romano, provided with a long and heavy pendulum, which registers shocks that occur at great distances. This instrument, which was devised by Dr. Agamennone, has worked so well tha[t] others are to be established in various parts of the kingdom[.] The department of terrestrial magnetism has been occupied with the preparation of a series of magnetic charts, and a[n] account is given of some modifications and improvements made in a small portable magnetometer, for the study of loca[l] magnetic disturbances.

AN interesting paper on the temperature variation in the electrical resistance of some organic bodies (esters of the fatty acids), by Prof. A. Bartoli, is published in the *Proceedings* o[f] the Reale Instituto Lombardo di Scienze e Lettere. The liquids examined were in most cases obtained from Kuhlbaum, and the author gives their boiling point. The conclusions to which the author has come are as follows:—(1) In a series o[f] esters derived from a given alcoholic radicle with different acids of the fatty series the conductivity, both at ordinary temperatures and at the boiling point, decreases with increase in the complexity of the constitution of the body. In addition, the alcoholic radicle affects the conductivity, which diminishes with increased complexity; thus, while methyl valerate conducts to a fair extent, amyl valerate is an insulator. (2) In general the conductivity of these esters increases with increase of temperature, the rate of change with temperature being smaller for those having a more complex composition than for those with a simpler formula. Thus, while the rate of change is considerable for amyl valerate, amyl butyrate, and isobutyl valerate, it is small in the case of methyl formate, methyl acetate, and ethyl formate. (3) Of the sixty different bodies experimented upon, one sample of ethyl acetate had a conductivity which decreased with increase of temperature; another sample of the same body, however, which the author considers to be purer, gave an increasing conductivity. A sample of isobutyl acetate also gave a negative rate of variation with temperature. These anomalous results the author considers to be due to the presence in the samples of a small quantity of one of the alcohols. (4) The addition of from 1 to 20 per cent. of any alcohol to any of the esters experimented upon, gives a solution of which the variation of the conductivity with temperature is negative, while the addition of a phenol, a ketone, an analine, or a paraldehyde of any acid, gives a solution whose resistance increases with rise of temperature.

IN a paper contributed to the *Archives Néerlandaises*, M. P. Zeeman gives an account of the observations he has made on the Kerr phenomenon on the reflection from surfaces of iron, cobalt, and nickel in a magnetic field. The author has continued the experiments commenced by M. Sissingh, using a slightly modified form of apparatus. He finds that the difference between the observed and calculated phases (obtained from Lorentz's formulæ) is practically constant for radiation of all wave-lengths, and is equal to 80° in the case of iron. Similar results were obtained with nickel and cobalt. In the case of these two metals the author, after attempting to obtain suitable mirrors by the deposit of the metal on polished iron, or by electrolysis, was obliged to have plane faces cut on blocks of the pure metal, which when polished formed good mirrors.

THE specific heat of gases at constant pressure has been investigated by Dr. Silvio Lussana, by means of a new and ingenious apparatus. The contrivance, as described in the *Nuovo Cimento*, is intended to overcome the difficulty of providing a sufficient quantity of gas to experiment upon. With the resources of an ordinary physical laboratory it is difficult to obtain a pure gas in sufficient quantity to make an impression upon the calorimeter, so Dr. Lussana decided to use the same quantity over and over again. Two substantial iron tubes were placed vertically, and communicated at the bottom by means of an india-rubber tube strengthened with five layers of canvas. They were partly filled with mercury, and by elevating or lowering one of them the mercury could be made to completely fill the one or the other. When one tube was full of mercury, the other was filled with the gas to be investigated, and the amount of gas which filled the tube could be driven out and through the calorimeter by lowering the tube. The gas was then made to pass through an india-rubber tube leading to a brass worm immersed in a heating bath, and another immersed in water, which constituted the calorimeter. It then passed through a small subsidiary worm, to test whether it had lost all the heat acquired, and finally entered the other iron tube which was being emptied of mercury. By means of a short circuit provided with a valve, the gas and the mercury in the two iron tubes could be exchanged, and the same process repeated. The water equivalent of the calorimeter was determined experimentally by sending a measured quantity of hot water through it. To ensure constancy of pressure, the level of the mercury was always adjusted to the same fiducial mark on a short length of glass tubing introduced in the india-rubber tube. The gas was introduced by a Natterer compression pump. Seeing that pressures were employed up to forty atmospheres, special care had to be bestowed upon stop-cocks and junctions, some of which were constructed in a novel manner. The results of the measurements, which promise to be of great interest, will shortly be published.

THE May number of the *Transactions of the North of England Institute of Technical Brewing*, a copy of which has been sent to us, contains an interesting and very useful paper by Mr. Fellowes, on "Some of the micro-organisms causing the diseases of beer." Mention is made of the important services rendered by Pasteur, Hansen, Van Laer, Lindner and others to this subject, and we are introduced to quite a number of microbic foes with all of which the brewer has to wage war. The cause of viscosity in beers has recently been elaborately studied by Van Laer, who has isolated certain micro-organisms which he has classed together under the name of *Bacillus viscosus*. When these organisms are introduced into sterilised wort along with pure yeast, the liquid is rendered more or less ropy, the degree of viscosity depending upon the proportion in which the disease organism is introduced. Curiously, however, although the *Bacillus viscosus* behaves in this characteristic manner in the case of Belgian beers, so far, similar results have not been obtained with it when subjected to the English system of fermentation. Mr. Fellowes has himself isolated various organisms present in samples of viscid beer, but has not been able to obtain with such pure cultures or individual varieties a viscosity equal to that of the sample from which they were originally derived. He suggests that the cause of this failure may be sought in the probable modifications induced in the physiological character of the micro-organisms during the process of isolation by means of gelatine cultures. In support of this supposition he refers to Prof. Percy Frankland's investigations on the fermentation of calcium citrate by means of a particular bacillus, which although in the habit of fermenting this substance, for years past absolutely refused to do so when introduced into calcium citrate solutions direct from gelatine cultures. Mr. Fellowes is of opinion that the viscosity in English beers may be due to the associated action of various micro-organisms present, their activity depending not only on the particular varieties, but also on the relative numerical strength in which they are present. It is obvious that to obtain such particular conditions artificially is by no means an easy task, but there can be no doubt that a wide field for research on the question of symbiotic fermentation, or the associated life of micro-organisms, remains yet to be explored.

The *Berichte der Deutschen Botanischen Gesellschaft*, vol. xii. part 5, contains a paper, by J. E. Humphrey, on nucleoli and centrosomes. The author favours the theory that the nucleolus is not a definite organ of the nucleus, but regards it, with Strasburger and Guignard, as a reserve material of the nucleus. In this connection he examined the nuclei of the sporangia of *Psilotum triquetrum*, in which Karsten considers that the centrosomes of the dividing nuclei arise from the nucleoli, and after division are re-included in the daughter nuclei. His observations, however, lead him to the conclusion that the nucleoli and centrosomes are completely distinct from one another, and that the latter are altogether extra-nuclear. Another interesting result, which he obtained in the course of his observations, is that the body, which is often found in connection with the nuclei of the pollen-sac, and which has been called the "paranucleolus," is probably not a natural structure, but is formed during the process of fixing the material in which it is found, as it was seen regularly on that side of the nuclei which was the last to be reached by the fixing fluid.

NATURALISTS may sometimes have wondered that a region so classical in the annals of marine biology as the neighbourhood of St. Vaast-la-Hougue was not earlier made the site of one of those marine laboratories which our neighbours across the Channel conduct with such efficiency and economy. For some years past, however, the Museum of Natural History of Paris has been engaged in altering and refitting the extensive buildings of an ancient *lazaret* on the island of Tatihou to this end, and at the first September meeting of the Academy of Sciences M. Edmond Perrier was able to report the practical completion of the laboratory. A circulation of sea-water has been fitted up throughout the laboratories and tank-rooms, and marine animals of all kinds live perfectly within the aquaria. M. Malard-Duméril, the naturalist in charge, and his staff reside permanently upon the spot, and there is full accommodation for eighteen additional naturalists. The work of the new laboratory is not, however, to be limited to the promotion of pure scientific research, but, if the hopes of its founders are realised, will also include operations on a practical scale in marine pisciculture.

On the title-page to the second edition of the "Manual of the Geology of India," recently noticed in Nature, the name of the author of that edition alone appears. The Government of India, on this circumstance being brought to their notice, have ordered the title-page in question to be cancelled, and a revised title-page, with the names of the original authors of the work inserted, to be substituted.

We are informed that Mr. J. Nisbet, some of whose books on Forestry were recently reviewed in these columns, has undertaken to contribute a series of short articles on "Birds in Relation to Forestry" to the Natural History Department of the *Yorkshire Weekly Post*.

The syllabus of the Manchester Municipal Technical School and Municipal School of Art, for the session 1894–5, has just been issued, and may be obtained from the director and secretary, or the Guardian Printing Works, Manchester. Attention is drawn to several new subjects and courses of instruction, among which we may mention—honours classes in theoretical mechanics, applied mechanics and steam, a course of lectures in hygiene, and special courses in magnetism and electricity for telegraph employés.

The fifth annual report of the Missouri Botanical Garden, covering the year 1893, has just come to hand, and forms a handsome volume. The year under review seems to have been a very satisfactory one for the garden, both from a financial and scientific standpoint. In addition to the reports of the officers of the Board and of the director, the volume contains several scientific papers, some of which are illustrated; there are also several well-executed process illustrations of objects of interest in the garden.

We learn from the abstract of the *Proceedings* of the Linnean Society of New York for the year ending March 27, 1894, that at the annual meeting, held on the date mentioned, there were 136 resident and 35 corresponding members. At the beginning of the year the society had on its roll 37 resident and 37 corresponding members. During the year 29 papers were read, and 214 publications were added to the library.

Messrs. J. and A. Churchill have sent us the new edition —the third—of the translation, by T. H. Waller and H. R. Procter, of Kohlrausch's "An Introduction to Physical Measurements." The present edition is translated from the seventh German edition, and contains nearly four times the number of pages than the first German edition, which appeared in 1869. The tables have been corrected to the present state of knowledge, and a good deal of new matter has been embodied in them.

A magazine entitled the *American Historical Register* has been started this month in Philadelphia, the special mission of which is to form the medium of inquiry and communication between the members of various American patriotic associations, to chronicle their proceedings, and to preserve in its pages matters of historical value and of personal interest to their members; it bears, therefore, the sub-title of "Monthly Gazette of the Patriotic-Hereditary Societies of the United States of America." The magazine is tastefully printed on good paper, and several successful process illustrations grace its pages.

The *Journal* of the Royal Horticultural Society dated August has just reached us, and contains, in addition to the usual extracts from the *Proceedings* of the Society, the following papers:—"The Cedar of Goa," by Dr. M. T. Masters, F.R.S.; "The Deciduous Trees and Shrubs of Japan," by James H. Veitch; "Rare Trees and Shrubs in the Arnold Arboretum," by Maurice de Vilmorin; "Hybrid Narcissi," by the Rev. G. H. Engleheart; "Botanical Exploration in Borneo," by F. W. Burbidge; "Flowering Trees and Shrubs," by George Nicholson.

Messrs. Dulau and Co. have issued part xxxiv. of their catalogue of zoological and palæontological works, containing descriptions of the books on mammalia offered for sale by them.

We have received from Dr. F. Krantz, Rhenish Mineral Office, Bonn-on-the-Rhine, a catalogue of minerals, and plates of minerals for exhibiting optical phenomena, which he has for sale.

The additions to the Zoological Society's Gardens during the past week include a Common Marmoset (*Hapale jacchus*) from South-east Brazil, presented by Mr. J. C. Alleyne; a Boschbok (*Tragelaphus sylvaticus*, ♀) from South Africa, presented by Mr. J. E. Matcham; a Silver Pheasant (*Euplocamus nycthemerus*, ♀) from China, presented by Mr. Thomas Harris; a Larger Hill-Mynah (*Gracula intermedia*) from India, presented by Mr. Charles E. Brooke; a Cape Bucephalus (*Bucephalus capensis*) from South Africa, presented by Mr. A. W. Arrowsmith; a Common Chameleon (*Chamæleon vulgaris*) from North Africa, presented by Mr. G. T. Elphick; a Slowworm (*Anguis fragilis*), British, presented by Mr. G. H. Morton Middleton; a Malbrouck Monkey (*Cercopithecus cynosurus*, ♀) from West Africa, a Blue-fronted Amazon (*Chrysotis æstiva*), from South America, twenty Painted Terrapins (*Clemmys picta*) five Stink-pot Terrapins (*Aromochelys odorata*), an American Box Tortoise (*Terrapene carinata*) from North America, deposited; a —— Hedgehog (*Erinaceus*, sp. inc.) from India, a Mitred Guinea Fowl (*Numida mitrata*) from Madagascar, a Bull Frog (*Rana catesbiana*) from North America, purchased.

OUR ASTRONOMICAL COLUMN.

The Semi-Annual Variation of Meteors.—"It is a saying of Arago," wrote Prof. A. S. Herschel thirty years ago, "founded upon observation and confirmed by constant experience in later years, that the Earth encounters more shooting stars in going from aphelion to perihelion than in going from perihelion to aphelion." The fact of this semi-annual variation in the number of meteors has since been confirmed by many observers, and has also furnished a subject for much discussion. Mr. G. C. Bompas summarises the state of knowledge on the matter in the current number of the *Monthly Notices* of the R.A.S., and criticises the explanation believed to account for the facts of observation. The theory accepted by most observers is that the semi-annual variation referred to is due to the planetary motion of the Earth, just as the horary variation is due to the Earth's rotation. It will at once be seen that observations in the southern hemisphere supply a test of the validity of this explanation; for the greater number of meteors should appear in the southern hemisphere from January to June in each year—that is, when that hemisphere is in front of the Earth's orbital motion. From June to December, when the northern hemisphere is in front, we encounter a larger number of meteors than during the first half of the year. There can be no doubt that the change in the position of the Earth's axis relatively to her motion does really tend to increase the number of shooting stars seen in the second half of the year in the northern hemisphere, but Mr. Bompas thinks that this cause is insufficient to account for the very large increase observed, viz. from two to three times the number observed in the first half of the year. He has examined the meteor observations made by Dr. Neumayer at the Melbourne Observatory from 1858 to 1863, and he finds that the variation is not reversed, but follows the same law as in the northern hemisphere, the hourly number of meteors seen in the second half of the year exceeding the number seen in the first half. It seems, therefore, that some cause further than that hitherto assigned must help in producing the semi-annual variation of meteors. The whole discussion leads Mr. Bompas to submit: (1) That the explanation hitherto adopted of the semi-annual variation of meteors is inadequate; (2) that the variation is connected with and mainly due to the cosmical motion of the solar system; (3) that it renders highly probable the cosmical origin and motion of meteors.

GEOLOGIES AND DELUGES.[1]

IN the days when geology was young, now some two hundred years ago, it found a careful foster-mother in theology, who watched over its early growth with anxious solicitude, and stored its receptive mind with the most beautiful stories, which the young science never tired of transforming into curious fancies of its own, which it usually styled "theories of the earth"

Of these, one of the most famous in its day and generation was that of Thomas Burnett, published in 1684, in a work of great learning and eloquence. Samuel Pepys, of diary-fame, is said to have found great delight in it, and it is still possible to turn to it with interest when jaded with the more romantic fiction of our own day.

It was the fashion to commence these theories with chaos, and chaos, according to Burnett, was a disorderly mixture of particles of earth, air, and water, floating in space; it was without form, yet not without a centre, a centre indeed of gravity, towards which the scattered particles began to fall, but the grosser, on account of "their more lumpish nature," fell more quickly than the rest, and reaching the centre first accumulated about it in a growing heap, a heap, as we might now express it, of fallen meteorites; the lighter particles, which form fluids, followed the heavier in their descent, and collected around the solid kernel to form a deep ocean. This was at first a kind of emulsion, like milk, formed of oily and watery particles commingled, and just as in the case of milk, there separated on standing, a thick creamy upper layer, which floated on the "skim-milk" below. That this really happened, the good Burnett bravely remarks, "we cannot doubt." The finest dust of chaos was the last to fall, and it did not descend till the cream had risen; with which it mingled to form, under the heat of the sun, the earth's first crust, an excellent but fragile pastry, consisting of fine earth mixed with a benign juice, which formed a fertile nidus for the origin of living things. Outside nothing now was left, but the lightest and most active particles of all, and these "flying ever on the wing, play in the open spaces" about the earth, and constitute the atmosphere of air.

Such was the earth when first it formed the abode of unfallen man—perfect in form and beauty, for it was a true sphere, smooth as an egg; undisfigured by mountains, and unwasted by the sea. It was unfortunately but too like an egg, since its fragile shell rested on the treacherous waters of the interior abyss, "the waters under the earth," and the sun over-roasting, finally cracked and burst it; the broken fragments of the ruined world fell downwards into the abyss, and the subterranean waters rushed out in a mighty flood to remain as our present seas and oceans, from which the broken crust protrudes as continents and islands. As might naturally be anticipated, the bursting out of the abyss corresponds to the Noachian deluge, which we thus perceive to have been profounder in its origin and wider reaching in its effects than we might previously have supposed. This, for distinction, we may call Burnett's deluge; of his geology we may say that it is cosmological, since it endeavours to trace the history of the earth backwards to its origin in chaos; that it is catastrophic, because it attempts to account for all the great features of the earth by a single event which occurred suddenly and with violence; and that it is theologic, since it owes its inspiration to Holy Writ.

As geology grew older it went to school: what was the name of the school is not quite certain; some have called it "Science falsely so called," others, more briefly, "Inductive Science." However this may be, the immediate effect on the manners of young geology was very distressing. It grew contradictory, and was frank in the expression of obnoxious opinions. One of its most irritating remarks was that the world was not made in a week, and it would appear that at this time the relations of child and foster-parent became not a little strained. Still geology proved an apt scholar, and its progress was rapid. One of the most important lessons it learnt was that if we want to know how the world was made, the first essential is to study the earth itself, to investigate with patient drudgery every detail that it presents, and particularly the structures that can be seen in river-banks, sea-cliffs, quarries, pits, and mines. Thus it discovered that the solid land beneath our feet is to a large extent composed of layers of sediment which were once deposited more or less quietly at the bottom of ancient seas, and certain curious bodies known as fossils, it concluded to be the remains of plants and animals, sea-shells and the like, which were once the living denizens of these seas.

It discovered that these deposits lie so regularly one upon another, that it compared them to a pile of books, or to a slanting row of books lying cover to cover; and that in some cases, at least, the simile was not strained, will appear if we trace the structure of England from Oxford westwards towards Bristol. We then find that the thick bed of clay upon which Oxford stands, lies evenly on a series of gently sloping beds known as the lower Oolites; these in like manner repose on those thin seams of limestone and clay called the Lias, and these in their turn upon the red beds of the Trias. It might perhaps have been expected that this uniform arrangement would continue through the whole thickness of the stratified rocks, but it was discovered, and the importance of the discovery was recognised so early as 1670 by Bishop Steno, a man of great genius, that the regularity of the succession is liable to interruption at intervals. Thus as we approach Bristol, we encounter those beds of limestone which are associated with our coal-bearing strata, and which are consequently called "carboniferous"; but these are by no means related to the beds we have just passed over in the same manner as they are to one another—we do not find the highest bed of the carboniferous series offering its upper surface as a gently sloping platform on which the trias may rest; on the contrary, the carboniferous beds are seen to lie in great rolling folds, with the tops of the rising folds absent, as it were sliced off, and it is on the edges not on the surface of these beds that the red trias layers are seen to be spread out. This sudden change in disposition may well be called a break in the succession of the rocks, and, as if to emphasise it and compel attention to it, we find it accompanied by a complete change in the character of the fossils, those occurring in the carboniferous rocks being of entirely different kinds to those which are found in the overlying beds.

Evidently the carboniferous beds could not have been laid down in the sea in the steeply folded form they now present, at first they must have been spread out in nearly horizontal layers, and the folded form must have been subsequently impressed upon them, no doubt by the action of some stupendously powerful force. Subsequent also must have been the removal of the upper parts of the folds and the general planing down which they appear to have undergone.

To the young geology all this might seem perfectly clear, but in its impulsive explanations it assumed that nature must have frequently acted in a great and terrible hurry: thus the folding of the rocks was supposed to have been produced suddenly and violently by a single mighty convulsion, which simultaneously changed sea-floors into mountain chains, split open the land in wide gaping chasms—our present river valleys—and with the same blow destroyed every living inhabitant in the world.

But the discordance between two sets of rocks is met with not once only, but several times, in the stratified rocks of the earth's crust, and for every discordance there must have occurred a corresponding catastrophe.

These catastrophes were as wonderful as Burnett's, and there were more of them, so that at this stage of its existence geology was appropriately designated "catastrophic." It had completely severed the apron-strings, and ceased to be theologic, but it still to its credit remained cosmologic. It traced the earth from chaos up to a stage when islands and continents rose out of a primeval ocean, the waters of which were boiling; saw it peopled with strange and various forms of life, and watched it run its course, rejoicing in the sun, "chearfull, fresh, and full of joyaunce glad," then pictured it overtaken with disasters, shaken with earthquakes, overwhelmed by floods, and agonising in the labours of a new birth. Calm followed after storm, and life rejoiced afresh in a remade world to be again destroyed. Thus, through alternations of peace and strife, the earth moved on its changeful way, to the crowning creation of man, who was himself a living witness of the last great catastrophe of all, the Noachian deluge. Its waters covered the whole earth, to the tops of the highest mountains under heaven, and on their retreat they left behind, as a standing witness to their extension, great sheets of sediment, supposed to be spread out over the entire surface of the globe, and appropriately named the "diluvium." The diluvium may be seen in most parts of the British Isles, except in the south of England; it consists of clays and sands, containing vast numbers of curiously scratched stones.

[1] British Association Address to working men, by Prof. Sollas, F.R.S.

As the powers of geology matured it became increasingly able to dispense with catastrophes. The very diluvium itself was shown to be local in its distribution, and glacial in its origin; masses of moving ice, like that which buries the greater part of Greenland out of sight, covered a large part of the temperate regions, and this it was that produced the curious scratched stones and the deposits containing them, which are consequently no longer called "diluvial" but "glacial." More important yet, land could be shown to be still actually rising from the sea, and mountains growing into the air, but so slowly that the fact was not established without much dispute, which is hardly yet over. Valleys could be shown to result, not from any bodily fracturing of the land, but from the slow wearing action of the rivers which flow through them, and the waves of the sea were shown to be capable of cutting down cliffs and of reducing the land to a plain.

From these facts the discordance in the succession of stratified rocks found an easy solution. Recurring to the instance of the carboniferous rocks and their relations to the trias, we no longer need suppose that the stupendous force which folded the carboniferous rocks and raised them into the air, acted suddenly or even very rapidly; judging from the rate at which mountains rise now, their upheaval may have proceeded slowly; a few feet in a century would suffice. If we allow but one foot in a century, it would only require two millions of years to produce a mountain range 20,000 feet in height. The movement might naturally be expected to be accompanied by earthquakes, but there is nothing to lead us to suppose that these would be on a much grander scale than those of the present. During its slow elevation, the mountain range would be exposed to wind and weather, rain and rivers would carve it out into ridges and valleys and frost would splinter its peaks into spires and pinnacles. Subsequently it would sink beneath the sea, and the waves of the sea, as they battered down its cliffs, would remove the last remnants which had escaped the rain and rivers, and roll over an unbroken plain. On this plain, as it continued slowly to subside beneath the sea, the immense deposits of the trias, lias, lower oolites, and Oxford clay would be piled up.

If the rise of the sea-floor into the Bristol Alps took place slowly, and involved a great lapse of time, so equally did the sinking of the land to form the sea-floor afresh, and in this long interval time was afforded for great changes in the organic world; and thus we reach an explanation of the great and striking differences which distinguish the fossils of the carboniferous rocks from those of later date.

There is no insuperable difficulty in this explanation; its great merit lies in its accordance with the course of nature as we observe it at the present day; and henceforward it became the motto of geology that the processes of the present furnish the key to the interpretation of the past. The changes in which the life of the earth is manifest are not only slow and gradual now, but they have ever been the same. The earthquakes, which in ancient times shook the land, were no more violent than those of which we have lately read in the daily newspapers; the ancient volcanoes were not more terrible in their outbursts than Krakatoa; floods were not more appalling than those which still from time to time sweep away tens or even hundreds of thousands of human beings from the Ganges Plain, and the earth, instead of falling into convulsions every now and then, proceeds on the even tenour of her way, without haste and without rest, preserving a uniformity in her progress which impresses us with its solemn grandeur, but which sometimes seems a trifle monotonous. From its belief that an unbroken uniformity in the operations of nature extends from the present into the most remote past, geology now came to be called "uniformitarian." It was no longer theologic, no longer catastrophic, and, I am sorry to add, no longer cosmologic. It persistently refused to inquire into the early history of our planet, and restricting its study to the accessible parts of the earth's crust, it abdicated its regal position as the science of the earth, and became as it were a mere petty chieftain, dealing only with rocks and the fossils they contain; the fossils, by the way, not rightly belonging to its province at all. And it was because it passed from being a science of the earth to become a mere study of rocks and fossils, that Hutton was able to make his famous declaration that as a result of his inquiries into the system of nature he could discover "no vestige of a beginning, no prospect of an end." Apart from this, however, and in its self-limited career, geology pursued a luminous advance, and as it did so the Noachian deluge began to sink into an oblivion which it might be thought to have scarcely merited. For if the biblical account is to be taken literally, it furnishes us with a catastrophe of the first order, and since it is said to have occurred comparatively recently, or at least in historic time, the uniformitarian, by his own principles, would have been compelled to infer, as the catastrophist had done, that such deluges form a part of the orderly scheme of the world. The universality of the deluge had, however, for various reasons, been denied, not only by geologists, but by writers of other schools of thought, and towards the middle of the century, belief in it amongst the learned was gradually expiring; such a number and variety of convincing arguments as converged against it could indeed but lead to that result; and that the deluge, so far from being universal, was a local, and very local phenomenon, became an article of belief, so settled amongst all good geologists—and I think I may add theologists—that it may be said to have finally fallen into the deep slumber of a decided opinion, from which I for one have no desire to arouse it.

Thus the deluge, so far from shaking the uniformitarian position, was rather itself submerged by uniformitarian views, and growing geology was in danger of taking the uniformitarian formula for an infallible dogma. It was saved from this by physics, a clever brother of its own, which had now discovered the famous principle of the "conservation of energy," and another equally famous, "the dissipation of energy." From these it was deducible that the duration of the earth as a living planet must be strictly limited in time. It must have had a beginning, and at the beginning was furnished with a store of energy, which it has ever since been spending. In this spending of energy its life consists, and when the store is at length exhausted its life will cease, and it will become numbered amongst the dead planets.

A good deal of this uniformitarian geology might perhaps itself have guessed, had it extended its views beyond rocks and fossils to the stars and other shining bodies which people the vast realms of space. The present then, strange to say, will still afford a key to the past. We have but to turn to the sun, our nearest luminary, though still more than ninety millions of miles away from us, and in that great orb we find much to suggest the state of our planet some ninety millions of years ago or more. It is scarcely necessary to remind you of the fact that the sun is a body so hot that the most refractory substances known to us on the earth exist in it in a state of gas or vapour: tongues of glowing gas shoot from it like flames; the clouds which emit its brilliant light are probably clouds of carbon or silicon, which have momentarily condensed from a gaseous state; and rain, if rain ever occurs, must be a rain of molten metals, such as iron, which will be dissipated in gas before it has fallen very far.

If we proceed to the more remote nebulæ, largely composed of glowing masses of gas, we find a suggestion of a stage more embryonic still, when the earth had as yet no separate existence, but formed, with its sister planets and the sun, a single shining cloud. On the other hand, if we turn our gaze on our nearest relative—offspring possibly—that dead planet, the moon, we may read in its pallid disc the sad reminder, "Such as I am, you, too, some day will be."

But this was not all that was contained in the admonition of physics; it showed not only that the earth is mortal, but that its span of life, as measured in years, or millions of years, is brief compared to the almost unlimited periods which geology had been in the habit of postulating. If catastrophic geology had at times pushed nature to almost indecent extremes of haste, uniformitarian geology, on the other hand, had erred in the opposite direction, and pictured nature when she was "young and wantoned in her prime," as moving with the tame sedateness of advanced middle age. It became necessary, therefore, as Dr. Haughton expresses it, "to hurry up the phenomena."

With its uniformitarianism thus moderated, geology has again become cosmologic, and neglecting no study that can throw light on any question connected with our planet, has regained its position as the science of the earth: it is henceforth known as evolutional geology.

The change has not taken place without occasional relapses into catastrophism. Some indications of this can, I fancy, be perceived in the writings of that eminently great geologist Suess, who, amongst other suggestions savouring of heresy, has lately recalled attention to the "Deluge," and endeavoured to show that though certainly local, and indeed confined to the

Mesopotamian valley, it was on a grander scale than we had been accustomed to suppose, or, in plain language, a genuine historic catastrophe.

A local flood must have had a locality, and the clue to this is furnished by Genesis itself, which informs us that Abraham, the founder of the Hebrew race, left his ancestral city, "Ur of the Chaldees," at a time long subsequent to the flood; it is, therefore, rather in the land of the Chaldees than in Palestine, that we should be led to seek the scene of this momentous tragedy.

This land is no other than the famous and once beautiful valley of Mesopotamia, through which the great Euphrates and arrow-swift Tigris flow to empty themselves into the Persian Gulf. Almost lost sight of for awhile, interest in it was re-awakened some seventy years ago by the investigations commenced by Mr. Rich, and followed up with such wonderful results by Botta, Place, Layard, George Smith, and others. Their discoveries have revealed to us in unexpected fulness the details of a complex and advanced civilisation almost, if not quite, as ancient as the Egyptian, and far more profoundly interesting, for the ancient nations of Mesopotamia are the intellectual forefathers of the modern world. The learning of the Chaldees was the heritage of the Jews and Greeks, from these the torch was handed on to the Romans, and Jew and Greek and Roman inspired, and still inspire, for good and evil, the civilisation of the nineteenth century. There is much more of the Chaldean in every one of us than we are given to imagine.

The people whom we find in possession at the dawn of history were Semites, the parent stock from which the Jews subsequently branched off; and one has but to glance at their faces and forms, as portrayed in their statues and pictures, to recognise the strong family likeness, while the emphasis with which muscular development is expressed in parts of the human figure suggests that the remarkable assertion, "The pride of a young man is in his legs," was a Semitic opinion long before the time of Solomon.

Just as Egypt is the gift of the Nile, so is Mesopotamia equally the gift of the Tigris and Euphrates, for it is built up of the mud brought down from the mountains by these two streams into the Persian Gulf, which is thus in process of obliteration. So long as the two great rivers were not regulated, they produced terrible floods in the wet season; and one of the earliest works of the Chaldeans was to control their flow by great dams, and by diverting a part of their water into canals. These canals covered the country like a network, and served not merely to ease the rivers, but also to irrigate the land, which thus richly supplied by water, became, under the hot sun, so fat and fruitful, that corn is said to have borne 300-fold. Groves of palms, orchards, with grapes and many other luscious fruits, were cultivated, while the pastures supported abundant flocks and herds. It was a true garden of Eden, and differed chiefly from the biblical paradise, which Delitsch thinks was actually situated within this garden, in the fact that even here man had still to earn his bread in the sweat of his brow. This the Turks, who now possess the country, have no inclination to do, and consequently it is rapidly returning to its primitive desolation. Were England as enterprising as she was in the time of Elizabeth, we should rent this land from the Porte, run a railway through it, and thus shorten our route to India by a thousand miles, farm it, and thus provide ourselves with one of the richest granaries in the world.

In a land so favoured, it is nothing wonderful that the inhabitants teemed in millions, villages were everywhere dotted about, and in their midst great and flourishing cities arose: Ur, the City of the Moon-good; Erech, the City of Books; Nippur, and, most famous of all, proud Babylon, "the Gate of God," which stood on the left bank of the Euphrates, some 280 miles above its present mouth. In early times, probably about 2300 B.C., the Jews left this beautiful land for some unknown reason, and after various vicissitudes settled in Palestine. Another branch of the Chaldean stock migrated in later times to the northern part of the Tigris valley, where they built many mighty cities, and founded the warlike kingdom of Assyria. Of their cities it is sufficient to mention Assur, which gave its name to the kingdom, and Nineveh, which afterwards became the capital.

The Mesopotamian plain, owing to the way in which it has been produced, is an almost dead flat, and offers no natural elevations for building; the Chaldees, therefore, to raise the foundations of their palaces, temples, and houses above the reach of floods and fever, and for better defence against their enemies, constructed, with incredible labour, great mounds, by piling together quantities of sun-dried bricks and rubbish, and building round this a thick wall of burnt bricks, well cemented together. Some of these mounds, as that of Kojundjik at Nineveh, are as much as 60 feet in height, and it has been computed that this mound alone would have required the labour of 20,000 men for six years in its construction. But there was never any difficulty in obtaining all the labour that was wanted. Prisoners of war were compelled to work under the stick, and the building of mounds was one of the wholesome occupations to which the Jews were set during their captivity in Assyria.

On the mound of Kojundjik stood two great palaces, one of them that of King Assurbanipal. It was evidently not merely a royal residence, for one of its chambers at least was devoted to public purposes; this was the king's library, to which the citizens, who were taught in their early years to read and write, had free access. Whether any of the books were written on papyrus is uncertain; all that have survived the conflagration, in which the palace was destroyed, are on tablets of kiln-made brick. Of such tablets many thousands have been recovered, not only from Nineveh, but from other towns, and many of them are now preserved in the British Museum. Thus within the last fifty years modern Europe has obtained a glimpse, and more than a glimpse, into the literature of a civilisation that perished just as the Roman was coming into existence; for, as Sir Walter Raleigh puts it, "In Alexander's time learning and greatness had not travelled so far west as Rome, Alexander esteeming of Italy but as a barbarous country, and of Rome as but a village. But it was Babylon that stood in his eyes, and the fame of the east pierced his ears."

The recovered literature covers a vast field of human interest, in science, as in astronomy and mathematics, particularly in astronomy, for the Chaldeans were famous star-watchers, and had already named the stars and constellations, associating them with the deeds and mighty works of their heroes and demigods, so that the star-lit sky became a pictured dome, and the zodiac a frieze to the Assyrian, reminding him of history or fable, like the sculptures and paintings which adorned the king's palaces; in religion and poetry, and in commerce, many of the tablets recording business contracts, and revealing a system of mortgage and banking, money being frequently lent at from 13 to 20 per cent., which was moderate; for the advantages of cent. per cent. were already known and appreciated by these simple Semitic folk.

It was amongst the tablets from King Assurbanipal's library at Nineveh, that George Smith, now over twenty years ago, made a famous discovery. He found a fragment of a tablet, bearing words, which he deciphered as follows:—"On the Mount Nizir the ship stood still. Then I took a dove, and let her fly. The dove flew hither and thither, but finding no resting-place, returned to the ship." Every Englishman who knows his Bible would have guessed, as George Smith immediately did, that he had before him a piece out of a Chaldean account of the deluge. He searched for more fragments, and found them. He went out to Assyria, visited the King's palace, and found still more tablets and pieces of tablets, some of them just those he required to fill up missing gaps in the story. Since its first translation by its discoverer it has been again translated and retranslated by some of the acutest scholars in Europe, so that we now possess a fairly complete knowledge of it; a few missing words or even lines, and occasional obscurities occur, but these are of no great importance. In a town which has the privilege to number the distinguished Assyriologist, Prof. Sayce, among its residents, there will be no necessity to present the story more than briefly. It runs as follows:—Sitnapistim, the Chaldean Noah, is warned by Ea, the god of wisdom and the sea, that the gods of Surippak, a city on the Euphrates, even then extremely old, had decided in council to destroy mankind by a flood. Sitnapistim is told to build a ship in which to save himself, his family, household, and belongings. Anticipating the curiosity of his neighbours, since he had never before built a boat, he asks what answer he is to make when questioned as to his unusual proceedings. Ea, who as the god of wisdom is naturally a master of evasion, provides him with a subterfuge, and Sitnapistim sets about building his boat. He forms it of timber and reeds, and makes it water-tight by filling up the crevices with pitch, which he poured over it both within and without. It is of great interest, as showing the local colouring of the legend and the survival of an ancient custom. To observe that this practice of paying the native boats of the Euphrates with pitch has persisted in Mesopotamia down to the present day, natural pitch being used, which occurs at various localities in the valley, but particularly near the town of Hit. Sitnapistim's method of procedure, both in building and paying his boat, may still be witnessed at Hit as a matter of almost every-day occurrence.

Sitnapistim having provisioned the vessel, and brought into it all his goods and chattels, received an intimation of the immediate approach of the catastrophe; he went on board with his family and friends, closed the roof, and prudently entrusted the helm to the sailor—Buzar-sadi-rabi. Heavy rain fell during an anxious night, and as soon as daybreak appeared—

"There arose from the foundation of heaven, a dark cloud,
The storm-god Ramân thundered in its midst and
Nebo and Merodach went in front.
As leaders they passed over mountain and plain
Ninib went therein, and the storm behind him followed.
The Anunnaki raised high their torches,
With their radiant brightness the land glittered,
The turmoil of Ramân reached to heaven
All that was light was turned to darkness.

* * * * * *

In the earth men perished. . . .
Brother beheld not his brother, men knew not one another In the heaven
The gods were terrified by the deluge, and
Hastened to ascend to the heaven of Anu.
The gods were like a dog—sat down cowering on the ring wall of heaven.
Ishtar cried like one filled with anger.
Cried the mistress of the gods—the sweet-voiced—
'The former generation is turned to clay. . . .
What I have borne, where is it?
Like fish spawn it fills the sea.'"

For six days the flood lasted and ceased on the seventh, and then Sitnapistim is made to say—

"I looked on the sea and called aloud,
But the whole of mankind was turned to clay.
I opened the air-hole, and the light fell on my face:
I bowed low, sat down, and wept,
Over my face flowed my tears."

Sitnapistim then beheld the land, Mount Nizir, on which the ship grounded. It remained swinging there for seven days; on the seventh day Sitnapistim sent out a dove, which returned, then a swallow, which flew to and fro, but also returned, and finally a raven:—"The raven went, saw the going down of the waters, came croaking nearer, but did not come back." Sitnapistim then left the ship with his people, built an altar on the summit of the mountain, and offered sacrifice. The poem then runs—

"The gods smelt the savour, the gods smelt the sweet savour,
The gods gathered like flies over the sacrificer
The mistress of the gods, Ishtar, lifted up the (bow?) which Anu had made according to her wish."

A discussion then takes place among the gods, who all through are very human, and in its course Ea suggests to Bel, who seems to have been the prime mover in all the mischief, that he should for the future destroy mankind in a less undiscriminating manner—by wild beasts, pestilence, and famine. The scene ends happily with the apotheosis of Sitnapistim and his wife.

The surprising resemblance of the story to the biblical narrative, extending into identity of words, as in the case of the "gods smelt the sweet savour," points to direct derivation or borrowing, and there can be very little doubt in deciding on which side the borrowing lay. The biblical narrative is indeed a Jahvistic or Monotheistic edition of the Chaldean. To this conclusion the most distinguished Assyrian scholars have been led. I need only mention here Prof. Sayce, whose opinion is expressed on page 119 of his work on "The Higher Criticism and the Monuments," published by the Society for Promoting Christian Knowledge, during the current year.

The Chaldean story certainly reduces the flood to much smaller dimensions, and so far brings it nearer the range of probability; the rain lasted only seven days, and the waters have subsided sufficiently at the end of a fortnight for Sitnapistim to land. They do not cover all the high mountains, and the stranding of the ship on Mount Nizir when the flood was at its climax, gives us a maximum height, which it cannot have exceeded; for if this mountain had been deeply submerged, it could not have arrested the passage of the ship. The height of the Nizir mountains is about 1000 feet above the sea-level, which still leaves room for a very respectable flood.

The scepticism which prevailed in the middle of this century with regard to legends seems to have given place to an almost equally great credulity. The older argument seemed to be that the presence of some obviously unveracious statements in a legend condemned the rest, want of faith in some was want of faith in all; while the more modern view would appear to be that since so many discredited legends have been found to enshrine some important truth, all are to be assumed trustworthy till they are proved otherwise.

It may be in this spirit that Suess has elaborately discussed the Chaldean legend as though it presented us with a trustworthy account of the Mesopotamian deluge.

Reasoning from the facts as it records them, Suess lays great stress on the course taken by the ship from Surippak, supposed to have been situated near the mouth of the Euphrates, to the land of Nizir, a distance of about 240 miles up stream. Had the flood been produced solely by heavy rainfall and a consequent overflowing of the swollen rivers, the ship instead of being carried inland would have been drifted out to sea, *i.e.* southwards into the Persian Gulf. Suess therefore suggests that a great wave was produced in the Persian Gulf, partly by a cyclone and partly by an earthquake. This wave of twofold origin then rolled in upon the low-lying land of Mesopotamia, and drove its floods of water up the valley till they washed the foot of the Nizir Hills.

Of all catastrophes none are more terrible, none more disastrous than those thus produced. When the shock of an earthquake occurs beneath the sea, and affects the adjacent land, a trembling of the ground is first felt, then the sea retires and leaves the beach bare, only to return in a long mighty wave which breaks with violence on the shore. Thus on October 28, 1746, Callao in Peru, after being shaken by an earthquake, was overwhelmed by a sea-wave and utterly destroyed; of its 5000 inhabitants only 200 survived the flood. Still more destructive was the famous earthquake of Lisbon, November 1, 1755, when the inhabitants, without a warning, were destroyed in the falling city, and in six minutes 60,000 persons perished. The sea in this case, as in others, retired first, and then rose 50 feet or more above its usual level, swamping the boats in the harbour; at Cadiz the wave is said to have reached a height of 60 feet, and it was felt over the greater part of the North Atlantic Ocean, arriving even on our own shores, as at Kinsale in Ireland, where it rushed into the harbour and poured into the market-place.

That a great sea-wave so produced might have thus arisen in the Persian Gulf is quite within the bounds of possibility, particularly as a zone of the earth's crust, very liable to earthquakes, stretches across the mouth of the Gulf near the Ormus Mountains.

But if we are to follow the legend, we must follow it faithfully, and as a result of the most recent investigations it turns out that all the passages which were supposed to refer to an earthquake have been mistranslated. The earthquake is thus put out of court, and we are left with what help we can get from the hurricane, a kind of disturbance which often vies with the earthquake in the destructive nature of the sea-waves to which it gives rise.

The Andaman Islands of the East Indies are a centre which give birth to some of the most terrific hurricanes in the world. Travelling more or less westwards and northwards, these whirlwinds sweep over the waters of the Bay of Bengal and raise the sea into waves mountains high, which every now and again rush over the low-lying lands of the Ganges delta, overwhelming the unfortunate inhabitants by myriads. Thus on the night of October 14, 1737, one of these waves, estimated at 40 feet in height, suddenly overtook the dwellers by the Ganges and destroyed them to the number of 100,000, or, as some say, 300,000 souls. These storms do not, as a rule, travel towards the Persian Gulf, and the North Arabian Sea is singularly free from them; but Suess, tracing the course of the storm of October 24, 1842, suggests that for once, in the case of the deluge, an East Indian storm may have lost its way and blundered, as it were, into the Persian Gulf. The track of this storm of 1842 was as follows:—At 5 o'clock on October 24 it reached Pondicherry; it then slightly altered its direction and veered more to the south-west, and on the 25th at midday it crossed the western Ghats, and then divided into two parts; the south centre need not concern us. The northern centre travelled north-eastwards towards the Persian Gulf, and was felt from the Gulf of Aden to Cap Guardafui, wrecking in this tract a number of vessels.

The greatest estimated height of storm-waves is from 40 to 45 feet, and, as Suess points out, it must have needed a much greater wave than this to drown out all Mesopotamia up to the Nizir Hills. How much greater, is a question we are fortunately able to answer positively, thanks to the accurate measurements made by the engineer Czernik during a survey for a projected railway. The Tigris rises very slowly from its mouth inland, but at Bagdad it is already 154 feet above the sea-level, and at Mansurijah, the lowest point where its tributary Diala Tschai emerges from the Hamrin Mountains, the height is given as 285 feet; but the land of Nizir lies even still more to the north than this, and the Lower Zab, which cuts through it, cannot have a less elevation than 600 or 700 feet. No storm wave of which we have any record, no recorded earthquake wave, nor any combination of the two, approaches even remotely the height that would be required to carry the sea even to Bagdad; while as for the Nizir Mountains, the Valiant Phersor, who "nearly spoilt the flood," might have drank up all the sea-water which came there without any assistance from Glenlivat. If we admit that the Tigris valley was ever submerged up to this point and restored to its original condition in the course of fourteen days, we are confronted with a catastrophe not only stupendous in degree, but of a nature beyond our present powers of explanation.

But are we compelled to admit anything of the sort, and would it not be well before doing so to inquire a little more closely into the credentials and character of the Chaldean story? We have seen that the tablets on which it occurs were found in King Assurbanipal's library, and it is fairly certain that they were copied from others much older preserved in the ancient city of Erech, the city of books. It is indeed probable that the tablets in Erech may date from the time of King Khammarubi, or from about 2350 B.C. The tablets present themselves therefore with good recommendations, and we proceed to the character of the story itself. It does not occur alone, but as one chapter out of twelve in a long poem of about 3000 lines, concerning the adventures of a mythical hero named Izdubar or Gizdubar, perhaps the same as Nimrod, that "mighty hunter before the Lord" of biblical story, and plainly the prototype of the Greek Heracles.

The first tablet, containing the first chapter, is incomplete. So far as can be made out, it sets forth the misfortunes of the city of Erech, probably under the oppression of its Elamite enemies, who were so terrible in battle that poor Ishtar, its protecting goddess, "could not lift up her head against the foe."

The second and third introduce Gizdubar, already famous as a hunter, as the hero, who was looked for to deliver the city. His rivals induce Ururu, the mother of the gods, to fashion a strange being, Eabani, half man and half bull, to fight with Gizdubar. This monster comes to Erech, bringing with him a powerful lion, desert-bred, to fight Gizdubar; but the hero succeeds in slaying the lion, and so wins the friendship and esteem of Eabani. In the fourth and fifth tablets the friends encounter and overcome the terrible tyrant Humbaba, whose voice was as "the roaring of the storm, his mouth wickedness, and his breath poison." The sixth tablet, which is well preserved, tells how the hero was beloved of Ishtar. "Be my husband," she says, "and I will be thy wife. I will make thee to ride in a chariot of gold and precious stones, with golden wheels and diamond horns. When thou enterest our house under the pleasant fragrance of the cedar, men shall kiss thy feet. Kings, princes, and lords shall bow down before thee, and bring tribute." Gizdubar, however, is not to be seduced; he repels the advances of the goddess, who then presents herself as a naturally angry woman before her father Anu, and persuades him to frame a divine bull which is to destroy Gizdubar. He and Eabani together slay this bull, however, and the goddess, now terribly incensed, pronounces a terrible curse upon Gizdubar. The seventh tablet is unfortunately missing. The eighth, ninth, and tenth narrate how Gizdubar, suffering under the divine anger, loses his friend Eabani, and is smitten with a grievous illness. He journeys to the river's mouth to consult his divine ancestor Sitnapistim. On his way he crosses a desert where "scorpion men" guard the dark path to the "waters of the dead," which separate him from his quest. On the shore of this sea he finds a park of the gods, with wonderful trees bearing precious stones for fruit. After waiting here a long time a ferryman takes him over to the fields of the blessed, where he meets Sitnapistim. He tells his sorrowful tale, and the heart of Sitnapistim is filled with pity; but, alas! neither gods nor men can give him help. In the eleventh tablet Gizdubar inquires of Sitnapistim how he became immortal, and receives in answer the story of the deluge. After its recital Sitnapistim heals Gizdubar of his disease, and gives him the plant of life, its name being "Altho'-a-grey-beard-the-man-becomes-young-again." Unfortunately an evil demon robs him of this on the way home. In the twelfth and last tablet Gizdubar returns to Erech, and utters a lament over his lost friend Eabani, whose ghost subsequently appears and recounts the doings of the dead in Hades.

Thus the deluge story is a myth within a myth, containing statements plainly unveracious; and how we are to distinguish in this mass of fiction the true from the false passes the wit of man to conceive. If we say of the deluge-part of it that it is a gross exaggeration, the judgment will sound mild, but this is all that is requisite to reduce the catastrophe to commonplace proportions.

Whether Gizdubar ever existed in the flesh or not has been doubted; it is certainly remarkable that each of the chapters of the poem corresponds to one of the signs of the zodiac, and they are arranged in the same order as the signs of the zodiac. A fanciful correspondence is thus drawn between the succession of events in the life of Gizdubar and the yearly course of the sun through the heavens, and it has consequently been maintained that Gizdubar is no other than the sun himself personified. The stages in the life of man find, however, so ready an analogy in the course of the sun, that this conclusion is by no means forced upon us, and we may turn to another identification of more significance in our inquiry. It is that of the Greek story of Heracles with the legend of Gizdubar. Heracles himself is no other than a Greek Gizdubar, the Chaldean Eabani corresponds to the centaur Cheiron, the tyrant Humbaba to the tyrant Geryon, the divine bull to the bull of Crete, the park of the gods to the garden of the Hesperides, the lion slain by Gizdubar to the lion of Nemea which Hercules slew, and finally, just as Gizdubar is ferried across the waters of the dead, so Hercules is taken by Helios in the golden boat of the sun across the ocean.

As the Greeks have borrowed so much of the legend it would be surprising if they had not taken the rest, including the story of the deluge, and accordingly we find the Greeks provided with a legend of the flood, or with more than one, as they appear to have had more than one Heracles: but that which most closely accords with the Chaldean, is the flood of Deukalion.

On the other hand the Egyptians, who had sun-stories of their own, did not borrow the legend of Gizdubar, and are silent as to a deluge; a fact of extreme importance when we consider that the Egyptian civilisation was contemporaneous with the Chaldean, if not indeed older. The Nile is gentler in its overflowing than the Tigris, so that Egypt did not suffer under the scourge of unexpected floods.

If, finally, we turn to China, also possessed of very ancient historic records, and liable to the destructive deluges of the Yellow River, which have earned for it the designation "The Curse of China," we discover a deluge story of great importance, to which Suess has already called attention. In the third Schu of the Canon of Yao, a monarch who reigned, it is supposed, somewhere about 2357 B.C., and therefore contemporaneous with Khammurabi, we read:—The Tî said, "Prince of the Four Mountains, destructive in their overflowings are the waters of the flood. In their wide extension they inclose the mountains and cover the great heights, threatening the heaven with their floods, so that the lower people is unruly and murmur. Where is a capable man whom I can employ this evil to overcome?" Khwan was engaged, but for nine years he laboured in vain: a fresh engineer, named Yü, was therefore called in; within eight years he completed great works: he thinned the woods, regulated the streams, dammed them, and opened their mouths, provided the people with food, and acted as a great benefactor to the State.

It is refreshing thus to pass from the ornate deceptions of legend to the sober truth of history; and if the facts on which the Gizdubar legend of the deluge is founded could be expressed in the same simple language, we should probably find it narrating similar events, or events as little calculated to surprise us as those of the straightforward Chinese Schû.

History then fails to furnish evidence of any phenomenon which can be called catastrophic in the geologic sense of the word, and geology has no need to return to the catastrophism of its youth; in becoming evolutional it does not cease to remain essentially uniformitarian.

And the careful foster-mother? She too, as it appears to me, has widened her studies, and must, I should think, recognise with pride the stalwart growth of her early friend. May they be drawn nearer together, and feel the warm glow which is produced by the sympathy of a common love for truth.

THE INTERNATIONAL GEOLOGICAL CONGRESS AT ZURICH.

THE sixth meeting of the International Geological Congress was held at Zurich from Wednesday, August 29, to Monday, September 3, and was highly representative. Over 220 members were present, including leading geologists from all parts of Europe. Swiss and German members were in the majority. We may mention the names of MM. Renevier, Heim, Golliez, Forel, Schardt among the Swiss representatives, and Baron Richthofen, MM. Beyrich, Hauchecorne, Zittel, Credner, Groth, Gumbel among the German. From Austria there were present, among others, MM. Suess, Mojsisovics, Tietze, Penck; from France, Prince Roland Bonaparte, MM. Gaudry, de Lapparent, Michel Levy, Bertrand, de Margerie; from Britain, Sir A. Geikie, Sir J. Lubbock, Prof. Hughes, Prof. Sollas, Mr. W. Topley; from Scandinavia, Prof. Brögger; from Belgium, Prof. Dewalque; from Italy, Prof. Capellini, MM. Pellati, de Gregorio; from Russia, MM. Karpinsky, Nikitin, Pavlov, von Toll; from Roumania, M. Stefanescu; from the United States, Profs. R. Pompelly, Lester Ward, van Hise. Prof. Haeckel, of Jena, was also present at several meetings.

Prof. Capellini opened the Congress, and called Prof. Renevier to the presidential chair for the meeting at Zurich. The new President intimated in his address that, according to a decision of council, the official language of the Congress should remain as before, French; at the same time communications made in German would be accepted, and would be reported in the same language. Communications written in other languages had to be translated into French.

Without doubt the most important feature of the Congress was the new international geological map, which has been under course of preparation in Berlin since the Congress meeting of 1881, and is now exhibited for the first time. A report on its progress was read by Dr. Hauchecorne, of Berlin. The topographical groundwork has been prepared by Kilpert, to scale 1 : 1,500,000; the system of geological colouring followed has been most successful, and the Congress has certainly every reason to be satisfied with the result of the co-operation of the various surveys and societies to produce an international map. The whole map will contain 49 sheets; only six are now ready for issue, including the north west part of Europe, Northern Germany, with parts of France, Belgium, Poland, &c. The next part, to be issued within a year, will contain ten sheets, and will include the British Isles, France, Spain and Portugal, Italy, and Switzerland. Some difficulty has arisen in regard to the older Palæozoic rocks of various districts, and also as to the method of showing the Quaternary beds. It is now settled that solid rocks, where their distribution is known, will be shown by thin bands of colour over the general colour for Quaternary beds. (We reserve a fuller notice of this important work until the sheets are published.)

The subscription for the entire map is £4, but this can be paid in instalments as the various parts are published. The proportion for the first part will be 10s. Subscriptions must be sent to Dietrich Reimer, Berlin, before the end of December 1894; after that the subscription price will be raised.

On three days of the Congress meeting, communications were delivered to a general assembly of members; on one day, sections were formed, and a large number of papers in this way read. Unabated interest made itself felt throughout. At the general assembly on August 29, Prof. Suess gave an address "On the Southern and the Northern Alps," in which he distinguished two main directions of movement in the Alps. The Northern zone and the Central chain of the Alps formed a region of "zufluss" (flow towards the North Pole); the Southern zone, continued into the Dinarian Alps, was a region of "abfluss" (flow away from the North Pole). In the former case the relations were in harmony with those of general European movements; in the latter, the relations were associated with those of Asiatic chains.

Prof. Heim described the "Geology of the neighbourhood of Zurich," and made it most clear by reference to a splendid set of original maps and models. During the course of the Congress Prof. Heim also organised several excursions on the lake and on its banks, demonstrating that post-glacial movements of old fluvial terraces are in direct connection with the origin of the Lake of Zürich. As might have been expected, animated discussions were held among the members on the points at issue—the origin of the lake-basin, proofs of interglacial periods, mountain-movement which had affected glacial deposits, original and ultimate direction of the valleys, &c.

On August 31, the general assembly was addressed by M. Michel Levy and Prof. von Zittel. Michel Levy's subject was "The principles to be followed in a universal classification of the rocks." He regretted the confusion which threatened petrography with regard to its classification and nomenclature. Every day the number of names derived from particular localities increased, and useless synonyms were added. He proposed that some general system of classification should be agreed upon by petrographers, and suggested it might be founded (1) on the *texture*—affording the great divisions; (2) on the essential *constituent minerals*, to give the names of the smaller groups. In compliance with M. Michel Levy's desire, a Congress commission was appointed to consider and revise the nomenclature.

Prof. von Zittel spoke on "Phylogeny, Ontogeny, and systematic arrangement." He gave a word of warning against the assumption that Darwin's Theory of Descent had been actually demonstrated by palæontology. In his experience its application to palæontology had been in but few cases successful. Great breaks occurred between the various classes of fossil animals for which there was still no sufficient explanation. Again, Ernst Haeckel's law, that the development of one individual repeats the development of the whole family, had been confirmed in few classes of palæontological forms. The tendency of recent research had been becoming more and more subjective; even young investigators freely constructed new species, new genera, a new system of classification or line of descent. Others as freely questioned the validity of the new names and families, until a kind of anarchy prevailed in some of the groups of the plant and animal kingdom. Solid facts and experiences must be carefully studied, while theory, even the most brilliant, must be held at its mere theoretical value.

At the general sitting on Saturday, September 1, Sir Archibald Geikie and M. Marcel Bertrand spoke. Sir A. Geikie's paper, delivered in French, was on the "Banded Structure of oldest Gneisses and Tertiary Gabbros." Intrusive basic rocks of Tertiary age in which no mechanical deformation had taken place, had assumed a banded structure during their crystallisation from the original magma, the bands being occasionally plicated. The structure exactly resembled what is observed in many old banded gneisses, and arguing from analogy, these gneisses might have acquired their banding during their original consolidation, and not as the result of subsequent dynamometamorphism. A series of photographs admirably illustrated this suggestion.

M. Bertrand treated the "Structure of the French Alps and the recurrence of certain facies." After describing the metamorphism of various sedimentary formations into the condition of gneiss as the result of great dynamic changes, he pointed out that in different countries and in quite different formations certain facies followed each other in the same order of succession. These were a deep-sea facies, a "Flysch" facies formed during uprise, followed by an archipelago and river facies. In the French Alps, for example, the deep-sea facies was represented by the Devonian gneiss, the period of movement by the carboniferous deposits, the shallow water by the later red sandstones. Taking the Swiss Alps, the same facies recurred in younger formations; one might distinguish gneiss of Permian age, Flysch—(1) fine and schistose of Triassic and Jurassic age; (2) the coarser deposits of Cretaceous and Eocene age—and ultimately the archipelago facies of molasse and nagelflue in young Tertiary and Glacial time.

M. de Margerie read the report of the Commission of Bibliography. In accordance with the council, the Commission offers to furnish gratuitously a copy of the Catalogue of Geological Bibliographies, at present in the press, not only to all the members of the preceding Congress, as had been agreed upon at Washington, but also to those of the Congress of Zurich. The sectional meetings on Thursday, August 30, were of a special character. At the General Geology Section, with Prof. de Lapparent as president, most of the papers related to glacial questions. The Congress, acting upon proposals of

Prof. F. A. Forel and Captain Marshall Hall, has appointed a committee to investigate the variations of glaciers. Representatives of various countries are appointed. Prof. Forel and Dr. L. du Pasquier will have charge of this committee, the expenses of which will be defrayed by Prince Roland Bonaparte, the representative of France on the committee.

Dr. A. Rothpletz spoke on "Overthrusts and their methodical investigation"; M. Steinmann gave a note on the "Extent of the Indo-Pacific Cretaceous region." The Section of Stratigraphy and Palæontology, presided over by M. Gaudry, heard papers by Prof. Hull, by MM. Sacco, Fallot, Mayer-Eymar, Depéret; on "Tertiary strata and their classification," by Profs. Steinmann and Boehm, and by M. Pavlov on "Cretaceous strata"; by M. Kilian, on "the limit of the Jurassic and Cretaceous systems"; and by M. Stephanescu, on the "Fossil camel in Roumania." The other sections were Mineralogy and Petrography, M. Michel Levy presiding; and Applied Geology, Dr. Hauchecorne presiding. At the Mineralogy and Petrography Section several papers were read; among others, one on the petrography of Attica, by Prof. Lepsius, on grorudites and tingnaites, by Prof. Brogger. Prof. Groth showed a simple apparatus for demonstrating the direction of the vibrations in biaxial crystals.

An interesting interlude was formed at the meeting on August 31, by the presentation to Geheimrath Beyrich of a magnificent wreath of Alpine flowers made in the name of the assembled geologists. The day was the eightieth anniversary of Beyrich's birth, and Prof. Heim expressed the feelings of all present in the warm words of congratulation and appreciation which he addressed to the veteran geologist. Not less touching was the reply of the Geheimrath to the graceful token of love and respect from his colleagues of all European nations.

Space will not permit a description of the excellent exhibition of maps, photographs, models, and specimens in connection with the Congress. Exhibits had been sent from all countries. Also the great collection of the Zürich museums was an attraction in itself, and Prof. Heim was untiring in his efforts that all the guests should see all and even more than all which they had hoped to observe. The new geological map of Switzerland, scale 1 : 500,000, prepared by Heim and Schmidt, won the admiration of all, and together with the geological guide-book of the excursions published by the organisation committee, will remain as a valuable, lasting witness of the enterprise and energy displayed by Switzerland and her professors on the occasion of the sixth Congress.

It is rather unfortunate that the weather, which had been the best of summer weather during the excursions in the Jura Mountains previous to the meeting, and throughout the meeting itself, should have broken just as the excursions into the Alps began. Rain and mist undoubtedly bid fair to mar the enjoyment and lessen the benefits. From September 17 to 23 an excursion will be conducted by Profs. Penck, Bruckner, and du Pasquier, for the study of glacial appearances in the Alps. A special paper has been published by these three geologists, more especially with a view to this excursion, but also of general interest, entitled "The Glacial System of the Alps."

The seventh meeting of the International Geological Congress will be held in 1897 at St. Petersburg. The geological tours proposed were shown in a map of Russia exhibited during the Congress. An excursion across Russia and the Ural Mountains will precede the St. Petersburg meeting, and one is arranged to be undertaken to the Caucasus and the Caspian Sea at the close of the meeting. The Czar, it is said, has invited the Congress to St. Petersburg, and has already subscribed 30,000 roubles to defray in part the expenses of the Congress.

THE INTERNATIONAL CONGRESS OF HYGIENE.

THE International Congress of Hygiene and Demography, recently held at Budapest, does not appear to have been very successful from a scientific point of view. The medical journals say that serious work was impossible at the Congress, owing to the numerous social amusements and entertainments provided for the members. This opinion is borne out in a report in the *Times*, to which we are indebted for the following notice.

Our contemporary remarks that unless some sweeping reforms are introduced into the procedure of the Congress the same loss of prestige which has reduced other similar institutions to impotence or extinction seems certain to overtake it. The Congress appears to have ended in a chaotic confusion for which the word fiasco is none too strong, and the principal reasons for this unfortunate state of things are said to be (1) an overwhelming development of what may be called the picnic element; (2) an abuse of the system of passing sectional resolutions; (3) the superabundance of papers.

But, in spite of the confusion and turmoil resulting from the foregoing defects of procedure, an abundance of valuable material was brought forward at the Congress, some of which might, under more favourable circumstances, have been focussed into a shape which would exercise a real influence on practical questions of public health and social economy. Much sound and useful work, for instance, was done upon such questions as the housing of the working classes, the influence of dwellings and occupations upon health, the movements of population, and especially the townward migration, upon the condition of the insane, upon school hygiene, practical sanitation, and many others. The real scientific life of the Congress, however, lay in the department dealing with infectious disease and bacteriology. Here three crowded meetings took place on three successive days to discuss the following questions:—(1) Immunity from infectious disease; (2) diphtheria; (3) cholera.

The first of these is of great practical importance, because the future of medicine, from the present bacteriological point of view, lies in solving the problem of immunity. According to one school immunity is effected by certain cells (leucocytes) which eat up the germs, and are therefore called phagocytes. This fascinating theory was introduced a few years ago by M. Metchnikoff, the eminent chief of the Pasteur Institute in Paris; but the balance of opinion seems to be turning against it in favour of the theory that the germs are mainly destroyed by certain chemical substances contained in the watery part of the blood. Prof. Buchner, of Munich, is a prominent supporter of this theory, and his paper, read at the Congress, summarises the latest views on the subject. "The natural capacity for resistance to infection (the so-called natural immunity) rests on essentially different conditions and causes from the artificial or acquired immunity. The former rests on the one side upon the bactericidal activity of a substance called Alexine, which is secreted by the organism, on the other by a natural insusceptibility of the cells and tissues of the body to particular bacterial poisons. The leucocytes play an important part in the natural protection of the organism, not, however, as phagocytes, but through the action of substances secreted by them. Acquired immunity, upon the other hand, rests on the presence of modified bacterial products, the so-called Antitoxine, either in the blood or in the tissues of the body." M. Metchnikoff defended his theory of phagocytosis with great vivacity, but the other leading bacteriologists present, including Prof. Roux, of Paris, were on the other side. The debate marks a step in the advance of knowledge, though not a very decided one.

The morning devoted to diphtheria was the central point of the Congress. An overflowing and animated audience attended the meeting. This fearful disease is the most burning question in the medical world at the present time, partly because of its alarming increase, and more recently because of the hopes entertained of the new method of treatment, derived from bacteriological research. Prof. Löffler, the eminent discoverer of the diphtheria bacillus, opened the proceedings by reading the German report, which recommended "immediate bacteriological examination of all suspected cases; notification to the police of all bacteriologically determined cases and of all doubtful ones; isolation of every case; protective inoculation with serum of persons about the invalid, particularly children; extension of this principle as far as possible in families and schools; disinfection, keeping of convalescents apart until the bacillus has disappeared."

Similar drastic measures were recommended in the French report. The English report did not suggest any practical measures for dealing with the evil, but pleaded for more careful study, and more accurate knowledge of its causes and conditions. The Danish, Hungarian, Swedish, and Swiss reports also pleaded for further investigation. It is much to be regretted that the Congress could not find time to formulate some, and carefully-weighed, conclusions on this important matter.

In a debate on cholera, which followed in the same section, Prof. Max Gruber said, at the commencement of his address, that the bacteriology of the disease is by no means so simple as was once supposed; "the deeper investigation goes the greater the difficulties that rise up before us." Continuing, the *Times* reports him as remarking that the result of his own investigations had brought him to doubt the specific character of the cholera bacillus. "The question," he said, "is in this strange position—that, while we know with certainty that the vibrios which appear in cholera are the cause of the symptoms of the disease, we do not know for certain that these vibrios are of a distinct species. We cannot say for certain whether in all cases of true cholera they belong to a single species or to several, whether they are distinct from our own native vibrios or not." He was inclined to think they were not distinct, and propounded a quite new theory to the effect that these native and harmless vibrios take on an injurious character and give rise to cholera when some other at present undiscovered germ is introduced; for it is certain that cholera is introduced, and yet apparently the germs are here all the time. M. Metchnikoff, on the other hand, defended the specific character of the cholera vibrio, but admitted that it was not everything. It is frequently present, and yet does no harm. To explain this he has invented yet another theory, very curious and rich in appalling possibilities. The cholera germ, he thinks, is only powerful for evil when the native bacilli of the human interior, the *flora* of the stomach and intestines, as he quaintly calls them, are favourable to its growth. It is pointed out by our contemporary that these utterances are interesting as marking a distinct change of front and a distinct advance in knowledge. Bacteriologists, as the result of their own investigations, are beginning to come into line with the position long maintained by other observers, who reached their conclusions by the old method of studying the facts of epidemic disease. The germ is, no doubt, the cause of the disease, but it alone will not suffice. Its effects depend upon the conditions in which it is placed, upon its environment; it must have a favourable soil in which to grow, or it changes into a harmless variety. And this bacteriological doctrine has an important bearing on the encouragement of hygiene, for it helps us to understand more precisely how hygienic measures work in rendering the soil unfavourable to the growth of the injurious micro-organisms.

SCIENCE IN THE MEDICAL SCHOOLS.

THE students' number of the *Lancet* furnishes some interesting information upon the curricula of the medical schools of Great Britain. With the idea of seeing how far science instruction in subjects not purely medical is provided in these schools, we have prepared the subjoined table, from lists given in our contemporary, of classes to be held during the session

—	Physiology.	Biology or Zoology.	Botany.	Chemistry.	Practical Chemistry.	Natural Philosophy or Physics.	Practical Physics.	Bacteriology.	Hygiene or Public Health.	Natural History.
METROPOLITAN MEDICAL SCHOOLS.

1894–95, which begins next month. The table does not pretend to be complete; nevertheless, it will serve to show the kind of science subjects on which lectures are given to medical students outside medical technology. The courses advertised are indicated by crosses.

It has not been considered necessary to tabulate courses only given in two or three medical schools. Organic chemistry, for instance, is only down as a specific subject in the lists of lectures at the London Hospital and the University College Hospital. Probably the reason for this is that, at many colleges, the lectures on chemistry embrace the organic and the inorganic branches. Chemical physics is down in the medical curricula of the University College, Mason College, Cambridge University, and Yorkshire College, and physiological chemistry is among the courses at St. George's Hospital and Oxford University. Though psychological medicine is taught in a number of colleges, psychology only appears as the subject of lectures at St. Bartholomew's Hospital, Charing Cross Hospital, Edinburgh School of Medicine, and Queen's College, Cork. In the first two of these institutions, and also at Oxford University, pharmacology is treated distinct from practical pharmacy. It will be seen from the table that, in Scottish medical schools, the students are instructed in natural history, whereas this subject does not appear in the lists of lectures in the medical schools of England and Ireland.

Courses of lectures on bacteriology are advertised to take place at nine medical schools, but it must not be supposed that they are the only schools having facilities for carrying on this study. The *Lancet* has something to say on bacteriology and the medical curriculum. Our contemporary points out that "it is now almost imperative that those who are engaged in the teaching and study of medicine should consider the position of bacteriology in medical education with regard (*a*) to students proper, and (*b*) to those students of more mature years known as post-graduates. We think that the time has nearly come when it will be insisted upon that every medical student should receive not only some systematic instruction in the principles of bacteriology, but, more important still, should be put through a thorough, if short, course of practical laboratory instruction, in which the theories propounded in the class-room may be clearly illustrated. . . . Many of the medical schools have already recognised this fact, and in London alone there are now several well-equipped bacteriological laboratories where a thorough course of instruction can be obtained by the medical student. Guy's Hospital, University College Hospital, St. Bartholomew's Hospital, for example, have all acquired special facilities for carrying on the work; but there is still much room for the more general teaching of the subject. In the large university medical schools, especially in Oxford, Cambridge, Victoria, Durham, Edinburgh, Aberdeen, and Glasgow, the subject is more or less thoroughly taught, but not in all cases as practically as is desirable."

FORTHCOMING SCIENTIFIC BOOKS.

THE following scientific books are reported as being in preparation for the forthcoming publishing season. The list, though not so lengthy as the one we printed a year ago, is still a representative one, and lovers of each and every branch of science appear to be well catered for:—

Messrs. Macmillan and Co. announce:—"A Treatise on Bessel Functions," by Profs. G. B. Matthews and A. Gray; "Elementary Treatise on the Theory of Functions," by James Harkness and Frank Morley; "Elliptic Functions," by A. C. Dixon; "Practical Plane Geometry," by J. Humphrey Spanton; "An Introductory Account of Certain Modern Ideas and Methods in Plane Analytical Geometry," by Dr. Charlotte Angas Scott; "Integral Calculus and Differential Equations for Beginners," by Joseph Edwards; "Geometrical Conic Sections," by Charles Smith; "Elementary Mensuration, with Exercises on the Mensuration of Plane and Solid Figures," by F. H. Stevens; "The Theory of Light," by Thomas Preston, second edition, thoroughly revised; "Magnetism and Electricity," by Prof. Andrew Gray, illustrated; "Steam and the Marine Steam Engine," by John Yeo, with illustrations; "Pumping Machinery," by Dr. Julius Weisbach; "A Laboratory Manual of Physics and Applied Electricity," arranged and edited by Edward L. Nichols, vol. ii. Senior Course and Outline of Advanced Work, by George S. Moler, Frederick Bedell, Homer J. Hotchkiss, Charles P. Matthews, and the Editor, illustrated; "Theoretical Chemistry," by Prof. Nernst, translated by Prof. Charles Skeele Palmer; "Manual of Physico-Chemical Measurements," by Prof. Wilhelm Ostwald, translated, with the author's sanction, by Dr. James Walker, illustrated; "Lassar Cohn's Organic Chemistry," translated by Alexander Smith; "The Rise and Development of Organic Chemistry," by the late C. Schorlemmer, F.R.S., translated and edited by Prof. Smithells; "Chemical Analysis of Oils, Fats, Waxes, and their Commercial Products," by Prof. R. Benedikt, translated, edited, and enlarged by Dr. J. Lewkowitsch; "The Planet Earth, an Astronomical Introduction to Geography," by R. A. Gregory, illustrated; "Papers on Geology," by Joseph Prestwich, F.R.S.; "The Cambridge Natural History," edited by J. W. Clark, S. F. Harmer, and A. E. Shipley; vol. iii. "Molluscs," by Rev. A. H. Cooke; "Aquatic Insects," by Prof. L. C. Miall, F.R.S., illustrated; "Text-book of the Diseases of Trees," by Prof. R. Hartig, translated by Dr. W. Somerville, with a Preface by Prof. H. Marshall Ward, F.R.S., with numerous illustrations; "Timber and Timber Trees, Native and Foreign," by Thomas Laslett, new edition, revised by Prof. H. Marshall Ward, F.R.S.; "A Text-book of Comparative Anatomy," by Dr. Arnold Lang, translated into English by Henry M. Bernard and Matilda Bernard, vol. ii.; "Human Anatomy," by Prof. Wiedersheim, translated from the last German edition by H. M. Bernard, revised and annotated by Prof. G. B. Howes, illustrated; "A Text-book of Pathology, Systematic and Practical," by Prof. D. J. Hamilton, vol. ii.; "Lessons in Practical Bacteriology," by Dr. A. A. Kanthack and J. H. Drysdale; "Mental Development in the Child and the Race," by Prof. J. Baldwin; "A Course of Experimental Psychology," by Dr. J. McKeen Cattell; Leibnitz's "Nouveaux Essais," translated by A. G. Langley; "The Right to the Whole Produce of Labour: the Origin and Development of the Theory of Labour's Claim to the Whole Product of Industry," by Prof. Menger, translated by Mary E. Tanner; "Elementary Course of Practical Science," part ii., by Hugh Gordon; "Short Studies in Earth Knowledge," by William Gee, with illustrations; "Physiography for Beginners," by J. E. Marr, F.R.S., and Alfred Harker; "Physiology for Beginners," by Dr. Michael Foster, F.R.S., and Dr. L. E. Shore; "Agriculture, Practical and Scientific," by Prof. James Muir; "Horse-Breeding for Farmers," by A. E. Pease; "Garden Plants and Flowers: a Primer for Amateurs," by J. Wright; "Greenhouse and Window Plants, a Primer for Amateurs," edited by J. Wright; "Vegetables and their Cultivation, a Primer for Amateurs, Cottage Gardeners, and Allotment Holders," by A. Dean, edited by J. Wright; "The Mechanism of Weaving," by Thomas William Fox; "Boot and Shoe Manufacture," by C. W. B. Burdett, with numerous illustrations; "Facts about Processes, Pigments, and Vehicles: a Manual for Art Students," by A. P. Laurie, illustrated.

Messrs. Sampson Low and Co. will issue:—"Instruction in Photography," "Photography with Emulsions," "Negative Making," "Colour Vision" (being the Tyndall Lectures delivered before the Royal Institution during the present year), all by Captain Abney, C.B., F.R.S.; "Art and Practice of Silver Printing," written by Captain Abney in conjunction with H. P. Robinson; "Pictorial Effect in Photography," "The Studio, and what to do in it," "Letters on Landscape Photography," by H. P. Robinson; "Specifications, for the use of Surveyors, Architects, Engineers, and Builders," by J. Leaning; "Sweet-scented Flowers and Fragrant Leaves: interesting Associations gathered from many Sources, with Notes on their History and Utility," by Donald McDonald, with sixteen coloured plates; "A Text-book of Mechanics and Hydrostatics, by Herbert Hancock, with over 400 diagrams; "Thermodynamics: treated with Elementary Mathematics, and containing applications to Animal and Vegetable Life, Tidal Friction and Electricity," by J. Parker, with numerous diagrams; "The Theory and Practice of Handwriting: a Practical Manual for the Guidance of Inspectors, School Boards, Teachers, and Students," with diagrams and illustrations, by John Jackson, second edition, greatly enlarged with two additional chapters, two extra appendices, and several pages of facsimile illustrations.

Messrs. Swan Sonnenschein and Co. will publish:—"A

Student's Text-book of Botany," by Dr. Sidney H. Vines, F.R.S., second half, completing the work; also the complete work in one volume; "Text-book of Embryology: Invertebrates," by Drs. Korschelt and Heider, translated and edited by Dr. E. L. Mark and Dr. W. L. Woodworth; part i., fully illustrated; "The Cell: its Anatomy and Physiology," by Dr. Oscar Hertwig, translated and edited by Dr. H. J. Campbell, fully illustrated; "Text book of Palæontology for Zoological Students," by Theodore T. Groom, fully illustrated, forming a supplement to Claus and Sedgwick's "Text-Book of Zoology"; "Lectures on Human and Animal Psychology," by Prof. Wilhelm Wundt, translated and edited by James Edward Creighton and Edward Bradford Titchener; "Handbook on Systematic Botany," by Dr. E. Warming, translated and edited by Prof. M. C. Potter, fully illustrated; "Introduction to Physiological Psychology," by Dr. Theodor Ziehen, with 21 illustrations, a new and revised edition; "Zoology: Introduction to the Study of," by B. Lindsay, illustrated; "Fishes," by the Rev. H. A. Macpherson. "Flowering Plants," by James Britten; "Grasses," by W. Hutchinson; "Mammalia," by the Rev. H. A. Macpherson; "Pond Life," by E. A. Butler; "English Coins," by Llewellynn Jewitt, new edition; "Rainmaking and Sunshine," by John Collinson.

Mr. Murray's list contains:—"The Life and Correspondence of William Buckland, D.D., F.R.S.," sometime Dean of Westminster, twice President of the Geological Society, and first President of the British Association, by his daughter, Mrs. Gordon, with portraits and illustrations; "The Life of Prof. Owen, based on his Correspondence, his Diaries, and those of his Wife," by his grandson, the Rev. Richard Owen, with a chapter by the Right Hon. T. H. Huxley, with portraits and illustrations, 2 vols.; "The Scientific Papers and Addresses of Werner von Siemens," volume ii., including the following subjects: induction writing telegraph, magneto-electric quick type-writer, electric water-level indicator, mine exploder, alcohol meter, the universal galvanometer, automatically-steered torpedoes, automatic electric lamp, electric plough, electric elevator, electricity meter, energy meter, &c., with illustrations; "Handbook of Ancient Roman Marbles, consisting of a History and Description of all Ancient Columns and Surface Marbles still existing in Rome, with a List of the Buildings in which they are found," by the Rev. H. W. Pullen; "An Introduction to Physical Science," by Prof. John Cox; "The History of Astronomy," by Arthur Berry.

Messrs. Longmans and Co. have in the press, or in preparation:—A new edition, in four volumes, of Prof. Max Muller's "Chips from a German Workshop." The first volume will contain "Recent Essays," the second "Biographical Essays," the third "Essays on Language and Literature," and the fourth "Essays on the Sciences of Language, of Thought, and of Mythology"; "Butterflies and Moths (British)," by W. Furneaux, with twelve coloured plates and a large number of illustrations in the text; "Studies of Nature on the Coast of Arran," by George Milner, with illustrations; "From Edinburgh to the Antarctic," by W. G. Burn Murdoch; profusely illustrated by the author; supplemented by the Science Notes of the naturalists of the expedition, W. S. Bruce, J. J. W. Campbell, and C. W. Donald; "A Primer of Evolution: being a popular abridged edition of 'The Story of Creation,'" by Edward Clodd, with illustrations; "The Teaching of Physical Exercises," by F. J. Harvey; "Jacquard Weaving and Designing," by F. T. Bell; "The Magnetic Circuit in Theory and Practice," by Dr. H. Du Bois, translated from the German.

Mr. Edward Stanford's forthcoming works include:—"Cloudland," a study of the nature and forms of clouds, by the Rev. W. Clement Ley, with a number of coloured illustrations and reproductions from photographs; a third edition of Prof. James Geikie's "The Great Ice Age," almost entirely rewritten and with a new chapter on "The Glacial Phenomena of North America," by Prof. T. C. Chamberlin, also some new maps and diagrams; an addition, by Dr. Guillemard, on "Malaysia and the Pacific Archipelagoes," to Stanford's "Compendium of Geography and Travel," with numerous new illustrations and maps; and in the same series, volumes on "Africa" and "Asia," by A. H. Keane; a second edition of J. Scott Keltie's "The Partition of Africa," brought up to the most recent changes, and with some new maps.

In Messrs. Blackie and Son's list we notice:—"A Text-book of Organic Chemistry," by Dr. A. Bernthsen; translated by Dr. George M'Gowan, new edition, thoroughly revised and much enlarged by author and translator; "Elements of Metallurgy," by W. Jerome Harrison and William J. Harrison, jun., fully illustrated; "The Natural History of Plants: their Forms, Growth, Reproduction, and Distribution," from the German of Prof. Anton Kerner von Marilaun, translated by Prof. F. W. Oliver, with assistance of Marian Busk and Mary Ewart, with about 1000 original woodcut illustrations and sixteen plates in colours, issued in sixteen parts, also in four half-volumes, at intervals of four months.

Messrs. Whittaker and Co. will shortly issue a new edition, mostly rewritten, of Gisbert Kapp's "Electric Transmission of Energy;" "Model Engine Construction," by J. Alexander, with working drawings; "Steel Works Analysis," by Prof. J. O. Arnold; "Steam Power and Mill Work," by G. W. Sutcliffe; "The Manufacture of Modern Explosives," by Oscar Guttmann; the third and fourth (concluding) parts of C. Gordon Brodie's "Dissections Illustrated"—they will include the head, neck, and thorax, and the abdomen, respectively.

Messrs. Crosby Lockwood and Son have nearly ready for publication:—D. K. Clark's new volume on "Tramways, their Construction and Working," in which will be given a comprehensive history of the earlier forms, as well as the latest developments of tramways in this country and abroad, including the various modes of traction; a popular handbook on "Fertilisers and Feeding Stuffs, their Properties and Uses," by Dr. Bernard Dyer, with Notes on the Fertilisers and Feeding Stuffs Acts of 1893, by Mr. A. J. David.

Mr. T. Fisher Unwin is preparing:—"Travels and Studies in the Far East," by Henry Norman, illustrated; the volume supplementary to "Climbing and Exploration in the Karakoram Himalayas," by Prof. W. M. Conway, containing the scientific memoranda of the expedition by the author and various specialists; "In the Guiana Forest," by James Rodway, illustrated; "The Mountains of California," by John Muir, illustrated; and "The Story of Australian Exploration," by R. Thynne, illustrated.

The Clarendon Press will publish shortly:—"A Glossary of Greek Birds," by D'Arcy W. Thompson; "Index Kewensis," compiled at the expense of the late C. R. Darwin, under the direction of Sir Joseph D. Hooker, by B. Daydon Jackson, part iii.; "A Monograph on the Oligochæta," by Frank E. Beddard, F.R.S.; "A Manual of Crystallography," by M. H. N. Story-Maskelyne, F.R.S. (This work, which has been so long announced, is on the point of publication.)

Messrs. W. and R. Chambers have in the press, or in preparation:—"Chambers's Concise Gazetteer of the World," topographical, statistical, and historical, with pronunciation of the more difficult names of places and information regarding the derivation of names; "Elementary Science," by S. R. Todd; "Organic Chemistry," part ii., by Prof. Perkin and S. Kipping.

Messrs. Chapman and Hall announce:—"The Progress of Science: its Origin, Course, Promoters, and Results," by V. Marmery; "Naval Architecture and Shipbuilding," by G. V. C. Holmes, illustrated; "Machine Construction: a Key to the Examinations of the Science and Art Department," by Hy. Adams; "A Text-book of Mechanical Engineering," by Wilfrid J. Lineham; "Practical Plane and Solid Geometry," by Henry Angel; "The Nests and Eggs of Non-Indigenous British Birds," by Charles Dixon.

Messrs. A. and C. Black's arrangements include:—"Monism; or, the Confession of Faith of a Man of Science," by Prof. Ernst Haeckel, translated from the German by J. D. F. Gilchrist; "The Senile Heart: its Symptoms, Sequelæ, and Treatment," by Dr. George William Balfour; the last part of the "Dictionary of Birds," by Prof. Newton.

Messrs. Cassell and Co. have in hand:—"The Electric Current, how Produced and how Used," by R. Mullineux Walmsley; a new edition of "Electricity in the Service of Man," revised by Dr. Walmsley; "The Year-Book of Treatment for 1895."

Messrs. G. Bell and Sons promise:—"Arithmetic for the Standards," by Charles Pendlebury and W. S. Beard; "Cotton Weaving," by R. Marsden, illustrated; an authorised abridgment of "Webster's International Dictionary," entitled "Webster's Brief International Dictionary."

Messrs. Methuen and Co. will publish in their University

Extension Series:—"Insect Life," by F. W. Theobald, illustrated.

In Mr. Edward Arnold's list we find:—"Psychology for Teachers," by Prof. C. Lloyd Morgan; "Systematic Science Teaching," by Edward G. Howe.

The S.P.C.K. announce:—"Edible and Poisonous Mushrooms: what to eat and what to avoid," by Dr. M. C. Cooke, with eighteen coloured plates illustrating forty-eight species.

Messrs. G. P. Putnam's Sons will issue:—"Diagnosis, Differential Diagnosis, and Treatment of Diseases of the Eye," by Dr. A. E. Adams.

Messrs. W. B. Whittingham and Co give notice of a book entitled "What is Heat?—a Peep into Nature's most Hidden Secrets," by Frederick Hovenden.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Major Craigie, the Director of the Statistical Department of the Board of Agriculture, has presented a report on the distribution of grants for agricultural education in Great Britain in the financial year 1893–94. From a summary in the *Times*, it appears that out of the total vote of £8000 entrusted to the Board of Agriculture for educational purposes the necessary provision had been made for the cost of inspection, and the sum of £7450, which remained available, had been applied in the form of specific grants, a small sum being devoted to the reproduction of the records of the Rothamsted experiments for the past fifty years. The Board had been confirmed by further experience in their estimate of the value of establishing fully-equipped agricultural departments in collegiate institutions capable of aiding the work of distinct groups of local authorities charged with the provision of technical education. The collegiate centres established by the several University colleges at Bangor, Leeds, Newcastle, and Aberystwyth had continued to develop and to extend their usefulness as centres of educational energy for the surrounding counties. Further centres had been fully equipped and new agricultural teaching organisations definitely set on foot, on lines more or less similar, at Cambridge, Nottingham, and Reading. In Scotland, where the institution of definite centres was being more slowly developed than in England, several of the south-western counties had continued to make use of the facilities for agricultural instruction offered by the central classes provided, and by the itinerant lecturers supplied for local work by the Glasgow and West of Scotland Technical College. Besides assisting institutions such as the Durham College of Science and the Glasgow Technical College, where lectures on certain forestry subjects were included in the general curriculum, the Board had again been able to repeat the grant towards the cost of the special forestry class established in the University of Edinburgh. An endeavour had been made to continue, although necessarily on a reduced scale, the assistance given to experimental work, and provision had also been made for experiment stations or demonstration plots at each of the Welsh colleges. A beginning in the same direction had been made at Reading. The grants awarded by the Board during the year range from £800, given to the University College of North Wales, at Bangor, the Yorkshire College, Leeds, and the Durham College of Science, Newcastle-on-Tyne, to £25 given to the Dounby Science School, Orkney. In all there were twenty grants, eight being for work in collegiate centres, five for agricultural experiments, three for dairy instruction, one for special cheese research and agricultural experiments, one for forestry work, and two for special classes.

SCIENTIFIC SERIALS.

American Journal of Science, September.—The effect of glaciation and of the glacial period on the present fauna of North America, by Samuel H. Scudder. Statistics of the number of genera and species found in the areas formerly covered by the ice-sheet and the driftless areas respectively, and of the number common to both, would indicate whether the northern fauna had recovered from the effects of glaciation. Tables are given showing this for the Coleoptera, as the best known among insects, which are very sensitive to climatic changes. The conclusion arrived at is that, on the whole, the fauna has nearly or quite recovered from its enforced removal from the Northern States and Canada.—Tertiary and later history of the island of Cuba, by Robert T. Hill. No positive evidences of subsidence after the beginning of Tertiary time could be discovered. Nowhere do the rivers show any revival or other evidence of subsidence below the sea-level, but all have continuous downward cutting sections. On the other hand, some of these streams are now forming delta deposits in places outside their mouths, which is more indicative of present elevation than of subsidence. Since the old folding or orogenic movements occupied at least a small portion of post-Tertiary time, we may reasonably conclude that the periods of uniform uplifting must have taken place at least since the beginning of the Pleistocene. In other words, they are comparatively modern in geologic time—some of them absolutely recent.—Thermoelectric heights of antimony and bismuth alloys, by C. C. Hutchins. The best combination for a thermo-function from these alloys is, for one element, bismuth with from 2 to 5 per cent antimony; and for the other, bismuth with from 5 to 10 per cent. tin. They may be cast into thin leaves as follows: Two pieces of plate glass are smoked slightly, or are very finely ground, and rubbed with plumbago. The metal being melted upon charcoal or under fused sodium chloride, a little pool is found upon one plate, and the other is applied to it as quickly as possible. Leaves thus obtained can be worked with a fine file as thin as 0·03 mm. and are sufficiently tough to stand ordinary treatment.—On the nitrogen content of California bitumen, by S. F. Peckham. Oils from the tunnels in Wheeler's cañon on the south side of the Sulphur Mountain yielded 1·1095 per cent. of nitrogen. These and other oils of this region issue from strata protected from infiltration of rain-water and accompanying oxygen by overlying formations.

Quarterly Journal of Microscopical Science, vol. xxxvi. part 3.—Prof. A. G. Bourne gives an exhaustive account of the structure of *Moniligaster grandis*; and adds a revision of the genus, including diagnoses of some new species. Some good coloured figures of the different species accompany Prof. Bourne's memoir.—Mr. E. W. Macbride has a review of Spengel's monograph on Balanoglossus, and criticises that author's views on the affinities of the Enteropneusta.—Under the name *Monocystis herculea*, Mr. W. C. Bosanquet gives a number of observations on the structure and life history of a large Gregarine found in the earth-worm *Lumbricus herculeus*.

Wiedemann's Annalen der Physik und Chemie, No. 9.—On refractive power and density of dilute solutions, by W. Hallwachs. The increase in the difference of molecular refraction previously observed with increasing dilution is completely explained by the peculiar behaviour of the density. The constitutive influences analogous to dissociation, which find their most characteristic expression in the changes of electric conductivity, have no effect upon the refractive power.—On the motion of dielectric bodies in the homogeneous electrostatic field, by L. Graetz and L. Fomm. Mascart and Joubert, in their development of Poisson's original theory, assume that small bodies placed in a dielectric do not exert any forces upon each other. This is contradicted by experiments upon small bars and plates of dielectric materials introduced into homogeneous fields, which tend to turn their axes and planes respectively into a direction parallel to the lines of force. When the condenser plates are statically charged, the rotations depend upon the sign of the charge, but in the case of oscillations they are always in the same direction and proportional to the square of the difference of potential. A small disc, made of sulphur or paraffin, suspended between the plates may be used as a "dielectric voltmeter."—On electric oscillations of long duration and their effects, by H. Ebert. The author investigates the conditions of obtaining the best luminous effects of the type of those produced by Tesla. He points out that the secondary circuit must be turned to the primary, and that the condensers must have the least possible capacity. He describes a "luminescence lamp" made of a glass globe containing a piece of luminous paint. Oscillations are conducted to tinfoil armatures on the globe, and produce vivid luminescence. The light effects were about one-thirtieth or one-fortieth of the amyl-acetate standard. The energy consumed counted by millionths of a watt, so that the economy of the new lamp is very striking, consuming as it does only about a two-thousandth of the energy consumed by the acetate lamp. The difficulty involved in the fact that the high frequency currents employed could not be conducted any distance without encountering enormous inductive resistances, could be got over by effecting the transformation in the immediate neighbourhood of the lamp. Since only condensers of small capacity and inductance are required, a transformer might be attached to the lamp itself.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 21.—"On the Evolution of the Vertebral Column of Fishes." By Dr. H. Gadow, F.R.S., and Miss E. C. Abbott.

The following are a few of the more important points in the paper:—Each skleromere lies within the influence or range of action of two successive myomeres. Taken as a whole, the skleromere is "interprotovertebral," more correctly bi-protovertebral, because it is composed of two successive sklerotomes, namely, the ventral half of one and the dorsal half of a second.

Consequently, the "resegmentation" or "neugliederung" is brought about in a manner fundamentally different to that hitherto supposed to have taken place. If A and B mean two successive sklerotomes, a and b their dorsal, α and β their respective ventral halves, then the new skleromere is composed of $b + \alpha$ and not of $\frac{A + B}{2}$.

The formation of a skleromere by the combination of alternating dorsal and ventral halves of sklerotomes explains also the presence of eight (four pairs) cartilaginous pieces, namely, basalia (so-called dorsal and ventral arches) and interbasalia (so-called intercalary pieces) for each complete segment.

Concerning the formation of centra or bodies of the vertebræ, we distinguish:—

I. *Chorda-centra, i.e.* centra cut out of the full of the chordal sheath, which itself has been strengthened by invasion of cartilaginous cells from the skeletogenous layer. Chorda-centra are possessed by all Elasmobranchs, potentially by Dipnoi and Holocephali.

II. *Arch-centra, i.e.* centra formed by the skeletogenous mass which remains entirely on the outside of the chordal sheath, which latter takes no share in their formation: osseous Ganoids and Teleostei.

Chorda-centra and arch-centra represent two different modes of development, each starting from an acentrous condition. This can be expressed as follows:—

Chordal sheath remaining entirely cordagenous.	Chordal sheath strengthened by invasion of skeletogenous cells, therefore with possibility of chorda-centra.
Cyclostomata.	
Cartilaginous Ganoids.	Dipnoi and Holocephali.
Formation of Centra.	
Osseous Ganoids, Teleostei.	Elasmobranchs.
ARCH-CENTRA.	CHORDA-CENTRA.

The formation of chorda-centra being independent of the arcualia explains how and why the number of "centra" does not necessarily agree either with that of the arcualia or with that of the trunk-segments, *e.g.* Hexanchus and tail of most other Elasmobranchs.

In *Amia calva*, the *postcentrum, i.e.* the posterior, archless disk of a complete tail-vertebra, is formed by the interdorsalia and interventralia of the same sklerotome, while the *precentrum, i.e.* the arch bearing disk or anterior half is formed by the basidorsals of the same sklerotome and the basiventrals of the next previous sklerotome. The intermuscular septum runs obliquely across the precentrum, or, in other words, the precentra are bi-protovertebral or bi-myomeric, but not the postcentra.

In *Lepidosteus* the combination of parts into one vertebral complex is superior to that of Amia, because each vertebra belongs, with its entire anterior half, to one, and with its posterior half to the next following myomere. The vertebræ are now truly bi-protovertebral or bi-myomeric.

PARIS.

Academy of Sciences, September 10.—M. Lœwy in the chair.—Truffles (*Terfas*) from Tunis and Tripoli, by M. Ad. Chatin. Truffles have been received by the author from Tunis belonging to the species *Terfezia Claveryi*. They seem always to occur in company with a herb called by the natives *Arong-Terfess*, which is *Helianthemum sessiliflorum*, Pers. (*Cistus sessiliflorus*, Desf.). Truffles similarly received from Tripoli are classed as *Terfezia Boudieri*.—On the equations of mechanics, by M. Wladimir de Tannenberg.—On Pfaff's problem, by M. A. J. Stodolkievitz.—On another determination of the circle derived from seven right lines and on some of its applications, by M. Paul Serret.—On Diptera harmful to cereals; observations from the Paris Entomological Station in 1894, by M. Paul Marchal. *Cecidomya destructor* (Say) has been very prevalent among wheat in the West. Oats have hitherto been considered proof against Hessian fly, but a form of Cecidomya has ravaged large districts in 1894. It remains to be seen whether this fly is a new species or only a variety of *Cecidomya destructor* modified by the difference of food. Other pests noted which have caused serious damage are the following: *Cecidomya* (*Diplosis*), *tritici* (Kirb.), *Oscinis pusilla* (Meig.), *Camarota flavitarsis* (Meig.), which has not heretofore been considered as injurious to cereals, and *Elachiptera cornuta* (Meig.).—On the recent fall of aeroliths in Greece, by M. C. Maltézos.

THE WORKS OF HENRY J. S. SMITH.

The Collected Mathematical Papers of Henry John Stephen Smith. 2 vols. Edited by Dr. J. W. L. Glaisher. (Oxford: Clarendon Press, 1894.)

THE long looked for collected papers of Prof. H. J. S. Smith, late Savilian Professor of Geometry in the Jniversity of Oxford, have now appeared in two handome quarto volumes issued by the Clarendon Press at)xford. This fact is, as far as England is concerned, he mathematical event of the year, and is of the utmost mportance to mathematicians in general, and to the ising race of investigators in pure mathematics in paricular. The work has a portrait on the frontispiece, nd is introduced by a biographical sketch by Dr. Charles I. Pearson, and recollections by Prof. Jowett, Lord Bowen, Mr. J. L. Strachan-Davidson, and Mr. Alfred Robinson, also by an introduction by Dr. J. W L. Glaisher. A perusal of the sketch is calculated to greatly npress the reader with the all-round scholarship and ntellectual eminence of its subject. To have gained, mongst other honours, the Ireland University Scholarhip, and subsequently to have become one of the most rofound and rigorously exact mathematicians the world as ever known, implies the possession of powers of mind hat must fill any chronicler or student of past events ith amazement. There are men who will succeed in ny line of life or branch of study by sheer mental trength; they have the faculty of becoming fascinated y any pursuit in which inclination, force of circumtances, or accident leads them to engage; with them tudy is intense concentration leading, through a flood of ew ideas, to such an admiration for and interest in the ubject, of whatever kind, as can only be experienced by nother in some special branch for which his mind is articularly and peculiarly adapted.

That Prof. Smith was such a man, was the general elief of his contemporaries. Prof. Conington said to he biographer, "I do not know what Henry Smith may be t the subjects of which he professes to know something; ut I never go to him about a matter of scholarship, in a ne where he professes to know nothing, without learning nore from him than I can get from anyone else."

At one time it appeared to be probable that he would evote himself to chemical science, but, looking back, here seems to be little doubt that pure mathematics was he branch of knowledge towards which he felt himself nost attracted, and which was in reality best adapted o call forth his grand powers for close and accurate hinking, and to give scope to his brilliant imagination.

The recollections are of great interest. They show learly the extent to which he was admired and loved by hose who were privileged to know him best. Dr. Glaisher's introduction is chiefly, though not wholly, of nathematical interest, and will be further alluded to. The works set forth were published between the years 851 and 1883. They may be considered as arranging hemselves under four heads: (1) Theory of numbers; 2) elliptic functions; (3) geometry; and (4) addresses. Space merely permits me to note some of the original contributions to science which stand forth pre-eminently, and helped to build up a great reputation.

During the years 1859 1865 was produced the "Report on the Theory of Numbers," compiled for the British Association for the Advancement of Science. Prof. Smith said of Clifford that he was "above all and before all a geometer"; so of him it may be said that he was above all and before all an arithmetician, and that the Report could not have come under a stronger hand. It contains an account, confessedly not exhaustive, of the state of knowledge at the date of writing. There is interpolated in the history of the science, as it was originated by Gauss and Legendre, and developed by Cauchy, Jacobi, Lejeune-Dirichlet, Eisenstein, Poinsot, Kummer, Kronecker, and Hermite, a considerable amount of masterly criticism as well as original work. He considers the higher arithmetic to be comprised of two principal branches, the theory of congruencies and the theory of homogeneous forms. It will be observed that he does not include the combinational or partitional analysis. He doubtless did not regard this important subject as a branch of arithmetic proper, but rather as occupying the ground intermediate to arithmetic and algebra. It is, in point of fact, far less abstruse and less dependent upon methods which are regarded as purely arithmetical. In the future, however, it is probable that it will be recognised that the combinational analysis is able to throw quite unexpected light on the theory of congruencies, and is worthy of being considered as an important instrument of research in arithmetic proper. As an example it may be stated that the enumeration of certain permutations on a circle yields the number

$$\frac{1}{n} \Sigma \phi(d)\, x^{\frac{n}{d}},$$

where x and n are any positive integers, d a division of n, and $\phi(d)$ the totient of n; and hence

$$\Sigma \phi(d)\, x^{\frac{n}{d}} \equiv o \bmod n$$

a congruence which includes several of the elementary results of the theory of numbers. The author's intention was to present the theory of homogeneous forms in the following order:—(1) Binary quadratic forms; (2) binary cubic forms; (3) other binary forms; (4) ternary forms; (5) other quadratic forms; (6) forms of order n decomposable into n linear factors. It is much to be regretted that only the first of these was given in the report. A consideration of the remaining divisions seems to have convinced him that much remained to be done, and he appears to have deferred these matters for future investigation by himself. The solution of the so-called "Pellian Equation" is of primary importance in the theory of quadratic forms of positive and not square determinant, and we find in the foot-note of p. 193, vol. i. "There does not seem to be any ground for attributing either the problem or its solution to Pell." This is particularly interesting to those who were privileged to listen to Prof. Mittag Leffler's paper on automorphic functions, which was read before Section A of the British Association at Oxford. The Professor inveighed against the too common practice of associating mathematicians' names with theories and theorems on the ground that mistakes are of frequent occurrence and necessarily so;

he instanced the use made by Poincaré of the names of Fuchs and Klein in regard to theories, priority in respect of which those eminent men would be the first to repudiate. In the present instance we find that the problem of the "Pellian Equation" was proposed by Fermat and solved by Lord Brouncker, and these facts need not detract in the least from the reputation earned by Pell by his skill in the Diophantine analysis.

In the solution of the problem of the "Composition of Quadratic Forms," Prof. Smith introduces the important notion of fundamental sets of solutions of indeterminate systems of equations, and thus replaces Gauss' purely synthetical solution by analysis. In the arrangement of the genera of quadratic forms into classes he extends to irregular determinants the principles employed by Gauss for the case of regular determinants.

Gauss' geometrical representation of forms of a negative determinant is given at length. Klein has recently, in the lectures on mathematics delivered before the Evanston Colloquium in the autumn of 1893, given a remarkably simple statement of the method, and has introduced the expressions "line lattice" and "point lattice" to describe the diagrams. He also has extended the method to forms of positive determinant in the *Göttingen Nachrichten* for January 1893. To this the reader's attention may be directed as elucidating and amplifying Prof. Smith's statement of the work of Gauss. Klein's lecture VIII. (Evanston) should also be referred to in connection with the theory of complex primes and the ideal numbers of Kummer.

On the completion of the report, his attention was directed to the subject of ternary quadratic forms. At the time an important memoir by Eisenstein had appeared, in which were defined the ordinal and generic characters of ternary quadratic forms of uneven determinant; but several of the results were left undemonstrated. Prof. Smith supplied the omissions, and extended the results to the more difficult and complicated case of the even determinant. By giving a table for forming the complete generic character of any form, he accomplished for the ternary theory that which had been already carried out by Lejeune-Dirichlet for the binary theory. He gave, moreover, a demonstration of the criterion for distinguishing between possible and impossible generic characters. This he was enabled to do by the important new notion of a certain particular generic character, termed by him "the simultaneous character of a form and its contravariant," which had not been regarded by Eisenstein. He gave a more complete definition of a "genus" of forms as dependent upon transformation by substitutions, and showed that two forms are or are not transformable into one another according as their complete generic characters do or do not coincide. He proved the formulæ which assign the weight of a given genus or order both for even and uneven discriminants. This he accomplished by a comparison of two expressions, obtained by different methods, for the limiting ratio of the sum of the weights of the representations, by a system of forms representing the classes of any proposed genus, of all the numbers contained in certain arithmetical progressions and not surpassing a given number, to the sesquiplicate power of the given number when that number is indefinitely large. This paper is one of great power, constituting one of his most important contributions to science.

The above was followed by another great work "On the Orders and Genera of Quadratic Forms" containing more than three indeterminates. This paper will always be a celebrated one in the history of mathematics. It contains under date 1867, implicitly, the solution of the problem proposed fifteen years later for the Grand Prix des Sciences Mathématiques by the French Academy. The problem referred to was given as "Théorie de la décomposition des nombres entiers en une somme de cinq carrés." In the paper of 1867 it was indicated that the four, six, and eight-square theorems of Jacobi, Eisenstein and Liouville were deducible from the principles set forth. He then completed Eisenstein's "enunciation" of the five-square theorem by bringing under view the numbers which contain a square divisor, and added the corresponding seven-square theorem. The demonstrations were not given, but a general theory, which includes these theorems as corollaries, was given in detail. On these facts being pointed out to Hermite, a correspondence ensued, which the reader will find given, with comments, in the introduction by Dr. Glaisher. The result was that Prof. Smith sent in his demonstrations, and that ultimately the prize was divided between him and M. Hermann Minkowski, of Königsberg. The latter memoir followed closely the lines of the paper of 1867, a fact which gave rise at the time to much discussion concerning the action that was taken by the French Academy. The prize memoir is the concluding paper of vol. ii.

Passing over, for want of space, other arithmetical work of much value, a few words may be said concerning the papers on elliptic functions, which constitute the bulk of the second volume.

The paper, "Mémoire sur les équations modulaires," contains a theory of singular beauty. Mathematicians were aware, thanks to profound researches of Kronecker and Hermite, of the intimate relations that exist between the theory of binary quadratic forms of negative determinant and the transformation of elliptic functions, but beyond Kronecker's elliptic function solution of the "Pellian Equation," no association had been discovered between the binary quadratic forms of positive determinant and the elliptic functions.

In this paper it is shown that if

$$F(k^2, l^2) = 0$$

be the modular equation for the transformation of order N, the Cartesian equation

$$F(\tfrac{1}{2} + X + iY, \tfrac{1}{2} + X - iY) = 0$$

is a curve which gives an exact image of the complete system of forms of positive determinant N. By the simple process of enumerating the spirals and the convolutions of each spiral, he determines the number of non-equivalent classes and the complete system of "reduced" forms in each class.

In "Notes on the Theory of Elliptic Transformation" will be found a complete discussion of the case in which the modular equation has equal roots; it is shown that the squares of the corresponding multipliers are always different, and that this is consistent with Kœnigsberger's theorem, which states that the multiplier is a rational function of the squares of the moduli. The latter is shown, in fact, to break down when the modular equation has equal roots.

The long memoir on the Theta and Omega Functions was originally written as an introduction to the long-expected "Tables of the Θ Functions." It may be regarded as an advanced work on elliptic functions, in which the arithmetical treatment is given the prominent place. The theory of the transformation, and in particular of the modular equations and the associated curves, is exhibited with remarkable elegance.

Everywhere the treatment is characterised by extreme rigour. In fact, the subject matter, dealt with in these volumes, leads to work of so recondite a nature that only an investigator to whom any slurring over of difficulty, or exceptional case is absolutely repulsive, can expect to make a real advance. Those who look chiefly to results, and do not care to know the precise circumstances under which they exist, may be warned off the monument to Prof. Smith's genius which is given to the world in these pages.

On two principal occasions Prof. Smith found opportunity to place his views on mathematics in general before the scientific world. We have the valedictory address to the London Mathematical Society, delivered in the year 1876, on his retiring from the office of president. He took as his text some "comparatively neglected regions of pure mathematics"; and now, after an interval of eighteen years, it is a matter of great interest to re-survey the ground and estimate the advances that have been made. In the theory of numbers, then as always the subject of his predilection, he called attention to the state of knowledge with respect to (1) the theory of homogeneous forms; (2) the theory of congruences; (3) the determination of the mean or asymptotic values of arithmetical functions. With respect to quadratic forms of four or more indeterminates, he referred to the fundamental theorem of M. Hermite concerning the finiteness of the number of non-equivalent classes of forms having integral coefficients and a given discriminant; and to the researches of Zolokoreff and Korkine on the minima of positive quadratic forms. In a foot-note also he referred to his own great work "On the Orders and Genera of Quadratic Forms containing more than Three Indeterminates." These three papers mark the extent to which the inquiry had been pushed at that time. The latter is much the most important, and, so far as I know, but little further progress in the same direction has since been made. In the theory of congruences an important advance has been made by G. T. Bennett, in a paper published in the *Phil. Trans. R S.* vol. 184A. The investigation is "On the Residues of Powers of Numbers for any Composite Modulus, Real or Complex." Remarking that primitive roots exist only when the modulus is a power of an uneven prime or the double of a power of an uneven prime, and that a primitive root may be said to "generate" by its powers the complete set of residues, Bennett exhibits the mode of formation, and the relations connecting, the most general set of numbers capable of generating the $\phi(m)$ numbers which are prime to any composite modulus m, and extends his results to complex numbers.

Prof. Smith gave an historical account of our knowledge of the series of prime numbers. Prof. Sylvester has made a considerable contraction of Tchébychef's limits, and has established important general principles in connection therewith.

Passing on to the discussion of the transcendency of e and π, it may be noted that since the address was delivered (in fact, six years subsequently) the question has been triumphantly set at rest for ever by the labours of Hermite and Lindemann. The former established the transcendency of e, and the latter, standing on the shoulders of the former, demonstrated the transcendency of π. Lindemann's proof shows that π cannot be the root of any algebraic equation, and marks a distinct epoch in the history of mathematical science. The death-blow was thus given to the circle squarers in 1882 (*Math. Ann.* vol. xx.). Quite recently extraordinarily simple proofs of the transcendency of both numbers have been given by Hilbert. Prof. Smith noted and lamented the want of advanced treatises in English on various branches of pure mathematics. Our position to-day in this respect exhibits a marked improvement. On differential equations, theory of functions, integral calculus, theory of numbers, important works by English and American authors have been published, and certain eminent mathematicians are known to be engaged in the preparation of advanced works, which will shortly appear and further fill in the gaps.

Prior to the above, in 1873, was delivered the address to the Mathematical and Physical Section of the British Association. Remarking on the recent appearance of Maxwell's "Electricity," he observes: "It must be considered fortunate for the mathematicians that such a vast field of research in the application of mathematics to physical inquiries should be thrown open to them at the very time when the scientific interest in the old mathematical astronomy has for the moment flagged, and when the very name of physical astronomy, so long appropriated to the mathematical development of the theory of gravitation, appears likely to be handed over to that wonderful series of discoveries which have already taught us so much concerning the physical constitution of the heavenly bodies themselves." Mathematical astronomy to-day, it may be said, no longer flags. Thanks to the work of Hill, Poincaré, and Gylden, the subject has received a new impulse, and the world of science watches with intense interest the process of its evolution under the powerful hands of these mathematicians.

Prof. Smith had much at heart the organisation of scientific education as influencing the supply of scientific men. He asserts the importance of assigning to physics a very prominent place in education. He gives as his opinion that from the sciences of observation the student "gets that education of the senses which is after all so important, and which a purely grammatical and literary education so wholly fails to give." These are weighty words when we consider the all-round attainments of their author, and that he was, in particular, a classical scholar of the first rank. The effect of these volumes on the progress of research is sure to be considerable. A student will have before him work whose style has never been surpassed, and demonstrations which are absolutely rigorous. In the latter respect Gauss' work seems to have left a lasting impression upon his mind.

I conclude by quoting the noble words from the British Association address:—

"But in science sophistry is impossible: science knows no love of paradox; science has no skill to make the worse appear the better reason; science visits with a not long-deferred exposure all our fondness for preconceived opinions, all our partiality for views that we have ourselves maintained, and thus teaches the two best lessons that can well be taught—on the one hand the love of truth, and on the other sobriety and watchfulness in the use of the understanding."

P. A. MACMAHON.

ABSTRACT GEOMETRY.

Grundzüge der Geometrie von mehreren Dimensionen und mehreren Arten gradliniger Einheiten in elementarer Form entwickelt. Von Guiseppe Veronese. (Leipzig: Teubner, 1894.)

MODERN speculations on the Foundations of Geometry have raised the question of the character of Geometry as a science, and the question has been answered in different ways. Some writers have held that our space-intuition is an absolute guarantee of the truth of geometrical axioms; others have treated Geometry as a science of observation and experience, whose results accordingly are liable to the same kind and degree of inexactness as any other Physical Science. If either of these answers were correct, the method of Geometry would seem to require revision. The method is to deduce the properties of figures by logical processes from definitions and a few propositions (Axioms) assumed in advance. But if space-intuition were a sufficient guarantee for the truth of the Axioms, it would seem to serve equally well for a guarantee of the truth of many of the Propositions, and there would appear to be no good reason for assuming as few as possible and deducing the rest. If, again, Geometry is to be purely a Natural Science, there would be simplicity in proving its propositions by the help of well-made constructions and good instruments of measurement. There seems to be room for a third view of Geometry as an abstract formal science to which the method always known as geometrical would be proper and natural. In such a view abstraction might be made of all space-intuition, and there would remain a body of logical truths in which the Axioms would occupy the place of Definitions or well-defined Hypotheses. The science would be at the same time founded upon intuition and independent of intuition. If its Definitions and Hypotheses are never in contradiction with themselves, or with each other, or with our space-intuition, then will its conclusions always be verified within the limits of exactness that belong to observation. It will be a formal science ready for practical applications.

The theory of Abstract Geometry in the sense just described is the subject-matter of Prof. Veronese's treatise. He lays down in his Preface the nature of Geometrical Axioms as the simplest truths of space-intuition: he describes the character of a system of Axioms in that they must be independent, as few as possible, and yet sufficient for the establishment of the properties of figures without tacit assumption of other axioms. No definition or axiom is satisfactory which contains any notion not previously cleared up, or anything to be afterwards deduced. Any geometrical figure regarded as existing in the space of intuition may be replaced by a well-defined mental object or "Form," in the sense of the word fully described in the Introduction. The geometrical axioms are replaced by hypotheses serving to discriminate among possible forms or possible formal relations. Intuition is taken as a guide to the choice of hypotheses. The distinction is drawn between Abstract Geometry and its practical applications, and it is pointed out that there may be axioms of great importance for the latter which are useless restrictions in the former: such axioms are that the space of intuition is the Euclidean space form, and that the space of intuition has three dimensions. For our author all conceivable space forms are in theory equally admissible, and the number of dimensions of space is unlimited. The straight line, the plane, space of three or n dimensions, are all regarded as existing in the General Space. His method is the method of Pure Geometry, and his work is free from any trace of axes, coordinates, and Algebraic processes. Apparently this method has not previously been applied to the discussion of space of more than three dimensions.

A reader who approached Prof. Veronese's book in the hope of finding a logical development in purely Geometrical form of the theories of the non-Euclidean Geometry would be disappointed, for the work is throughout subordinated to the Euclidean system; nor would the reader be better satisfied if he sought merely for the logical establishment of the Euclidean system, for it is throughout treated as a limit included in a more general possible system. It is well known that the Euclidean Geometry is the limiting form between the Hyperbolic and Elliptic Geometries, and this is the case whatever more particular character we attribute to either of these Geometries. Hyperbolic Geometries differ with the form chosen for the "Absolute," there are two Elliptic Geometries according as two straight lines have one or two common points. All these systems have Euclid's system as a limit. In the elements of an Abstract Geometry developed in an orderly way we shall be presented time after time with a choice of hypotheses. Our choice at any time will determine to some extent the space form of which we treat. Our series of hypotheses will limit us to a particular space form. If one of our hypotheses is the existence of straight lines, we shall come upon the Euclidean system or a non-Euclidean system having the Euclidean as its limit. We may state at once that Prof. Veronese's hypotheses lead him to a system which, in an absolute sense, is the so-called Spherical Geometry, as distinguished from the Elliptic Geometry proper. According to this system two straight lines cut in two "opposite" points, and the length between opposite points is constant. This, however, is only true in an "absolute sense," the length in question being actually infinite in comparison with any perceivable length treated as a unit. The doctrine of the "actually infinite" is that laid down in the Introduction. The artifice of using two units, the finite or Euclid's unit, and the infinitely great or Riemann's unit, is an essential part of the theory, and is referred to in the title of the book.

Let us now look a little more closely at the abstract development of Geometry as treated by Prof. Veronese. Such notions as "point" and "line" are suggested by simple intuitions; abstractly considered what are they? The point is simply the fundamental element of geometrical forms. It is an axiom that there are different points, but all points are identical. A straight line is a continuous point-system of one dimension, identical in the position of its parts, and determined by two of its points. Here it is to be observed that the straight line is not necessarily determined by *any* two of its points. It is an axiom that any point on the line and any point off the line determine only a single straight line. Hence if there are two or more points on a straight line by which it is not determined, any straight line through one goes through all. So far the Euclidean and non-Euclidean systems are not in any way discriminated. The choice of a system, excluding the Hyperbolic Geometry, is made by means of an hypothesis concerning different units. Let straight lines be drawn from a point, and any length in one of them chosen as a unit. On each of them there will be a "range of the scale" with that line as unit, and, as in the Introduction, there will be points outside the range of the scale. The points within the range of the scale form the finite domain about the point. The points at an actually infinite distance of the first order form the domain of the infinitely great of the first order. There can thus be a number of domains of infinitely great or infinitely small order of the space about a point. Suppose a point A taken on a straight line, and a point R outside it, and let the distance between them be chosen as a unit. Then if we join R to a point B on the line at a finite distance from A, the lines R B, A B are different relatively to the unit; if the distance A B is infinitely great in comparison with A R, they coincide relatively to the unit. The hypothesis which excludes the Hyperbolic Geometry is that two straight lines going from a point which in any domain are different relatively to the unit of that domain will not in any other domain coincide relatively to the unit of that domain, and it is proved that, on this hypothesis, two straight lines joining a point R to points at infinity in opposite directions on a line A B lie in the same straight line through R.

A point-system, defined as a straight line is defined, may be closed or open. In the former case starting from one point, and going through the system continuously in one direction, the point of starting will be ultimately arrived at; in the latter it will never be arrived at. If we assume the straight line open, and make the hypothesis just now described to exclude the Hyperbolic Geometry, we shall come to an absolute Euclidean Geometry. If we assume the straight line closed, but its entire length actually infinite in comparison with a perceivable unit, we shall come to a Spherical or Elliptic Geometry which coincides with the Euclidean in the domain of the perceivable unit about any point. This is the assumption chosen by Prof. Veronese. But there is still a choice open between the Spherical and the properly Elliptic Form. As mentioned above, the former is chosen by means of the hypothesis that a straight line contains pairs of points by which it is not determined. This hypothesis is adopted to avoid the kind of complication which occurs in the Elliptic Geometry, and which may be associated with the statement that the plane of the Elliptic Geometry is "unifacial" in the sense in which that word is used in Geometry of Position; but it is pointed out that for the purpose of obtaining a system including Euclid's as a limit, the hypothesis is a pure convention.

We have described the foundations of Prof. Veronese's system at considerable length, because it is by these that his system must be judged. For the subsequent developments it will be almost sufficient to say that they are clear and orderly, and, in places, very interesting. The construction of the plane by means of a pencil of rays meeting a straight line, leads to the essential properties of the plane and of plane figures. The like method by means of the "star" of rays from a point outside a plane to points on the plane, leads to the properties of figures in space of three dimensions. The word Star (*Stern*) is introduced in place of the older Sheaf of rays (*Strahlen-Bündel*). The construction of space of four dimensions is made by means of a star of rays from a point outside a space of three dimensions to the points within it, and so on for a space of any number of dimensions. Abstractly considered there cannot be in the nature of the case any restriction of Geometric Forms to space of three dimensions. All the forms—the straight line, plane, &c.—are treated first as Euclidean and afterwards as "complete" in the sense of the Spherical Geometry above described. The Euclidean forms first considered are regarded as the parts of the complete forms in the domain of the perceivable unit.

The use of more than one unit precludes the application to geometric magnitude of the axiom V of Archimedes; but there is another principle which has frequently been supposed to lie at the basis of Geometry with which our author also dispenses, we refer to the Principle of Superposition, or Motion without Deformation. He points out that, although this principle has been very extensively used as the test of equality, it yet involves in its statement the notion of equality, albeit in a limited form, and, as a test of equality, it is thus without meaning in an abstract sense. By placing the notion of equality of geometric magnitudes, or, as he says, identity of figures, on a different footing, he is enabled to prove the equality of congruent and symmetric figures, and to establish the idea of motion without deformation by means of continuous systems of identical figures.

The reader will see that the purpose of the book is not didactic, but the author hopes to produce a book adapted for learners, founded on the principles laid down, but limited to the Euclidean domain of a single unit. We shall look forward with much interest to its appearance. The indictment of Euclid is perhaps not yet complete, as almost every advance in Geometry throws light on some weakness in his logic, or defect in his method; but it is not too much to say that no well-reasoned didactic treatise on Elementary Geometry has yet appeared. In the meantime those who have studied the subject in the existing defective works will do well to clear their ideas by reading at least some parts of Prof. Veronese's.

A. E. H. L.

THREE GREAT EMPIRES.

Primitive Civilisations; or, Outlines of the History of the Ownership in Archaic Communities. By E. J. Simcox. Two vols. (London: Swan Sonnenschein and Co., 1894.)

THE two stout volumes which represent the work before us cover so wide a field, that it is practically impossible to enter into any detailed criticism of their contents. All that it is possible to do within the limits of a review is to give a summary of the facts and arguments which they contain, and to remark in general terms on the views of the authoress.

Beginning in chronological order, Miss Simcox opens with a description of the civilisation of ancient Egypt, and no plainer evidence can be afforded of the great strides which have of late been made in Egyptology than that which is supplied by her book. Until quite modern times Herodotus may be said to have been the chief authority on Egyptian history; but the recent excavations, and the increased and increasing power which the key of the hieroglyphics has placed in our hands, has opened a new and wide knowledge of much that relates to ancient Egypt. One primary point on which Miss Simcox dwells has yet to be proved to demonstration. This is the question—whence and by what route or routes the earliest Egyptians reached the banks of the Nile? It is generally admitted that they were immigrants from Asia, and three roads leading to the land of the Pharaohs were therefore open to them. Some have supposed that, having wandered to the south of Arabia, they crossed into Egypt in the neighbourhood of the Straits of Bab-el-Mandeb; others hold that the route across the Red Sea to Kosseir was the one which they followed; and yet others are of opinion that they crossed by the Isthmus of Suez. Against this last route there is much to be said; but one fact which Miss Simcox mentions appears to give it some support. As has lately been shown by Dr. Terrien de la Couperie, the Chinese word for "north" originally signified nothing more nor less than "back," and the name of the "south," "the front." In the case of the Chinese these terms are peculiarly appropriate, since having entered the country of their adoption from the north, that point of the compass would be at their back, with the south fronting them. The early Egyptians, Miss Simcox tells us, applied precisely the same terms, "back" and "front," to Lower and Upper Egypt, and these expressions would, at first sight, lend colour to the theory that the Egyptians, like the Chinese, entered the new country from the north. It is possible that some fresh discovery may throw a new light on this problem, and until it does we must be content to possess our souls in patience.

We may say at once that Miss Simcox's book is extremely interesting. The facts are marshalled in good order, and her literary style is clear and graphic. The portion of her work which will probably attract the greatest share of attention is that in which she draws comparisons between the early histories of Egypt and China. Many of the details of Egyptian history in the earliest times find parallels among the primitive Chinese States. The hereditary princes of Egypt find their counterparts in the feudal princes of China; while the book of Kaquimna and the lessons of Ptah-hotep remind one irresistibly, both in matter and manner, of the Chinese classics. Both countries were essentially democratic in their institutions; in both high offices were open to all, and the voice of the people was in matters of administration the ultimate court of appeal. These and many other points of agreement are dwelt upon by Miss Simcox at some length; while, at the same time, she has reproduced from the pages of Maspero, Lepsius, Erman, Birch, Eisenlohr, Griffith, and others, a full and graphic account of the manners and customs of the ancient dwellers by the Nile.

The civilisation of Babylonia follows after that of Egypt, and much that the authoress says about it points inevitably to a close connection between the two empires.

As yet we are not in a position to say which is the earliest; and this is another point upon which it is necessary to suspend one's judgment. Comparatively little at present is known of that great centre of culture in Babylonia. And it may be, as Miss Simcox seems to imply, that the primitive civilisations all sprang from a common nursery between Khotan on the east and the sources of the Karun on the west. So far as China is concerned, we have preserved in the literature of the country far fuller and more complete information, and Miss Simcox has therefore been able to fill a whole volume with matters pertaining to the people of the Flowery Land. Of course, all her information is second-hand, and, fortunately, she has for the most part consulted trustworthy authorities. So much, however, cannot be said of some few of the works from which she occasionally quotes, and the result is that the picture she draws is on some points more ideal than real. She has taken the Chinese too much at their own estimate, and has accepted their high-sounding professions as representing solid verities. In this way she has succeeded in throwing a *couleur de rose* over everything Celestial.

According to her, the people are everywhere well-to do, justice is evenly administered, honesty prevails, education is universal, and even girls up to a certain age enjoy the same educational privileges as their brothers. A practical acquaintance with the country makes large inroads on these deductions. To anyone who has passed beyond the neighbourhoods of the treaty ports into the interior, it is manifest that the great bulk of the people live perpetually on the verge of starvation. The least failure of crops or disturbance of trade produces wide spread misery and destitution, and the want of intercommunication, which Miss Simcox does not regard as serious, is consequently one of the most pressing needs of the empire. The administration of justice is an open shame, and the provision, of which Miss Simcox approves, by which criminals are compelled to confess their guilt before punishment can be inflicted upon them, is productive of great cruelty and flagrant wrong. As to education, it has recently been officially stated by the Commissioner of Imperial Customs at Chefoo, that in the surrounding province—the province of Confucius and Mencius—only about 30 per cent. of the men can read and write; "of these, 2 per cent. can compose well, 8 per cent. fairly well, and 10 per cent. conduct commercial correspondence, while the knowledge of the remaining 10 per cent. is very slight. Of the women, a very few, belonging to the richest families (perhaps 500 in the whole province), can read and write a little, but the number of those who can even read at all is small, being, if anything, over-estimated at 1 in 1000."

In a work dealing with such wide and far-reaching subjects, it is quite impossible that an author should not occasionally be led astray. Truth compels us to admit that Miss Simcox is not an exception to this rule, but she has yet succeeded in producing an extremely interesting and able work, and one which sums up with clearness the current knowledge we possess of the civilisations of these three great empires.

OUR BOOK SHELF.

Celestial Objects for Common Telescopes. Vol. ii. By the late Rev. T. W. Webb. Fifth edition. Revised and enlarged by the Rev. T. E. Espin, M.A., F.R.A.S. Pp. 280. (London: Longmans, Green, and Co., 1894.)

WE have already noticed (NATURE, vol. xlix. p. 339) the first volume of this edition of Webb's famous "Celestial Objects." The volume under review completes the work. All astronomers are familiar with this guide to the starry heavens, and most are agreed in thinking that the preparation of a new edition could not have been placed in better hands than Mr. Espin's. It is always a risky proceeding to put new wine into old bottles, nevertheless, in the case before us, an analogous task has been successfully accomplished. Substantial additions have been made in the new volume. All double stars having primaries above magnitude 6·5, and distances less than twenty seconds of arc, have been included. After lists of the binary and double stars in each constellation stars with remarkable spectra are placed. With the latter are arranged variable stars, and then follow the positions and descriptions of conspicuous nebulæ and clusters. Altogether the volume contains the places of 2272 double stars, 629 stars with remarkable spectra, and 276 nebulæ; a total of 3177 objects. The Right Ascensions and Declinations have been brought up to 1900.

It is almost unnecessary to commend the book to practical astronomers, for they are all acquainted with its merits. Certainly no possessor of a workable telescope can dispense with this trustworthy guide to celestial sights.

Ponds and Rock-Pools, with Hints on Collecting for, and the Management of, the Micro-Aquarium. By Henry Scherren. (London: The Religious Tract Society, 1894.)

THE chapters of this little book appeared originally in the *Leisure Hour*, but have been, we are told, "considerably enlarged and very carefully revised." The work is divided into six chapters, devoted respectively to the subjects of "Pond and Rock-Pool Hunting," "The Beginnings of Life," "Sponges and Stinging Animals," "Worms," "Starfish, Anthropods, and Molluscs," and "The Micro-Aquarium." The author has a pleasant, straightforward style, and has avoided as far as possible the use of high-sounding names and language calculated to deter his unscientific readers from taking up the study of the contents of "Ponds and Rock-Pools." His task has been made considerably easier by the insertion in the text of some sixty-six very creditable figures, and he has produced a book full of helpful hints to the young collector, and one which should, we think, have the effect of causing many to strive to know more about the hidden beauties of nature. The general get-up of the book is everything that could be wished.

Newfoundland as it is in 1894: A Handbook and Tourist's Guide. By Rev. M. Harvey, LL.D., F.R.S.C. (London: Kegan Paul, 1894.)

THIS book does not require a lengthy notice in these columns, being interesting more from a commercial than a scientific point of view. The author, who has lived for more than forty years in the colony, is evidently quite an enthusiastic lover of Newfoundland, and has written this handy volume for the purpose of making the country better known, and attracting to it the attention which it deserves, and which the author considers it has failed to receive in the past. Mr. Harvey has certainly done his best to alter this condition of things, and has brought together in a readable form a great deal of information respecting the physiography and topography of the island, its roads and railways, agricultural resources and forest wealth, minerals, fisheries, characteristics of the people, and other facts likely to be of service to the intending visitor or settler.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Logic of Weismannism.

SOME time ago, when I read an account of Prof. Weismann's experiment on the larvæ of blow-flies, as described in his Romanes lecture, a criticism of it occurred to me, which I have recently communicated to Mr. Herbert Spencer. This was that in the experiment the quantity of food (flesh) was diminished, while the nature of it remained the same; whereas in the case of bees it is well known that the difference between the food of the worker larvæ and the royal larvæ is one of quality, not of quantity. The royal food is pollen, and is highly nitrogenous, while the food of the worker larvæ is chiefly honey. In the case of Termites, Grassi has found that the fertile individuals are fed during development on the secretion of the salivary glands of other individuals, while the sterile forms are supplied only with macerated wood-dust.

But I was not aware, until I procured the printed version of the lecture, that Weismann had actually mentioned facts proving the importance of nitrogenous food in relation to the reproductive organs of the blow-fly. He seems serenely unconscious that these facts, mentioned in the notes to his lecture, entirely neutralise the force of his argument in the text. In note 11 he states that his blow-flies when abundantly fed on carrots and sugar, laid no eggs for more than a month, but as soon as meat was supplied they sucked it greedily, and laid a great number of eggs a week afterwards. In later experiments, when the flies were fed from the first with sugar and meat juice, the deposition of eggs commenced ten days after the metamorphosis. Weismann infers that rich food is necessary in the imago stage if the egg-cells are to ripen, and adds that in the case of bees the queen lays eggs because supplied with nitrogenous food in the imago state, while the workers are poorly fed. These remarkable facts concerning the relation between egg-laying and nitrogenous food in the adult blow-fly strongly suggest that if the larvæ were deprived of nitrogenous food during development, the ovaries would not be perfectly developed.

Weismann contends that the bee has the specific property of responding to imperfect nutrition in the larval state by the imperfect development of the ovaries. As proof of this, he states that blow-fly maggots occasionally starved, but fed exclusively on meat like those which were not starved, laid normal eggs in normal abundance, and were only smaller in size. The evidence is quite irrelevant. The point is that the larva of the worker-bee is supplied with a non-nitrogenous diet, that of the queen bee with one highly nitrogenous. What is required is evidence that the larva of the blow-fly can fully develop its ovaries when deprived of nitrogenous food. Instead of this, Weismann supplies the information that the blow-fly when reared on a restricted quantity of nitrogenous food, can lay eggs if further fed with proteids in the imago stage, but if deprived of proteids in the imago stage it lays no eggs. Of the anatomical condition of the reproductive organs in the flies experimentally reared no evidence is vouchsafed.

Plymouth, September 15. J. T. Cunningham.

"Darwinism is not Evolution."

I was very much struck—having heard the admirable reply which Prof. Huxley gave to Lord Salisbury on the evening of August 8—to find a passage in "Darwin's Life and Letters" (vol. iii. p. 13) which is the exact counterpart of the chief point in Huxley's retort. Darwin writes to Lyell (March 12, 1863): "I must feel convinced that at times . . . you have as completely given up belief in immutability of specific forms as I have done. . . . The more I work the more satisfied I become with variation and natural selection, but that part of the case I look at as less important, though more interesting to me personally."

It was whispered in Oxford that Huxley had spoken of Darwinism rather lightly in comparison with evolution. The above-quoted passage shows that even in this respect Darwin himself had set the example.

I have reason to believe that these illustrious examples will not be very generally followed. A. A. W. H.

Utrecht, September 11.

Extraordinary Phenomenon.

Having recently had before me your number of the 6th inst.,[1] I feel very desirous to bring under your notice, for insertion in your journal, the description of a most extraordinary and singular phenomenon as was observed by me at Llanberis, N. Wales, on Sunday, August 26 last, about 10.30 p.m.; especially as I perceive that the time of my observation coincides precisely with the time recorded in that number by John W. Earle, at Gloucester, describing his observation of a remarkable meteor which he discovered.

I was outside the hotel in Llanberis at 10.30 p.m. admiring the lustre of the stars—for it was a cloudless night—when, gazing upwards into the region of Cassiopeia, I was startled by a sudden flash from a brilliant effulgence of white light situated proximately to the two stars of greatest magnitude in that constellation, which immediately resolved itself into a clearly defined disc, about three times the diameter of Jupiter. After a brief interval I observed a body of brilliant orange colour discharged from the disc, which was projected directly towards Perseus. This body assumed a form resembling an elongated flatfish, but terminating in a point, the disc forming a nucleus to the apparition, which was marvellous to behold; but its visibility proved to be only of short duration, for the white disc, or nucleus, suddenly disappeared, leaving the orange-coloured mass quiescent for about half a minute, and then I saw it fade away gradually, and it vanished out of my sight.

The appearance of this strange body did not occupy more than five minutes of time; its dimensions in length I estimated was about fifteen degrees of arc. I likewise noticed an important fact—that it evidenced no motion in space.

During my professional career, including Arctic and Equatorial services, a great part was spent in nightly watchings, in which all sorts of meteoric phenomena came under my notice, yet I never beheld one which manifested such marked singularity and distinctiveness combined. I could only regret that no one was at hand to affirm what I saw.

With reference to the meteor observed by John W. Earle in Ursa Major, I wish to mention that a building excluded that constellation from my sight, therefore it establishes a very interesting and important fact that these two extraordinary phenomena, one in Ursa Major, the other in Cassiopeia, were so distinctly noticed by two observers so remote from each other at the very same moment.

Erasmus Ommanney, Admiral.

29 Connaught Square, W., September 24.

"Aurelia aurita."

At the Plymouth Laboratory, in July last, I examined 383 adult specimens of *Aurelia aurita*, and found eight specimens (2·08 per cent.) showing a numerical variation in the generative sacs and buccal arms.

One specimen with 3 generative sacs, 3 buccal arms, and 9 tentaculocysts. Three specimens with 3 generative sacs, 3 buccal arms, and each one has traces of a fourth generative sac and a fourth arm. Two have 8 tentaculocysts, and one has 10 tentaculocysts. One specimen with 5 generative sacs, 5 buccal arms, and 8 tentaculocysts. Three specimens with 6 generative sacs, 6 buccal arms; two have 11 tentaculocysts, and one has 12 tentaculocysts. Six specimens with the normal number of buccal arms and generative sacs show a variation in the size and shape of the sacs. There appears to exist a correlation between the generative sacs and buccal arms, but the tentaculocysts vary independently of the other organs.

I found 87 specimens (22·8 per cent.) showing a variation in the number of tentaculocysts. Twenty specimens possess less than the normal number, and the remainder show an excess. The range of variation extends from 6 to 15 tentaculocysts.

Edward T. Browne.

University College, London, September 15.

Science in the Medical Schools.

In the issue of Nature of September 20, I notice a table of the scientific classes which are to be given in the medical schools of Great Britain during the session 1894–95. In this table I find that the subject of "biology or zoology" is indicated by a cross (×) as being taught in all the medical schools of Scotland with the exception of the University of Aberdeen. You will, doubtless, allow me to point out that in this matter Aberdeen is in precisely the same position as Edinburgh and Glasgow. A course of zoology is delivered in the University of Aberdeen in the winter session, and a second course in the summer session, and there is, in addition, a course of practical zoology.

University, Aberdeen. H. Alleyne Nicholson.

ON THE DOCTRINE OF DISCONTINUITY OF FLUID MOTION, IN CONNECTION WITH THE RESISTANCE AGAINST A SOLID MOVING THROUGH A FLUID.

§ 1. The doctrine that "discontinuity," that is to say finite difference of velocity on two sides of a surface in a fluid, would be produced if an inviscid incompressible fluid were caused to flow past a sharp edge of a rigid solid *with no vacant space between fluid and solid* was, I believe, first given by Stokes in 1847.[1]

It is inconsistent with the now well-known dynamical theorem that an incompressible inviscid fluid initially at rest, and set in motion by pressure applied to its boundary, acquires *the* unique distribution of motion throughout its mass, of which the kinetic energy is less than that of any other motion of the fluid with the same motion of its boundary.

§ 2. The reason assigned for the formation of a surface of finite slip between fluid and fluid was the infinitely great velocity of the fluid *at* the edge, and the corresponding negative-infinite pressure, implied by the unique solution, *unless the fluid is allowed to separate itself from contact with the solid.* This an inviscid incompressible fluid certainly would do, unless the pressure of the fluid were infinitely great everywhere except at the edge. In nature the tendency to very great negative pressure arising from greatness of velocity of a fluid flowing round a corner is always obviated by each one of three defalcations from our ideal:—

(I.) Viscosity of the fluid, preventing the exceeding greatness of the velocity.

(II.) Compressibility of the fluid.

(III.) Yielding-ness of the outer boundary of the fluid.

§ 3. Defalcation (I.) is in many practical cases largely operative when air is the fluid; but (II.) is also largely operative in some very interesting cases, such as the whistling of a strong wind blowing round a sharp corner or through a chink; the blowing against the sharp edge in the embouchure of an organ-pipe, and in the mouth-

[1] "Collected Papers," vol. i. pp. 310, 311.

piece of a flageolet or of a small "whistle"; and the blowing across the end of a tube or a hole in the side of a tube, to cause a key or a flute to sound.

§ 4. Defalcation (III.) is largely operative, and (II.) but little, in many practical cases of most common occurrence in the flow of water. It is probable that much of the foam seen near the sides and in the wake of a screw steamer going at a high speed through glassy-calm water, is due to "vacuum" behind edges and roughnesses causing dissolved air to be extracted from the water. A stiff circular disc of 10-inch diameter, and 1/10 of an inch thick in its middle, shaped truly to the figure of an oblate ellipsoid of revolution would cause a vacuum[1] to be formed all round its edge, if moved at even so small a velocity as 1 foot per second under water of any depth less than 63 feet; if water were inviscid: and at greater depths the motion would, on the same supposition, be wholly continuous, with no vacuum, and would be exactly in accordance with the unique minimum energy solution.[2]

While the velocity of the fluid across the equator is 63·7 feet per second, the velocity across each of the two parallel circles whose radii are 4·218 inches (the radius of the equator being 5 inches) is only 1 foot per second.

§ 5. The exceedingly rapid change of shape of the fluid flowing across the equatorial zone between these circles, with velocity at the surface augmenting from 1 foot per second to 63 feet per second in advancing over a distance of less than ·85 of an inch of the surface from one of the small circles to the equator, and diminishing again from 63 to 1 from the equator to the other parallel, in a small fraction of a second of time would, if the fluid is water or any other real liquid, give rise, through viscosity, to forces greatly diminishing the maximum velocity, and causing, through fluid pressure, the motion of the water to differ greatly from that of the minimum-energy solution, not only near the equator, or in its wake, or over the rear side of the disk; but over all the front side also, though no doubt much more on the rear side and in the wake, than on the front side, and in the fluid before it.

The viscosity would also, at less depths than 63 feet, have great effect in keeping down the maximum velocity; and it is possible that even at 10 or 20 feet a greater velocity than 1 foot per second might be required to make vacuum round the equator of our disc of 10 inches diameter and the $\frac{1}{2000}$ of an inch radius of curvature which its elliptic meridianal section gives it. But it seems quite certain that there must be much forming of vacuum, and consequent extraction of air and rising of bubbles, to the surface, from the somewhat sharp corners, and roughnesses, of iron, in the hull of an ordinary iron sailing ship or steamer, going through the water at twelve knots (that is, 20 ft. per second). KELVIN.

(*To be continued.*)

[Correction on previous short article, "Towards the Efficiency of Sails, &c." In last line but two, for 2π substitute $\frac{1}{2}\pi$. In last line but one, delete 4, and for 8 substitute 32.]

[1] Single word to denote space vacated by water.

[2] From the elementary hydrokinetics of the motion of an ellipsoid through an inviscid incompressible fluid, originated by Green, who first gave the solution for the case of translational motion of the ellipsoid, we know that, if θ denoting the angle between the axis of an oblate ellipsoid of revolution, of which the equatorial and polar areas are a, b, the velocity of the fluid flowing over this point of the surface is

$$\frac{(a^2 - b^2)V \sin\theta}{b\left\{b + \frac{a^2}{\sqrt{(a^2 - b^2)}} \sin^{-1}\frac{\sqrt{(a^2 - b^2)}}{a}\right\}},$$

if the velocity of the fluid at great distances from the solid is V, and in parallel lines, and the solid is held fixed in the fluid, with its axis parallel to these lines. Taking $a = 100b$ in this formula, we reduce it to $\frac{200}{\pi} V \sin\theta$ approximately within 1 per cent.; and taking $\sin\theta = 1$, and $V = 1$ foot per second, we find 63·7 feet per second for the velocity across the equator. Hence the gravitational head corresponding to the "negative-pressure" is $(63{\cdot}7^2 - 1^2)/64{\cdot}4$, or very approximately 63 feet, which proves the statement in the text.

SCIENCE, IN SCHOOL AND AFTER SCHOOL.

IT is an unfortunate accident of the conditions under which instruction in science has grown up, that in speaking of science teaching two essentially dissimilar things should be confused. This confusion has very seriously affected—and still affects—the development of method in this country. It arises from the fact that, twenty or thirty years ago at least, the ordinary schoolmaster was quite without the knowledge necessary to teach science, and that even when his scientific knowledge was a measurable quantity, that ignorance of psychology which was and which remains one of his most constant characteristics, rendered him incapable of innovations upon the tradition of mental training he cherished. Consequently what knowledge people obtained of the growing body of science came after the elementary stage of education was over, when their minds and senses had already received a considerable amount of cultivation and were, for good or evil, definitely developed in a prescribed way. The teaching given, therefore, did not aspire to be so much educational as *instructive*; it made the best of a bad job, and without any belated attempts to alter the fundamental intellectual mechanism, placed therein so much of the new facts and views as the circumstances permitted. It was addressed primarily to adolescence and to the adult, its methods were by lecture, diagram and text-book, and the written examination or a practical examination, turning chiefly on the identification of specimens or the interpretation of diagrams, was the adequate measure of its value. Such teaching can affect the taught only through their opinions and knowledge; it can discover scientific capacity, but it can neither develop nor very largely increase it, because it comes too late in the mental life. It is typically represented by the innumerable classes over which the Science and Art Department presides.

On the other hand, we have the science teaching that is *educational*, that takes the pupil still undeveloped and trains hand, eye, and mind together, enlarges the scope of the observation, and stimulates the development of the reasoning power. Such science teaching occurs at present most abundantly in theoretical pedagogics. It is, however, undoubtedly the proper science teaching for the school, if science is to have a place in the school. For it is universally conceded nowadays that the school is a training place, that there the vessel is moulded rather than filled, and that the only justification for the introduction of science is its educational value. Equally indubitable is it that it should be confined to school limits. An attempt to make the adult science teaching educational in the same sense, would be—to complete the image—extremely like putting a well-baked—if imperfect—vessel back upon the potter's wheel.

Now, hitherto the chief influence of this confusion has been to hamper truly educational science teaching in schools. Those who had as adults studied science under the Science and Art Department, or in University lecture theatres, took their text-books and the methods under which they had acquired their knowledge into the school, where the conditions were altogether different. The course of science lessons began as a lecture in which the class listened to colourable imitations at second or third hand of this or that eminent exponent of scientific theory. The more discerning teachers after a time realised the futility of requiring genuine lecture notes from such immature minds, and supplied the deficiency *by dictating* a colourable imitation. They also provided copies on the blackboard for such original sketches as were required, and indeed went to very considerable pains to keep the outward appearance of the lecture system intact. Examiners of schools—being selected without the slightest reference to their capacity to examine—fell very readily into this view, that school science-teaching was adult science-teaching in miniature; as some parents hold that infant costume should be a simple and economical adaptation of the parental garments. And so an elaborate system of lecturing, note dictating, "model answer" grinding, has been evolved, which is not only not educational and a grievous waste of the pupils' energies, but which seriously discredits the claims of science upon the school time, in the eyes of ordinary educated people.

This has been particularly the case in many middle class schools, though the recent abolition of the second class pass in the May examination has done much, as the Forty-first Report of the Department shows, towards mending the mischief. In connection with countless higher grade and small grammar schools, classes, containing as a rule only elementary pupils, and aiming really only at second class passes, have been organised from year to year. Not only was the science-teaching given in the evening classes, but a considerable portion of the daytime was devoted to model answer drill and to mechanical copying out from the text-book. The minimum of apparatus required by the Department formed a picturesque addition to the schoolroom. This discipline resulted in remunerative grants for second class passes, but it resulted in very little else. except perhaps a certain relaxation of the pupil's handwriting and a certain facility in the misuse of scientific phrases. The certificates were framed and glazed, the teacher added a few modest comforts to his home, and there the matter ended.

The examinations of the Science and Art Department were scarcely to blame in this matter, although the blame has been generously awarded them. The Science and Art Department is a large and convenient mark, it is perfectly safe to throw at, and to attack it has something of the romantic effect of David against Goliath. But we must remember that its classes were primarily, as they are still in intention, continuation and adult classes, an outcome of the Mechanics' Institute movement, and it was an unforeseen accident, and one the full bearing of which only became apparent in the course of years, that they should so seriously affect the teaching of middle-class, and even of the higher standards of elementary, schools. For their proper purpose as a test of lecture teaching, the departmental examinations are generally efficient. Far more blameworthy are examining bodies whose work is specially directed to school needs. The College of Preceptors, for instance, while subsidising lecturers upon Educational Theory, has done nothing to promote practical work in schools, and many of its examinations set a premium upon that vicious lecture and text-book cramming which educational theory condemns. And in public schools over which the Department has no influence, young gentlemen from the older universities, beginning educators without of course the faintest knowledge of educational technique, set up precisely the same imitation of the professorial course. We have in consequence such a standing argument against science teaching as that naive testimony of a prominent headmaster, that he found boys who had followed the classical course for some years, and who then took up "science as beginners, speedily outstripped those who, to the exclusion of literary work, had been engaged during the same time in what he regarded as scientific studies.

So far the confusion between the two forms of elementary instruction has hampered science-teaching. But there can be no doubt that the educational reformer is abroad. A large, if somewhat inchoate, body of criticism has grown up, and good resolutions in the matter are epidemic. A really educational scheme of instruction in physics and chemistry now exists, having its base upon the Kindergarten, and developing side by side with elementary work in mathematics. Mr. Earl's recently published book upon Physical Measurements is an admirable exposition of what is here intended by educational science-teaching. In this, information is entirely subordinated to mental development. His course is devoted to the measurement of space, mass and time, and to the observation and methods of recording various changes involving precise determinations. The first exercise requires the pupil to "measure the size or dimensions in inches of the paper on which you are writing, using for your standard a strip of paper one inch in length, and which you have divided into halves, quarters, and eighths"; and the book concludes with experiments upon torsion and the rotation of suspended bodies. The course must inevitably constitute a firm foundation of definite concepts, and develop a clear and interrogative habit of mind. It marks the line along which school science teaching must move in the future, if it is to attain that predominance which its advocates claim for it. Yet at the same time it may not be premature to notice that the new movement has its dangers.

These dangers arise from the confusion between the two distinct forms of science-teaching whose existence is necessitated by the present condition of things. In the past the error has been to treat children like adults; in the future it may be that adults will be treated like children. Such exercises as the one we have noticed, are excellent in developing concepts, but scarcely anything could be devised more irksome and exasperating to a mind already provided with a basis of definite ideas. Nothing, for instance, could be better calculated to discourage an intelligent student of eighteen or nineteen, curious about physics, than a day or so spent in manufacturing an unreliable millemetre scale. The problems of the science are already more or less vaguely in his mind, and there is every reason why these should be made the starting-point. To produce an intellectual parallel to the spiritual re-birth, is as impossible as it would be to refer an unsatisfactory chicken back to the egg to reconsider its ontogeny. We have now, and shall have for an indefinite number of years, to provide for the needs of a great number of people whose intellectual development is nearly or quite at an end, whose curiosity about nature is already aroused, and whose practical needs are also pressing for scientific information, and yet who are ignorant of any but the veriest commonplaces of science. For them the Science and Art Department classes were designed and are well adapted. It will be an unfortunate thing if the criticisms of the educational reformer should so far overshoot the mark as to affect their instruction. Yet one might suggest that a downward age limit, similar to that of the London University Matriculation, might save many a schoolmaster from the temptations of the possibility of grant-earning—a temptation, however, from which the abolition of the second class in the elementary stage has already to some extent relieved him.

H. G. WELLS.

WITH PROF. HEIM IN THE EASTERN ALPS.

THE excursion with Prof. A. Heim, of Zurich, which came to a happy end on September 15 at Lugano, was one full of interest to students of tectonic geology. It afforded those who were fortunate enough to take part a rare opportunity of seeing in the field some of the classic sections with which the name of Heim has been for many years associated, and, better still, of seeing the genial author of the "Mechanismus der Gebirgsbildung" himself climbing his native Alps as nimbly as a chamois, and expounding his own work face to face with the hard facts on which his conclusions have been based. The party, numbering at the outset twenty-three, left Zurich on the 3rd, after the close of the Geological Congress, and took train to Appenzel, spending the first night at Weissbad, a village nestling peacefully beneath the rugged peaks of the Santis Range. This magnificent buttress of the

Eastern Alps consists of a series of steep compressed folds of cretaceous strata rising through the Flysch and Molasse conglomerates that form the lower spurs to the north, and the summit of Säntis is the highest of one of the sharp anticlines of the range. Finer examples of sharp anticlinal peaks and ridges separated by equally acute synclinal gorges it would be difficult to find, and the well-marked petrographical and palæontological character of each zone leave no room for doubt as to the sequence and structure of the different formations. The summit of Säntis (8200 feet) is an overturned anticline of Gault, covered by a thick bed of "Seewerkalk," the highest cretaceous rock in the district, and the structure is exposed in splendid cliff sections on the sides of the peak. Prof. Heim, who is an adept at drawing panoramic sketches, was anxious that we should have an opportunity of verifying his elaborate panorama of the surrounding district, but unfortunately the mist, which had come on, did not clear off the top till the afternoon of the second day, and even then we had only a short glimpse of the glorious view beneath. Two nights were spent in the inn erected by the Alpine Club, a short distance below the observatory on the summit of Santis, and the descent to Wildhaus was made on the north side over a steep path leading across a compressed synclinal fold of Seewerkalk, where a good example was seen of the middle part of a double fold, compressed and drawn out so as to pass almost into a thrust-plane. A better example of the "Verkehrten Mittelschenkel" was, however, seen a few days afterwards in the Mattstock near Amden, where the middle members of a compressed monoclinal fold were found in normal order from Flysch to Neocomian and Gault, but drawn out and evidently much diminished in thickness. At Obstalden, on the Wallen See, a few days were spent among the rocks on either side of the lake, a recent fall of snow having obscured the sections on the higher Alps, which we had intended to visit. One of the most interesting tectonic features of this district is an important thrust-plane, traversing the face of the Leistkamm on the north side of the lake, and repeating the section of cretaceous rocks in the mountain. The thrust-plane forms a barrier to the downward passage of water through the limestones above, and its outcrop is marked by a line of springs, one of which gushes out of the cliff in a large waterfall opposite Muhlehorn. After a visit to the Mürchenstock, with its contorted anticlinal core of Permian Verrucano conglomerate and its wrinkled skin of Jurassic rocks, we made our way southward to Glarus, and the greater part of the last week was devoted to the exploration of the celebrated "Doppelfalte" of the Glärnish, in which the red Verrucano is seen to have been pushed on to the top of Jurassic and Eocene rocks exposed in a series of magnificent mountain sections. At Lochseite, near Schwanden, a few miles south of Glarus, the massive Verrucano is seen projecting in a thick ledge from the hillside over the so-called Lochseitenkalk, a crushed irregular bed of mylonised limestone resembling that found near the great thrust-planes in the North-west Highlands. At Lochseite the thrust-plane is so sharp and clear that a knife could be drawn along between the rocks on either side, and the under-surface of the hard Verrucano is slickened and polished at places as smooth as glass. A full view of this tremendous overthrust was, however, not obtained until we had climbed some 8000 feet to the crest of the Bütistock and Kalkstöckli, between Linthal and Elm, where the sharp-cut and wonderfully straight line of the great displacement was seen in profile crossing from ridge to ridge and peak to peak, and producing a marked feature in the mountain panorama. At one place where the Verrucano has been eroded off, the party rested on the smooth surface of the thrust-plane which forms the crest of the ridge, where they were photographed, with Prof. Heim standing in the midst expounding the classic sections around him. The south wing of the "Doppelfalte," or thrust-plane, was crossed between Elm and Flims at the Segnes Pass, at a height of 8615 feet, and here also the outcrop was seen in stupendous cliff sections. The overlying Verrucano being darker in colour than the limestones below, the line of displacement is everywhere very sharp and distinct. The nummulite limestone, where it approaches the thrust-plane, is drawn out and schistose, and a distinct passage was traced between unaltered nummulites and those only slightly distorted, to a rock in which they were rolled out into ribbons, which, but for the intermediate specimens, could not have been recognised as being of organic origin. The Verrucano itself is also squeezed and schistose, and the pebbles are compressed into augen, surrounded at places by sericite and mica schist. The vast interglacial (?) landslip at Flims, on the Vorder Rhein, was the last of the important objects we visited, and after a passing look at the crystalline rocks of the St. Gotthard Massiv, the party reached Lugano in detachments, where they rejoined the other members of the Congress, all highly pleased with their respective excursions across the Alps, and were greeted on their arrival by a discharge of artillery, followed in the evening by a splendid pyrotechnic display on the lake.

H. M. C.

NOTES.

THE Physical Society, which has for many years met in the Royal College of Science at South Kensington, give notice of some important changes. The Council have, after careful consideration, come to the conclusion that the meetings of the Society would be more accessible to the majority of the members if they were held in some more central situation, and the meetings will therefore henceforward be held on the same day and at the same hour as heretofore, but in the rooms of the Chemical Society, in Burlington House. All communications to the secretaries or other officers of the Society may in future be addressed to Burlington House or to the secretaries at their respective addresses as given in the list of members of the Society. The Council have also decided to initiate the publication of a series of abstracts of papers on physics, but the resources at their command being slender make it necessary to begin cautiously. At first abstracts will only be given of papers which appear in a certain number of the more important foreign magazines. They will for a time be edited by Mr. Swinburne, and will be published regularly at the beginning of each month in the form of a supplement to the Proceedings of the Society. The first number will be issued in January 1895. Should the scheme prove successful it is intended to enlarge its scope. For some time past printed copies of the more important papers have been circulated before the meetings among members who are likely to take part in the discussion on them; it has, however, been felt that cases may arise in which the author may wish that his paper should be published as soon as possible. The Council have therefore decided that, if an author so desires, and if such a course appears desirable, they will take steps to ensure that the publication of a paper is not in any way delayed in order that it may be read before publication, and that they will if necessary postpone the reading and discussion of a paper until after it has been published.

WE are informed that a petition, signed by a number of science masters, has been sent, through Sir Henry Roscoe, to the Secretary of State for War, supporting the Departmental Committee's proposal to introduce a compulsory science subject into the entrance examinations for Woolwich, which, the masters consider, will encourage thorough science teaching in the schools, and be to the advantage of education generally.

The death is announced of Prof. Comm. Ariodante Fabretti, Director of the Historical and Philological Section of the Turin Academy of Science.

The fourteenth annual congress of the Sanitary Institute is taking place this week at Liverpool, and was opened on Monday last by the holding of a reception in the Town Hall by the Lord Mayor of Liverpool, who is also chairman of the local committee. The new president—Sir Francis S. Powell, M.P., —afterwards delivered his inaugural address. In the evening the Lord Mayor opened an exhibition of sanitary appliances. On Tuesday the congress, divided into five sections, resumed its sittings.

The programme for the sixty-sixth annual congress of the German Naturalists and Physicians at Vienna, from September 24 to 30, contained arrangements for no fewer than three addresses by the late Prof. von Helmholtz, all of which were to have been delivered in the general meetings. Dr. F. Klein, the Professor of Mathematics at Göttingen, has undertaken to fill one of the gaps by reading a paper upon Riemann's influence in the development of modern mathematics.

A telegram from St. Paul, Minnesota, through Reuter's special service, on Monday gave notice of the occurrence, on the evening of Friday, September 21, of a very disastrous cyclone in America. A strip of country in Iowa, Minnesota, and Wisconsin, about 200 miles in length, is reported to have been devastated, and not only was immense destruction done to property, but serious loss of life occurred, the number of persons who perished being variously estimated at figures varying from fifty-two to one hundred. The storm was accompanied by hail and torrents of rain, as well as thunder and lightning. Starting ten miles south of Spencer, North-West Iowa, the cyclone swept across the State to the north of Emmetsburg and Algona, almost wiping out of existence the town of Cylinder and laying waste the country districts in its track. Passing by Mason City, it ravaged the country to the north-west of Osage, and then changed its direction somewhat towards the north-east, crossing the Minnesota line and working great havoc in Leroy, where a fire broke out and a whole block of houses was destroyed. The cyclone swept down Spring Valley, and then turned again to the east, wrecking the hamlets of Homer and Lowther. It next crossed the Mississippi and destroyed many farm buildings near Marshland, Wisconsin. Considerable damage was also done at Dodge Centre, though it was not in the path of the main cyclone.

A Central News telegram of September 25 announces that a destructive storm has occurred in Japan, by which the districts of Okita and Twate have been laid waste. Fifteen thousand houses are reported to have been destroyed, and 300 persons to have perished. Great havoc has also been wrought among the shipping.

University College, Dundee, has been benefited to the extent of some £35,000 by the bequest of the late Mrs. Margaret Harris, of Dundee.

Dr. A. Zimmermann has been appointed Extraordinary Professor of Botany at the University of Tubingen; and Dr. Solereder Curator of the Botanical Institute at Munich.

Accounts have been received from Prof. Stirling, F.R.S., of the safe return to Adelaide, South Australia, of the Horn Expedition for the exploration of the central portion of that country, the departure of which was announced in these columns some three months ago (p. 174). We are glad to say that considerable success has attended the whole journey, no doubt in consequence of the foresight with which preparations had been made for it; and though the work of the expedition was at times sufficiently trying, nothing that could be called a misadventure took place. Above all, there was no collision, nor indeed any trouble with the natives; and there had been good rains in the Macdonnell Ranges, the examination of the western termination of which formed the chief work to be done. The course of the expedition is briefly outlined by Prof. Stirling as follows:—From Crown Point the party traversed the Finke River to running water; thence the Palmer River to Tempe Downs, the Levi Range, Petermann Creek, and the George Gilles Range, where one section diverged to Ayers's Rock and Mount Olga, the rest proceeding westward to Lacorie's Creek and northward to Glen Edith, along Carmichael Creek to Mereenie Bluff, thence into the northern watershed following Darwent Creek to Haast's Bluff, and so eastward to Glen Helen. The united party then travelled eastward to Mount Sonder, which was ascended, and thence through the southern ranges of the Macdonnells to the Finke River and Hermannsburg. Here section one again diverged to the Glen of Palms, and another to the North Macdonnells by way of Ellery's Creek and Brinkley's Bluff to Aine Springs, where it was met by the other members of the expedition, some of whom had journeyed thither by Owen's Springs, and others by Stuart's Pass and Burt's Plains. The zoological collections formed are said to be generally good, and it has again been Prof. Stirling's good fortune to discover a new type of Marsupial. This is stated to be about as big as a small rat, with a shrew-like aspect, and a very curious flattened and fat tail. Its scientific description will probably be undertaken by Prof. Baldwin Spencer. Prof. Stirling again met with his old friend *Notoryctes*, but only obtained two examples, one of them being alive, though it soon died, notwithstanding all the care that was taken of it. The rare Alexandra parakeet was also met with; but in one locality only. Some twenty new species of terrestrial mollusks seem also to have been found, and it is expected that about seven or eight new species of plants are contained in the botanical collection, which shows a greatly extended range of many kinds that had before been supposed to be much restricted. An examination of the geological formations is adverse to the hope of metalliferous developments to the southward of the Macdonnell Ranges. It remains to be said that all the journeying was accomplished by the aid of camels, which, as before, proved themselves to be essential agents in the exploration of Central Australia. The mode in which the scientific results of the expedition are to be published is uncertain, and possibly will not be decided until the return to Adelaide of Mr. Horn, who defrayed all, or nearly all, the cost, and is accordingly to be congratulated—together with the several members of the expedition—on the success which has attended an enterprise which has been conducted with so much good spirit.

We learn from the *Botanical Gazette* that an expedition through Eastern Africa for the collection of natural history specimens, and to secure photographs, was intended to start from Pretoria about August 1. Passing through Matabeleland, the extreme western portion of the East African Portuguese possessions, and along the western shore of Lake Nyassa, it expected to reach Zanzibar in about twelve months. The chief attention will be paid to plants and insects.

Dr. A. Baldacci is at present engaged on a botanical expedition in the Balkan Peninsula, with the especial object of exploring the mountain-chains of Albania.

We learn, from the *American Naturalist*, that the University of Illinois is about to open a permanent station on the Illinois River, for the biological study of the flora and fauna of the waters of that State. The laboratory will be established at Havana, and, together with the State Fish Commission, will be under the direction of Prof. S. A. Forbes. Among the problems to be investigated are the effect of the periodical overflow and recession of the river on the abundance, variety, and interaction generally of the various groups of plants and animals represented in those waters.

The following are the subjects for competition for the two Walker Prizes in Natural History, given annually by the Boston (Mass.) Society of Natural History for the next two years:—1895: A study of the "Fall Line" in New Jersey; (2) a study of the Devonian formation of the Ohio Basin; (3) relations of the order Plantoginaceæ; (4) experimental investigations in Morphology or Embryology. 1896: (1) A study of the area of schistose or foliated rocks in the Eastern United States; (2) a study of the development of River Valleys in some considerable area of folded or faulted Appalachian structure in Pennsylvania, Virginia, or Tennessee; (3) an experimental study of the effects of close-fertilisation in the case of some plant of short cycle; (4) contributions to our knowledge of the general morphology or the general physiology of any animal, except man. The memoirs must be written in the English language, and the prizes of the value of 60 and 50 dollars respectively—the competition for which is open to all—will not be awarded unless the memoirs presented are of adequate merit. Each memoir must be accompanied by a sealed envelope enclosing the author's name and superscribed with a motto corresponding to one borne by the manuscript, and must be in the hands of the Secretary on or before the first of April of the year for which the prize is offered.

The French Society for the Encouragement of National Industry has issued a list of prizes to be offered for competition next year in connection with chemical research. The following are among the principal subjects proposed: (1) Recent progress in the manufacture of chlorine; prize, 2000 francs. (2) The utilisation of the residues of manufactories; prize, 1000 francs. (3) A prize of 2000 francs for an experimental study of the physical or mechanical properties of one or several metals or alloys, chosen from those that are in current use. (4) 2000 francs for manufacturing in France, for trade purposes, anhydrous sulphuric acid and "smoking" sulphuric acid. A special note is given with each subject explaining the reasons for which the prize is offered, but it is understood that the money will be withheld in the event of the papers sent in not proving sufficiently interesting.

The Entomological Society will meet on Wednesday, October 3, at 8 p.m., when the following papers will be read:—"Catalogue of the *Pterophoridæ*, *Tortricidæ*, and *Tineidæ* of the Madeira Islands, with notes and descriptions of New Species," by Lord Walsingham, F.R.S.; "Palæarctic Nemouræ," by Kenneth J. Morton.

The majority of the Medical Schools of the metropolis will open on Monday next, and in several instances an introductory address will be dispensed with, and in its place some form of festive gathering will be held. Addresses will, however, be delivered as follows:—At St. George's Hospital, by Dr. Isambard Owen, the dean of the school; at Guy's Hospital, by Mr. Lockhart Stephens; at St. Mary's Hospital, by Dr. Scanes Spicer; at the Middlesex Hospital, by Dr. Boxall; at University College Hospital, by Dr. H. R. Spencer; at Westminster Hospital, by Mr. G. Hartridge; and at the School of Medicine for Women, by Miss M. Sturge. There will be dinners in connection with the following hospitals:—St. Bartholomew's, St. Thomas's, the London, St. George's, King's College, St. Mary's, the Middlesex, and the Westminster. At the Charing Cross Hospital there will be an evening reception, at which the prizes for the year will be distributed by Prof. Alexander Macalister, F.R.S. The Rector of Lincoln College, Oxford, will distribute the prizes at the St. Thomas's Hospital.

Prof. H. Alleyne Nicholson will deliver the Swiney Lectures on Geology on the Mondays, Wednesdays and Fridays of October, taking as his subject "The Making of the Earth's Crust." The lectures, for which no charge for admittance is made, will be delivered at 3 p.m. in the Lecture Theatre of the South Kensington Museum. The Swiney Lecturer for next year is Dr. J. G. Garson.

The eighteenth course of lectures of the Sanitary Institute will be delivered at the Parkes Museum, Margaret Street, W., at 8 p.m. on each Monday, Wednesday, and Friday of this autumn, from Wednesday, October 17, when the opening lecture, which is specially intended for those desirous of becoming sanitary officers, will be delivered. The secretary of the institute will be happy to supply full information respecting the lectures.

The following popular science lectures will be delivered at the Royal Victoria Hall, Waterloo Bridge-road, S.E., during the coming month:—October 2, on "Hearing," by Prof. W. D. Halliburton; October 9, on "Wonders in Nature," by Mr. R. Kerr; October 16, on "The Work of the Air on the Earth," by Mr. F. W. Rudler; October 30, on "Light, what it is and how it is measured," by Prof Carlton Lambert. There will also be a lecture on October 23, but the subject has yet to be decided upon. Each lecture will be illustrated by means of the lantern.

The prospectus has been issued of a very elaborate "Systematic Botany of North America," to be published in seventeen vols., by a Board of editors under the presidency of Prof. N. L. Britton. The account of each natural order will be a monograph by a separate author. The area comprised in the "Flora" will be the American continent north of Mexico.

The *Lancet* states that the Queen has been graciously pleased to intimate to Dr. Thorne Thorne, C.B., the principal medical officer of the Local Government Board, her appreciation of the services which have been rendered by the Medical Department of the Board in taking the measures which it has adopted for preventing the entrance of cholera into this country.

A new chemical laboratory, in connection with the Imperial University of St. Petersburg, will be opened next month. The building will contain, in addition to laboratories and a lecture theatre, dwelling accommodation for the professors and their assistants. The cost of erection has been over £25,000, four-fifths of which have been defrayed by the Minister of Education, and the remainder by the University.

A circular has been sent to us announcing the conditional re-starting of our American contemporary *Science*, the publication of which was on March 23 suspended, owing to lack of support. The journal is to be subsidised by the American Association for the Advancement of Science, and by Prof. A. Graham Bell and the Hon. Gardiner G. Hubbard; and provided there be a liberal response to the circular from intending subscribers, the journal will be resuscitated before long.

Prof. Brunchorst has published an account of the laboratory and scientific appliances of the Marine Zoological Station at Bergen. Established in 1892, the station has always been kept open throughout the entire year, the fjords on the west coast of Norway remaining open throughout the winter, and the air temperature seldom falling much below the freezing-point.

The following ode to Helmholtz appeared in *Punch* of last week, and seems to us so admirable that we reprint it:—

HELMHOLTZ.

What matter titles? Helmholtz is a name
That challenges, alone, the award of Fame!
When Emperors, Kings, Pretenders, shadows all,
Leave not a dust-trace on our whirling ball,
Thy work, oh grave-eyed searcher, shall endure,
Unmarred by faction, from low passion pure.
To bridge the gulf 'twixt matter-veil and mind
Perchance to mortals, dull sensed, slow, purblind,
Is not permitted—yet; but patient, keen,
Thou on the shadowy track beyond the Seen,
Didst dog the elusive truth, and seek in sound
The secret of soul-mysteries profound,
Essential Order, Beauty's hidden law!
Marvels to strike more sluggish souls with awe,
Great seekers, lonely-souled, explore that track,
We welcome the wild wonders they bring back
From ventures stranger than an earthly Pole
Can furnish. Distant still that mental goal
To which great spirits strain; but when calm Fame
Sums its bold seekers, Helmholtz, thy great name
Among the foremost shall eternal stand,
Science's pride, and glory of thy land.

From time to time paragraphs appear in the daily papers informing the public that a cure for consumption has been discovered. The last of these so-called discoveries has been heralded in the *Times* (September 14), where it is stated on the authority (?) of the Havas Agency, that a Genoese physician has been able to cure twenty-five out of twenty-seven hopeless cases of consumption by the subcutaneous injection of asses' blood. Strangely enough, the medical papers have remained silent, and we cannot help thinking that it would have been well had the *Times* not been so eager to advertise this mode of treatment before it had gone through the ordeal of medical criticism. The subcutaneous injection of serum of animals into phthisical patients has been extensively tried already and has failed, and it is not likely that asses' serum would have more therapeutic properties than that of dogs or goats, which has proved a failure. It is likely, moreover, that such a premature announcement will do a great deal of harm by raising the hopes of patients and their friends—hopes which are almost sure to be disappointed.

According to news received by the Agent-General for Tasmania, the whale fishery industry of that colony, which for some years past has been in a feeble condition, has recently undergone a revival, whales having been frequently seen on the Tasmanian coasts within the last month or so.

The third annual report of the Department of Agriculture of the Yorkshire College, Leeds, has reached us, and tells of a vast amount of work accomplished during the period under review.—1893–94. The courses of lectures for farmers, &c., and classes for elementary teachers and dairy teachers, and the travelling dairy schools, seem, on the whole, to have been well attended, and the committee has reason for the feeling of satisfaction to which it gives expression. A prospectus of the courses in agriculture for the session 1894–95 is now ready, and may be had of the secretary.

A series of new boron compounds containing fluorine and alcohol radicles, derived from the interaction of boron fluoride and alcohols, are described by M. Gasselin in the September number of the *Annales de Chimie et de Physique*. The mono- and di-fluorine compounds derived from methyl and ethyl alcohol have been isolated in the pure state, and prove to be substances of great chemical activity, affording numerous interesting reactions. When boron trifluoride gas is passed into methyl or ethyl alcohol, strongly cooled by a freezing mixture, the gas is rapidly absorbed and the liquid becomes considerably heated. The reaction occurs in exactly equal molecular proportions, and upon subsequent distillation of the liquid product two main substances are eventually isolated. The first is the di-fluorine compound $B\begin{smallmatrix}F_2\\ OCH_3\end{smallmatrix}$ or $B\begin{smallmatrix}F_2\\ OC_2H_5\end{smallmatrix}$, while the second is a remarkable molecular compound of boron trifluoride with methyl or ethyl ether, $BF_3.(CH_3)_2O$ or $BF_3.(C_2H_5)_2O$. The reaction is quantitatively expressed by the following equation, in which R represents the alkyl radicle:

$$7\,BF_3 + 7\,ROH = B\begin{smallmatrix}F_2\\ OR\end{smallmatrix} + 3\,(BF_3 . R_2O) + 2\,BF_4H + 2\,HF + B(OH)_3.$$

Di-fluor methyl borate $B\begin{smallmatrix}F_2\\ OCH_3\end{smallmatrix}$ distils over as a colourless liquid boiling at 89°. It solidifies in the receiver in the form of long crystals which melt at 41°·5. The analogous ethyl compound boils at 82°, and the crystals melt at 23°. The liquids fume strongly in the air, disseminating suffocating vapours. Water decomposes them with great energy, producing boric acid, fluoboric acid, and the free alcohol. They are insoluble in hydrocarbons, but dissolve with decomposition in alcohol. They are quite permanent in contact with metallic sodium, even under pressure at 100°. Sodium methylate or ethylate, however, react with great energy when brought in contact with them, and if equal molecular proportions are employed, the mono-fluorine compounds are produced.

$$B\begin{smallmatrix}F_2\\ OR\end{smallmatrix} + RONa = B\begin{smallmatrix}F\\ (OR)_2\end{smallmatrix} + NaF.$$

The methyl compound $B\begin{smallmatrix}F\\ (OCH_3)_2\end{smallmatrix}$ boils at 53°, and is a particularly mobile and strongly fuming liquid, which burns with a brilliant green flame, surrounded by a dense white cloud. The ethyl compound is a liquid of similar properties, which boils at 78°. Water decomposes both compounds with some violence and considerable evolution of heat. The molecular compounds of boron trifluoride with methyl and ethyl ether are fuming liquids boiling, respectively, at 126° and 123°, which are likewise energetically decomposed by water. They have been independently prepared by direct union of gaseous boron fluoride with gaseous methyl ether in the one case, and ordinary ethyl ether in the other. The union is instantaneous, and accompanied by considerable rise of temperature in each case. In the case of the formation of the methyl compound a dense cloud is produced the moment the constituent gases come in contact, and the sides of the vessel become covered by hot drops of liquid which rapidly coalesce to form a considerable bulk of the new substance.

The additions to the Zoological Society's Gardens during the past week include a Sykes's Monkey (*Cercopithecus albigularis*, ♂) from East Africa, presented by Miss Marion L. Leitch; a Macaque Monkey (*Macacus cynomolgus*, ♀) from India, presented by Captain W. Townsend; two Alligators (*Alligator mississippiensis*) from the Mississippi, presented by Mr. L. Watson; two Giant Toads (*Bufo marinus*) from Brazil, presented by F. E. Blaaw, Esq.; twenty European Tree Frogs (*Hyla arborea*) European, presented by Mr. G. B. Coleman; an Ostrich (*Struthio camelus*, ♂) from Africa, a Greater Sulphur-crested Cockatoo (*Cacatua galerita*) from Australia, deposited; a Red-sided Eclectus (*Eclectus pectoralis*) from New Guinea, a Toco Toucan (*Rhamphastos toco*) from Guiana, a Diamond Snake (*Morelia spilotes*) from New South Wales, received in exchange; an African Wild Ass (*Equus taeniopus*, ♂), an Axis Deer (*Cervus axis*, ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

The Accuracy of Astronomical Observations.—At the tenth general meeting of the Association Géodésique Internationale, Prof. Cornu read a paper on the necessity of introducing additional precautions in astronomical observations requiring great accuracy. The subject of the paper was suggested by the interpretation put upon observed variations of latitude. Prof. Cornu first remarked that, while carrying out their experiments on the earth's density some time ago, J. B. Baille and himself found that the constant of gravitation appeared to undergo an annual variation, being a little greater in spring than in autumn. A minute examination of the experimental conditions showed the investigators that this periodic anomaly was purely an apparent phenomenon, and that it was caused by an annual variation in the temperature of the room in which the apparatus was placed. It is impossible not to be struck with the analogy of these results and those of the variations of latitude. In both cases the period is approximately an annual one, and the maxima and minima occur in spring and autumn respectively. The question arises, therefore, whether astronomers have been careful to eliminate all the meteorological causes affecting their results, and whether their claims for marvellous accuracy are not, to some extent, exaggerated. Prof. Cornu has applied the reasoning of the physicist to astronomical observations and instruments. Beginning with the meridian circle, he points out that, on a divided circle one metre in diameter, one-tenth of a second of arc corresponds in round numbers to $\frac{1}{2000000}$ of a metre, or 0.0005 mm., that is, a semi-micron. But numerous metrological experiments have shown that, even under the most favourable conditions, a semi-micron is the limit of precision in differential linear measures on scales one metre long; and to attain this limit, it is necessary to put the scales side by side in a bath having a practically constant temperature. But the circles of meridian instruments are subjected to all sorts of variations, hence it seems affectation to assume that observations made with them are true to one-tenth of a second of arc; yet that assumption is made in the discussion of observations of latitudinal variations. When the spirit-level, the telescope, and the micrometer are criticised from this physical point of view, they are found wanting in the extreme accuracy usually ascribed to them. And, in addition to the innate defects in the parts of a meridian instrument, there are the temperature variations which almost baffle estimation. Several additional precautions should be taken to reduce this vitiating cause. In the first place, the distribution of temperature around and inside the instrument should be frequently determined, so that the proper corrections for refraction could be made. The conductivity of the parts of the instrument ought also to be increased, and made as nearly equal as possible, in order to reduce flexional and torsional effects produced by inequality of temperature. Another improvement would be to reduce the quantity of heat emitted by light-sources in observatories, and, finally, attempts should be made to give the air in the telescope tube the same temperature as that outside; so that systematic errors of refraction might be eliminated. Prof. Cornu thinks it is only by having recourse to precautions of this kind that definite results on the variability of latitudes can be obtained. In the actual state of the observations, he says, two purely physical objections exist against the reality of the phenomenon. They are:—(1) Is it certain that observations of latitude by the Talcott method are free from periodic annual errors due to meteorological influences, particularly to the variation of temperature during different seasons? (2) Can it be demonstrated that the astronomical data used in the preparation of the catalogues of the stars employed in these observations are also free from the errors referred to?

Liverpool Observatory.—In a small pamphlet, published by order of the Mersey Docks and Harbour Board, we have placed before us some extracts from the report of the Director of the Observatory, Mr. W. E. Plummer, to the Marine Committee. The excessive briefness of the extracts in question curtail our remarks very considerably. The transit instrument, for time determinations, has been used on every possible occasion, and the normal clock has been maintained more accurately during cloudy weather by the adoption of separate clock errors and rates for the Bond and Molyneux clocks. The determination of the longitude (not *longtitude*, as is twice printed) of the Observatory has not yet been completed, as the repetition of the signals has not yet been effected, but the inquiry at present indicates a change from previous values, the Observatory acquiring a new position some 400 yards west of the old one. The latitude observations, by the method of transits of zenith stars over the prime vertical, although said to give this quantity with great exactness, are likely to be disappointing when used for discussing the small variation in latitude, for the instrument and its mounting have shown signs of a slight instability. Besides the observations of comets, stellar parallaxes, by the method of chronographic record of meridian transits, have been investigated. The meteorological observations have, as usual, been continued, and the present report contains numerous tables of the results obtained.

The Variable R Lyræ.—The variability of this star was first pointed out by Baxendall in 1856, and its period was stated to be one of forty-eight days. At a somewhat later date Schonfeld, from a few more observations, deduced a forty-six-day period. Generally the observations have been somewhat scarce, but more recently their number has been considerably increased Yendell, Sawyer, Plassmann, and Knopf having been chiefly responsible for these. That the time had arrived when a more thorough investigation of this "lichtwechsel" might be attempted, is the opinion of Herr A. Pannekoek, and the details of his work will be found in *Astronomische Nachrichten*, No. 3252. In the examination of the observations it was soon found out that the period did not appear to remain constant. In the earlier epochs, commencing in 1887 and continuing up to the past year, the numbers indicated clearly a period of about forty-six days, but recently they have somewhat increased. In general, also, it has been noticed that the time for the increase in the light curve is shorter than that for the decrease. Herr Pannekoek concludes, however, from his work, that R Lyræ does not vary its brightness so irregularly as is supposed. He suggests that the observed apparent deviations recorded can be attributed to special errors of observation. He is of opinion, however, that perhaps when many more observations are at hand, we shall be in a far better position to investigate the subject more thoroughly, and to state more definitely through what amplitudes these light variations swing.

The Cleaning of Object-glasses.—Owners of telescopes (refractors) will no doubt be glad to have a few words of practical advice, from one who can speak from long experience, with regard to the cleaning of object-glasses. The advice in question is extracted from an article, by Mr. Brashear, in the September number of *Popular Astronomy*, and we do not hesitate in helping to distribute it. The reader may be rather surprised to hear that the use of fine chamois-skin, tissue-paper, or an old soft silk handkerchief, or "any other such material to wipe lenses, as is usually advised," are not advocated. The reason for this is, not that the materials themselves do the mischief, but that the chief enemy to an object-glass, "dust particles," and these most likely of a siliceous nature, must not on any account be rubbed on the glassy surface. The receipt, in a few words, may be summed up as follows:—If the lenses be dirty or dusty, a tuft of cotton or a camel's-hair brush may be at first applied, but pains should be taken that no pressure be given to either. For further cleaning, a *wooden* bowl, previously washed out with soap and water, should be filled with clean water of approximately the same temperature as the objective. A little ammonia (quantity, a teaspoonful to half a pail of water) should be added to the water. "Cheese-cloth" is strongly recommended as a means of applying the soap to the glass; but this, first, should be "thoroughly washed with soap and water," and thrown away when done with. Plenty of water must always be used. A third or fourth cloth should be used to wipe the objective dry. "Vigorous rubbing will do no harm if the surfaces have no abrading material on them, and I have yet to injure a glass cleaned in this way." If the objective be not taken from the cell, the camel's-hair brush and the soap-and-water process can be still used, and the work finished with a dry cheese-cloth. Mr. Brashear gives good reasons for taking the lenses apart from time to time, and giving them a thorough clean; and he adds that everyone who owns and uses a telescope should be so familiar with his objective that he can take it apart and put it together just as well as the maker of it. In moist climates particularly this should be done frequently.

ON THE MAGNITUDE OF THE SOLAR SYSTEM.[1]

NATURE may be studied in two widely different ways. On the one hand, we may employ a powerful microscope which will render visible the minutest forms and limit our field of view to an infinitesimal fraction of an inch situated within a foot of our own noses; or, on the other hand, we may occupy some commanding position, and from thence, aided perhaps by a telescope, we may obtain a comprehensive view of an extensive region. The first method is that of the specialist, the second is that of the philosopher, but both are necessary for an adequate understanding of nature. The one has brought us knowledge wherewith to defend ourselves against bacteria and microbes which are among the mostly deadly enemies of mankind, and the other has made us acquainted with the great laws of matter and force upon which rests the whole fabric of science. All nature is one, but for convenience of classification we have divided our knowledge into a number of sciences which we usually regard as quite distinct from each other. Along certain lines, or, more properly, in certain regions, these sciences necessarily abut on each other, and just there lies the weakness of the specialist. He is like a wayfarer who always finds obstacles in crossing the boundaries between two countries, while to the traveller who gazes over them from a commanding eminence the case is quite different. If the boundary is an ocean shore, there is no mistaking it; if a broad river or a chain of mountains, it is still distinct; but if only a line of posts traced over hill and dale, then it becomes lost in the natural features of the landscape, and the essential unity of the whole region is apparent. In that case the border-land is wholly a human conception of which nature takes no cognisance, and so it is with the scientific border-land to which I propose to invite your attention this evening.

To the popular mind there are no two sciences further apart than astronomy and geology. The one treats of the structure and mineral constitution of our earth, the causes of its physical features and its history; while the other treats of the celestial bodies, their magnitudes, motions, distances, periods of revolution, eclipses, order, and of the causes of their various phenomena. And yet many, perhaps I may even say most, of the apparent motions of the heavenly bodies are merely reflections of the motions of the earth, and in studying them we are really studying it. Furthermore, precession, nutation, and the phenomena of the tides depend largely upon the internal structure of the earth, and there astronomy and geology merge into each other. Nevertheless the methods of the two sciences are widely different, most astronomical problems being discussed quantitatively by means of rigid mathematical formulæ, while in the vast majority of cases the geological ones are discussed only qualitatively, each author contenting himself with a mere statement of what he thinks. With precise data the methods of astronomy lead to very exact results, for mathematics is a mill which grinds exceeding fine; but after all, what comes out of a mill depends wholly upon what is put into it, and if the data are uncertain, as is the case in most cosmological problems, there is little to choose between the mathematics of the astronomer and the guesses of the geologist.

If we examine the addresses delivered by former presidents of this Association, and of the sister—perhaps it would be nearer the truth to say the parent Association on the other side of the Atlantic—we shall find that they have generally dealt either with the recent advances in some broad field of science, or else with the development of some special subject. This evening I propose to adopt the latter course, and I shall invite your attention to the present condition of our knowledge respecting the magnitude of the solar system; but in so doing, it will be necessary to introduce some considerations derived from laboratory experiments upon the luminiferous ether, others derived from experiments upon ponderable matter, and still others relating both to the surface phenomena and to the internal structure of the earth, and thus we shall deal largely with the border-land where astronomy, physics, and geology merge into each other.

The relative distances of the various bodies which compose the solar system can be determined to a considerable degree of approximation with very crude instruments as soon as the true plan of the system becomes known, and that plan was taught by Pythagoras more than five hundred years before Christ. It must have been known to the Egyptians and Chaldeans still earlier, if Pythagoras really acquired his knowledge of astronomy from them, as is affirmed by some of the ancient writers, but on that point there is no certainty. In public Pythagoras seemingly accepted the current belief of his time, which made the earth the centre of the universe, but to his own chosen disciples he communicated the true doctrine that the sun occupies the centre of the solar system, and that the earth is only one of the planets revolving around it. Like all the world's greatest sages, he seems to have taught only orally. A century elapsed before his doctrines were reduced to writing by Philolaus of Crotona, and it was still later before they were taught in public for the first time by Hicetas, or, as he is sometimes called, Nicetas, of Syracuse. Then the familiar cry of impiety was raised, and the Pythagorean system was eventually suppressed by that now called the Ptolemaic, which held the field until it was overthrown by Copernicus almost two thousand years later. Pliny tells us that Pythagoras believed the distances to the sun and moon to be respectively 252,000 and 12,600 stadia, or taking the stadium at 625 feet, 29,837 and 1492 English miles; but there is no record of the method by which these numbers were ascertained.

After the relative distances of the various planets are known, it only remains to determine the scale of the system, for which purpose the distance between any two planets suffices. We know little about the early history of the subject, but it is clear that the primitive astronomers must have found the quantities to be measured too small for detection with their instruments, and even in modern times the problem has proved to be an extremely difficult one. Aristarcus of Samos, who flourished about 270 B.C., seems to have been the first to attack it in a scientific manner.

Stated in modern language, his reasoning was that when the moon is exactly half full, the earth and sun as seen from its centre must make a right angle with each other, and by measuring the angle between the sun and moon, as seen from the earth at that instant, all the angles of the triangle joining the earth, sun, and moon would become known, and thus the ratio of the distance of the sun to the distance of the moon would be determined. Although perfectly correct in theory, the difficulty of deciding visually upon the exact instant when the moon is half full is so great that it cannot be accurately done even with the most powerful telescopes. Of course, Aristarcus had no telescope, and he does not explain how he effected the observation, but his conclusion was that at the instant in question the distance between the centres of the sun and moon, as seen from the earth, is less than a right angle by 1/30 part of the same. We should now express this by saying that the angle is 87°; but Aristarcus knew nothing of trigonometry, and in order to solve his triangle he had recourse to an ingenious but long and cumbersome geometrical process which has come down to us, and affords conclusive proof of the condition of Greek mathematics at that time. His conclusion was that the sun is nineteen times further from the earth than the moon, and if we combine that result with the modern value of the moon's parallax, viz. 3422·38 seconds, we obtain for the solar parallax 180 seconds, which is more than twenty times too great.

The only other method of determining the solar parallax known to the ancients was that devised by Hipparchus about 150 B.C. It was based on measuring the rate of decrease of the diameter of the earth's shadow cone by noting the duration of lunar eclipses, and as the result deduced from it happened to be nearly the same as that found by Aristarcus, substantially his value of the parallax remained in vogue for nearly two thousand years, and the discovery of the telescope was required to reveal its erroneous character. Doubtless this persistency was due to the extreme minuteness of the true parallax, which we now know is far too small to have been visible upon the ancient instruments, and thus the supposed measures of it were really nothing but measures of their inaccuracy.

The telescope was first pointed to the heavens by Galileo in 1609, but it needed a micrometer to convert it into an accurate measuring instrument, and that did not come into being until 1639, when it was invented by William Gascoigne. After his death in 1644, his original instrument passed to Richard Townley, who attached it to a fourteen-foot telescope at his residence in Townley, Lancashire, England, where it was used by Flamsteed in observing the diurnal parallax of Mars during its oppo-

[1] Address [illegible] before the [illegible] Association [illegible] at its Brooklyn Meeting, August [illegible], by the retiring President, William Harkness.

sition in 1672. A description of Gascoigne's micrometer was published in the "Philosophical Transactions" in 1667, and a little before that a similar instrument had been invented by Auzout in France; but observatories were fewer then than now, and so far as I know J. D. Cassini was the only person beside Flamsteed who attempted to determine the solar parallax from that opposition of Mars. Foreseeing the importance of the opportunity, he had Richer despatched to Cayenne some months previously, and when the opposition came he effected two determinations of the parallax; one being by the diurnal method, from his own observations in Paris, and the other by the meridian method, from observations in France by himself, Romer and Picard, combined with those of Richer at Cayenne. This was the transition from the ancient instruments with open sights to telescopes armed with micrometers, and the result must have been little short of stunning to the seventeenth century astronomers, for it caused the hoary and gigantic parallax of about 180 seconds to shrink incontinently to ten seconds, and thus expanded their conception of the solar system to something like its true dimensions. More than fifty years previously Kepler had argued from his ideas of the celestial harmonies that the solar parallax could not exceed sixty seconds, and a little later Horrocks had shown on more scientific grounds that it was probably as small as fourteen seconds, but the final death-blow to the ancient values, ranging as high as two or three minutes, came from these observations of Mars by Flamsteed, Cassini, and Richer.

Of course the results obtained in 1672 produced a keen desire on the part of astronomers for further evidence respecting the true value of the parallax, and as Mars comes into a favourable position for such investigations only at intervals of about sixteen years, they had recourse to observations of Mercury and Venus. In 1677 Halley observed the diurnal parallax of Mercury, and also a transit of that planet across the sun's disc at St. Helena, and in 1681 J. D. Cassini and Picard observed Venus when she was on the same parallel with the sun; but although the observations of Venus gave better results than those of Mercury, neither of them was conclusive, and we now know that such methods are inaccurate, even with the powerful instruments of the present day. Nevertheless, Halley's attempt by means of the transit of Mercury ultimately bore fruit in the shape of his celebrated paper of 1716, wherein he showed the peculiar advantages of transits of Venus for determining the solar parallax. The idea of utilising such transits for this purpose seems to have been vaguely conceived by James Gregory, or perhaps even by Horrocks; but Halley was the first to work it out completely, and long after his death his paper was mainly instrumental in inducing the Governments of Europe to undertake the observations of the transits of Venus in 1761 and 1769, from which our first accurate knowledge of the sun's distance was obtained.

Those who are not familiar with practical astronomy may wonder why the solar parallax can be got from Mars and Venus, and not from Mercury, or the sun itself. The explanation depends on two facts—firstly, the nearest approach of these bodies to the earth is for Mars 33,874,000 miles, for Venus 23,654,000 miles, for Mercury 47,935,000 miles, and for the sun 91,239,000 miles. Consequently, for us, Mars and Venus have very much larger parallaxes than Mercury or the sun, and of course the larger the parallax the easier it is to measure. Secondly, even the largest of these parallaxes must be determined within far less than one-tenth of a second of the truth; and while that degree of accuracy is possible in measuring short arcs, it is quite unattainable in long ones. Hence one of the most essential conditions for the successful measurement of parallaxes is that we shall be able to compare the place of the near body with that of a more distant one situated in the same region of the sky. In the case of Mars, that can always be done by making use of a neighbouring star, but when Venus is near the earth she is also so close to the sun that stars are not available, and consequently her parallax can be satisfactorily measured only when her position can be accurately referred to that of the sun; or, in other words, only during her transits across the sun's disk. But even when the two bodies to be compared are sufficiently near each other, we are still embarrassed by the fact that it is more difficult to measure the distance between the limb of a planet and a star or the limb of the sun, than it is to measure the distance between two stars; and since the discovery of so many asteroids, that circumstance has led to their use for determinations of the solar parallax. Some of these bodies approach within 75,230,000 miles of the earth's orbit, and as they look precisely like stars, the increased accuracy of pointing on them fully makes up for their greater distance, as compared with Mars or Venus.

After the Copernican system of the world and the Newtonian theory of gravitation were accepted, it soon became evident that trigonometrical measurements of the solar parallax might be supplemented by determinations based on the theory of gravitation, and the first attempts in that direction were made by Machin in 1729 and T. Mayer in 1753. The measurement of the velocity of light between points on the earth's surface, first effected by Fizeau in 1849, opened up still other possibilities, and thus for determining the solar parallax we now have at our command no less than three entirely distinct classes of methods, which are known respectively as the trigonometrical, the gravitational, and the photo-tachymetrical. We have already given a summary sketch of the trigonometrical methods, as applied by the ancient astronomers to the dichotomy and shadow cone of the moon, and by the moderns to Venus, Mars, and the asteroids, and we shall next glance briefly at the gravitational and photo-tachymetrical methods.

The gravitational results which enter directly or indirectly into the solar parallax are six in number, to wit: first, the relation of the moon's mass to the tides; second, the relation of the moon's mass and parallax to the force of gravity at the earth's surface; third, the relation of the solar parallax to the masses of the earth and moon; fourth, the relation of the solar and lunar parallaxes to the moon's mass and parallactic inequality; fifth, the relation of the solar and lunar parallaxes to the moon's mass and the earth's lunar inequality; sixth, the relation of the constants of nutation and precession to the moon's parallax.

Respecting the first of these relations, it is to be remarked that the tide-producing forces are the attraction of the sun and moon upon the waters of the ocean, and from the ratio of these attractions the moon's mass can readily be determined. But unfortunately the ratio of the solar tides to the lunar tides is affected both by the depth of the sea and by the character of the channels through which the water flows, and for that reason the observed ratio of these tides requires multiplication by a correcting factor in order to convert it into the ratio of the forces. The matter is further complicated by this correcting factor varying from port to port, and in order to get satisfactory results long series of observations are necessary. The labour of deriving the moon's mass in this way was formerly so great that for more than half a century La Place's determination from the tides at Brest remained unique, but the recent application of harmonic analysis to the data supplied by self-registering tide gauges is likely to yield abundant results in the near future.

Our second gravitational relation, viz. that connecting the moon's mass and parallax with the force of gravity at the earth's surface, affords an indirect method of determining the moon's parallax with very great accuracy if the computation is carefully made, and with a fair approximation to the truth even when the data are exceedingly crude. To illustrate this, let us see what could be done with a railroad transit such as is commonly used by surveyors, a steel tape, and a fairly good watch. Neglecting small corrections due to the flattening of the earth, the centrifugal force at its surface, the eccentricity of its orbit, and the mass of the moon, the law of gravitation shows that if we multiply together the length of the seconds pendulum, the square of the radius of the earth, and the square of the length of the sidereal month, divide the product by four, and take the cube root of the quotient, the result will be the distance from the earth to the moon. To find the length of the seconds pendulum we would rate the watch by means of the railroad transit, and then making a pendulum out of a spherical leaden bullet suspended by a fine thread, we would adjust the length of the thread until the pendulum made exactly 300 vibrations in five minutes by the watch. Then, supposing the experiment to be made here, or in New York city, we would find that the distance from the point of suspension of the thread to the centre of the bullet was about 39 and 1/8 inches, and dividing that by the number of inches in a mile, viz. 63,360, we would have for the length of the seconds pendulum one-sixteen hundred and twentieth of a mile. The next step would be to ascertain the radius of the earth, and the quickest way of doing so would probably be, first, to determine the latitude of some point in New York city by means of the railroad transit; next, to run a traverse survey along the old Post Road from New York to Albany, and finally, to determine the latitude of some point in Albany. The traverse survey should surely be correct to one part in three hundred, and as the distance between the two cities is about two degrees, the difference of latitude might be determined to about the same percentage of accuracy. In that way we would find the length of two degrees of latitude to be about 138 miles, whence the earth's radius would be 3953 miles. It would then only remain to observe the time occupied by the moon in making a sidereal revolution around the earth, or, in other words, the time which she occupies in moving from any given star back to the same star again. By noting that to within one-quarter of her own diameter we should soon find that the time of a revolution is about 27·32 days, and multiplying that by the number of seconds in a day, viz. 86,400, we would have for the length of the sidereal month 2,360,000 seconds. With these data the computation would stand as follows:—The radius of the earth, 3953 miles, multiplied by the length of a sidereal month, 2,360,000 seconds, and the product squared, gives 87,060.000,000,000,000,000. Multiplying that by one-fourth of the length of the seconds pendulum, viz. 1 6480 of a mile, and extracting the cube root of the product, we would get 237,700 miles for the distance from the earth to the moon, which is only about 850 miles less than the truth, and certainly a remarkable result considering the crudeness of the instruments by which it might be obtained. Nevertheless, when all the conditions are rigorously taken into account, these data are to be regarded as determining the relation between the moon's mass and parallax rather than the parallax itself.

Our third gravitational relation, to wit, that existing between the solar parallax, the solar attractive force and the masses of the earth and moon, is analogous to the relation existing between the moon's mass and parallax and the force of gravity at the earth's surface, but it cannot be applied in exactly the same way, on account of our inability to swing a pendulum on the sun. We are therefore compelled to adopt some other method of determining the sun's attractive force, and the most available is that which consists in observing the perturbative action of the earth and moon upon our nearest planetary neighbours, Venus and Mars. From this action the law of gravitation enables us to determine the ratio of the sun's mass to the combined masses of the earth and moon, and then the relation in question furnishes a means of comparing the masses so found with trigonometrical determinations of the solar parallax. Thus it appears that notwithstanding necessary differences in the methods of procedure, the analogy between the second and third gravitational relations holds not only with respect to their theoretical basis, but also in their practical application, the one being used to determine the relation between the mass of the moon and its distance from the earth, and the other to determine the relation between the combined masses of the earth and noon and their distance from the sun.

Our fourth gravitational relation deals with the connection between the solar parallax, the lunar parallax, the moon's mass and the moon's parallactic inequality. The important quantities are here the solar parallax and the moon's parallactic inequality, and although the derivation of the complete expression for the connection between them is a little complicated, there is no difficulty in getting a general notion of the forces involved. As the moon moves around the earth she is alternately without and within the earth's orbit. When she is without, the sun's attraction on her acts with that of the earth; when she is within, the two attractions act in opposite directions. Thus in effect the centrifugal force holding the moon to the earth is alternately increased and diminished, with the result of elongating the moon's orbit towards the sun and compressing it on the opposite side. As the variation of the centrifugal force is not great, the change of the form of the orbit is small, nevertheless the summation of the minute alterations thereby produced in the moon's orbital velocity suffices to put her sometimes ahead, and sometimes behind her mean place to an extent which oscillates from a maximum to a minimum as the earth passes from perihelion to aphelion, and averages about 125 seconds of arc. This perturbation of the moon's node is known as the parallactic inequality because it depends on the earth's distance from the sun, and can therefore be expressed in terms of the solar parallax. Conversely, the solar parallax can be deduced from the observed value of the parallactic inequality, but unfortunately there are great practical difficulties in making the requisite observations with a sufficient degree of accuracy. Notwithstanding the ever-recurring talk about the advantages to be obtained by observing a small well-defined crater instead of the moon's limb, astronomers have hitherto found it impracticable to use anything but the limb, and the disadvantage of doing so as compared with observing a star is still further increased by the circumstances that in general only one limb can be seen at a time, the other being shrouded in darkness. If both limbs could always be observed, we should then have a uniform system of data for determining the place of the centre, but under existing circumstances we are compelled to make our observations half upon one limb and half upon the other, and thus they involve all the systematic errors which may arise from the conditions under which these limbs are observed, and all the uncertainty which attaches to irradiation, personal equation, and our defective knowledge of the moon's semi-diameter.

Our fifth gravitational relation is that which exists between the solar parallax, the lunar parallax, the moon's mass, and the earth's lunar inequality. Strictly speaking, the moon does not revolve around the earth's centre, but both bodies revolve around the common centre of gravity of the two. In consequence of that an irregularity arises in the earth's orbital velocity around the sun, the common centre of gravity moving in accordance with the laws of elliptic motion, while the earth, on account of its revolution around that centre, undergoes an alternate acceleration and retardation which has for its period a lunar month, and is called the lunar inequality of the earth's motion. We perceive this inequality as an oscillation superposed on the elliptic motion of the sun, and its semi-amplitude is a measure of the angle subtended at the sun by the interval between the centre of the earth and the common centre of gravity of the earth and moon. Just as an astronomer on the moon might use the radius of her orbit around the earth as a base for measuring her distance from the sun, so we may use this interval for the same purpose. We find its length in miles from the equatorial semi-diameter of the earth, the moon's parallax and the moon's mass, and thus we have all the data for determining the solar parallax from the inequality in question. In view of the great difficulty which has been experienced in measuring the solar parallax itself, it may be asked why we should attempt to deal with the parallactic inequality which is about twenty-six per cent. smaller? The answer is, because the latter is derived from differences of the sun's right ascension which are furnished by the principal observatories in vast numbers, and should give very accurate results on account of their being made by methods which insure freedom from constant errors. Nevertheless, the sun is not so well adapted for precise observations as the stars, and Dr. Gill has recently found that heliometer measurements upon asteroids which approach very near to the earth yield values of the parallactic inequality superior to those obtained from right ascensions of the sun.

Our sixth gravitational relation is that which exists between the moon's parallax and the constants of precession and nutation. Every particle of the earth is attracted both by the sun and by the moon, but in consequence of the polar flattening the resultant of these attractions passes a little to one side of the earth's centre of gravity. Thus a couple is set up, which, by its action upon the rotating earth, causes the axis thereof to describe a surface which may be called a fluted cone, with its apex at the earth's centre. A top spinning with its axis inclined describes a similar cone, except that the flutings are absent, and the apex is at the point upon which the spinning occurs. For convenience of computation we resolve this action into two components, and we name that which produces the cone the luni-solar precession, and that which produces the flutings the nutation. In this phenomenon the part played by the sun is comparatively small, and by eliminating it we obtain a relation between the luni-solar precession, the nutation and the moon's parallax, which can be used to verify and correct the observed values of these quantities.

In the preceding paragraph we have seen that the relation between the quantities there considered depends largely upon the flattening of the earth, and thus we are led to inquire how and with what degree of accuracy that is determined. There are five methods, viz. one geodetic, one gravitational, and three astronomical. The geodetic method depends upon measurements of the length of a degree on various parts of the earth's surface, and with the data hitherto accumulated it has proved quite unsatisfactory. The gravitational method consists in determining the length of the seconds pendulum over as great a range of latitude as possible, and deducing therefrom the ratio of the earth's polar and equatorial semi-diameters by means of Clairaut's theorem. The pendulum experiments show that the earth's crust is less dense on mountain plateaux than at the sea coast, and thus for the first time we are brought into contact with geological considerations. The first astronomical method consists in observing the moon's parallax from various points on the earth's surface, and as these parallaxes are nothing else than the angular semi-diameter of the earth at the respective points as seen from the moon, they afford a direct measure of the flattening. The second and third astronomical methods are based upon certain perturbations of the moon which depend upon the figure of the earth, and should give extremely accurate results, but unfortunately very great difficulties oppose themselves to the exact measurement of the perturbations. There is also an astronomico-geological method which cannot yet be regarded as conclusive, on account of our lack of knowledge respecting the law of density which prevails in the interior of the earth. It is based upon the fact that a certain function of the earth's moments of inertia can be determined from the observed values of the coefficients of precession and nutation, and could also be determined from the figure and dimensions of the earth if we knew the exact distribution of matter in its interior. Our present knowledge on that subject is limited to a superficial layer not more than ten miles thick, but it is usual to assume that the deeper matter is distributed according to La Grange's law, and then by writing the function in question in a form which leaves the flattening indeterminate, and equating the expression so found to the value given by the precession and nutation, we readily obtain the flattening. As yet these six methods do not give consistent results, and so long as serious discrepancies remain between them, there can be no security that we have arrived at the truth.

It should be remarked that in order to compute the function of the earth's moments of inertia, which we have just been considering, we require not only the figure and dimensions of the earth and the law of distribution of density in its interior, but also its mean and surface densities. The experiments for determining the mean density have consisted in comparing the earth's attraction with the attraction either of a mountain, or of a known thickness of the earth's crust, or of a known mass of metal. In the case of mountains, the comparisons have been made with plumb-lines and pendulum ; in the case of known layers of the earth's crust, they have been made by swinging pendulums at the surface and down in mines ; and in the case of known masses, they have been made with torsion balances, fine chemical balances, and pendulums. The surface density results from a study of the materials composing the earth's crust; but notwithstanding the apparent simplicity of that process, it is doubtful if we have yet attained as accurate a result as in the case of the mean density.

Before quitting this part of our subject, it is important to point out that the luni-solar precession cannot be directly observed, but must be derived from the general precession. The former of these quantities depends only upon the action of the sun and moon, while the latter is affected in addition by the action of all the planets, and to ascertain what that is we must determine their masses. The methods of doing so fall into two great classes, according as the planets dealt with have or have not satellites. The most favourable case is that in which one or more satellites are present, because the mass of the primary follows immediately from their distances and revolution times, but even then there is a difficulty in the way of obtaining very exact results. By extending the observations over sufficiently long periods the revolution times can be ascertained with any desired degree of accuracy, but all measurements of the distance of a satellite from its primary are affected by personal equation, which we cannot be sure of completely eliminating, and thus a considerable margin of uncertainty is brought into the masses. In the cases of Mercury and Venus, which have no satellites, and to a certain extent in the case of the earth also, the only available way of ascertaining the masses is from the perturbations produced by the action of the various planets on each other. These perturbations are of two kinds, periodic and secular. When sufficient data have been accumulated for the exact determination of the secular perturbations, they will give the best results, but as yet it remains advantageous to employ the periodic perturbations also.

Passing now to the photo-tachymetrical methods, we have first to glance briefly at the mechanical appliances by which the tremendous velocity of light has been successfully measured. They are of the simplest possible character, and are based either upon a toothed-wheel, or upon a revolving mirror.

The toothed-wheel method was first used by Fizeau in 1849. To understand its operation, imagine a gun-barrel with a toothed-wheel revolving at right angles to its muzzle in such a way that the barrel is alternately closed and opened as the teeth and the spaces between them pass before it. Then, with the wheel in rapid motion, at the instant when a space is opposite the muzzle, let a ball be fired. It will pass out freely, and after traversing a certain distance, let it strike an elastic cushion and be reflected back upon its own path. When it reaches the wheel, if it hits a space it will return into the gun-barrel, but if it hits a tooth it will be stopped. Examining the matter a little more closely, we see that as the ball requires a certain time to go and return, if during that time the wheel moves through an odd multiple of the angle between a space and a tooth the ball will be stopped, while if it moves through an even multiple of that angle the ball will return into the barrel. Now imagine the gun-barrel, the ball, and the elastic cushion to be replaced respectively by a telescope, a light wave, and a mirror. Then if the wheel be moved at such a speed that the returning light wave struck against the tooth following the space through which it issued, to an eye looking into the telescope all would be darkness. If the wheel moved a little faster and the returning light wave passed through the space succeeding that through which it issued, the eye at the telescope would perceive a flash of light ; and if the speed was continuously increased, a continual succession of eclipses and illuminations would follow each other according as the returning light was stopped against a tooth, or passed through a space further and further behind that through which it issued. Under these conditions the time occupied by the light in traversing the space from the wheel to the mirror and back again would evidently be the same as the time required by the wheel to revolve through the angle between the space through which the light issued and that through which it returned, and thus the velocity of light would become known from the distance between the telescope and the mirror together with the speed of the wheel. Of course the longer the distance traversed, and the greater the velocity of the wheel, the more accurate would be the result.

The revolving mirror method was first used by Foucault in 1862. Conceive the toothed-wheel of Fizeau's apparatus to be replaced by a mirror attached to a vertical axis, and capable of being put into rapid rotation. Then it will be possible so to arrange the apparatus that light issuing from the telescope shall strike the movable mirror and be reflected to the distant mirror, whence it will be returned to the movable mirror again, and being thrown back into the telescope will appear as a star in the centre of the field of view. That adjustment being made, if the mirror were caused to revolve at a speed of some hundred turns per second, it would move through an appreciable angle while the light was passing from it to the distant mirror and back again, and in accordance with the laws of reflection, the star in the field of the telescope would move from the centre by twice the angle through which the mirror had turned. Thus the deviation of the star from the centre of the field would measure the angle through which the mirror turned during the time occupied by light in passing twice over the interval between the fixed and revolving mirrors, and from the magnitude of that angle together with the known speed of the mirror, the velocity of the light could be calculated.

In applying either of these methods the resulting velocity is that of light when traversing the earth's atmosphere, but what we want is its velocity in space which we suppose to be destitute of ponderable material, and in order to obtain that the velocity in the atmosphere must be multiplied by the refractive index of air. The corrected velocity so obtained can then be used to find the solar parallax, either from the time required by light to traverse the semi-diameter of the earth's orbit, or from the ratio of the velocity of light to the orbital velocity of the earth.

Any periodic correction which occurs in computing the place of a heavenly body, or the time of a celestial phenomena, is called by astronomers an equation, and as the time required by light to traverse the semi-diameter of the earth's orbit first presented itself in the guise of a correction to the computed times of the eclipses of Jupiter's satellites, it has received the name of the light equation. The earth's orbit being interior to that of Jupiter, and both having the sun for their centre, it is evident that the distance between the two planets must vary from the sun to the difference of the radii of their respective orbits, and the time required by light to travel from one planet to the other must vary proportionately. Consequently, if the observed times of the eclipses of Jupiter's satellites are compared with the times computed upon the assumption that the two planets are always separated by their mean distance, it will be found that the eclipses occur too early when the earth is at less than its mean distance from Jupiter, and too late when it is further off, and from large numbers of such observations the value of the light equation has been deduced.

The combination of the motion of light through our atmosphere with the orbital motion of the earth gives rise to the annual aberration, all the phases of which are computed from its maximum value, commonly called the constant of aberration. There is also a diurnal aberration due to the rotation of the earth on its axis, but that is quite small, and does not concern us this evening. When aberration was discovered the corpuscular theory of light was in vogue, and it offered a charmingly simple explanation of the whole phenomenon. The hypothetical light corpuscles impinging upon the earth were thought to behave precisely like the drops in a shower of rain, and you all know that their apparent direction is affected by any motion on the part of the observer. In a calm day, when the drops are falling perpendicularly, a man standing still holds his umbrella directly over his head, but as soon as he begins to move forward he inclines his umbrella in the same direction, and the more rapidly he moves the greater must be its inclination in order to meet the descending shower. Similarly the apparent direction of oncoming light corpuscles would be affected by the orbital motion of the earth, so that in effect it would always be the resultant arising from combining the motion of the light with a motion equal and opposite to that of the earth. But since the falsity of the corpuscular theory has been proved that explanation is no longer tenable, and as yet we have not been able to replace it with anything equally satisfactory based on the now universally accepted undulatory theory. In accordance with the latter theory we must conceive the earth as ploughing its way through the ether, and the point which has hitherto baffled us is whether or not in so doing it produces any disturbance of the ether which affects the aberration. In our present ignorance on that point we can only say that the aberration constant is certainly very nearly equal to the ratio of the earth's orbital velocity to the velocity of light, but we cannot affirm that it is rigorously so.

The luminiferous ether was invented to account for the phenomena of light, and for two hundred years it was not suspected to have any other function. The emission theory postulated only the corpuscles which constitute light itself, but the undulatory theory fills all space with an imponderable substance possessing properties even more remarkable than those of ordinary matter, and to some of the acutest intellects the magnitude of this idea has proved an almost insuperable objection against the whole theory. So late as 1862 Sir David Brewster, who had gained a world-wide reputation by his optical researches, expressed himself as staggered by the notion of filling all space with some substance merely to enable a little twinkling star to send its light to us; but not long after Clerk Maxwell removed that difficulty by a discovery coextensive with the undulatory theory itself. Since 1845, when Faraday first performed his celebrated experiment of magnetising a ray of light, the idea that electricity is a phenomenon of the ether had been steadily growing, until at last Maxwell perceived that if such were the fact the rate of propagation of an electromagnetic wave must be the same as the velocity of light. At that time no one knew how to generate such waves, but Maxwell's theory showed him that their velocity must be equal to the number of electric units of quantity in the electromagnetic unit, and careful experiments soon proved that that is the velocity of light. Thus it was put almost beyond the possibility of doubt that the ether gives rise to the phenomena of electricity and magnetism, as well as to those of light, and perhaps it may even be concerned in the production of gravitation itself. What could be apparently more remote than these electric quantities and the solar parallax? And yet we have here a relation between them, but we make no use of it, because as yet the same relation can be far more accurately determined from experiments upon the velocity of light.

Now let us recall the quantities and methods of observation which we have found to be involved either directly or indirectly with the solar parallax. They are the solar parallax, obtained from transits of Venus, oppositions of Mars, and oppositions of certain asteroids; the lunar parallax, found both directly, and from measurements of the force of gravity at the earth's surface; the constants of precision, nutation, and aberration, obtained from observations of the stars; the parallactic inequality of the moon; the lunar inequality of the earth, usually obtained from observations of the sun, but recently found from heliometer observations of certain asteroids; the mass of the earth, found from the solar parallax, and also from the periodic and secular perturbations of Venus and Mars; the mass of the moon, found from the lunar inequality of the earth, and also from the ratio of the solar and lunar components of the ocean tides; the masses of all the planets, obtained from observations of their satellites whenever possible, and when no satellites exist, then from observations of their mutual perturbations both periodic and secular; the velocity of light, obtained from experiments with revolving mirrors and toothed wheels, together with laboratory determinations of the index of refraction of atmospheric air; the light equation, obtained from observations of the ellipses of Jupiter's satellites; the figure of the earth, obtained from geodetic triangulations, measurements of the length of the seconds pendulum in various latitudes, and observations of certain perturbations of the moon; the mean density of the earth, obtained from measurements of the attractions of mountains, from pendulum experiments in mines, and from experiments on the attraction of known masses of matter made either with torsion balances or with the most delicate chemical balances; the surface density of the earth, obtained from geological examinations of the surface strata; and lastly, the law of distribution of density in the interior of the earth, which in the present state of geological knowledge we can do little more than guess at.

Here then we have a large group of astronomical, geodetic, geological and physical quantities which must all be considered in finding the solar parallax, and which are all so entangled with each other that no one of them can be varied without affecting all the rest. It is therefore impossible to make an accurate determination of any one of them apart from the remainder of the group, and thus we are driven to the conclusion that they must all be determined simultaneously. Such has not been the practice of astronomers in the past, but it is the method to which they must inevitably resort in the future. A cursory glance at an analogous problem occurring in geodesy may be instructive. When a country is covered with a net of triangles it is always found that the observed angles are subject to a certain amount of error, and a century ago it was the habit to correct the angles in each triangle without much regard to the effect upon adjacent triangles. Consequently the adjustment of the errors was imperfect, and in computing the interval between any two distant points the result would vary somewhat with the triangles used in the computation—that is, if one computation was made through a chain of triangles running around on the right-hand side, another through a chain of triangles running straight between the two points, and a third through a chain of triangles running around on the left-hand side, the results would usually all differ. At that time things were less highly specialised than now, and all geodetic operations were yet in the hands of first-rate astronomers who soon devised processes for overcoming the difficulty. They imagined every observed angle to be subject to a small correction, and as these corrections were all entangled with each other through the geometrical conditions of the net, by a most ingenious application of the method of least squares they determined them all simultaneously in such a way as to satisfy the whole of the geometrical conditions. Thus the best possible adjustment was obtained, and no matter what triangles were used in passing from one point to another, the result was always the same. That method is now applied to every important triangulation, and its omission would be regarded as proof of incompetency on the part of those in charge of the work.

Now let us compare the conditions existing respectively in a triangulation net and in the group of quantities for the determination of the solar parallax. In the net every angle is subject to a small correction, and the whole system of corrections must be so determined as to make the sum of their weighted squares a minimum, and at the same time satisfy all the geometrical conditions of the net. Like the triangles, the quantities composing the group from which the solar parallax must be determined are all subject to error, and therefore we must regard each of them as requiring a small correction, and all these corrections must be so determined as to make the sum of their weighted squares a minimum, and at the same time satisfy every one of the equations expressing the relations between the various components of the group.

Thus it appears that the method required for adjusting the solar parallax and its related constants is in all respects the same as that which has so long been used for adjusting systems of triangulation; and as the latter method was invented by astronomers, it is natural to inquire why they have not applied it to the fundamental problem of their own science? The reasons are various, but they may all be classed under two heads. First, an inveterate habit of over-estimating the accuracy of our own work as compared with that of others; and second, the unfortunate effect of too much specialisation.

The prevailing opinion certainly is that great advances have recently been made in astronomy, and so they have in the fields of spectrum analysis and in the measurements of minute quantities of radiant heat; but the solution of the vast majority of astronomical problems depends upon the exact measurement of angles, and in that little or no progress has been made. Bradley, with his zenith sector, a hundred and fifty years ago, and Bessel and Struve, with their circles and transit instruments, seventy years ago, made observations not sensibly inferior to those of the present day, and indeed it would have been surprising if they had not done so. The essentials for accurately determining star places are a skilled observer, a clock, and a transit circle, the latter consisting of a telescope, a divided circle, and four micrometer microscopes. Surely no one will claim that we have to-day any more skilful observers than were Bessel, Bradley, and Struve, and the only way in which we have improved upon the telescopes made by Dollond one hundred and thirty years ago, is by increasing their aperture and relatively diminishing their focal distance. The most famous dividing engine now in existence was made by the elder Repsold seventy-five years ago; but as the errors of divided circles and their micrometer microscopes are always carefully determined, the accuracy of the measured angles is quite independent of any small improvement in the accuracy of the division or of the micrometer screws. Only in the matter of clocks has there been some advance, and even that is not very great. On the whole, the star places of to-day are a little better than those of seventy-five years ago, but even yet there is great room for improvement. One of the commonest applications of these star places is to the determination of latitude, but it is very doubtful if there is any point on the face of the earth whose latitude is known certainly within one-tenth of a second.

Looking at the question from another point of view, it is notorious that the contact observations of the transits of Venus in 1761 and 1769 were so discordant that from the same observations Encke and E. J. Stone got respectively for the solar parallax 8·59 seconds and 8·91 seconds. In 1870 no one thought it possible that there could be any such difficulty with the contact observations of then approaching transits of 1874 and 1882, but now we have found from sad experience that our vaunted modern instruments gave very little better results for the last pair of transits than our predecessors obtained with much cruder appliances in 1761 and 1769.

The theory of probability and uniform experience alike show that the limit of accuracy attainable with any instrument is soon reached; and yet we all know the fascination which continually lures us on in our efforts to get better results out of the familiar telescopes and circles which have constituted the standard equipment of observatories for nearly a century. Possibly these instruments may be capable of indicating somewhat smaller quantities than we have hitherto succeeded in measuring with them; but their limit cannot be far off, because they already show the disturbing effects of slight inequalities of temperature and other uncontrollable causes. So far as these effects are accidental, they eliminate themselves from every long series of observations, but there always remains a residuum of constant error, perhaps quite unsuspected, which gives us no end of trouble. Encke's value of the solar parallax affords a fine illustration of this. From the transits of Venus in 1761 and 1769 he found 8·58 seconds in 1824, which he subsequently corrected to 8·57 seconds, and for thirty years that value was universally accepted. The first objection to it came from Hansen in 1854, a second followed from Le Verrier in 1858, both based upon facts connected with the lunar theory, and eventually it became evident that Encke's parallax was about one quarter of a second too small. Now please observe that Encke's value was obtained trigonometrically, and its inaccuracy was never suspected until it was revealed by gravitational methods which were themselves in error about one-tenth of a second, and required subsequent correction in other ways. Here then was a lesson to astronomers, who are all more or less specialists, but it merely enforced the perfectly well-known principle that the constant errors of any one method are accidental errors with respect to all other methods, and therefore the readiest way of eliminating them is by combining the results from as many different methods as possible. However, the abler the specialist the more certain he is to be blind to all methods but his own, and astronomers have profited so little by the Encke-Hansen-Le Verrier incident of thirty-five years ago that to-day they are mostly divided into two great parties, one of whom holds that the parallax can be best determined from a combination of the constant of aberration with the velocity of light, and the other believes only in the results of heliometer measurements upon asteroids. By all means continue the heliometer measurements, and do everything possible to clear up the mystery which now surrounds the constant of aberration; but why ignore the work of predecessors who were quite as able as ourselves? If it were desired to determine some one angle of a triangulation net with special exactness, what would be thought of a man who attempted to do so by repeated measurements of the angle in question, while he persistently neglected to adjust the net? And yet, until recently, astronomers have been doing precisely that kind of thing with the solar parallax. I do not think there is any exaggeration in saying that the trustworthy observations now on record for the determination of the numerous quantities which are functions of the parallax could not be duplicated by the most industrious astronomer working continuously for a thousand years. How then can we suppose that the result properly deducible from them can be materially affected by anything that any of us can do in a lifetime, unless we are fortunate enough to invent methods of measurement vastly superior to any hitherto imagined? Probably the existing observations for the determination of most of these quantities are as exact as any that can ever be made with our present instruments, and if they were freed from constant errors they would certainly give results very near the truth. To that end we have only to form a system of simultaneous equations between all the observed quantities, and then deduce the most probable values of these quantities by the method of least squares. Perhaps some of you may think that the value so obtained for the solar parallax would depend largely upon the relative weights assigned to the various quantities, but such is not the case. With almost any possible system of weights the solar parallax will come out very nearly 8·809 seconds $\pm$ 0·0057 seconds, whence we have for the mean distance between the earth and sun 92,797,000 miles, with a probable error of only 59,700 miles; and for the diameter of the solar system, measured to its outermost member, the Planet Neptune, 5,578,400,000 miles.

THE METEOR AND METEOR-STREAK OF AUGUST 26, 1894.

THE present year will certainly be remarkable for its large meteors. One of the most brilliant class of these phenomena appeared on January 25, and a fortnight later (February 8) a fireball was seen as a conspicuous object even in the presence of the midday sun, for the time was only 28 minutes after noon. The early evening of February 21 furnished another of these brilliant objects, but the observations were neither numerous nor exact, and all that could be definitely gleaned from them was that the body disappeared at a height of 30 miles over Bolton in Lancashire. On April 22, before daylight had gone, a fine meteor descended over the extreme south-east part of England, crossing the Strait of Dover from Hastings in the direction of Amiens in France. On May 18 a large daylight meteor was observed in Scotland and Ireland. Several additional instances of these striking visitors have been recently recorded, and the Perseids presented a few fine specimens, though the season has been a very cloudy and unpropitious one for all kinds of celestial observation.

The magnificent meteor which forms the subject of this paper, appeared on August 26 at 10h. 20m. It did not owe its parentage to the great Perseid system, for it came too late in the month, and, moreover, its direction of flight is not conformable.

Those fortunate persons who happened to be out of doors at the time named, were startled by a bright lightning-like flash,[1] and naturally looking upwards for the cause, they either saw the end part of a fine meteor, or the dense streak it had projected as a glowing column of phosphorescence upon the dark ground of the sky. This streak was quite a remarkable feature in connection with the meteor, for on three grounds it merits careful consideration—viz. for its duration, for the proper motion it soon exhibited under the influence of the atmospheric current in which it was situated, and for the nondescript shapes it assumed. Before giving any particulars it may, however, be interesting to quote from some of the descriptions.

Mr. H. Corder, Bridgwater, writes that on August 26, 10.20, there was a very interesting meteor, but that its actual descent was unfortunately hidden by a wall. He afterwards, however, saw a bright streak in the position 138° + 62° to 137½° + 58½°. This, as seen with a binocular, soon became crooked, and drifted very slowly, until it finally disappeared at 10.50, half an hour afterwards, at the point 98° + 64°. Mr. Corder adds that this is the longest duration of any meteor-streak he has ever seen.[2]

FIG. 1.—Successive appearances of the meteor-streak as observed by Mr. Corder at Bridgwater.

Mr. S. A. Saunder, Crowthorne, near Wokingham, reports the time as 10.19. The length of the meteor's path, as he observed it, was about 20°; it moved quickly, and left a persistent streak of about 3° in length some 5° above its point of disappearance. This remained visible as a distinct trail for 20 or 30 seconds, and as a decreasing luminous patch at about 185° + 44° for two or three minutes. The path must have slightly preceded ε Ursæ Majoris, and probably crossed 190° + 57°.

A correspondent, writing to the *Daily News* from Wood Green, says that at 10.18 he observed an exceptionally brilliant meteor about the size of a cricket-ball and of a pale blue colour. It appeared near to the foremost star in Ursa Major, and was visible for some seconds. The chief peculiarity in addition to its great brilliancy, was that it left a long broad trail of light in the sky, which remained some time after the meteor had vanished, and then faded away very slowly.

Mr. E. W. Coker, writing from Coventry to the *English Mechanic*, states that at 10.20 he observed a nebulous light in the north-west part of the heavens. Its form was elongated, and he compares it with a dense cluster of star-dust. He saw it first through a window with the naked eye, and brought a telescope to bear upon it, but it had evidently passed its brightest, and was then fading rapidly. Its situation was in 213° + 48°.

Colonel G. L. Tupman has kindly sent me two observations from Harrow, which mutually corroborate each other as to the end point near α Boötis (Arcturus) in azimuth 110° west of south, and altitude 11° or 12°. The streak endured so long that one of the observers got a telescope and watched it for some time. He remarked that the lower part of the streak and Arcturus would have been in the field of his finder together.

Mr. T. M. Dunmur, writing from Trefriw, says:—"The meteor, while excelling in brightness though not in duration of flight any that I have had the good fortune to witness, was in respect of the glowing trail which succeeded quite unprecedented in my experience. It was vividly luminous, and the denser portion at once began to collect in a semicircular shape. This breaking-up absorbed the remainder of the trail, and still clearly visible slowly drifted toward, across, and beyond the 'Milky Way,' when it faded from sight not less than eight minutes from its first appearance."

There are some other descriptions from the Midlands and South of England, but it is singular that no reports have come to hand from North Wales, Cheshire, and Lancashire, over which the region the meteor appeared, and where its brilliancy must certainly have been very great.

[1] The flash was seen by the writer at [illegible] seeking, but the meteor itself and its streak were hidden by a house which obstructs the view of the north-north-west sky.

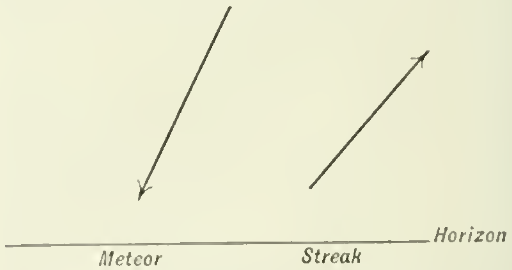
[2] The [illegible] durable streak ever seen by the writer was that of a Leonid fireball which appeared [illegible] November [illegible] at [illegible], and left a visible streak for three-quarters of an hour.

On comparing the various observations together, it is found that they agree much better than is usually the case in a miscellaneous collection of this sort. The real path of the meteor in the air is therefore determinable within very moderate limits of error. The Harrow position near Arcturus for the end part of the streak, offers, however, a discordance with the other observations, and there is reason to suppose that the star α Canum Venaticûm was mistaken for Arcturus. It is necessary for consistency that the azimuth of 110 west of south, as seen from Harrow, should be increased to 132° west of south, when it will be correctly directed towards Denbigh, near which place the meteor streak was situated when first evolved.

When the meteor was first seen it was about 90 miles high and over the river Mersey, at a point 20 miles west of Ormskirk. Passing rapidly almost due south, it ended at a height of 30 miles above Ruthin, Denbighshire. The angle of the meteor's descent was 63°, and the length of its observed path 66 miles. The earth-point is indicated 6 miles south of Llangollen, and the astronomical radiant was at 305° + 79° near the 4½ mag. star κ Cephei. This position is confirmed by a statement of Mr. Corder's, that he saw a few other meteors giving a radiant at 300° + 80°, and believed the large meteor would be found to belong to it, though its direction was not precisely conformable.

The luminous streak was about 9 miles in length, and its central portion 47 miles high over a place 6 miles east-north-east of Denbigh. The direction of its drift was eastwards towards Chester, and it passed over that town at a height of 68 miles, so that it was ascending rapidly in the atmosphere. It disappeared, according to the last view obtained of it by Mr. Corder, at 10.50 with his binoculars, when vertically over a point 2 miles west of Middlewich at a height of 83 miles. The angle of its ascent was 49°, and during the 30 minutes of its visibility it traversed 48 miles, so that its rate of motion was 141 feet per second, or 96 miles per hour. This velocity is about equal to that of one of the most destructive hurricanes possible. The movement of the streak was probably controlled by two influences, the easterly direction being due to a wind current in the upper atmosphere, while its rapid ascent was a necessary consequence of the light gaseous material of which it was composed.

The relative angles of descent of the meteor and ascent of its streak are shown in the following diagram:—



At the time of the meteor's appearance the air appears to have been pretty calm; in the north of England the wind was very slight from east, while in the south the direction was from south. The surface current would therefore appear to have been very different to that at a great altitude.

The radiant of the fireball is not a well-known one for the date, but in 1893 I saw a few meteors during the period from August 4–16 from 310° + 77°, and in 1885, September 4–5, a feeble radiant was seen at 315° + 76°. On September 1, 1878, at 10.20, I observed a very brilliant streak-leaving meteor with a path from 161° + 70° to 155° + 56°, and attributed the radiant as at 315° + 76°. On September 8, 1878, and on September 7, 1888, I saw fireballs, brighter than Venus, that were directed from the same radiant point. There would appear, therefore, to be a well defined shower of large meteors from the northern part of Cepheus at the close of August and beginning of September. Mr. Corder also informs me that on September 8, at 11.3, he saw another fireball descending from 142° + 54° to 144° + 51° in Ursa Major. The same object was seen at Leeds, from which place it was projected on the stars of Aquarius, and there is reason to believe that this brilliant meteor, like that of August 26, and the fireballs of September 1878 and 1888, before referred to, had their derivation from the shower of κ Cepheids.

W. F. DENNING.

THE INDEXING OF CHEMICAL LITERATURE

At the recent meeting of the American Association for the Advancement of Science the Committee on Indexing Chemical Literature presented to the Chemical Section its twelfth annual report. The following is a reprint of an advance copy of the report. During the current year the following bibliographies have been printed in the channels indicated :—

(1) Index to the Literature of Didymium, 1842-1893. By A. C. Langmuir. School of Mines Quarterly (Columbia College, New York). Vol. xv. pp. 33-47. November 1893. In this index the author follows the plan originally proposed by H. C. Bolton in 1870.

(2) The Tannins, a monograph on the history, preparation, properties, methods of estimation and uses of the vegetable astringents. With an index to the literature of the subject. Vol. ii., the Tannins of oak-bark, mangrove, canaigre, chestnut. By Henry Trimble. Philadelphia, 1894. Pp. 172. 12mo. Ill.

This forms the second volume of the work previously noted in our reports. The carefully compiled bibliography contains about 325 titles.

Reports of progress have been received from several chemists. Prof. Arthur M. Comey announces that the first volume of his Dictionary of Chemical Solubilities, devoted to inorganic compounds, has gone to press, and will be published before the close of the year. The second volume is also in active preparation.

Dr. Alfred Tuckerman reports that the United States Section of his Bibliography of Mineral Waters will be ready for the printer in a few months.

Prof. Clement W. Andrews states that he had done much work on a Bibliography of the Polariscopic Determination of Sugar; but, learning that Prof. H. W. Wiley, chief chemist of the U. S. Department of Agriculture, was engaged in a similar undertaking, generously handed over to him all the material he had accumulated. The combined manuscripts have recently been returned to Prof. Andrews, who will continue the work.

Prof. H. W. Wiley reports great activity on the part of the Division of Chemistry of the U. S. Department of Agriculture, in the preparation of bibliographies and special indexes, but he is obliged to admit difficulties in securing the printing of the manuscripts. We quote the following paragraphs from his letter, dated June 29, 1894, addressed to the chairman of the committee :—"The elegant bibliography of heavy metals occurring in canned goods, by Mrs. K. P. McElroy, has not yet found an avenue for publication." . . . "We also have a very complete bibliography of carbohydrates from the point at which they were left by Tollens in his Handbuch, in 1888, up to the close of 1892. This work was partly done by myself, but chiefly by Mr. H. E. L. Horton, and we were assisted greatly by receiving many hundred titles from Prof. C. W. Andrews, of the Massachusetts Institute of Technology. But what we can do with such a bibliography, comprising as it does three or four thousand titles, I do not know. The Department of Agriculture will not publish it, it is too large for the Journal of the American Chemical Society, and so it lies idle." . . . "A very complete bibliography of agricultural chemistry for the year ending 1893 has also been completed by the committee appointed by the Association of the Official Agricultural Chemists, of which Dr. William Frear is chairman. This bibliography I submitted to the Assistant Secretary of Agriculture with the request that it be published as a part of the Proceedings of the Association, but this request was not complied with. The same committee has in preparation a complete bibliography of agricultural chemistry for the year ending June 30, 1894, and this report will be presented to the meeting of the Association of Official Agricultural Chemists in August at Washington. We shall then have unpublished a complete bibliography of all agricultural chemical topics for the two years ending June 30, 1894."

Mr. P. H. Seymour's "Bibliography of Aceto-Acetic Ester" is in the printer's hands, and will be published by the Smithsonian Institution during the summer.

Prof. F. W. Clarke reports that he is engaged on a new edition of his "Recalculation of Atomic Weights."

Prof. H. C. Bolton has begun a "Supplement to his Bibliography of Chemistry," and last winter visited the chief libraries of Italy in search of material.

Dr. H. P. Talbot, of the Massachusetts Institute of Technology, with the co-operation of Dr. H. C. Bolton, has begun a second edition of the "Index to the Literature of Manganese," published by the latter in 1875, with the intention of bringing it down to date.

Prof. James Lewis Howe, of Louisville, Ky., reports progress on a Bibliography of the Platinum Metals.

Dr. W. H. Magee, of Cornell University, has completed Indexes to the Literature of Cerium and of Lanthanum, and the MSS. have been approved by your committee, and, together with Mr. Langmuir's Index to the Literature of Didymium, have been recommended to the Smithsonian Institution for publication. The three Indexes have been accepted by the Smithsonian, and will appear in the Miscellaneous Collections.

Prof. Charles E. Munroe reports that part ii. of his "Index to the Literature of Explosives" does not complete his work, as stated in the Eleventh Annual Report; he is engaged on a continuation.

Dr. Claude Augustus Oscar Rosell's thesis, presented to the Columbian University, Washington, D. C., in June, entitled "Investigation of the Properties of Ferric Acid," contains an exhaustive bibliography of the Ferrates and Ferric Acid; the channel of publication is not yet determined.

Prof. J. Christian Bay reports progress on a bibliography of alcoholic fermentation, and has commenced a bibliography of glycogen.

The annual reports of this committee are properly confined to the productions of Americans; but the chairman begs leave to direct attention to indications of a growing appreciation of the value of special bibliographies on the part of European chemists, confirming by their recent and proposed activities the work begun in America, at the chairman's suggestion, now more than twelve years ago. Several European countries have long published periodical bulletins of all books issued in their own lands, but they are, as a rule, too comprehensive in scope for the convenience of the specialist in science. Since the "Biblioteca Historico Naturalis," published at Göttingen, dropped chemistry from its pages (in 1887) the most useful bibliography of current scientific works has been the well-known "Naturæ Novitates" (Friedlaender, Berlin), now in its sixteenth year; however, this trade serial is stronger in German than in other languages, and falls short of the completeness desirable.

In technology and technical chemistry the admirable "Repertorium der technischen Literatur" (Leipzig), in its continuation, affords invaluable assistance to the industrial chemist. Recently, too, the following periodical has been established: "Bibliotheca polytechnica; internationale Bibliographie der gesammten neuen technischen Literatur, herausgegeben von Fritz von Szczepanski." (St. Petersburg and Leipzig, 1893.) 8vo. 12 numbers per annum. This includes chemistry pure and applied.

The need of an exhaustive authoritative bibliography of current chemical books of the world is still felt.

In a private letter to the chairman of your committee, Dr. Bechhold, of Frankfort-on-Maine, announces his intention of publishing a full and complete Index to Current Chemical Literature in all languages, on a most comprehensive plan; the first number of this serial will be awaited by chemists with great interest.

Heinrich Wien (Vienna) and F. A. Brockhaus (Leipzig), announce the publication of a "Universal Index to the World's Technical and Scientific Literature." This ambitious undertaking is intended to embrace both books and periodicals, and to represent all the known literature that has appeared in every part of the world; five parts are projected, viz. chemistry, medicine, mining, photography, electricity.

As most of the members of the Chemical Section are aware, a call has been issued for an International Congress of Applied Chemistry, to be held, under the patronage of the Belgian Government, at Brussels in August 1894. At that meeting it is proposed to found a Review of Reviews of Applied Biological Chemistry in several languages, to contain a *résumé* of chemical work in that branch from all parts of the world. The Secretary General of the Congress is M. Sachs, 58 Rue d'Allemagne, Brussels.

At the Congress of Chemists held in Chicago, in August 1893, your chairman had the honour to read an address on an "International Index to Chemical Literature" (*J. Am. Chem. Soc.*, xv. Oct. 1893), in which he proposed a simple scheme for indexing current periodical chemical publications by international co-operation. It is extremely gratifying to record that the necessity of international co-operation has since been suggested by so weighty an authority as the Royal Society (London). That splendid monument of the bibliography of science, "The Catalogue of Scientific Papers," published by the Royal Society, has failed to satisfy the requirements of students in science, owing to the lack of a subject-index to the prodigious material classified under the names of the authors; but according to a circular issued by the Royal Society in April, "it is hoped that a key to the volumes already published may be eventually issued." The Royal Society further announces its intention of continuing the "Catalogue of Scientific Papers" after Jan. 1, 1900, on an enlarged and improved plan, with the aid of international co-operation, and asks for suggestions as to the best methods of inaugurating such a scheme.

Although this report deals with chemistry, it may be proper to mention here an important undertaking in another branch of science, as it affords an additional instance of the progress now making towards international co-operation in bibliography. At the Washington meeting of the International Congress of Geologists a committee on the Bibliography of Geology was appointed for the purpose of preparing a list of the geologic bibliographies now in existence. This work is now approaching completion under the direction of M. Emmanuel de Margerie (Paris), the Secretary of the International Committee.

American botanists also are showing their appreciation of bibliographical work. A committee of the Torrey Botanical Club publishes in the Bulletin of the Club an "Index to recent Literature relating to American Botany." This Index was begun in January 1894, and is continued each month; the arrangement is alphabetically by authors.

At the Chicago Congress of Chemists a committee was appointed to bring about the organisation of a triennial (or quinquennial) international meeting of chemists. Prof. Frank W. Clarke, one of the members of your committee, is chairman of that body. Perhaps the future World's Chemical Congresses may arrange the publication of an exhaustive Index to the Chemical Literature of the World by international co-operation, either in accordance with the scheme proposed by your chairman in his address at Chicago, or in some more efficient way.

Thus, it is evident that immense progress is being made in the compilation of indexes and bibliographies in many branches of science, in both Europe and America; it is to be hoped that American chemists, who have been in some measure pioneers in the matter, will feel stimulated to still greater exertions than before.

The chairman has a limited number of copies of the Tenth Report, containing a list of forty-five Indexes to Chemical Literature, which he will be glad to send to applicants. Communications should be addressed to the Chairman, at the University Club, New York City.

Committee,
H. CARRINGTON BOLTON, *Chairman*,
F. W. CLARKE,

ALEXIS A. JULIEN,
JOHN W. LANGLEY,
ALBERT B. PRESCOTT (in Europe),
ALFRED TUCKERMAN.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 17.—M. Lœwy in the chair.—A note was presented by M. Faye concerning the International Geodetic Association at Innspruck, and intimating the probability of a certain number of geologists being requested to join its permanent Commission.—Shooting-stars observed in Italy in August 1894; a note by P. François Denza. The numbers of shooting-stars observed at some four-and-twenty stations scattered all over Italy are recorded. The swarm was thicker on the night of 10–11 than on other nights. By observations made at the Vatican, the principal radiant point had the co-ordinates $\alpha = 45°$, $\delta = 54°$.—On the problems of dynamics of which the differential equations allow an infinitesimal transformation, by M. P. Stackel. An infinitesimal transformation P_f, which allows $n - 1$ differential equations between the independent variables $p_1, p_2, \ldots, p_n$ which determine the position of the mobile system, does not exist when the variables $p_1, p_2, \ldots, p_n$ are so chosen that: (1) The function of the forces Π depends only on $p_2, p_3, \ldots, p_n$; (2) the expression of the acting force is reduced to

$$\tfrac{1}{2}e^{cp_1}\sum_{\kappa,\lambda} b_{\kappa\lambda}(p_2, p_3, \ldots, p_n)\frac{dp_\kappa}{dt}\frac{dp_\lambda}{dt};$$

c is an arbitrary constant, and the coefficients $b_{\kappa\lambda}$ depend only on the arguments $p_2, p_3, \ldots, p_n$. Then the infinitesimal transformation P_f has the canonic form $P_f = \frac{\partial f}{\partial p_1}$. These conditions are necessary and sufficient.—On the linear equations from the derived partials of the second order, by M. A. Petot.—On the mixture of liquids, by M. J. de Kowalski. The author has endeavoured to obtain experimental confirmation of Van der Waals' theory of the miscibility of liquids if sufficient pressures be applied. Negative results only were obtained in the cases of isobutyl alcohol and water and ether and water. The system ethyl alcohol: isobutyl alcohol: water with a blue colouring matter, completely mixing at 22°·7, gave at 19°·5 mixture at a pressure of 880 to 900 atmospheres. At 19° the same system showed no signs of becoming homogeneous, even under a pressure much greater than 1000 atmospheres.—On the presence of *Thylles gommeuses* in the vine, by M. Louis Mangin.—On a vine disease caused by *Aureobasidium vitis*, by M. P. Eloste. The disease known as the "maladie rouge" has been widely disseminated this year. The author has found the mycelium of *Aureobasidium vitis* in the altered parts of the leaves, but he has not yet found its fructifications, nor is its parasitism completely proved; a full description of the progress of the disease in an attacked plant is given.—A waterspout at sea, by M. Génot.

ANOTHER SUBSTITUTE FOR DARWINISM.

Nature's Method in the Evolution of Life. (London: T. Fisher Unwin, 1894.)

ALMOST every educated man who can write good English, but who cannot understand Darwin's theory of Natural Selection, seems to feel compelled to explain his difficulties and to offer his own preferable theory in the form of a volume on Evolution. We are thankful that the present anonymous volume is a small one; but that is its chief, if not its only merit. The writer has not, in the first place, made any serious attempt to understand the theory he objects to as inadequate; and, in the second place, his own theory is so vague and so entirely unsupported by either fact or argument as to be altogether worthless. A few extracts from the book will serve to support both these statements.

In the first chapters discussing the Darwinian theory we have this statement:—

"Deviations, although minute, tend, it is alleged, to accumulate, and the accumulations over prolonged periods of time ultimately produce variations from the original type, sufficient to constitute new species." (p. 10.)

Of course no such "tendency" was ever alleged by Darwin. The difference in size between the Shetland pony and the dray-horse is said to be due to difference of climate and food—

"There is no reason to doubt that the size of the former is due to an unfavourable climate and insufficient quantity and quality of food, and that of the latter to comfort combined with a generous diet."

But he ignores the case of the lap-dog and Italian greyhound on the one hand, and the Dingo or Esquimaux dog on the other, where the same contrasted conditions have apparently acted in a manner precisely opposite. Again, he seems to think that the struggle for existence is only the struggle for food, and that such a struggle must cause deterioration. He supposes the case of rabbits on a small island, and says—

"The rabbits possessing the strongest vitality and able to live on the smallest quantity of food, will have proved themselves the fittest. . . . But have the rabbits of the highest type come through the struggle unscathed? Have the fittest of the survivors become fitter to continue the conflict than the rabbits that were fittest when the conflict began? If so, it would follow that scarcity of food is more favourable to animal life than abundance." (p. 28.)

Here he clearly falls into confusion through some idea of abstract "fitness"—fitness independent of the conditions of existence, as shown by his statement on the next page that the struggle for existence "is evidently inimical to beneficial variation." Again (p. 31) he asks: "Is there any ground for believing that excessive use develops beneficial variation?" showing that he entirely misunderstands the theory of the natural selection of individual variations.

This misconception is further shown by quoting the inability of the ostrich to fly as an example of "the failure of natural selection"; and as a still more glaring example of this failure he refers to the curious Chaparral Cock of California, a ground cuckoo which lives in the open woodlands, runs very quickly, but rarely flies. The alleged "failure" is supposed to exist because the mounted cowboys catch the bird with their whips, and it does not escape by flying! It never seems to have occurred to this writer that both these birds are striking examples of the success of natural selection, since they have both become well adapted to a terrestrial life, as shown by their abundance in individuals. The notion seems to be that every bird which cannot fly as well as a swallow or a falcon must be a failure. Yet on the author's own theory, which, as we shall see, is a modified form of special creation, the failure, if it existed, would be even more deplorable.

This theory, which he calls "Nature's Law of Selection," is thus defined—

"What, for want of a better term, we call the progress of species, is not evolving a new organism out of one previously existing, but by substituting another more closely adapted to the conditions." (p. 62.)

How this other one is substituted is a mystery which is but imperfectly explained further on, in a chapter on "The Method of Evolution," in which we are told that—

"Every organism is the product of a particular combination of force acting on matter according to certain fixed laws, and that the same combination of force, united with matter, has a constant and persistent individuality, which is reproductive."

And this enigmatical proposition is supposed to be made clearer by the next sentence.

"As there are elemental substances, so there may be elemental forces possessing special qualities and affinities, which may have, from time to time, as conditions became favourable, combined with each other to work out evolution." (p. 67.)

If the former statement was obscure, this latter statement, of what "may be" and "may have," renders that obscurity perceptibly greater. Then follow several pages about the Power Loom as compared with the Loom of Life, after which we have a further statement of how the different life forces have acted successively on the simple cell "embodying the first vital force," and thus developed the various organisms. (p. 71.) In order to give us a concrete example of the theory at work, we have this account of the origin of the whale, and the author may well be complimented on his courage in attacking so difficult a problem which almost brought Darwin himself to grief. But a greater than Darwin is here. Read and wonder.

"According to our theory, the life force of the whale proceeds to fashion its skeleton on the type of its terrestrial antecessor, and builds the structure to the junction of the antecedent form with the new, and somewhat beyond the first point of differentiation between them. The bones of the hind limbs begin to be formed, but forthwith the new force special to the whale, coming into play, supersedes the forces that would have completed the antecedent type, and the whale is produced."

That is how it was done! For brilliancy of invention and clearness of exposition this is only comparable with that fascinating account, by Adrianus Tollius, of the origin of stone implements by natural causes, as quoted by Mr. Tylor.

"He gives drawings of some ordinary stone axes and hammers, and tells how the naturalists say that they are generated in the sky by a fulgureous exhalation conglobed in a cloud by the circumfixed humour, and are as it were baked hard by intense heat, and the weapon becomes pointed by the damp mixed with it flying from the dry part, and leaving the other end denser, but the exhalations press it so hard that it breaks out through the cloud, and makes thunder and lightning. But, he says, if this be really the way in which they are generated, it is odd that they are not round, and that they have holes through them, and those holes not equal through, but widest at the ends. It is hardly to be believed he thinks."[1]

Here we have an example of a brilliant and comprehensive theory—a theory able to explain everything, yet subject to petty criticism! And we fear that our anonymous author's equally brilliant theory of the orgin of the whale will be not less unfortunate. Of course we are assured that the theory explains almost everything—homology, embryology, rudimentary organs, &c., though he does, modestly, admit that it does *not* explain why hybrids are sterile. In order not to misrepresent the writer one more passage must be quoted, because he there brings his ideas more nearly into accord with that theory of discontinuous variation which has been recently put forward.

"Evolution proceeded by successive distinct gradations or stages. The differentiation of every new species resulted from forces *ab extra* superimposed on, and, to some extent, superseding or modifying the forces that produced the species or genus immediately preceding in the same line of development. The fecundated ovum of a species was, as it were, fecundated a second time with a new force, and the ovum thus bi-fecundated produced, instead of the species to which it belonged, a new species built upon a modification of its predecessor."

The theory is therefore one of special creation through the ordinary process of descent. The "new forces *ab extra*" which produced a whale from a terrestrial animal were also at work every time one species of tit, or warbler, or beetle, or snail, was modified in adaptation to a slightly different mode of life, and became a new species. Thus all is explained; except why there is any variation of these specially adapted species, why they increase at such an enormous rate necessitating such wholesale destruction, why there is any struggle for existence. All these phenomena, which are the very essence of a theory of descent with modification by natural selection, are entirely out of place in a theory of special creation, and are therefore the condemnation of any such theories.

ALFRED R. WALLACE.

THE MEAN DENSITY OF THE EARTH.

(*The Mean Density of the Earth. An Essay to which the Adams Prize was adjudged in* 1893 *in the University of Cambridge.* By J. H. Poynting, Sc.D., F.R.S. London: C. Griffin and Co., Limited, 1894.)

THIS essay, which contains an account of Prof. Poynting's well-known investigation of the mean density of the earth, though the last Adams prize essay, is the first to which that prize has been awarded for experimental work. We hope that it is the first of a long series of essays in which the candidates will attack the questions proposed by experiment as well as by mathematical analysis. We can hardly expect, however, that the level reached by the magnificent experimental work of Prof. Poynting will always be maintained.

The essay consists of two parts, the first containing an account of previous determinations of the mean density, the second an account of Prof. Poynting's own determination by means of the ordinary balance.

The first part begins with an account of the astronomical or geodetical methods, in which the attraction of a mountain was compared with that of the earth, as in the experiments of Bouguer in Peru, of Maskelyne and Hutton on Schehallien, of James and Clark on Andrews Seat, of Carlini on Mount Cenis, and of Mendenhall on Fujiyama; or with that of the slab of matter above the surface of a mine as in Airy's Harton Pit experiments, and von Sterneck's experiments in Pribram and Freiberg The beautiful method employed by von Sterneck in his pendulum experiments ought to be more widely known in England. The object of the astronomical method has undergone a curious reversal. It was originally to deduce the mass of the earth from a supposed knowledge of the distribution of matter in the locality of the experiment, whereas now it is rather to find the distribution of matter in this locality, assuming the mass of the earth to be known.

The other methods are laboratory methods, and depend upon the measurement of the attraction between known masses. Prof. Poynting points out a very interesting under-estimate of this attraction made by Newton. In the Principia, Newton estimated that two spheres of the density of the earth, each a foot in diameter, would, if separated by quarter of an inch and left to their own attractions, take nearly a month to come into contact. Prof. Poynting shows that there is a mistake in the arithmetic, and that in reality the spheres would come into contact in between five and six minutes.

It is now very nearly a century since the first measurements of the attraction between two masses in a laboratory were published by Cavendish ("Experiments to Determine the Density of the Earth," *Phil. Trans.* 1798), who used the torsion balance. Since then this method has been used by Reich, Baily, Cornu and Baille, and Boys; while the ordinary balance has been used by von Jolly, Prof. Poynting himself, and by König, Richarz and Krigar Menzel, working in collaboration, while the method of the pendulum balance has been used by Wilsing. The labour expended over these investigations may be estimated from the fact that, to take only two modern instances, Prof. Poynting's experiments extended over twelve years, while those of Cornu and Baille were commenced in 1870, and are not yet completed. The essay contains a clear and critical account of the preceding experiments. The result of the criticism is to raise, if possible, Cavendish's fame as an experimenter. Of Baily's laborious research, Prof. Poynting says: "The critical examination it has received in later years has entirely destroyed any confidence in the result. It remains, however, as a most remarkable and useful example of the danger of substituting multiplication of observations for consistency." The contrast between the amount of work which has been published on the numerical magnitude of the attraction, with that which has appeared on the effects, if any, which modifications of the surroundings exert on this attraction is very remarkable. Newton's hollow pendulum experiments, repeated with greater accuracy by Bessel, seem to be almost the only investigations which have been published on what may be called the physical properties of gravitational attraction. As far as we know, the attraction between two given masses depends merely upon their geometrical configuration; it is independent of the medium between them, of the physical state of the masses, whether they are solid, liquid or gaseous, amorphous or crystalline; it does not depend upon the temperature of the masses. Indirect evidence, often derived from the Cavendish experiments, shows that the preceding statements must at least be very approximately true. Again, chemical analysis is founded on the hypothesis that the weight of an atom of a chemical element is unaltered whatever chemical combinations it may form, or whatever the temperature to which it may be raised. It is, however, often difficult to tell the degree of approximation to the truth of the preceding statements which is indicated by such indirect evidence, and a direct experimental investigation to determine an inferior limit to the accuracy of some of the preceding statements would not be superfluous. Take the case, for example, of the statement that the weight of an atom cannot be altered by chemical combination: it would be for the advantage of science if this were proved with the utmost possible accuracy attainable by present methods for some definite chemical combinations. The question is of interest in connection with the view that the atoms of elements are aggregations of atoms of some primordial substance not very much lighter than hydrogen. The values of the atomic weights of the elements is inconsistent with this view if each atom of the primordial element retains its weight unaltered in the complex atom. If, however, it suffers a slight change of weight, then we might expect to find traces, though perhaps faint ones, of such a change in ordinary chemical combinations.

Another question which has excited some interest is a possible connection between the magnitude of gravitational attraction and temperature. Prof. Hicks has pointed out that Baily's results gave a value for the mean density of the earth which uniformly diminished as the temperature increased, indicating, if the effect is a real one, that the attraction between two masses increases with the temperature, and von Sterneck, in his experiments at Freiberg, found a remarkable relation between the temperature and the value of gravity. Prof. Poynting discusses these and other results, and comes to the conclusion that they are to be explained by other causes, and do not afford any evidence at all that the attraction between bodies varies with the temperature. The point is one which has a direct bearing on Prof. Poynting's own experiments, as the final value for the mean density is got by taking the mean of two sets of experiments, and as the temperature in the two sets differed by about 3·5° C., an uncorrected temperature effect would affect the result.

We are very glad to find from this essay that Prof. Poynting is engaged on an investigation as to whether the attraction between two crystals depends on the relative position of their axes.

The second part of the essay consists of Prof. Poynting's paper "On a Determination of the Mean Density of the Earth," published in the *Phil. Trans.* for 1891. This, in addition to the actual determination of the mean density, is almost a treatise on the method of using a balance so as to get great sensitiveness. The work is a model of patient care and skill, as well as of clearness of exposition, and we feel as we read it that the utmost has been made out of the apparatus and the method. Prof. Poynting is of opinion that it is only air-currents which prevent the balance being used with an accuracy far beyond anything hitherto approached; the ordinary balance is more sensitive than the torsion balance to air-currents, since these produce the greatest disturbance in the vertical direction, which is the direction of displacement in the ordinary balance. Prof. Boys has shown that to minimise the effect of air-currents the size of the apparatus ought to be reduced as much as possible. Prof. Poynting says that if he were designing his apparatus again, instead of using, as he did, an exceptionally large balance, he would go to the opposite extreme and use a very small one.

Of all the methods hitherto used to determine the mean density of the earth, the arrangement used by Prof. Boys seems to be the one capable of the greatest accuracy. There are, however, certain points about the method of the common balance, such as the simplicity of the most important measurements, and the absence of the necessity to determine a time of swing with great accuracy, which make it worthy of such a work as Prof. Poynting has devoted to it.

The mean density of the earth found by Prof. Poynting is 5·49. Prof. Boys' result is 5·53.

MINING.

A Text-book of Ore and Stone Mining. By C. Le Neve Foster, B.A., D.Sc., F.R.S. 8vo. Pp. 744, with Frontispiece and 716 Illustrations. (London: C. Griffin and Co., Limited, 1894.)

In view of the paramount importance of the production of minerals to Great Britain, and of the constant enterprises for working gold ores and other minerals in most of our colonies, it is certainly remarkable that there has hitherto been no satisfactory systematic treatise on metalliferous mining available. It is a matter of congratulation, therefore, that so eminent an authority as Dr. Le Neve Foster has found time, with his many duties as H.M. Inspector of Metalliferous Mines, and as Professor of Mining at the Royal College of Science and Royal School of Mines, to fill up so important a gap in technical literature. His compendious volume will undoubtedly be warmly welcomed as an invaluable work of reference, not only by mining students, but by all English-speaking mining engineers. The subject is so extensive, that the author's task of keeping his text-book within moderate limits, without erring on the side of omission, was one of considerable difficulty. He has, however, been thoroughly successful; and the extremely methodical arrangement of the material obviates, as 1 did in the case of Rankine's engineering treatises, the possibility of the work becoming rapidly obsolete.

The subject has been divided into the following chapters: (1) Occurrence or manner in which the useful minerals are found in the earth's crust; (2) prospecting or search for minerals; (3) boring; (4) excavation; (5) supporting excavations; (6) exploitation or working away of minerals; (7) haulage or transport along roads; (8) winding or hoisting in shafts; (9) drainage; (10) ventilation; (11) lighting; (12) descent and ascent; (13) dressing; (14) principles of employment; (15) legislation; (16) condition of workmen; and (17) accidents. The mining of coal is not dealt with; a special treatise having been published, as a companion volume, by Mr. H. W. Hughes.

In the first chapter, the time-honoured definition of mineral veins as the contents of fissures is wisely expanded by the author. Veins, he states, are tabular mineral deposits formed since the enclosing rocks, and either occupying cavities formed originally by fissures, or consisting of rock altered in the vicinity of fissures. There can be no doubt that many so-called fissure-veins are really substitutional deposits, and the necessity for some change in the definition is apparent. The author enters a timely protest against the use of the word "gangue" for the veinstone, lode-stuff, or matrix. Mistranslated from the German *Gang* (vein) into French, and thence into English, it has lost its original meaning, and should be consigned to oblivion.

The fascinating but perplexing subject of the formation of mineral veins is clearly and concisely dealt with. Sandberger's lateral secretion theory, assuming that the minerals were leached out of the adjacent rocks and re-deposited in the vein cavity, is regarded by the author as not entirely proven. This view, it is interesting to note, is shared by Posepny, who in a paper read, last year, at the Chicago Congress, published since the appearance of Dr. Le Neve Foster's treatise, expresses the opinion that Sandberger's theory suffers from several fundamental defects, and by being accepted as a simple and welcome explanation of the genesis of ore-deposits, has hindered the progress of knowledge.

In studying the mode of occurrence of minerals, abstract definitions are not sufficient. The student must see how they can be applied in practice. The author, therefore, gives a carefully chosen series of examples of the modes of occurrence of the more important minerals arranged in alphabetical order. The thoroughness with which he deals with this section is evident from the fact that he gives accounts of the occurrence of carbonic acid, of petroleum, and of ice. Liquefied carbonic acid is now a regular article of commerce in Germany, whilst the American ice trade affords employment to 12,000 men, 1000 horses, and 100 steam engines. Full descriptions of the mining of ice, to which the author might usefully have given references, have been published in Helland's Norwegian treatise on mining, and in a paper read in 1883, by Mr W. P. Blake, before the American Institute of Mining Engineers.

The eleven chapters dealing with mining proper cover some 450 pages, and include descriptions and illustrations of all the important appliances used in mining work, including the most recent inventions. Indeed, if fault can be found with this section, it is that the author devotes too much space to inventions so recent that their advantages have not been thoroughly tested. The description of the Franke drill, for example, the smallest and lightest boring machine in practical use, introduced last year at the Mansfeld copper mines, occupies more space than that of the modern stamp battery.

The chapter on dressing, under which term the author includes the processes by which the miner prepares his product for sale, or by which he extracts a marketable product from it, covers 100 pages, and is of special interest. Bearing in mind the needs of teachers, the author supplies useful information enabling the student to construct ingenious models of glass-tubing, &c., to illustrate the principles of motion in water and in air, and the construction of dressing appliances. A mixture of like-sized grains of coal, calcspar and galena, minerals of distinctly different colour and specific gravity, is used in these experiments.

The author's classification of the dressing processes employed is quite novel. There are three main divisions, according as the process is effected solely by mechanical means, or is based upon the physical or chemical properties of the minerals treated. The main divisions are subdivided in the following manner:—

I. *Mechanical processes.*—(1) Washing in order to separate clay, mud, and sand; (2) hand-picking; (3) breaking-up, subdivision, or shaping; (4) agglomeration or consolidation; (5) screening or sifting—that is, classification according to size.

II. *Processes depending upon physical properties.*—(1) Motion in water; (2) motion in air; (3) desiccation; (4) liquefaction and distillation; (5) magnetic attraction; (6) separation according to degree of friability.

III. *Processes depending upon chemical properties.*—(1) Solution, evaporation, and crystallisation; (2) atmospheric weathering; (3) calcination; (4) cementation or precipitation by iron; (5) amalgamation.

This classification cannot fail to be of the utmost value to the student, even if the subdivisions are not strictly defined in reality. A carefully considered classification of this character converts dressing into a rational science, instead of leaving it, as is the case in the existing treatises on the subject, an unsystematic collection of heterogeneous facts. One cannot but regret that the exigencies of space have compelled the author to give but meagre information regarding some of the most important mechanical appliances. Dressing is, however, a special subject of sufficient importance to command a literature of its own, and it is to be hoped that the author may some day be induced to expand his classification into a complete treatise.

The 711 illustrations given by the author are clear and effective; and in all important cases the scale is indicated. The frontispiece, representing an overhand stope at the 274-fathom level at Carn Brea Mine, Cornwall, from a photograph by Mr. J. C. Burrow, is a most artistic piece of work and a triumph in underground photography. With his characteristic minute accuracy in detail and in nomenclature, the author has introduced the expression "274-fathoms level" in place of the usual "274-fathom level." No doubt he can bring forward arguments in favour of this practice, which he adopts throughout the book; but to Cornish ears it will sound as oddly as if he alluded to a 2-feet rule, or to a 2-years old colt, or as if he spoke of a Guardsman as a "six-feeter."

A very full and accurate index greatly adds to the value of the work. The insertion of the names of von Cotta, von Groddeck, and von Sandberger under the letter V is, however, open to objection.

Prof. Le Neve Foster is to be congratulated on having enriched our technical literature with a contribution of substantial value. Undoubtedly the best book on the subject in the English language, it bears comparison with the treatises of Callon and Haton de la Goupillière in French, and with those of Serlo and Koehler in German. It should find a place in every mine office, and, by being carefully studied by mine managers, should help to raise the British ore and stone mining industries from their present depressed condition.

BENNETT H. BROUGH.

DR. ADLER'S OBSERVATIONS ON GALL FLIES.

Alternating Generations: a Biological Study of Oak Galls and Gall Flies. By Hermann Adler, M.D., Schleswig. Translated and edited by Charles R. Straton, F.R.C.S., Ed., F.E.S. With illustrations. (Oxford: Clarendon Press, 1894.)

THE order *Hymenoptera* has never been a popular study, in the sense in which the *Coleoptera* and *Lepidoptera* have become so during the last century, but it probably numbers among its votaries nearly three times as many students as any of the remaining orders. Nor is this surprising, for although it cannot compete with the *Lepidoptera* in beauty of colouring, it surpasses the *Coleoptera* in its variety of form, and is probably more numerous in species than any other order. It supplies us with some of the most valuable products which are yielded by insects, such as honey and ink, and stands at the head of the insect world, both in intelligence and in diversity of habits.

The *Aculeata*, or ants, bees, and wasps, and, after these, the *Tenthredinidæ*, or saw-flies, have generally received most attention from those entomologists who have specially devoted themselves to the study of the *Hymenopteræ*. But within the last twenty or thirty years, several entomologists have occupied themselves with the study of the *Cynipidæ*, or Gall Flies, and have discovered a system of alternate generations in these insects almost as remarkable as that which had previously been observed in the *Aphididæ*, or Plant-lice, which belong to the very different sub-order *Homoptera*.

One of the most important contributions to this subject was Dr. Adler's treatise, "Über den Generationswechsel des Eichen-Gallwespen," which was published in the *Zeitschrift für wissenschaftliche Zoologie* for 1881 (vol. xxxv.), with three coloured plates; and it is this work which Dr. Straton has now brought within the reach of every English entomologist.

As a rule, works on many branches of science become obsolete shortly after publication, and are seldom required except by specialists; but this does not apply to observations on transformations and habits. Men who have sufficient patience, taste and opportunity to make such observations of real value are few and far between, and their results, if sufficiently accurate, remain of permanent value, however much they may be enlarged by future observations. Hence Dr. Straton has rendered a real service to science by publishing an English edition of a work of this description, which was originally issued several years ago in a costly periodical, which would hardly be accessible, even to those who can read the original, except [in metropolitan or university libraries. Dr. Adler's work has been carefully and accurately translated, including his descriptions of the insects observed, his table of alternating generations, and his observations on gall-formation, oviposition, &c.; and the coloured plates have been faithfully reproduced, though the original stones had been destroyed.

Dr. Straton has added an introduction, a chapter on *Cynips Kollari*, synoptical tables of galls, a classification of the *Cynipidæ*, and a bibliography and index. The introduction deals with the history of the study of galls, and the questions of parthenogenesis, alternating generations, &c., in arthropods, and more especially in the *Cynipidæ*, the changes in the ovum and sperm-cells being described in detail, with reference to the views of Weismann and others; and Dr. Straton's own remarks will be found interesting to embryologists in general. Incidental remarks on gall parasites, and other points unconnected with the main subject of the book, are occasionally introduced.

We have only to regret that it has not occurred to Dr. Straton to add the principal bibliographical references to descriptions, &c., of each species, and a note as to whether it is common or rare in England. These additions, which might have been placed between brackets, to distinguish them from Dr. Adler's work, would have added to the usefulness of the book, which may probably penetrate to country places where the information which it contains cannot be supplemented by reference to larger works; to which, however, it is very necessary to refer the student, that he may know what to consult if he wishes to pursue the subject further. This want is only imperfectly supplied by a bibliography, absolutely necessary as this is for advanced students, and also to indicate the extent of an author's reading, and the sources from whence he has derived his information.

W. F. K.

OUR BOOK SHELF.

Hygiene. By J. Lane Notter, M.A., M.D., and R. H Firth, F.R.C.S. Pp. 374. (London: Longmans, Green, and Co., 1894.)

Primer of Hygiene. By Ernest S. Reynolds, M.D. Pp. 158. (London: Macmillan and Co., 1894.)

THOUGH it is not expressly stated that Dr. Notter's book "has been designed to meet the requirements of the syllabus of the Science and Art Department," the work is issued in the series of manuals published by Messrs. Longmans for students working up for South Kensington examinations, from which fact it may be inferred that such students will use it as a text-book. And as the author is an examiner in hygiene under the Department of Science and Art, his book doubtless contains the kind of knowledge that commands marks. Therefore teachers would do well to adopt it for their classes; and all writers of other text-books covering the same ground may regard their works as doomed to rapid extinction. Whether an examiner should prepare a text-book for his own syllabus is a matter of opinion, and much can be said both for and against the system. But, however that may be, it is certain that persons desirous of passing an examination could not do better than read the works of the one who sets the questions. In the case of the book before us, we have no hesitation in saying that it is as clear and connected an exposition of the laws of health and causes of disease as anyone could desire, be he a sordid hunter after certificates or a true seeker after knowledge. The authors have treated their subject scientifically, and yet with few technicalities, hence their work should appeal to a large public. Beginning with a chapter on air, they pass to others on water and food, and then to soils, sites, and buildings. The fifth chapter is concerned with drainage, after which are treated personal hygiene, infection and disinfection, parasites, climate and weather, and finally vital statistics. It will be seen from this that the subject is not treated in all its bearings; nevertheless, what is included in the manual forms an excellent basis for further study. Students who use the book will find it a pleasant road to knowledge, and they may confidently put their trust in its contents.

We note that here and there the authors, like many other writers on hygiene, do not sufficiently distinguish between heat and temperature. For instance, on p. 283 it is written: "At the ordinary temperature of the air, water boils at 212° F., and the moment the temperature falls below that heat, steam condenses." In this sentence the word heat is used in the sense that a cook employs it, not as a scientific man should write it.

Dr. Reynolds' primer deals with those portions of hygiene which concern the health of the household. If its contents were more widely known, the mortality from preventible disease would be greatly diminished. The greatest praise that can be given to a primer is to say that readers of the book will acquire just the kind and amount of knowledge to make them, like Oliver Twist, hunger for more. This commendation can safely be given to Dr. Reynolds' little volume, which is a model of what an introduction to hygiene, suitable for the general reader as well as the elementary student, should be.

Fur and Feather Series.—The Grouse. By Rev. H. A. Macpherson, A. J. Stuart-Wortley, and George Saintsbury. Edited by Alfred E. T. Watson. (London: Longmans, Green, and Co., 1894.)

IN the book before us the grouse is regarded from three different standpoints, and treated accordingly. In the first, the Rev. H. A. Macpherson introduces us to his natural history from the point of view of sport, telling us, after he has devoted a chapter in praise of the bird, the manners and "private life" of the grouse; the enemies with which it has to deal; the variability of the plumage in which it is wrapped, and the methods by which grouse are captured by "becking." These chapters are full of anecdotes and thoroughly readable, and they make one long to hear the cocks uttering their clear ringing "Er—eck—kek—kek! wuk, wuk wuk."

The second part is devoted to the shooting of the bird, and is contributed by Mr. A. J. Stuart-Wortley, who handles the subject in a straightforward manner.

We might here discuss at length the contents of the seven chapters on this subject, but we will leave it to the reader to find out for himself what the author has to say on such subjects as Scotch and English driving, ground stock and poaching, records and remarks, shooting over dogs, &c.

The third and concluding section of the book deals with the last, but by no means the least important, stage of the grouse—his presence on the dinner table. Mr. George Saintsbury completes his task well in laying before the reader the numerous and widely different methods of cooking. Not only is the treatment applied to the bird as a whole, but also to such variations as grouse soup, *quenelles*, *croquettes*, *bouchées*, &c.

Summing up then in a few words, we may say that we have nothing but praise to bestow on the book, which is a very valuable contribution to natural history, and worthily keeps up the reputation of the admirable series of which it forms a part. Every naturalist and every carrier of the gun will find it delightful to read, and at the same time will, no doubt, receive many useful wrinkles. Besides the text being all that could be desired, the illustrations are really excellent. They are after the drawings of Mr. A. J. Stuart-Wortley and Mr. A. Thorburn, and were designed under the supervision of the first named.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Has the Case for Direct Organic Adaptation been fully stated?

THE heading of this letter is in the form of a question for the following reasons: (1) It is impossible to keep pace with the literature on the subject of Evolution while engaged on any other absorbing work; and (2) so many giants have been engaged in the discussion, that it requires courage even to suggest that a point has been overlooked. It seems to me that nothing could be added to Herbert Spencer's convincing arguments that acquired characters must somehow be transmitted. I wish merely to suggest a method of describing this transmission which I have never yet seen in print, and which, I must think, is not generally recognised, inasmuch as it modifies Weismann's "contradictory facts" into not insuperable difficulties.

While studying the Phyllopod Crustacean Apus, I came to the conclusion that it might be derived from an Annelid which bent its head segments round ventrally, and pushed the food into its mouth with its parapodia. Simple as the suggestion may seem, the facts are indisputable that Apus *can* be so deduced, and further, that there is a considerable mass of evidence to show that it actually was so deduced.[1] If so, we should have one group of animals, the Crustacea, developed from another, the Annelida, not primarily by the summation of a long series of small variations by the action of Natural Selection, but by the active adoption on the part of a portion of the latter of a special manner of feeding. We may perhaps briefly describe the process as follows. A certain number of Chætopod Annelids found themselves in a region where the most favourable diet was only to be obtained in the manner described; the mouth had to be turned down ventrally so as to open backwards, and the lateral parapodia (bordering it in its new position) raked the food together and pushed it into the mouth. Generations of these Annelids would be produced in the same region, and would, in response to the same stimulus, practise the same method of feeding. Natural Selection would perfect the habit, and also *inevitably perfect it earlier and earlier in the lives of succeeding generations.*

But here, it will be said, we have ultimately to call in the aid of the transmission of acquired characters by inheritance. Yes; but this inheritance comes in at the end of a long series without appreciable break in the regular sequence. The last stage of individual acquirement is when the very youngest animal capable of feeding adopts the perfected habit as it first feeding act—in response, that is, to the same stimulus from the environment which led its parents to adopt it. The very next stage is that in which the young animal places its head segments in the right position prior to being able to feed. Here we may assume either that the "instinct" has been inherited, or, considering that the possible positions of the head segments are not numerous, that Natural Selection winnowed out all those

[1] I have endeavoured to accumulate this evidence in the following publications: "The Apodidæ," NATURE Series, 1892, and "The Systematic Position of the Trilobites," in the *Quarterly Journal of the Geological Society*, August 1894.

whose heads were not ready. I prefer the former hypothesis, for it is not, in this case, the inheritance of characters casually acquired by a few chance individuals, but of characters which have been regularly acquired by the race for several generations as an active organic adaptation to the environment.

It is needless here to multiply illustrations, but this and kindred cases have led me to ask whether too much attention has not been paid to single organisms and the modifications of chance individuals, whereas if a whole colony of similar organisms invade a new region, all have to adopt new habits of life; the young members of the colony and the new young continually born, being plastic, will, before they are adults, show marked structural modifications in adaptation to these new habits. They are actively modified by these functional adaptations to their environment. Natural Selection will winnow out those who do not keep in training, and at the same time infallibly compel the successive generations to perfect themselves earlier and earlier. We should thus have stages (but without appreciable breaks in the sequence) in this evolutionary process. (1) The young are born and continue for some time like the ancestors of the group, while the adults show considerable structural modification; (2) the new-born young resemble the ancestors of the group, but commence early to show the functional adaptations of the adults; (3) the new-born differ slightly from the ancestors of the group, inheriting (or possessing "accidentally") slight modifications in the right direction which enable them still earlier to perfect the necessary adaptation; (4) the young are born with the structures necessary to the immediate adoption of the habits required by the environment.

It seems to me that, in this way, we actually have the transmission of acquired characters by inheritance, this inheritance coming in as a natural term at the end of a long series of individual acquirements. The prime factor in the evolution of new forms is, therefore, the vital response to the environment of living colonies of exquisitely sensitive organisms; Natural Selection not only perfects, but drives the resulting modifications back earlier and earlier in the life-history of each individual of the colony *until they are inherited.*

This principle, it seems to me, explains the degeneration of structures which are "only passively functional," such as a hard shell. If the environment no longer requires a shell, it will not be maintained. It is inherited, say, from ancestors, but each fresh generation, or in the case of the Crustacea, each moult, gives a new start. If the shell owed its origin to the inorganic environment, it would cease to be developed when the special stimulus to its production were withdrawn, for the skin which secretes the shell is passively functional only so far as the organism is concerned; as a living tissue it is actively responsive to its environment. Or again, the shell owed its origin to the protection it afforded from enemies, and thus partly to the survival of those which accidentally had slightly thicker skins; but partly, and I think chiefly, also to the powers of the skin as a complex tissue to resist the attacks of the many small enemies, such as animal and vegetable parasites, which are a constant element in almost all environments. In this case, also, with each generation or moult we have a fresh start; on the removal of the constant irritation from these enemies, the energies of the animal would be otherwise employed than in re-developing its shell.

In order to account for the progressive or retrogressive modifications in the sterile workers of Hymenopterous colonies, we have in the same way to assume the functional modification of the plastic young as the prime factor; Natural Selection not only perfects these modifications, but *drives them back earlier and earlier in the life histories of the individuals.* We can thus understand that a stage might be reached when the difference of the food administered to the larva might modify its course of development. The structural modifications of the workers in this case are not inherited, but they are also not primarily due to Natural Selection, but to the response of organisms *in ever-recurring plastic series* to the requirements of their environment.

Again, the ceaseless efforts of the young individuals of a colony to adapt themselves to a new environment can alone, it seems to me, account for the possible utilisation of congenital variations, which are useless in themselves without concomitant variations. These latter will be acquired by the efforts of the organism, so far, that is, as to render the former functionally useful.

On the other hand, the "time" difficulty in evolution admits of easy solution if it can be shown that groups of organisms actively respond to changes of environment, as plants adapt themselves to a new surface by the plasticity of their growing shoots. Further, the difficulty that organisms are known to have remained practically unchanged through immense geological periods, is explained by the supposition that their environment must have also remained practically unchanged.

For the solution of many of the difficulties in evolution, we have then to look to the functional response of *colonies* of organisms, and of the living parts of such organisms to their respective environments. This power of adjustment accounts not only for the formation, but also for the maintenance of species. The force of Heredity has been overstated, while the power of immediate vital response of delicately balanced organisms to every slight change in the environment has been very much understated. If we keep in view the ever-recurring generations of plastic young, the direct stimulus of the environment is seen almost necessarily to be a force of prime importance perpetually overmastering the somewhat exaggerated rigidity of species attributed to heredity. There is no such thing as rigidity; everything is rather in a state of flux. Is this unending variation, always in adjustment to the environment, due to Natural Selection taking advantage of the occasional accidental slips in an otherwise rigid heredity? or, is it due to the direct response of organisms in a state of finely balanced equilibrium? This latter seems to me the more probable, the resulting structural modifications being, on the one hand, hindered by Heredity; on the other, if the conditions require it, hastened and perfected by Natural Selection. This hastening action of Natural Selection leads inevitably to inheritance.

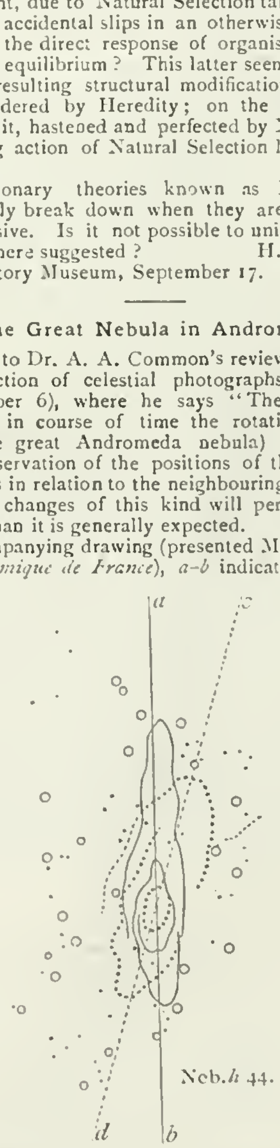
The evolutionary theories known as Lamarckism and Darwinism, only break down when they are supposed to be mutually exclusive. Is it not possible to unite them somewhat in the manner here suggested? H. M. BERNARD.

Natural History Museum, September 17.

The Great Nebula in Andromeda.

IN reference to Dr. A. A. Common's review of Dr. Roberts' beautiful collection of celestial photographs (NATURE, No. 1297, September 6), where he says "There is a fair presumption that in course of time the rotation of the outer portion (of the great Andromeda nebula) may perhaps be detected by observation of the positions of the two outer detached portions in relation to the neighbouring stars." I wish to point out that changes of this kind will perhaps be detected much sooner than it is generally expected.

In the accompanying drawing (presented May 2, 1894, to the *Société Astronomique de France*), *a–b* indicates the outline of



the small elongated nebula *h* 44, as it was seen by Trouvelot at Cambridge (Mass.) in 1874; *c–d* the limits of the nebulosity on Roberts' photograph (1889): the circular spots are stars, recognisable in the drawing. Unless this part of the Trouvelot drawing—the excellence of which is stated by Dr. Roberts himself—be very incorrect, the nebula would seem to have turned about 15° from left to right. The globular nebula (M. 32) to the other side of M. 31, seems also to have slightly shifted its position.

Evidence of the reality of such changes is of course only obtainable by comparing three or more photographs taken at comparatively wide intervals. In the meantime, this short notice in NATURE may call the attention of photo-astronomers to this interesting point.

Dordrecht, September 14. C. EASTON.

On the Identification of Habitual Criminals by Finger-Prints.

A PARLIAMENTARY Blue Book on "The Identification of Habitual Criminals," which has recently been issued, reports on *The Finger-Print System*, stated to have been "first suggested, and to some extent applied practically, by Sir William Herschel."

The chairman of the committee appointed by Mr. Asquith, whose report contains the above statement, refers me for his evidence on this point to Mr. Galton's work on "Finger-Prints" (Macmillan and Co., 1892).

My "careful study" of the subject is mentioned there, and an article of mine in NATURE, October 28, 1880 (vol. xxii. p. 605), is referred to. It is correctly indexed in the "Index Medicus" for the year, published in 1881, although Mr. Galton spells and indexes my name incorrectly. That article, I believe, is absolutely the first notice of the subject contained in English literature, and the conclusion I reached therein was that the patterns of the skin-furrows, with their distinctive loops, whorls, and lines, breaking and blending like the junctions in a railway map, were capable of being readily used as a reliable and permanent basis for the "scientific identification of criminals." I conclude my paper with the statement that "There can be no doubt as to the advantage of having, besides their photographs, a nature-copy of the for-ever unchangeable finger-furrows of important criminals."

Sir William Herschel wrote in NATURE, November 25 of the same year, alleging that he had "been taking sign-manuals by means of finger-marks for now more than twenty years." It does not yet appear that anything had been published on the subject by that gentleman till my contribution called forth his letter a month afterwards. The collections made by Sir W. Herschel were recently placed in Mr. Galton's hands, and that writer states that "they refer to one or more fingers, and in a few instances to the whole hand, of fifteen different persons." ("Finger-Prints," p. 9.)

It is not stated how many of these had been imprinted prior to my first calling attention to the subject. At present it would seem that Sir. W. Herschel had not accumulated the impressions at a more rapid rate than that of one person in two years! As we are informed in the letter to NATURE, referred to above, that the identification of pensioners had been secured in this way, that the method was in use in all the registration offices of the district, and that "on commitment to gaol, each prisoner had to sign with his finger," I should have expected that a somewhat more extensive collection might have been secured. As priority of publication is generally held to count for something, and as I knew absolutely nothing of Sir W. Herschel's studies, nor ever heard of anyone in India who did, some little evidence on the point of priority would be of interest even now.

Mr. Galton says, of Sir W. Herschel, "He informs me that he submitted, in 1877, a report in semi-official form to the Inspector-General of Gaols, asking to be allowed to extend the process; but no result followed." (p. 28.) A copy of that semi-official report would go far to settle the question of priority, as its date is nearly two years previous to my having noticed the finger-furrows. No reference to them was then to be found in any anatomical work that I could find access to, and no writer on identification had ever thought of them as a means to that end. My interest, like that of Purkenje, arose from a special study of the sense of touch, and I was then lecturing to medical students on the "Physiology of the Senses." Having myopic eyes which enable me to write with ease the Lord's Prayer three times in the space of a sixpence, I soon noticed the unique patterns which the papillary ridges formed. I happened to be studying the prehistoric pottery of Japan at the same time, and became interested in observing that these patterns were similar, but, I thought, finer and more slender than those of the present day, which pointed, I conjectured, to the employment of children in early fictile art. However that may be, my knowledge of the subject had a natural and independent genesis.

The subject of identification by this means has been brought under the notice of the authorities on criminal matters of different countries by me from time to time, and some years before Mr. Galton's work was published, Scotland Yard placed one of its most enlightened officers in communication with me on the subject. Inspector Tunbridge studied the subject with me during a forenoon. Even in 1880, I prepared copper-plate outlines of the two hands, accompanied with instructions as to obtaining finger-prints, and some two chief points on the palm, where the rugæ are characteristic. Sir W. Herschel's letter mentions prints of one finger only as being obtained from prisoners on commitment. On page 79 of the Blue Book mentioned above, "Instructions for taking Finger-Prints" are given for the benefit of prison warders, and the ten fingers are to be printed from, as I have advocated. I may add that I have not the slightest wish to diminish the credit that may be due to Sir W. Herschel. What I wish to point out is that his claim ought to be brought out a little more clearly than has yet been done, either by himself or by Mr. Galton. What precisely did he do, and when? HENRY FAULDS.

The Tetrahedral Carbon Atom.

YOUR reviewer, in his notice of my "Elementary Lessons in Organic Chemistry," takes exception to the statement that the carbon atom has been hypothetically regarded as tetrahedral in shape; he is presumably unacquainted with the criticisms of Lossen (*Berichte* 20, p. 3306) on Wislicenus's memoir, with Wislicenus's reply[1] (*Berichte* 21, p. 581), as well as with the pamphlet of Wunderlich ("Configuration organischer Molekule," Würzburg, 1886); he need not, however, search "the whole range of stereo-chemical literature" for references of this kind, as there is in the "Handbuch" of V. Meyer and Jacobson, pp. 433–436, a tolerably full discussion as to the ultimate cause of stereo-isomerism in carbon compounds, where it is stated (p. 434) that "the carbon atom may be regarded as a mass of finite extension in space, of any shape, with four points on its surface corresponding to the corners of a regular tetrahedron as the units of affinity."

Most writers on stereo-chemical subjects prefer to speak of the tetrahedral arrangement in space of the four valencies of the carbon atom, rather than of the tetrahedral shape of the carbon atom itself; but if the "valencies" are sufficiently material to have a definite position in space, they may fairly be regarded as parts of the carbon atom, which then becomes of finite size, and *for the purposes of stereo-chemistry* essentially tetrahedral in shape. This form of statement has the merit of simplicity, and is in itself less objectionable than the idea of "valencies" directed towards the corners of a tetrahedron; at the same time, I freely admit that the statement errs on the side of excessive simplicity, and is not what would be adopted before a class of honours students.

It is possible to connect the facts of stereo-isomerism to some extent by a series of separate propositions, and at the same time to avoid any reference to the distribution of the "valencies" in space, or to the finite size of the carbon atom; one of these propositions would be that "two carbon atoms connected by an ethylene linkage are no longer free to rotate round the axis which joins them"; but so soon as an attempt is made to unite these separate statements into one hypothesis, or to assign any reason for the proposition just quoted, it is impossible (as it appears to me) to escape from the dilemma; of the two alternatives, I think most chemists, who have not become blinded by long usage to the gross misuse which the word "valency" has suffered, will prefer to regard the carbon atom as finite in size with four points in it, occupying the corners of a tetrahedron, distinguished in some way beyond the rest as regards the action of chemical affinity.

This idea must be made more definite before the average student can derive much help from it in correlating the facts of

[1] Wislicenus says "the atom of carbon may possibly resemble very closely regular tetrahedron in shape."

stereo-isomerism; the essential part of it is retained in the assumption that the carbon atom is stereo-chemically to be regarded as tetrahedral in shape. If any student carries away the notion that this is believed to be the actual shape of the atom, there is no more mischief done than in that student's case who gathers the impression that the two carbon atoms united by an ethylene linkage are held together by two pairs of forces which do not act along the line joining the two atoms, but meet at an angle in empty space. G. S. TURPIN.

Huddersfield, September 24.

Careless Writing.

PROF. TILDEN, in his review, published in NATURE, September 20, takes exception to the loose phraseology adopted by writers on chemical subjects. This is, alas! only too common.

For example, in one of the best works on inorganic chemistry, written by a Professor of Chemistry whose writings are characterised by their logical clearness and philosophic reasoning, one may read:—

"When a molecule of hydrogen acts upon a molecule of chlorine to form two molecules of hydrochloric acid gas, 44,000 c. of heat are evolved." Of course, nobody can fail to understand what is meant. But as the words stand, it is certainly one of the most remarkable feats of science, and makes us feel that some happy mortal has succeeded in refining his faculties down to the degree of fineness, popularly ascribed only to a certain species of "demon." F. G. DONNAN.

Holywood, Belfast.

ON THE DOCTRINE OF DISCONTINUITY OF FLUID MOTION, IN CONNECTION WITH THE RESISTANCE AGAINST A SOLID MOVING THROUGH A FLUID.[1]

II.

§ 6. IN every case in which vacuum is formed at an edge of a solid moving in an inviscid incompressible fluid, under pressure constant at all infinitely great distances from the solid, a succession of finite individual vortices is sent from the edge into the liquid, *and the motion is essentially unsteady*. Each individual vortex has a finite endless vacuum for its core instead of the rotationally moving ring of fluid of the Helmholtz vortex ring. But it should be noticed that it would not be rings of vacuum, but bubbles, that would in many cases be first detached from the solid; that by the tumultuous collapse of bubbles they become rings; and that the case in which the collapse of a bubble, in our ideal fluid, could be completed to an annulment of volume, is of necessity infinitely rare; and that the case in which, when a bubble becomes a ring by the meeting of two points of collapsing boundary, there is exactly no circulation through the aperture, is infinitely rare.[2]

§ 7. In the case of our circular disc, it would be circular vortex rings that, if the water were inviscid, would be shed off from its edge when the depth is less than 63 feet. If the depth is very little less than 63 feet these rings would be exceedingly fine, and would follow one another at exceedingly short intervals of time. Thus quite close to the edge there would be something somewhat like Stokes' "rift," but with a rapid succession of vacuum rollers, as it were; and *no slipping* between the portions of the fluid on its two sides.

§ 8. At greater depths than 63 feet, if the water had absolutely no viscosity,[1] the motion would be continuous and irrotational, as described in § 4, text and foot-note: but any degree of viscosity, however slight, would, if the edge were infinitely sharp (instead of having a radius of curvature of 1/2000 of an inch, as has our supposed disc), give rise to a state of motion in its neighbourhood somewhat like to Stokes' rift,[2] "a surface of discontinuity extending some way into the fluid," but with the difference that there is no slip of fluid on fluid. A trail of rotationally moving liquid, a Helmholtz' "vortex sheet" of exceedingly small thickness, is thus left in the wake of the circular edge; which, while becoming thicker as it gets farther from the edge, becomes rolled up in a wildly tumultuous manner, giving the appearance of an irregular crowd of detached circular ring-vortices. This crowd follows the disc at an ever diminishing speed and widens outward farther and farther, and inwards encroaches more on the comparatively undisturbed middle of the wake, as it is left farther and farther behind the disc.

§ 9. Whether as in § 7 for an ideal inviscid incompressible fluid, or as in § 8 for a natural liquid such as water, the "wake," that is to say, the fluid on the rear side of the plane of the disc, as far as it is sensibly affected by the motion of the disc, must be as described in the last sentence of § 8. The rear of the wake is always moving forwards, that is to say, following the disc; but at a continually diminishing speed. Hence, if the disc has been set in motion from rest some finite time, t, ago, the whole wake must be included between the plane from which the disc started, and the plane in which the disc is now, at the time when we are thinking of it. These two planes are at the finite distance, Vt, asunder. In other words the wake extends to some distance less than Vt, rearwards from the disc.

§ 10. The shedding off of vortex rings from the edge of the disc, to follow in its wake at less speed than its own, essentially gives a contribution to negative pressure on the rear side of the disc equal to $\frac{d}{dt}\Sigma\kappa$; where $\Sigma\kappa$ denotes the sum of the circulations of all the coreless ring vortices, or of all the rotationally moving liquid, which have or has left the edge since the beginning of the motion. This, with the commonly assumed velocities of the fluid on the two sides of the rigid plane, seems insufficient to account for the excess of observed pressure above that calculated for a long blade by Lord Rayleigh's formula[3] referred to in my letter to NATURE, "Towards the Efficiency of Sails, &c.," and leaves some correction to be made on those assumed velocities. But the working out of this interesting piece of mathematical hydrokinetics must be deferred for a continuation of the present article in which supposed discontinuity of fluid motion, extending far and wide, as taught by many writers in many scientific papers and text-books since Stokes' infinitesimal rift started it in 1847, will be considered. KELVIN.

(To be continued.)

[1] Continued from p. 525.

[2] The whole subject of the motion of an incompressible inviscid fluid with vacuum on the other side of the whole or any part of its boundary is of surpassing interest. Consider for example an open fixed basin, with water poured into it and left not quite at rest under the influence of gravity; swinging slightly from side to side, let us suppose for example; the water perfectly inviscid, and vapour-less, but may be either cohesional or cohesionless; and there being perfect vacuum over all its free surface. Very soon it will certainly throw up a drop somewhere: and before very long it will become covered with spin-drift and will thus illustrate Maxwell's important allegation (which I believe to be true though it has been much doubted), that any conservative system must "sooner or later" pass through every possible configuration.

[1] Viscosity is resistance to change of shape in proportion to the speed o the change.

[2] Stokes, "Mathematical and Physical Papers," vol. 1. p. 310.

[3] In lines 9 and 10 of the printed letter (NATURE, Aug. 20, 1894, p. 425), for "something like five or ten," substitute 4·8. I unfortunately had not Lord Rayleigh's formula by me at the time the letter was written.

MR. SCOTT ELLIOT'S RUWENZORI EXPEDITION.

ABOUT three years ago, in NATURE (November 5, 1891), I gave an account, rescued from an American periodical, of the botanical results, slender enough it is true, but not without interest, of the Emin Relief Expedition, as described by Major Jephson. The most important feature was undoubtedly the small collection brought away "for Emin Pasha to classify" by Lieut. Stairs from "a high altitude on the slopes of Ruwenzori, or the Mountains of the Moon."

Last year Mr. Scott Elliot, an accomplished botanist and experienced African traveller, submitted to the Government Grant Committee of the Royal Society a scheme for an extended plan of botanical exploration in Central Africa. On the advice of the Board for Botany, Mr. Scott Elliot undertook the investigation of Ruwenzori, and through the kind aid of Sir John Kirk, such official facilities as were possible were obtained on his behalf.

Mr. Scott Elliot, not without many difficulties, has now reached his destination. The following letter, which is communicated to Nature at his request, raises a high expectation that he will succeed in thoroughly investigating the flora of this interesting region. It is a matter of sincere hope that his health will be spared for the task. Unfortunately the time is far distant when, as prophesied by Mr. Stanley, the "tender-hearted botanist" may be "conveyed from point to point without danger to his valuable life." The honour is all the greater to a man of by no means robust physique, who in the pure interests of science is willing to take his life in his hand in the prosecution of such a task.

W. T. Thiselton-Dyer.

Royal Gardens, Kew, September 25.

Ruwenzori, May 2, 1894.

I arrived here on April 1, but have unfortunately been able to do very little, as I have had severe fever. I may not have another opportunity of writing for a long time, so send this now. My route has been through Kavirondo, Usoga, and Uganda to Buddu, through Buddu to Karagwe, and thence diagonally across Ankobe to Toru. I find Uganda, Buddu, and Toru to consist of a plateau apparently gneiss and granite, about 4000–4500 feet high in most parts, but about this part of Toru 5000 or even 5300 feet. The whole of this plateau is cut up into innumerable swampy rivers, due to the comparative slow gradient of these rivers (the Victorian Nyanza being only 3850 feet). In Karagwe and Ankobe this plateau is covered by a series of folded schists and shale which extend with one break from Kitangule to within eight miles of the Albert Edward Nyanza, where the granite plateau is reached again. These schists are at 80°-90° dip, and strike usually 20°–30° east of north. A curious little chain of small volcanic craters, running east and west nearly, appears in the midst of the granite at Vijongo (on Lugard's map), that is, at the base of Ruwenzori, but I have not been able as yet to see much of the geology of Ruwenzori itself. The flora over the whole of this country up to 6000 feet is identical, and even at 6000 feet there are but few new species. It seems probable to me that this flora extends right down to the Zambesi. I have been able to get a fair number of species representing it, but in what condition they will reach England remains to be seen. Of trees there are very few. A tree *Euphorbia* and an *Erythrina* are the commonest. The most objectionable is a bamboo-like grass, often twenty feet high, which makes travelling most annoying. Another conspicuous plant is an Acanth with handsome red spikes of flowers and very large prickly leaves. There are two or three Helichrysums, numerous Commelinas and twining *Leguminosæ*, and, strangely enough, a *Rubus*, a buttercup, and three *Umbelliferæ*. I find also the same beetles, butterflies, and dragonflies everywhere.

The country as a whole seems very fertile, and the population is probably one-hundredth part of what it might be. The swamp rivers alluded to are probably the most extensive natural rice-fields in the world; but rice has only been grown in a very half-hearted manner. The banana supplies all the wants of the people. Tobacco could also be grown anywhere, and, as far as one can judge from the native plant, a very good kind could be produced. Coffee could also be grown, and cotton, and, in fact, most of the common tropical plants. Kasamaga, the king here, tells me he wants Europeans to settle here and teach his people; and a young fellow who is disposed to rough it, and fond of sport, might do very well here at Ruwenzori. He could support himself the first few years by ivory (shooting and trading), and by the time his plantation came into bearing there ought surely to be communication with the coast. A curious fact in natural history has come about here. Kabbarega has eaten up all the cattle in the country. There is scarcely a fowl left, and in consequence lions and leopards have taken wholesale to man-hunting. They have completely changed their manner of hunting in accordance with this. Usually speaking they are continually roaring on the trail, but here neither ever utters a sound, and though I have had two men injured, and been within a hundred yards of another man who was carried off, I heard nothing.

Mapping is very difficult here; the compass shows the most extraordinary variations, and the rivers are almost impossible to trace, even from a great height, as where I am now.

I have not been able yet to get at the higher flora. One curious fact is that the woods on Ruwenzori very closely follow the ordinary morning clouds and mists: these are usually at the same line every morning, and mount to the top towards evening. This line of wood or cloud is not, however, horizontal, but is highest at the main mass, and slopes gradually as the mountain chain sinks in height.

(Signed) G. F. Scott Elliot.

THE PHYSIOLOGICAL ACTION OF THE PARAFFIN NITRITES.[1]

THE valuable investigations described in this communication to the Royal Society have been made to determine more exactly the mode of action of paraffinic nitrites, and the part which the nitroxyl group NO_2 plays in their physiological action, and also to throw light on the effect of variations in their molecular constitution. For these objects a series of careful observations have been made as to the action of ten of the fatty nitrites on (1) blood pressure, (2) pulse frequency, (3) respiration, (4) striated muscle tissue.

The compounds selected for examination included the nitrites of methyl and ethyl, the primary and secondary propyl nitrites, the primary, secondary, and tertiary butyl nitrites, and three amyl nitrites (α and β isoprimary, and tertiary amyl nitrite). By this selection it has been possible to compare the action of a series of substances containing an atom of NO_2 united respectively to CH_3, C_2H_5, C_3H_7, C_4H_9, and C_5H_{11}, and thus to determine the modifying influence which these radicals exert on the action of the NO_2 group. It has also been possible to ascertain the effect produced by a modification of arrangement of the molecules in nitrites having the same composition as, *e.g.* in primary and secondary propyl nitrite,

$$CH_3CH_2CH_2NO_2, \text{ and } (CH_3)_2CHNO_2$$

It has long been known that the fatty nitrites lower blood pressure, but opinions have differed as to their mode of action, Filehne considering that this lowering is caused by a paretic influence on the vasa motor centres, whilst Brunton looks upon it as due to a direct effect on the vessels themselves. Cash and Dunstan are led by their experiments to range themselves on the side of

[1] *Phil. Trans.* vol. clxxxiv. (1893), B, pp. 505-639. A paper by Dr. J. Theodore Cash F.R.S., and Prof. Wyndham R. Dunstan.

Brunton, for they find that if the presence of amyl nitrite is confined to the vessels of the brain alone, a fall of pressure does not take place, but it does occur if blood containing the nitrite circulates in the peripheral vessels of the body, even though the access of any nitrite to the brain is prevented. They likewise find that nitrites are capable of influencing vessels in the area supplied by the splanchnic nerves after section of these nerves—another proof that the action of the nitrites is peripheral.

The part which the group NO_2 plays in its fatty compounds they have sought to determine by ascertaining quantitatively the comparative amount of influence which each nitrite exerts on blood pressure, pulse frequency, and respiration, when introduced into the circulation of anæsthesised cats, by inhalation or by injection into the arterial or venous system, and also by ascertaining the comparative effect of paraffinic nitrites on the pulse frequency in man.

The quantitative method is doubtless open to some fallacies, but from the extreme care which has manifestly been taken in conducting the experiments, and the laborious manner in which they have been repeated, it seems certain that the results are in the main reliable. With regard to the influence of the nitrites in accelerating the beat of the heart, it is shown that physiological activity increases with molecular weight; amyl nitrite is more powerful than butyl nitrite, butyl than propyl, and so on, methyl being the weakest of all.

The order in which the paraffinic nitrites reduce blood pressure in amount is somewhat, though not quite the same, as that in which they accelerate the pulse, but important exceptions occur, especially in the case of methyl nitrite, which occupies a higher position as a pressure reducing agent than it does as a pulse accelerator. On the other hand, as regards duration of subnormal pressure, the order is quite altered, the nitrites which depress blood pressure to the greatest extent acting for the most part for the shortest time.

The authors have also endeavoured to determine the comparative influence of the various nitrites on striated muscle by exposing the excised gastrocnemius and triceps muscles of frogs to equal quantities of their vapours, and recording the extent and duration of contraction produced with or without electric stimulation. This method is open to the objection that hydrolysis of nitrite vapours occurs very rapidly in the presence of aqueous vapour, nitrous acid being produced. Now, muscle tissue is very susceptible to the influence of acids, and it seems by no means certain that the contractions recorded may not have been in part, at least, due to the acid evolved from the nitrite decomposition. With one exception (propyl nitrite) it was noted that the nitrites with low molecular weight were the least powerful in causing muscle contraction, but they acted for the longest time.

Concerning the effects which constitution of the molecule apart from composition has, it was noted throughout that when the effects of primary, secondary, and tertiary nitrites having the same composition were compared, the secondary nitrite was found to have a more powerful influence on pulse acceleration, blood pressure, and muscular contraction than the primary, and the tertiary than the secondary.

The fact that the acceleration of the heart caused by the various fatty nitrites increases with their molecular weight indicates, as the authors justly assume, that the quickening action on the pulse cannot be simply conditioned by the amount of nitroxyl in their molecules, even though it may be true that the nitroxyl group itself quickens the heart's action, for the molecule of methyl nitrite, which is the least effective, contains the largest amount of NO_2, whilst that of amyl nitrite, which most powerfully accelerates the heart's action, contains less NO_2 than any of the other nitrites examined. A similar conclusion is drawn with regard to the influence of the nitroxyl element in causing lowered blood pressure. It is further pointed out, that the preponderance of the hydrocarbon molecules in the higher nitrites is not necessarily the cause of their increased influence in quickening the pulse and lowering pressure. There are other possible causes. After considering some of these the authors express their opinion that the more marked effect of the nitrites having the largest molecules but containing the smallest amount of NO_2 is due to their decreased chemical stability. They incline apparently to the view that the actual molecules of the paraffinic nitrites do not accelerate the heart's action and lower tension, and give reasons for believing that they may actually retard the rapidity of the heart's beat. When, however, the molecule is broken up, the nitrite element becomes active, entering, perhaps, into loose combination with hæmoglobin and certain tissues before it is finally oxidised and eliminated.

The lower combinations, such as ethyl and methyl, being, as they suppose, least easily broken up, exercise least power; on the other hand, for the same reason they act for a longer time, both in lowering tension and contracting striated muscle.

To the greater instability of secondary as compared with primary, and of tertiary as compared with secondary nitrites, they attribute their respectively greater power, rather than to the fact that in the secondary and tertiary compounds one and two methyl groups are respectively attached to the carbon combination of the nitroxyl group. Much remains to be done before the inferences drawn from the elaborate investigations, the results of which have been presented to the Royal Society, can be regarded as definitely proved; but this paper adds, in an important manner, not only to our knowledge of the action of the nitrites, but to our comprehension of the manner in which chemical agents influence the tissues, and become of therapeutic value.

THE LATE PROFESSOR J. P. COOKE.

THE death of Prof. J. P. Cooke was briefly announced in these columns on September 13. The following particulars, for which we are indebted to an obituary notice in the *Tribune* of Cambridge, U.S.A., will be read with melancholy interest by the scientific world:—

Josiah Parsons Cooke was born in Boston, October 12, 1827. He was prepared in the Boston schools, and entered Harvard College in 1845, graduating three years later. In the following year he was appointed an instructor, and, in 1851, Erving professor of mineralogy and chemistry, and director of the chemical laboratory of Harvard University, a post he held until his death.

At the time Prof. Cooke entered upon his duties as head of the chemical department at Harvard, the methods of instruction were of the most rudimentary sort. Students in chemistry were required only to hear so many lectures; work in the laboratory was thought unnecessary, its place being taken by the few experiments which the lecturer saw fit to perform before his classes. Now the chemistry courses at Harvard, as at all other American colleges, consist almost entirely of laboratory work. The credit for this change is due very largely to Prof. Cooke.

Prof. Cooke was made an LL.D. by the University of Cambridge in 1882, and received the same degree from Harvard in 1889. He was a Fellow of the American Academy and a Member of the National Academy of Science. He was a popular lecturer, and delivered several courses at the Lowell Institute, one of the best-remembered being that given in 1887 on the "Necessary Limitations of Scientific Thought."

He was the author of a number of books, pamphlets, and scientific papers. Perhaps the best known of his books was his "Religion and Chemistry," published in 1864, which maintained that the designs of a higher intelligence were to be discovered in the province of chemistry. Among other books were: "The New Chemistry," and its companion volume, "Laboratory Practice," reviewed in NATURE, vol. xlvi. p. 99, "The Elements of Chemical Physics," "The Principles of Chemical Philosophy," and "Scientific Culture."

Prof. Cooke was a highly cultivated man, whose attention was directed to many things outside of his own profession. One of his last published papers was written to recommend that scientific men should be educated more broadly. He did not believe in an exclusively scientific education.

His funeral on September 6 was attended by a group of men and women, whose mere presence was the highest compliment that could be paid to the memory of any man. The successors of Longfellow, Lowell, and the brilliant coterie with which Prof. Cooke was so long a part, were glad of the opportunity to show their love and respect for the man who was all but the last of his generation, there being only a very few of his early contemporaries left.

Among the well-known people present were President C. W. Eliot, Profs. H. B. Hill, W. W. Goodwin, Francis J. Child, Josiah Royce, C. L. Jackson, G. A. Bartlett, Edward Cummings, Ira N. Hollis, Dr. Samuel A. Green, Prof. William Watson (one of the secretaries of the American Academy of Arts and Sciences, of which Prof. Cooke was president), Dr. Henry P. Wolcott, and Dr. Benjamin E. Cotting.

NOTES.

Mr. Frank McClean, writing to Dr. Gill, under date of August 10, has expressed his desire to present a large equatorially mounted telescope, equipped for photographic and spectroscopic work, to the Royal Observatory at the Cape of Good Hope. With this object he has arranged with Sir Howard Grubb for the construction of a photographic refracting telescope of 24 inches aperture, and for an object-glass prism to work with it, having a refracting angle of 7½ degrees and the same aperture as the object-glass. The glass for the object-glass and prism have already been secured, and the definitive order for the instrument was given to Sir Howard Grubb on May 4 last. Coupled with the photographic telescope there is to be a visual refracting telescope of 18 inches aperture. The mounting is to be sufficiently elevated to allow a slit spectroscope, for the determination of stellar motions in the line of sight, to be attached to the photographic telescope, and the gift will include such a spectroscope, as well as an observatory of light construction. Subject to the concurrence of the Lords Commissioners of the Admiralty, Dr. Gill has cordially and gratefully accepted this noble gift to the Cape Observatory.

Capt. W. J. Wharton, the hydrographer of the Admiralty, has sent us a copy of a report, drawn up by Mr. P. W. Bassett-Smith, on the results of dredgings obtained on the great bank known as the Macclesfield Bank, in the China Sea. It may safely be asserted that never before has the biological condition of a sunken coral reef in mid-sea been so completely explored. One of the general results of the whole examination, hydrographical and zoological, is that on the whole of the two hundred miles forming the periphery of the bank, there exists a rim of coral in luxurious growth, and at a remarkably even depth below the surface of from ten to fourteen fathoms. Capt. Wharton points out that this evenness of depth is the most striking feature of the chart, and when the great distances are considered, this appears to be a strong argument against any movement of the bottom since the atoll form was assumed. It is at any rate quite evident that from the present time onwards no movement is necessary in order to form in the future a perfect atoll, the simple growth of the coral on the rim sufficing; and that we may have here an instance of a suitable original foundation for an atoll so formed, as pointed out by Mr. Darwin. Mr. Bassett-Smith's examination of the specimens was necessarily very cursory, and it is to be hoped that the mass of material collected may be thoroughly investigated by skilled zoologists at the British Museum, that full value may be obtained for the labour bestowed upon these examinations. The work is so admirable, and the results so important, that we shall return to the subject in a future issue.

At several London and provincial medical schools, on Monday last, the opening of the winter session was made the occasion for introductory addresses to the students. Dr. Isambard Owen, at St. George's Hospital, discoursed chiefly on the importance of mental training in medical study. He remarked that the method of the physician was the method ordinarily employed in all forms of physical investigation. Science consisted of soundly-drawn conclusions based upon accurately-made observations. Accurate observation was the foundation of all medical work; and Dr. Owen dwelt at some length on the fallacies of ordinary observation, and the scrupulous care needed to ensure exactitude. At St. Thomas's Hospital, the Rev. W. W. Merry delivered an address mainly concerned with Plato's criticisms upon the practice of medicine and surgery in Homeric times. Mr. G. Hartridge offered practical counsel to the students at Westminster Hospital, and, as an inducement to work, remarked that "the Royal Society numbers among its members a large proportion of medical men, a much larger number than all the other professions put together." At Middlesex Hospital, Dr. R. Boxall discoursed upon the relations existing between the public, the medical profession as a whole, and medical charities. Words of exhortation and advice were also offered at St. Mary's Hospital, by Dr. S. Spicer, and at University College Hospital, by Prof. H. R. Spencer. Miss M. Sturge advised the students at the London School of Medicine for Women to cultivate from the first a scientific habit of mind, as its possession was invaluable to the medical profession. Lord Bacon's words, "We must be content to stand before nature and ask questions; nature can only be subdued by submission," were quoted as a clue to the method of work of all great physicians.

The Council of the Institution of Civil Engineers has issued a long list of subjects upon which original communications are invited. Papers upon any question of professional interest will have their merits considered, even if they do not deal with subjects specified in the list. For approved papers the council has the power to award premiums, arising out of special funds bequeathed for the purpose, the particulars of which are as under:—(1) The Telford Fund, left "in trust, the interest to be expended in annual premiums, under the direction of the council." This bequest (with accumulations of dividends) produces £235 annually. (2) The Manby Donation, of the value of about £10 a year, given "to form a fund for an annual premium or premiums for papers read at the meetings." (3) The Miller Fund, bequeathed by the testator "for the purpose of forming a fund for providing premiums or prizes for the students of the said institution, upon the principle of the 'Telford Fund.'" This fund (with accumulations of dividends) realises nearly £140 per annum. Out of this fund the council has established a scholarship, called "The Miller Scholarship of the Institution of Civil Engineers," and is prepared to award one such scholarship, not exceeding £40 in value, each year, and tenable for three years. (4) The Howard

Bequest, directed by the testator to be applied "for the purpose of presenting periodically a prize or medal to the author of a treatise on any of the uses or properties of iron, or to the inventor of some new and valuable process relating thereto, such author or inventor being a member, graduate, or associate of the said institution." The annual income amounts to nearly £15. The next award will be in 1897. The council will not make any award unless a communication of adequate merit is received, but will give more than one premium if there are several deserving memoirs on the same subject. In the adjudication of the premiums, no distinction will be made between essays received from members of the institution or strangers, whether natives or foreigners, except in the cases of the Miller and the Howard bequests, which are limited by the donors. There is no specified date for the delivery of MSS., as when a paper is not in time for one session it may be dealt with in the succeeding one.

THE Queen has been pleased, on the recommendation of the Secretary for Scotland, to approve of the appointment of Mr. Angus Sutherland, M.P., as chairman of the Scottish Fishery Board.

THE death is announced of Prof. K. M. Albrecht, of Hamburg, at the age of forty-three. He was the author of several important researches in the domains of zoology and comparative anatomy.

DR. CHARLES L. EDWARDS has been appointed to the Chair of Biology in the University of Cincinnati, Ohio, U.S.A.

AT St. Helens, on Tuesday, Colonel Gamble laid the foundation-stone of an institute which is to form a central library and reading-room and a school for technical education and manual instruction. He has given the site, and will spend £20,000 on the building.

MR. WILLIAM LUNT, of the Royal Gardens, Kew, who acted as botanical collector to Mr. Theodore Bent's expedition to the Hadraumaut Valley, Southern Arabia, has been appointed, by the Secretary of State for the Colonies, Assistant Superintendent of the Royal Botanic Gardens, Trinidad.

SEVERAL earthquake shocks, accompanied by subterranean rumblings, were felt at Dortmund, Germany, on Tuesday morning, and caused some alarm.

AT the meeting of the Royal Photographic Society, to be held on Tuesday next, the medals will be presented to successful exhibitors at the annual exhibition, and the President will deliver an address.

THE new buildings of the Durham College of Science, Newcastle-upon-Tyne, will be opened by the Mayor of Newcastle on Tuesday, October 9.

SUNSHINE is such an untrustworthy quantity in the climate of the British Isles, that it is no wonder that professional photographers have for some time been developing methods for making themselves independent of it. Judging from the extent in which artificial illumination is used in photographic studios at the present time, it seems probable that a few years hence the sun will be largely (if not entirely) disregarded in negative-making. An exhibition of apparatus for illuminating studios, and some of the pictures obtained by means of artificial light, is now being held at the *Photogram* Commercial Museum, and will remain open until the end of this month. A number of interesting exhibits are on view. There are various magnesium lamps, electric lamps designed for portraiture work, and gas-light systems for studios. Two of the most interesting instances of the use of magnesium flash-lamps are to be found in the pictures obtained by Mr. J. C. Burrows in the tin mines of Cornwall, and Mr. H. W. Hughes in the coal mines of the Black Country. The exhibition well deserves a visit.

THE *Weather Review*, edited by Mr. John Eliot, and published every month by authority of the Government of India, always contains an admirable summary of the chief features of the weather in India during the month to which it refers. The annual summary, which has just reached us, contains a discussion of the meteorology of India for the year 1893. The report reminds us that meteorological data in India are chiefly utilised for the following purposes: (1) In the discussion of the prevalence and spread of diseases, more especially of cholera and other diseases of an epidemic character; (2) in connection with agricultural questions, more especially the progress and character of the crops as determined by the weather conditions of the period. In the monthly reviews, all the meteorological facts and data are therefore presented from these two points of view. For medical statistics India is divided into eleven provinces, which are believed to be fairly homogeneous so far as the conditions of the prevalence of the more common diseases are concerned. According to the second method of arrangement, there are fifty-two meteorological divisions, or areas divided from an agricultural standpoint. By following this plan, the meteorological data available are made to yield the greatest amount of good to the people of India.

QUESTIONS of natural history assume a particular value when they deal with the supply of a popular article of food, and we present, therefore, some conclusions recently arrived at by Mr. F. H. Herrick, of the U.S. Fish Commission, upon the reproductive habits of the American lobster (*Zoologischer Anzeiger*, xvii. No. 454). It is not improbable, as Mr. Herrick suggests, that the habits of the European lobster are essentially the same as those of its American relative. (1) The majority of adult females extrude their eggs during June, July, and August, but a considerable number—probably 10 per cent. of the entire number which breed in the year—lay eggs in the autumn, winter, and spring. (2) The lobster cannot possibly breed oftener than once in two years. (3) The eggs are carried by the mother for ten or eleven months: on the coast of Massachusetts, from the middle of July to the middle of the following June. (4) Sexual maturity is reached occasionally at a length of 8 inches, but sometimes not under 12 inches. The majority, however, are mature when $10\frac{1}{2}$ inches long. (5) The numbers of eggs produced by female lobsters at each reproductive period increase in a geometrical series, while the lengths of the lobsters producing these eggs vary in an arithmetical series. A lobster 14 inches long will produce four times as many eggs at one laying as a lobster of only 10 inches. (6) Out of the 10,000 eggs produced at one time, not more than two arrive at maturity, and even this estimate is probably too high, as the fisheries are now declining.

THE exact measurement of the density of very dilute aqueous solutions to within a millionth of its value, is the subject of a paper by F. Kohlrausch and W. Hallwachs in *Wiedemann's Annalen*. The method adopted was that of suspending a glass globe in the solution by a fine thread, and determining its weight. The thread found most suitable was a single smooth cocoon fibre. Small disturbing fibres or dust particles could be detected by the behaviour of the swinging balance. The stirring was done by means of a glass rod bent into a horizontal ring at the bottom, and carrying a ring of platinum foil. During stirring, the glass body was lifted by another glass ring provided with pieces of platinum wire to prevent the body sticking to it. The thermometer indicated hundredths of Centigrade degrees, and could be read to thousandths by the telescope. The sensitiveness of the balance employed was not excessive, since it gave a deflection of two-thirds of a millimetre for a milligram. The weight of the suspended body was 133·310 gr., and the loss of weight in the solutions was always over 129 gr., so that the thread was not required to support more than 4 gr. The loss of weight in pure water was 129·194 gr. at 17·5° C., and did not vary by more than 0·002 gr. in five months. The difference in the individual numbers for the loss of weight in any given liquid was 0·11 mg. on the average, which corresponds to about a millionth of the density to be determined. These very accurate determinations brought out some interesting details with regard to the "molecular volumes" of the substances in solution. Phosphoric and sulphuric acids showed a decided diminution of this volume at extreme dilutions, while sugar, hydrochloric and acetic acid, and sodium chloride and carbonate did not show this diminution.

THE *Annales de Chimie et de Physique* for September contains a paper, by M. Henri Bagard, on the thermoelectric force between two electrolytes, and on the Thomson effect in the case of electrolytes. The paper contains a very complete history of the work which has been done on this subject. The author uses a number of thermoelectric junctions joined in series, and measures the electromotive force developed by a given difference in temperature between the hot and cold surfaces of separation between the electrolytes by means of a capillary electrometer. This electrometer was capable of indicating an electromotive force of one-hundred-thousandth of a volt. In order to check the diffusion which takes place at the common surface of the electrolytes, the author uses a porous membrane. By using membranes composed of such different substances as goldbeater's skin and vegetable parchment, it was proved that the membrane had no effect on the electromotive force, except to cause it to diminish slightly with time. Thus the results obtained with a membrane are probably identical with what would be obtained could observations be made without a membrane, and without diffusion and convection currents being set up through the surface of separation. Observations were taken both while the temperature of one junction was rising and again when cooling. The points obtained during the second of these operations often fell below the curve given by the previous set. This effect, which never amounted to a difference of $\frac{1}{10000}$ volt, the author considers to have been entirely due to diffusion. Thermoelectric couples, consisting of solutions of two different salts, and of solutions of the same salt but of different concentration, were examined, and the results obtained are shown by means of curves. In order to examine the Peltier and Thomson effects in the case of electrolytes, small bolometers were employed to measure the change in temperature. The important fact that the Peltier effect is of opposite sign on opposite sides of the neutral point was amply verified, and it appears that the change of sign takes place at the neutral point. In all cases the thermoelectric phenomena, the Peltier effect and the Thomson effect gave results in the case of electrolytes similar to those obtained with metals.

"CREAMERIES and Infectious Diseases" is the title of a short paper which Dr. Welply has had reprinted from the *Lancet*. It is a most useful little pamphlet, inasmuch as it calls attention to a danger which, so far, has escaped public notice. Creameries receive, as is well known, their milk from a number of farms; but after the cream has been removed, some of the skim or separated milk is sent back to the farms, where it is consumed in various ways. The milk received from the various farms is all mixed together, and thus it is not difficult to see how one case of typhoid fever, or some other illness on one of these farms, may not only infect the creamery, but may, by means of the separated milk, infect the whole group of dairies supplying this creamery, thus starting an indefinite number of fresh disease centres. Dr. Welply describes an outbreak of typhoid fever which he traced to a creamery, and to the use of food or milk from dairies which became infected secondarily. In several of the dairies which he visited, he states that he found the dairy-maids acting in the dual capacity of milkers and nurses, and he is distinctly of opinion that the contagium got into the milk from the hands of the dairy-maids. It is clear that unless we can obtain stringent regulations passed, such as are in use in Denmark, Sweden, and Germany, and which our Board of Agriculture have published in their reports on dairy farming in these countries, unless we can procure similar legislative measures, co-operative dairy farming in England will always remain a continual source of danger to the public health. Dr. Welply says "it would be wise at all times to boil separated milk when used as an article of human diet"; we would go still farther, and say that it is undesirable to drink any milk which has not been previously thoroughly boiled, not warmed or brought to the boil, but boiled for several minutes. The National Health Society took this question up some years ago, and issued a short leaflet on the advisability of boiling all milk before use.

LUERSSEN AND HAENLEIN'S *Bibliotheca Botanica* will in future be edited by Prof. C. Luerssen and Prof. B. Frank.

MESSRS. BLACKIE AND SON have just issued part 6 of Prof. Oliver's translation of Prof. Kerner's "Natural History of Plants."

WE have received the Calendars for the Session 1894–5, of the University College, Bristol, the Durham College of Science, Newcastle-upon-Tyne, and the Merchant Venturers' Technical College, Bristol.

THE General Report on the Operations of the Survey of India Department for 1892–93 has just been issued from the office of the Superintendent of Government Printing, Calcutta.

THE June number of *Timehri*, the journal of the Royal Agricultural and Commercial Society of British Guiana, has just come to hand, and contains, as usual, a number of very varied and interesting papers, notably, "The Guiana Orchids," by the editor—James Rodway; "Late Rainfalls, some of their Effects," by James Gillespie; and "Some Enemies of our Canefields," by S. R. Cochran. The society celebrated the fiftieth year of its existence in March of this year, when a successful historical exhibition was held in honour of the event.

THE sixteenth annual meeting of the Greenock Natural History Society was held on September 28, Mr. T. L. Patterson, president, occupying the chair. During the session 1893–94 seven papers were read, viz.: "The Sorghum Sugar Experiments in the United States," by Mr. T. L. Patterson; "A Study of Fungi," by Dr. M. Calder; "Scenes from Australia," by Mr. Thomas Steel; "Gems and Precious Stones," by Mr. James M'Neil; "The Evolution of Navigation and Nautical Astronomy," by Mr. G. W. Niven; "Plants with Angular Stems," by Mr. John Ballantyne, Rothesay; "Notes on the Cladocera," by Mr. M. F. Dunlop.

"SCIENCE is measurement." Mr. J. Lawrence, of 56 Fulham Road, London, evidently believes that the converse of this is true, for he has sent us a "Tell-tale" milk-jug, which London milkmen will probably regard with sorrowful feelings. The object of the jug is to furnish householders with a standard wherewith to judge the probity of their dairymen. The jug is a glass measure graduated at every quarter-pint. Below each pint and half-pint mark three lines are etched showing the thickness of cream which should appear in milk of average quality, in milk of good quality, and in milk of very good quality after the liquid has been allowed to stand for a time. Both the quantity and the quality of the milk can thus be easily tested.

The Society for Promoting Christian Knowledge have just brought out a second edition of "Our Secret Friends and Foes," by Prof. Percy Frankland, F.R.S. It will be remembered that the volume was the source of a good deal of discussion between some members of the Society, who, with the late Lord Coleridge at their back, announced their intention of retiring from their membership unless the book was withdrawn from circulation, it being, according to their interpretation, written in support of vivisection. That the Society did not yield to the very considerable pressure brought to bear upon them, is evidenced by the appearance of the second edition, which, whilst containing an entirely new chapter on the action of light on micro-organisms, remains otherwise, with the exception of a few (mostly verbal) alterations, unchanged.

Messrs. Chapman and Hall will publish, almost immediately, a complete "Text-book of Mechanical Engineering," by Mr. W. J. Lineham, the Head of the Engineering Section of the Goldsmiths' Institute, New Cross. The work consists of nearly eight hundred pages and more than seven hundred figures. The first half is devoted to practical work, viz. casting and moulding, pattern-making, and casting design; metallurgy and properties of materials; smithing and forging; machine tools; marking off; fitting, machining, and erecting; boiler-making and plate-work. The second part of the book deals with theory and examples, the order of treatment being strength of materials; energy and the transmission of power to machines and heat engines; hydraulics and hydraulic machines. The book is not supposed to be an exhaustive treatise on mechanical engineering; nevertheless, it will be a valuable aid to engineering students and apprentices, and engineering draughtsmen generally.

Since the publication of "Forthcoming Scientific Books" in our issue of September 20, the following list of announcements has been sent to us by the Cambridge University Press:—"The Scientific Papers of John Couch Adams"; "A Treatise on Spherical Astronomy," by Prof. Sir Robert S. Ball, F.R.S.; "Hydrodynamics: a Treatise on the Mathematical Theory of the Motion of Fluids," by Prof. H. Lamb, F.R.S., new edition; "Catalogue of Scientific Papers compiled by the Royal Society of London," new series for the years 1874–83, vol. xi. in the press; "A Treatise on Geometrical Optics," by R. A. Herman; "An Introduction to Abel's Theorem and the allied Theory," by H. F. Baker; "A Treatise on Geometrical Conics," by F. S. Macaulay; "An Elementary Introduction to Mineralogy," by R. H. Solly; "Euclid's Elements of Geometry," Books XI. and XII., by H. M. Taylor; "Arithmetic for Schools," by C. Smith, with or without answers, second edition; "Key to C. Smith's Arithmetic"; "Practical Physiology of Plants," by F. Darwin, F.R.S., and E. H. Acton; "Practical Morbid Anatomy," by Dr. H. D. Rolleston and Dr. A. A. Kanthack; "The Distribution of Animals," by F. E. Beddard, F.R.S.; "Petrology," by A. Harker; "Text-book of Physical Anthropology," by Prof. Alexander Macalister, F.R.S.; "The Vertebrate Skeleton," by S. H. Reynolds; "Fossil Plants: a Manual for Students of Botany and Geology," by A. C. Seward; "Elements of Botany," by F. Darwin, F.R.S.; "Mechanics and Hydrostatics," by R. T. Glazebrook, F.R.S.; "Electricity and Magnetism," by the same author.

Messrs. Charles Griffin and Co. have also sent a list of the scientific books they hope to issue during the ensuing season; it is as follows:—"Petroleum," a treatise on the geographical distribution, geological occurrence, chemistry, production, and refining of petroleum; its testing, transport, and storage, and the legislative enactments relating thereto, together with a description of the Shale Oil industry, by Boverton Redwood, assisted by Geo. T. Holloway, with maps and illustrations; "Calcareous Cements: their Nature, Preparation, and Uses," with some observations on cement testing, by Gilbert R. Redgrave; "Griffin's Chemist's Pocket-book": tables and data for analysts, chemical manufacturers, and scientific chemists, by J. Castell-Evans; "Measurement Conversions" (English and French), 28 graphic tables or diagrams, showing at a glance the mutual conversion of measurements in different units of length, areas, volumes, weights, stresses, densities, quantities of work, horse powers, temperatures, &c., for the use of engineers, surveyors, architects, and contractors, by Prof. Robert Henry Smith; "The Metallurgy of Iron," by Thomas Turner; "An Elementary Text-book of Metallurgy," for the use of younger students and those commencing the study of metallurgy, by Prof. A. Humboldt Sexton, with numerous illustrations; "Kitchen Boiler Explosions: why they occur, and how to prevent their occurrence," a practical hand-book, based on actual experiments, by R. D. Munro; "Fibroid Diseases of the Lung, including Fibroid Phthisis," by the late Sir Andrew Clark, Bart., F.R.S., and Drs. W. J. Hadley and Arnold Chaplin, with tables, and eight plates in colours; "Practical Hygiene," including air and ventilation, water, supply and purity; food and the detection of adulterations, sewage removal, disposal, and treatment, epidemics, &c., by Surgeon-Major A. M. Davies, with illustrations; "A Manual of Ambulance," by J. Scott Riddell, with numerous illustrations and full-page plates; "The Hand-Rearing of Infants: a Guide to the Care of Children in Early Life," by Dr. John Benj. Hellier; "Year-book of the Scientific and Learned Societies of Great Britain and Ireland," compiled from official sources, including lists of the papers read during 1894 before Societies engaged in fourteen departments of research. Twelfth annual issue (early in 1895).

One of the most striking features of chemical progress at the present time is the rapid advance which is being effected in our knowledge of the compounds of nitrogen. Another compound of primary importance, symmetrical hydrazo-ethane, $C_2H_5NH.NHC_2H_5$, the symmetrical di-ethyl derivative of hydrazine, has been isolated in the laboratory of the Berlin University by Dr. Harries. Prof. Emil Fischer has already obtained the unsymmetrical di-ethyl hydrazine, and Prof. Curtius, to whom we owe the discovery of hydrazine itself, some time ago succeeded in obtaining the symmetrical di-benzyl hydrazine, but hitherto the simple symmetrical fatty hydrazines have eluded isolation. Indeed it is only by a somewhat circuitous, although practically quite easy, series of reactions that symmetrical di-ethyl hydrazine has at length been prepared. A remarkable derivative of hydrazine was first obtained, in which one hydrogen of each amidogen radicle was replaced by the radicle formyl, CHO, and the other by the metal lead, the compound being represented by the formula

$$\begin{array}{c} CHO{-}N{-}N{-}CHO. \\ \diagdown\;\diagup \\ Pb \end{array}$$

This substance, a white powder, is readily obtained by reacting with sodium upon di-formyl hydrazine, a compound with which Prof. Curtius has made us familiar, and subsequently decomposing the latter with sugar of lead. The lead compound, when slightly heated in a sealed tube with ethyl iodide, together with sand to maintain porosity, and magnesia to fix the liberated hydriodic acid, is converted into a compound in which the lead atom is replaced by two ethyl groups. This latter compound, a somewhat volatile liquid, is treated with fuming hydrochloric acid, which removes the formyl groups and converts the compound into symmetrical di-ethyl hydrazine hydrochloride, which is precipitated. Upon distillation with caustic potash the free di-ethyl hydrazine passes over at 85°. The new compound is a liquid of pleasant odour, reminding one at the same time of ether and of weak ammonia. It reduces Fehling's solution with great energy upon gently warming, and silver nitrate in the cold. It vigorously attacks caoutchouc. Its hydrochloride contains two molecules of hydrogen chloride, and crystallises well in plates melting at 160°. The symmetrical di-ethyl hydrazine behaves in a most interesting manner with certain oxidising agents, particularly mercuric oxide. The yellow oxide reacts in a most violent manner, but the red oxide affords a more manageable reaction; the products are a large quantity of mercury di-ethyl, $Hg(C_2H_5)_2$, and a smaller quantity of azoethane, $C_2H_5N = NC_2H_5$, the ethyl analogue of the well-known azobenzene. The symmetrical and unsymmetrical di-ethyl hydrazines are clearly distinguished by their reactions with nitrous acid, for while the latter yields di-ethylamine and nitrous oxide, the former affords ethyl nitrite together with a smaller quantity of a nitroso compound.

THE additions to the Zoological Society's Gardens during the past week include two Bonnet Monkeys (*Macacus sinicus*, ♂ ♂) from India, presented respectively by Mr. Philip E. Morel and Miss Ling; a Common Marmoset (*Hapale jacchus*) from Brazil, presented by Mr. A. E. W. Burns; a Brush-tailed Kangaroo (*Petrogale penicillata*, ♀) from New South Wales, presented by Lady Isabel Clayton; three Australian Cranes (*Grus australasiana*) from Australia, a Brown Crane (*Grus canadensis*) from North America, an Indian White Crane (*Grus leucogeranos*) from India, presented by Mr. E. W. Marshall; two Californian Quails (*Callipepla californica*) from California, presented by Mr. H. H. Howard Vyse; a Ground Hornbill (*Bucorvus abyssinicus*), from Nyassaland, presented by Mr. H. H. Johnston, C.B.; three Pratincoles (*Glareola pratincola*), four Night Herons (*Nycticorax griseus*), a Great Bustard (*Otis tarda*), South European, presented by Lord Lilford, three Dwarf Chameleons (*Chamaeleon pumilus*) from South Africa, presented by Mr. C. Stonham; two Cerastes Vipers (*Vipera cerastes*), two Egyptian Eryx (*Eryx jaculus*), a Cliffords Snake (*Zamenis cliffordi*) from Egypt, deposited; A Simonys Lizard (*Lacerta simonyi*) from the Island of Hiero, Canaries, presented by Mr. Sydney Crompton; a Deadly Snake (*Trigonocephalus atrox*) from Trinidad, presented by Messrs. Mole and Urich; an Axis Deer (*Cervus axis*), a Rufous Rat Kangaroo, *Hypsiprymnus rufescens* born in the Gardens.

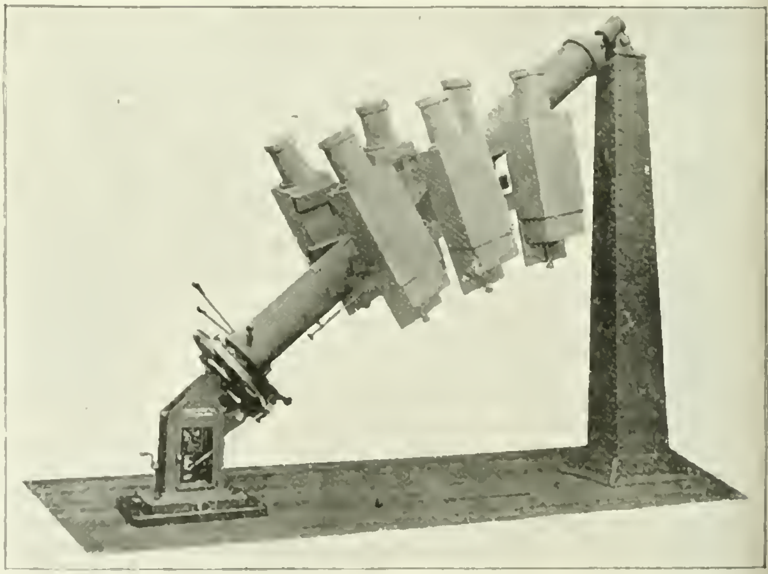
OUR ASTRONOMICAL COLUMN.

AN INSTRUMENT FOR PHOTOGRAPHING METEORS.—Up to the present time meteoric astronomy has had little, if any, instrumental equipment to further its development, the nature of the phenomena rendering simple naked eye observations the only available means of research. It is true that even now we know of a very considerable number of radiant points, and what is more, we have been able to note the daily movements of some of these in the heavens; but this knowledge has only been gained by the great patience and perseverance of astronomers, the most notable being Mr. W. F. Denning. With a thorough knowledge of the constellations, a good globe or star-map, and an accurate eye, he has been able to plot down track after track of these travellers through space, deducing from their paths the points in the heavens from which they are coming.

What will most probably lead to a great advance in the determination of the positions of these radiant points, is the introduction of photography for recording permanently the visible tracks in the sky. There may have been many attempts already for photographing these trails, and the writer himself a few years back, with an ordinary camera, was fortunate enough to catch nine trails on the sensitive plate. The camera being fixed and not equatorially mounted, the star images were consequently curved arcs, and not points. Even on this plate fairly accurate positions of the trails could have been obtained.

A somewhat unique instrument for locating the tracts of meteors and their radiant points, has recently been constructed by Messrs. Warner and Swazey for the Yale University Observatory. The accompanying illustration of the instrument is from *Popular Astronomy* for September.

The illustration shows the polar axis of the "English" form carrying a number of cameras. The axis is of a tubular form, about twelve feet long, the ends working on pivots which are capable of adjustment. The southern support is connected with clockwork, while that at the northern end is supported on a pillar in which are the driving weights in connection with the clock by cords passing under the floor. On the declination axis are fitted two arms which serve as supports to the cameras, three cameras being on the eastern and three on the western side. These cameras are so oriented that they take, in their



respective fields, adjoining portions of the sky, so that altogether they cover a very large area. The instrument is supplied with slow motions, both in right ascension and declination, and the clockwork has an electric control. Whether satisfactory results have yet been obtained, one cannot say, but the apparatus was intended to be used for the Perseid swarm of October last.

SUN-SPOT OBSERVATIONS AT THE POTSDAM OBSERVATORY.

IN the publications of the "Potsdam Astrophysical Observations," Dr. Sporer has previously (No. 17) presented us with the observations of the sun-spots for the years 1880 to 1884. The most recent addition to these records will be found in No. 32, in which are collected the sun-spot observations for the years 1885 to 1893. The observations themselves are given in all details, being grouped together with regard to the period of rotation. These are followed by a brief discussion, from which these notes and extracts have been made.

The following table, bringing together the results relative to frequency and positions (as regards latitude) of the spots may be first given, as many references will be made to the numbers therein :—

Year.	Frequency. Northern hemisphere.	Frequency. Southern hemisphere.	Frequency. Both hemispheres.	Mean heliographic latitude. Northern hemisphere.	Mean heliographic latitude. Southern hemisphere.	Mean heliographic latitude. Both hemispheres.
				°	°	°
1870	738	765	1503	+17·0	−18·9	17·9

1893	437	627	1064	14·4	15·3	14·9

From the table above, it will be seen that the minimum of 1878 was followed after 5·2 years by a maximum in 1884·0. The mean heliographic latitude of the spots at this period of maximum decreased to 12°, which is lower than was the case at the preceding maximum. Following this a minimum in 1889·5 occurred, the precession of spots disappearing at the mean latitude of 7°, and a new series beginning in 1889 at 40° on the southern hemisphere, and somewhat later at 23° and 35° on the northern hemisphere. Higher latitudes were at times recorded, the highest occurring in September 1893 and amounting to 42°. The mean yearly heliographic latitude for 1893 diminished to 15°. For the earlier part of the present year five periods of rotation have given for the mean latitude also 15°, indicating, when compared with the two foregoing periods, a further decrease in the numbers representing the "frequency." The time of maximum then can apparently be placed at 1893·5, but this would most probably have to be altered if the more recent observations show a further rising.

An examination of the Carrington observations also shows this movement in the heliographic latitude. Wolf, to explain it, suggested the existence of currents, which commenced with a minimum on both hemispheres in high latitudes, and continued to the following minimum towards lower latitudes. As indications of these currents, it might be stated that at the times of maximum suitable stripes appear on the meridian, which are for a long time free from spots and faculæ. This suggests that "special channels exist from time to time for the hypothetical currents."

Dr. Spörer next examines the old sun-spot observations for finding out the period from the "rate" of the heliographic latitudes. The cases he takes into consideration show, as he says, "eine genügende Uebereinstimmung mit den neueren Beobachtungen in Betreff des Ganges der mittleren heliographischen Breite während der Haufigkeits perioden. Dagegen scheinen nach dem Jahre 1614 in einen Zeitraume von 70 Jahren wesentlich andere Verhaltnisse geherrscht zu haben."

Different records, he goes on to say, agree that from 1645–70 the spots observed were few. After this the number increased, reaching an important maximum in 1716. It was even then remarked (in 1715) that it was curious to note that spots were visible on different parts of the solar disc at the same time. In 1704 and the following year, one case occurred in which spots at the same time, but on two different positions of the disc, were seen; it was here expressly stated that such had not been observed for sixty years. Other instances (two) of this "scarce" case occurred in 1707. In 1716, spots were seen for several days, in eight different places on the disc.

Bringing together the positions of the observed spots, as regards latitude, Dr. Sporer adds that from 1671–1713 none were found in high latitudes. The highest (in 1703) was 19°. Previous to this, from November 1700, the latitude lay between 2° and 12°. At this time higher latitudes had been normal, because from May 1695–Nov. 1700 not a single spot had been observed. For this reason Prof. Wolf is stated to have assumed a minimum (1698·0), and determined the following minimum 1712·0, the authenticated records giving the information that no spot appeared in the years 1711 and 1712.

Some interesting facts may be stated now regarding the spots on the respective northern and southern hemispheres. The deficiency of spots for the former is "noch besonders hervorzuheben." In 1671, during two periods of rotation, a spot (12° N. Lat.) was observed. In 1705 and 1707 a spot is also cited to have been seen, but the northern hemisphere was free from them until 1713, and it was not till 1714 that they were then found to be numerous; thus one can hardly assume that, besides those recorded on the northern hemisphere, more spots in greater number appeared, for Cassini mentioned expressly, from the observation of a spot from the year 1707, "the spot deficiency of the northern hemisphere," and at the same time remarked "that the constitution of the northern hemisphere was different in a certain manner from that of the southern hemisphere." A glance at the records for the period 1644–1670 also shows that in the "period of seventy years on the northern hemisphere certainly no periodicity of spots had occurred."

The behaviour of the two hemispheres, as regarded in the light of more recent observations, is also very striking, and since 1883 the southern hemisphere has received the greater preponderance of spots. This continued to be the case during the minimum, and only discontinued when a rise of the number of spots had begun on the two hemispheres. The year 1891 was a critical year, on account of the astonishing change that was brought about.

While on the southern hemisphere the number of spots only slowly increased, that on the northern hemisphere attained considerably greater proportions. The resulting ratio for the spots during the year 1891 was as 8 : 3 for the northern and southern hemisphere respectively. The nature of this preponderance for the northern hemisphere was not more than temporary, for in 1892 it had greatly diminished, and the southern hemisphere had again attained its old position. Last year the proportion for the northern and southern was as 7 : 10.

The division of the spots with regard to their heliographic latitude displays also differences for the two hemispheres. A table bringing together the results for five periods of rotation indicates a great difference in the mean values of the heliographic latitudes; this difference, on the other hand, is to a certain extent eliminated if one deals with the yearly mean.

Reference is made also to the great change that occurs in the "Rotationswinkel" of some spots. "The most simple case for such a difference of the angle of rotation teaches us, if only in the first instance a spot with a penumbra is present, that a division takes place, which results in the appearance of two separate spots. Such spots regularly move away from one another, each having a separate penumbra. The observations furnish examples which show that the distance of the spots for many days continually increases, and that the angle of rotation of the preceding spot is very considerably greater than that of the following one." The observations included in this volume contain examples of these in great number.

W. J. L.

PHYSICS AND ENGINEERING AT THE McGILL UNIVERSITY, MONTREAL.

SO long ago as 1855, Sir William Dawson pointed out the importance to the McGill University of a department of practical science. But though some attempt was made to carry out the suggestion, little success was obtained until 1878, when the department was constituted a Faculty of Applied Science, with Prof. H. T. Bovey as Dean. The Faculty passed through many vicissitudes, but it was placed on a firm basis at the beginning of last year, by the opening of well-furnished workshops and laboratories equipped with the best and most modern apparatus for scientific investigations in all kinds of engineering and physics. A description of the opening ceremonies has lately been published in a souvenir volume, together with descriptions of the main features of the laboratories. We are indebted to this volume for the following information, and to Dean Bovey for the accompanying illustrations.

The McDonald Engineering Building, erected and equipped through the munificence of Mr. W. C. McDonald, one of the Governors of the University, is a fine structure containing laboratories for all branches of engineering work. The Physics Building owes its existence to the generosity of the same donor. It has been designed for the teaching and study of physics (including mechanics) with special regard to (1) its intrinsic importance as an integral part of a liberal education in the Faculty of Arts; (2) its essential necessity as a study preliminary to the courses of engineering, mining, and practical chemistry in the Faculty of Applied Science, and (3) the prosecution of scientific research. The completeness and liberality with which all the necessary plant has been put into these buildings may be judged from the accompanying illustrations and brief descriptions. It will astonish the various authorities who have similar technical institutes under their control in this country, to know that the cost of the equipment alone of the two buildings came to very nearly one hundred thousand pounds sterling! Compare this princely generosity with the fact that only twenty-three thousand pounds were asked for to erect and equip the Engineering Laboratory of the University of Cambridge. The exact amount of Mr. McDonald's benefactions has not been told, but they are certainly nearer seven than six figures. Everything, in fact, required in the pursuit of physical and engineering study has been lavishly provided. Few occupiers of chairs of Physics here are in the fortunate position of Prof. Cox. He was instructed to spare no expense in obtaining everything required to carry on work in experimental physics. "From first to last," he says, "whether it was a question of part of the buildings or of the equipment, I have heard no other language from Mr. McDonald than 'Let us have everything of the best, with a definite aim for everything, but always the best.'"

The Thermodynamic Laboratory (Fig. 1), in which heat engines are studied, has a very notable equipment.

The great feature of interest is a four-cylinder steam engine arranged double tandem fashion, and intended for use in a large number of totally different ways. This machine, designed by Messrs. Schonheyder and Druitt Halpin, of London, under the general direction of Prof. Carus-Wilson, of McGill College, was manufactured by Messrs. Yates and Thom, Blackburn.

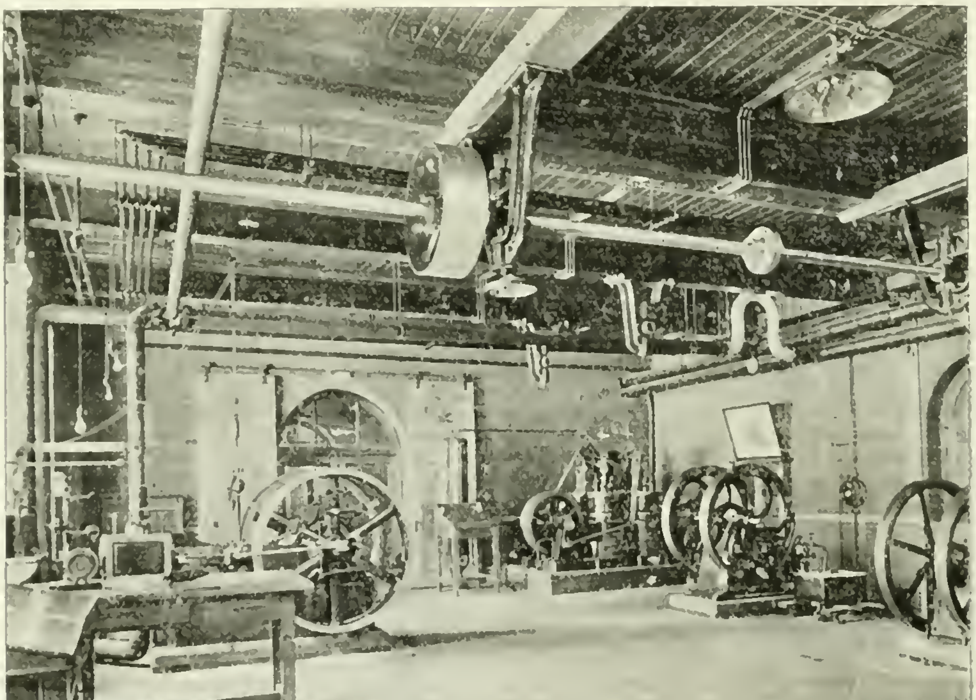

FIG. 1.—Thermodynamic Laboratory.

The engine may be described as a double tandem inverted direct acting quadruple expansion engine, to work at 200 lbs. pressure on the gauge, developing eighty horse-power at about 150 revolutions. The two engines may be uncoupled from each other, and run at different rates of speed on the plan proposed by Mr. John I. Thornycroft, and already carried out on the triple expansion engines at the Owens College, Manchester; and in this way the advantages of variation of relative cylinder volume are to some extent obtained.

The measurement of the power delivered to the brakes is made by means of hydraulic brakes of the types designed by the late R. E. Froude, and improved by Prof. Osborne Reynolds.

The steam pipes about the cylinders are so arranged that the engines may run either quadruple, triple, double, or single expansion. And as the pipes are led both to condenser and atmosphere, all these types may be tried either condensing or non-condensing.

In fact, a complete balance-sheet of the heat supplied, used, and rejected by the engines can be made, and the materials for the study of cylinder condensation by Hirn's analysis are easily obtained.

Several other engines and boilers are available for experimental purposes.

The Third-year Laboratory contains apparatus for the demonstration of the properties of the permanent gases and of steam; and a complete set of the most modern types of pyrometers and thermometers, gauges, mercury columns, planimeters, calorimeters, render possible investigation of many problems of importance to the engineering world.

In the third year, students of thermodynamics are taught the principles of the science by direct experiment; and original research is encouraged during the summer under the direction of the professor.

for many hours. The instrumental equipment consists of comparators, dividing engines; a portable Bessel's reversible pendulum, for the determination of gravity; an astronomical clock, break-circuit chronometer and chronograph; level triers, end-measuring gauges, and minor instruments.

The equipment of geodetic and surveying instruments for the use of students consists of transits and transit theodolites of various forms, levels of the Dumpy Wye and precision types, sextants for marine sounding and land work, plane tables of English and American forms, surveyors and prismatic compasses, current meters, an altazimuth for triangulation work, a zenith telescope, astronomical transits.

There are also hand levels, chains, steel bands, tapes, barometers, pedometers, and other minor instruments required for geodetic work.

The Mathematical Laboratory (Fig. 3) is liberally supplied with apparatus with which the student learns to make measurements of time, mass, distance, acceleration, and other quantities dealt with in the lectures, as well as to verify the fundamental

FIG. 2.—Geodetic Laboratory.

In the fourth year, engine boiler and fuel testing is largely worked at; and the higher parts of the subject are explained by reference to the results obtained from the indicator card, as measured and examined for moisture and heat exchange. The gas and hot-air engines are tested again and again, and the effect of the different factors which modify results pointed out by careful observation.

The Geodetic Laboratory (Fig. 2) is primarily designed for the investigation of apparatus used in geodetic and surveying operations; it also affords the means of producing standards of length and of graduating circles.

The laboratory is double-walled, and the inner wall, which is of brick, contains an air space. In the basement there is an air chamber, from which hot or cold air may be supplied to the work-room by a system of pipes. The air circulation is maintained by a fan which is driven by an electro-motor at any required speed. When the desired temperature is reached all openings are closed, and a practically uniform temperature held

laws of mechanics and to investigate various mathematical and dynamical constants. Special attention is directed to the general principles underlying the ordinary instruments of precision which are used in physics, the simpler forms of these instruments being put into the hands of the student at an early period in his course. The experiments are in almost all cases quantitative, and the learner is encouraged to attain the greatest possible precision which the nature of the experiment and the instruments available admit.

The Electrical Engineering Laboratories are under the care of Prof. C. A. Carus-Wilson. They consist of the magnetic laboratory, the electrical laboratory, the dynamo room and the photometer room.

The equipment in the magnetic laboratory comprises a ballistic galvanometer designed for use in a variable magnetic field (this can be connected with any apparatus in this room or in the dynamo room); a calibrating coil for the galvanometer, two magnetic yokes, a solenoid and spring balance for traction experiments up to one hundred pounds, fitted with search coil for ballistic tests; Ewing's magnetic curve tracer; round and rectangular bobbins for experiments in self-induction; a secohmmeter, telephones, rheostats, &c., and a set of secondary cells.

The electrical laboratory is situated over the dynamo room. Slate slabs are let into the wall on three sides of the room, and stout wooden tables placed down the centre. Current is supplied to all parts from the dynamo room. The apparatus here comprises a Thomson galvanometer, three Kelvin electrostatic voltmeters, two Siemens dynamo-meters, four d'Arsonval galvanometers, seven Weston ammeters and seven Weston voltmeters of different ranges, two Weston alternating wattmeters, two Kelvin balances, one of which is specially arranged for testing transformers; two Cardew voltmeters, several other ammeters and voltmeters of different types, standard cells, resistance boxes, rheostats, &c. All tests of transformers are carried on in this laboratory, the current being brought up from the dynamo room below.

dynamo, a 7 k.w. Fort Wayne dynamo, a 5 k.w. Brush arc light dynamo, a 7 k.w. Victoria Brush motor generator, a 15 k.w. Thomson-Houston incandescent dynamo, a 5 horse-power Crocker-Wheeler motor, and several smaller motors of different types; also a 12 k.w. Mordey alternator specially made for this laboratory (the armature coils can be moved through any angle, and two or three currents of any phase difference thus obtained). There are in the building at present eight motors driving lathes, fans, &c., besides a 10 horse-power electric elevator. The dynamo room also contains several transformers, arc lamps, &c., and a set of five enamel rheostats, each of which can be made to carry from 1 to 50 amperes on 100 volt circuit.

The photometer room is furnished with a Bunsen photometer and a Methven standard, and is specially arranged for testing incandescent lamps.

These four laboratories are supplemented by an *Electrical Workshop* containing a fine lathe, by the American Machine Tool Company, driven by an electric motor.

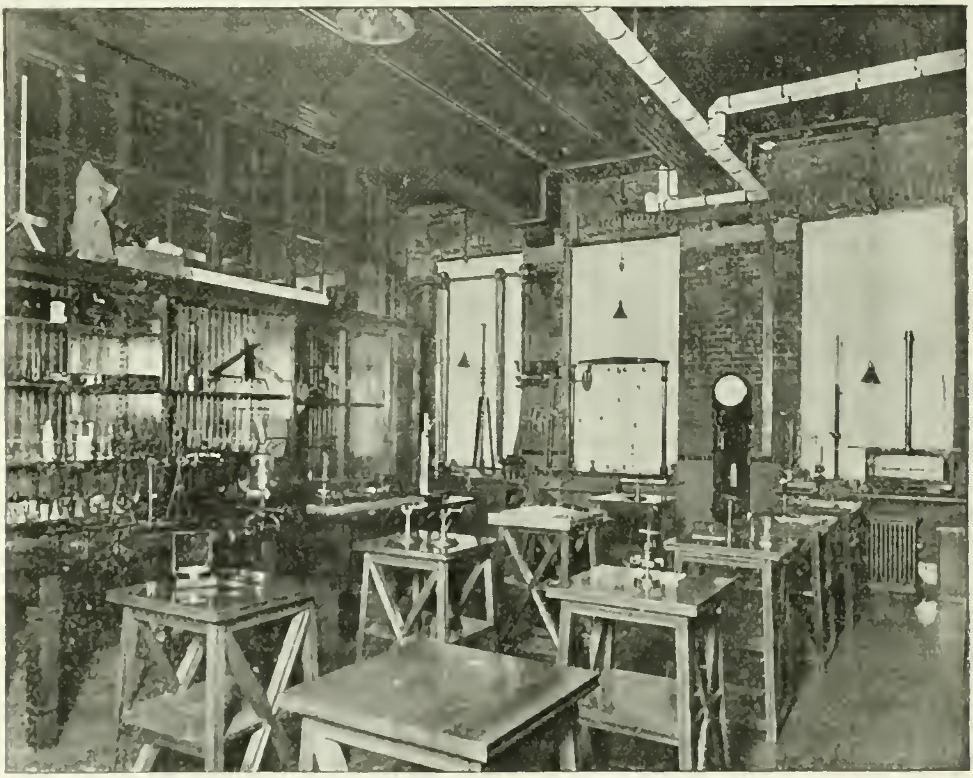

Fig. 3.—Mathematical Laboratory.

The dynamo room is on the ground floor. In one half of the room are placed the lighting, in the other the experimental dynamos. The *Lighting Dynamo* consist of a Siemens dynamo and an Edison-Hopkinson dynamo, each of 30 kilowatts output at 105 volts, and each driven by a 60 horse power Willans engine. The building is wired on the three-wire system, but can be run by either one of the dynamos when the load is light, or by a set of secondary cells of 800 ampere hours' capacity placed in another room. The lighting switch-board was made in the electrical workshop, and is fitted with Weston station ammeters and voltmeters. The *Experimental Dynamos* are driven off a main shaft either by a 90 horse-power MacIntosh and Seymour engine, or by a 25 k.w. Edison motor, as is most convenient. The main shaft is provided with ten magnetic clutch pulleys of 20 horse-power each, designed and fitted at the college, and with one magnetic clutch-coupling for 90 horse-power; the dynamos comprise two 12 k.w. Edison dynamos, a 7 k.w. Victoria Brush dynamo, a 6 k.w. Thomson-Houston arc light

The work in the Electrical Engineering Laboratories is commenced in the second term of the third year. By that time the students have gained a fair general acquaintance with electricity in the physical laboratory. They then begin a series of experiments on electricity and magnetism, using methods and instruments in ordinary practical use, confining their attention, however, to principles and not to their practical application. This term's work is preparatory to that of the fourth year, when students study the practical application of these principles in the dynamo room. Here they make experiments on electrical machinery of all kinds, and carry out tests of dynamos, transformers, motors, &c., under practical working conditions. They can also see a typical lighting station at work, and become familiar with the best practice and design in all branches of electrical engineering.

The practical instruction in the workshops is solely designed to give the student some knowledge of the nature of the materials of construction, to familiarise him with the more important hand and machine tools, and to give him some manual skill in the use of the same. For this purpose, the student, during a specified number of hours per week, works in the shops under the direct superintendence of the Professor of Mechanical Engineering, aided by skilled mechanics. The courses commence with graded exercises, and gradually lead up to the making of joints, members of structures, frames, &c., finally concluding in the iron-working department with the manufacture of tools, parts of machines, and, if possible, with the building of complete machines.

The machine shop and engine room (Fig. 4), an extremely good equipment, including twelve metal lathes for the special use of students, one large centre lathe, planing, shaping, universal milling, drilling and tapping machines, and all necessary centering and grinding machines. The shop, which is also used for fitting, contains seventeen vices and a very complete assortment of tools. All the machinery consists of types selected from the best manufacturers in England and America.

The hydraulic laboratory contains a tank twenty-eight by five by five feet square, perfectly flush on the inside, and specially designed for investigations as to the action of water under low pressures. The tank is provided with specially designed valves and gauges, which do not interfere in the slightest degree with the stream-line flow, and by means of which variations in pressure in different horizontal sections and under different conditions of flow, can be observed with accuracy. The tank has also fixed to it a recording hydraulic gauge, which has been designed to make one, two, four, eight, or twenty-four revolutions in a specified time. The tank discharges into a water-course about forty feet long and five feet wide. This course may be divided up into one, two, or more compartments, each compartment being carefully calibrated so that the amount of the discharge can be easily estimated. At the end of the course, provision is made for inserting weirs of various forms and dimensions. Over these weirs the water flows into large measuring tanks, which have been carefully calibrated, and each of which has a capacity of about 250 cubic feet. The volume by weight of water in each of these, or in all the tanks, may be observed at a glance by means of an indicator on the wall of the laboratory. Experimental work under high pressures up to 150 lbs. per square inch is rendered possible by a connection with the high-level reservoir of the city. By means of a stand-pipe with special fittings for pipes, nozzles, valves, &c., investigations can be made under any pressure from zero up to the maximum. Any desired head may be kept constant by means of a water-pressure regulator, designed for this laboratory. Pipes from six inches in diameter downwards, can also be led from this stand-pipe for a distance of about sixty feet, so that experiments on the frictional resistance to the flow of water in pipes can be carried out under varying pressures. Another special feature of this laboratory is an impact machine, designed by Prof. Bovey, for measuring the power and investigating the efficiency of water-jets in combination with buckets of different forms and sizes. The laboratory is also to have a set of pumps specially designed for experimental work and research. These pumps are to be adapted to work under all pressures up to 120 lbs. per square inch, and at all speeds up to the highes found practicable, with valves of the best kind and proportions. The equipment of the laboratory also includes a Venturi water-meter, water-meters of other kinds, gauges and gauge-testers, and in fact all the apparatus necessary for the scientific investigation of the properties of water and water-meters, and all kinds of hydraulic apparatus.

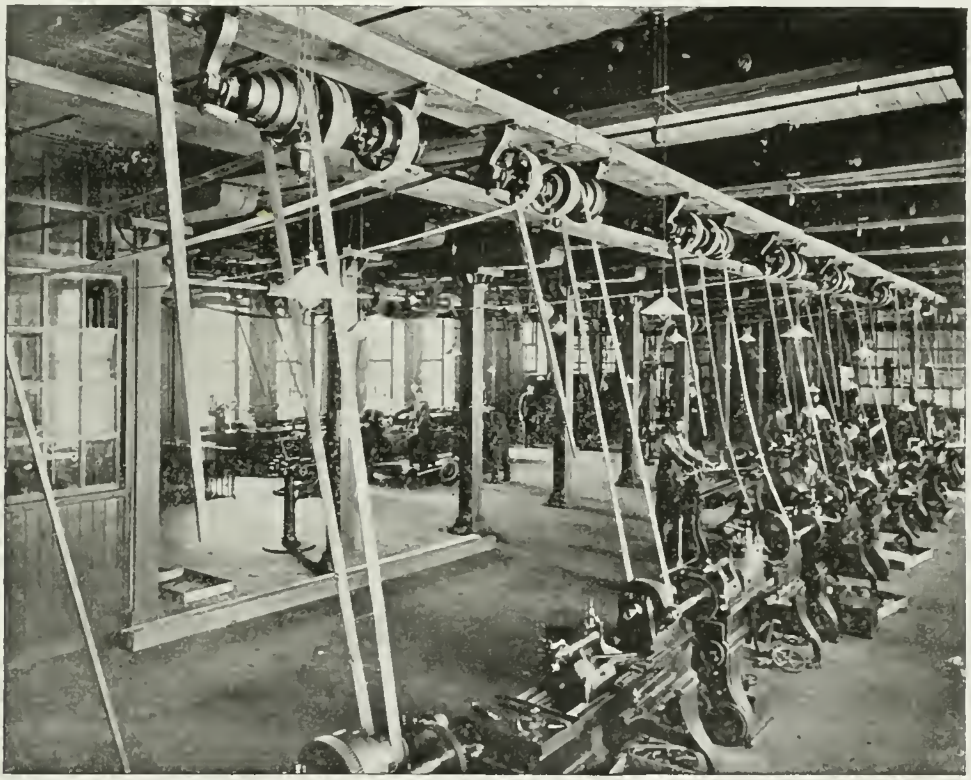

Fig. 4.—Machine Shop.

The main apparatus in the testing laboratories (Fig. 5) consists of a 75-ton Emery testing machine, with a capacity for tension specimens up to 66 in. in length, for compression specimens up to 85 in. in length, and for transverse tests up to 60 in. between bearings; a 100-ton Wicksteed testing machine (Fig. 6), with a capacity for tension specimens up to 72 in., for compression specimens up to 48 in. in length by 10 in. square; an Unwin testing machine for torsional, transverse, and tensile testing; an angle cathetometer (this instrument was specially designed and elaborated for the testing laboratory by Messrs. Nalder Bros., under the direction of Prof. Bovey, to enable

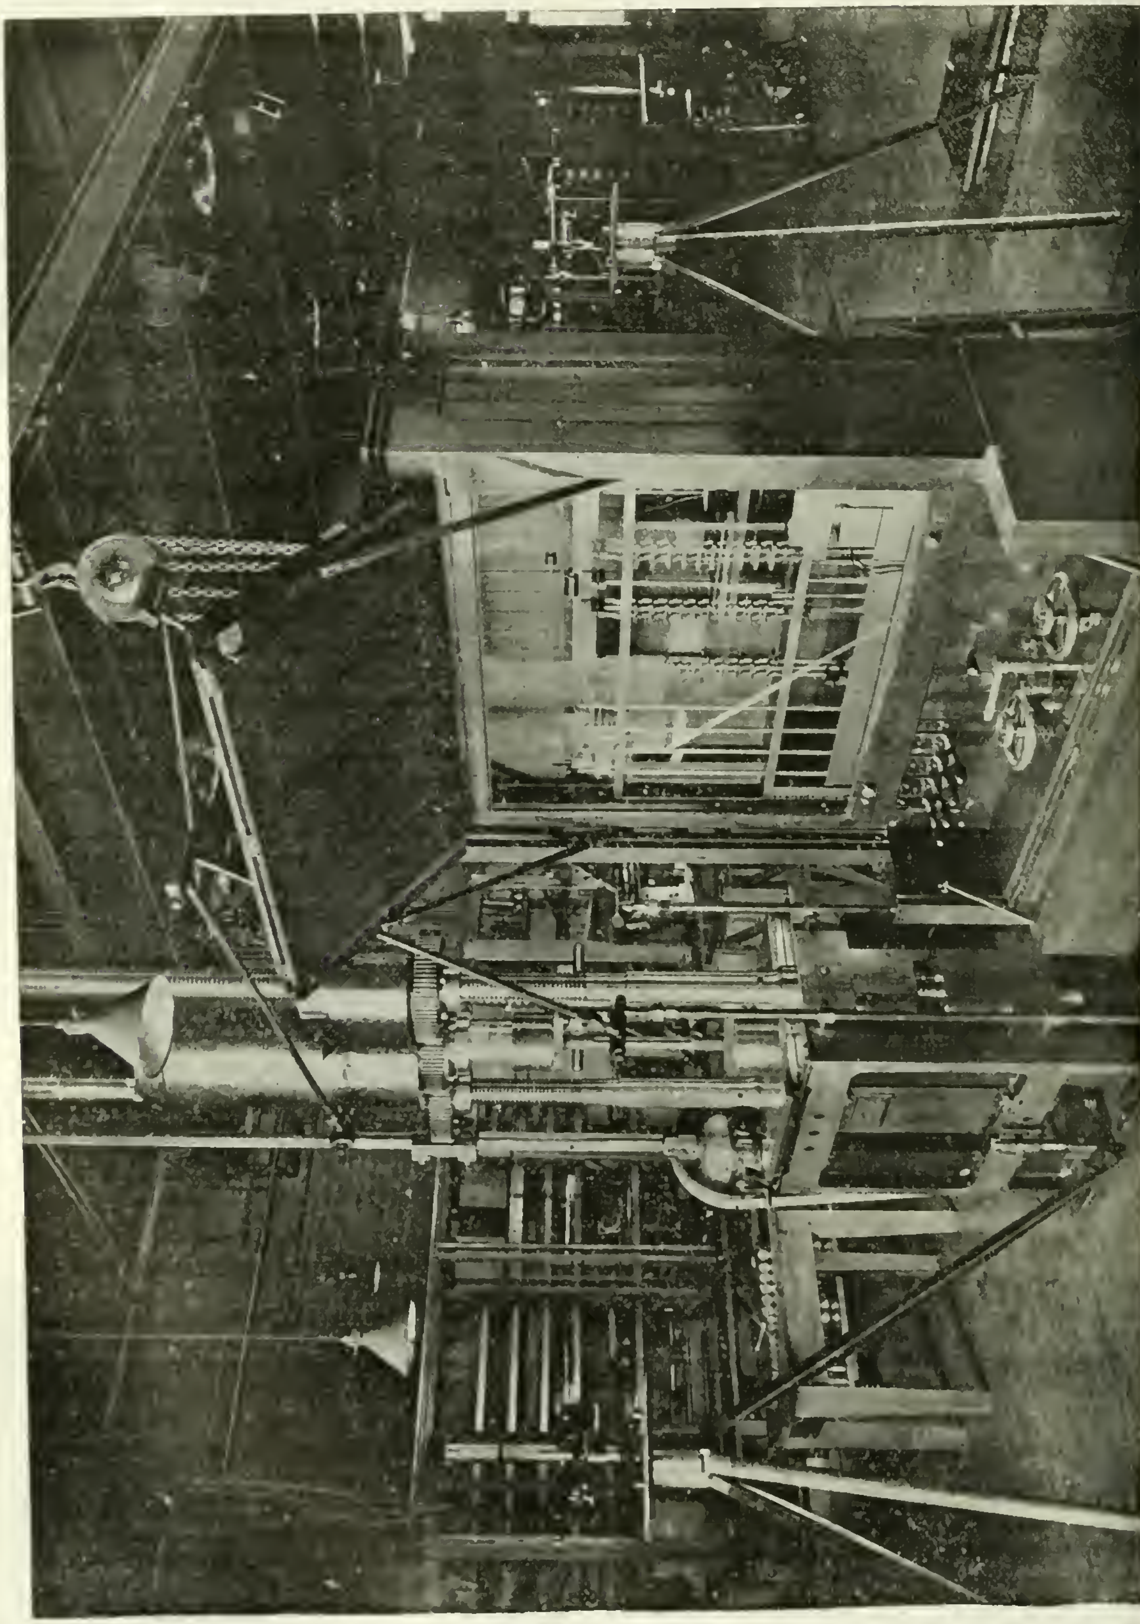

Fig. 5.—Testing Laboratory.

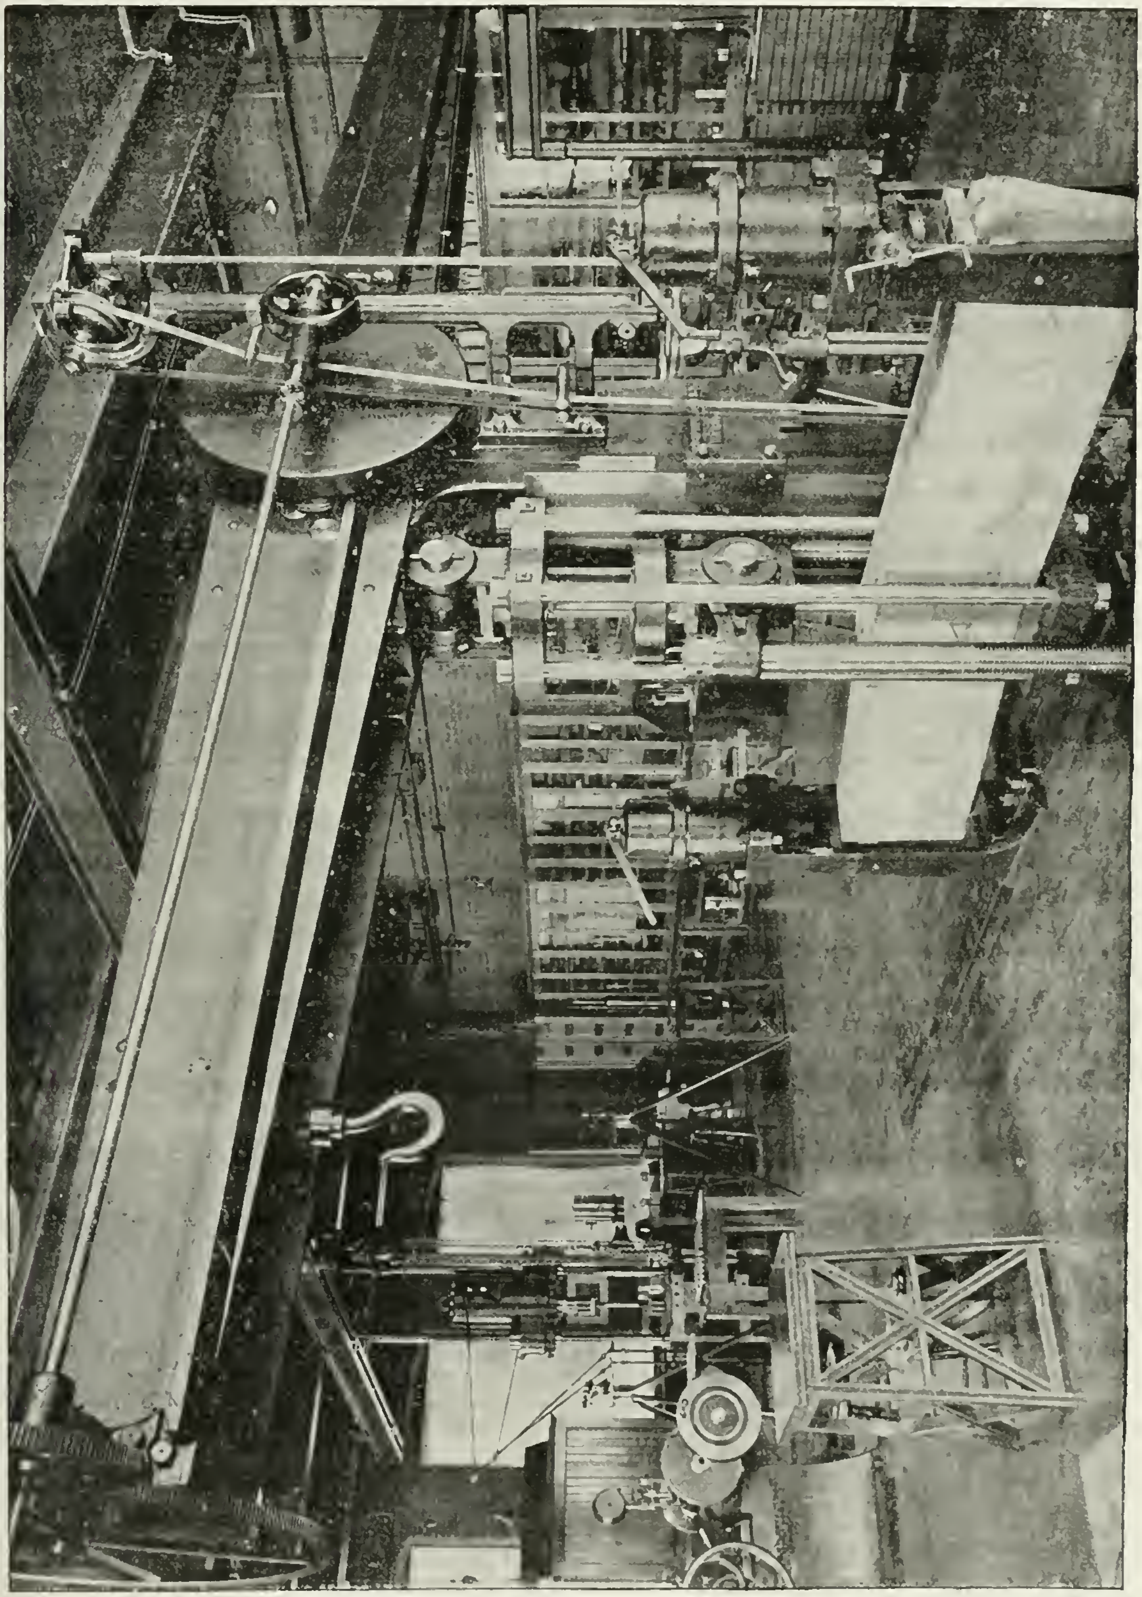

Fig. 6.—Wicksteed Testing Machine.

accurate measurements to be made in connection with the use of horizontal types of torsion testing machines, and also to measure any deflections of a pointer moving about a horizontal axis, through an angle not exceeding 180°; a cathetometer, specially designed for the testing laboratory.

An impact machine is being constructed, fitted with revolving drum, tuning-fork, &c., for recording deflections under rapidly repeated blows. With the aid of this apparatus valuable results may be expected from tests carried out upon materials subjected to repeated stresses.

In the laboratory there are also an Oertling bullion balance with a capacity up to 125 lbs. and down to 1/100 of a grain, and standard weights up to 100 lbs.; a Muir lathe, a shaping machine, and a grinding machine are provided, so that all the apparatus required for preparing the specimens for testing is at hand.

In addition to the above, the laboratories are supplied with numerous other small pieces of apparatus, amongst which may be mentioned Whitworth's measuring machine for measuring a variation of one-hundred-thousandth of an inch, Sweet's measuring machine, and a very complete and elaborate collection of micrometers, vernier calipers, caliper squares, depth gauges, rules, &c.

Our space will not permit us to give an adequate description of the laboratories and lecture-rooms which the McGill University owes to the benefactions of Mr. McDonald and Mr. Thomas Workman, and the mere enumeration of the experimental apparatus contained in them will raise a spirit of envy in the minds of the many workers whose expenditure on scientific instruments is curtailed within very narrow limits. Certain it is that these magnificent donations have provided Montreal with a school of practical science unsurpassed in its facilities for learning.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 24.—M. Lœwy in the chair.—Geodesy and its relations with geology, by M. H. Faye. Gravity has a greater numerical value in islands than in the midst of continents, as the constant is determined by pendulum observations; this is probably due to the more rapid cooling of the crust of the earth beneath extensive seas, as evidenced by the low temperature of water (1° or 2°) at depths at which the temperature is about 133° in land. The greater average density owing to the lower temperature accounts for the higher value of the constant at sea, notwithstanding the replacement of so much solid matter by the specifically lighter water. The author then draws attention to the need of aid from geologists in the further elucidation of the reasons for variations in the constant of gravity.—Truffles (Domalan) from Smyrna, by M. A. Chatin.—M. A. Pomel accompanies a copy of his "Monographie des Bœufs-Taureaux fossiles des terrains quaternaires de l'Algérie" by a brief note on its contents.—Experimental researches on the influence of low temperatures on the phenomena of phosphorescence, by M. Raoul Pictet. Substances showing strong phosphorescence after exposure to sunlight entirely lose this property on strongly cooling (say to −100°), but regain their power on being allowed to approach the ordinary temperature in the dark without further exposure to light. The time during which this *potential luminosity* may be retained, at temperatures such that most of the energy of heat vibrations is abstracted, is now being investigated.—Observations of the sun, made at Lyons Observatory with the Brunner equatorial, during the second quarter of 1894, by M. J. Guillaume. The distribution of spots and faculæ during April, May, and June is given in tabular form.—On the rotation of solar spots, by M. Flammarion. The observed rotations of spots on themselves in several cases are all in the same sense from south through west to north, and amount in one case to 77° in three days, in another to 152° in four days, and in a third case the rotation reaches 34° in two days. This law of rotation is not, however, applicable to cases where segmentation occurs.—On the theory of the Wimshurst machine, by P. V. Schaffers. It is shown that a small modification of the Wimshurst machine enables its efficiency to be doubled, and the reasons leading to this modification are discussed.—On the coexistence, in the same host, of a monosporous coccidian and a polysporous coccidian, by M. Alphonse Labbé.—On the function of the kidney in Helix, by M. L. Cuénot.—On the alimentation of two commensal organisms (*Nereilepas* and *Pinnothere*), by M. Henri Coupin.

THURSDAY, OCTOBER 11, 1894.

ASTRONOMICAL SPECTROSCOPY.

A Treatise on Astronomical Spectroscopy. A translation of Dr. J. Scheiner's "Die Spectralanalyse der Gestirne." Translated, revised, and enlarged by E. B. Frost, M.A. xiii. + 482 pp. 8vo., 81 woodcuts, 2 plates. (Boston and London: Ginn and Co., 1894.)

THE German original of this work appeared in the autumn of 1890, and was doubtless eagerly welcomed by many who had felt the want of a handbook of spectroscopy which gave a tolerably detailed account of the vast amount of work accumulated during the last twenty-five years. From the position of the author in the Astrophysical Observatory at Potsdam, it was to be expected that the subject would be treated in a scientific spirit, and that he would not merely produce a popular book, but one which would be of real use to students of the youngest branch of astronomy. These expectations were to a great extent fulfilled, although it must have been felt by many readers outside Germany that the book suffered from the same defect as Secchi's "Le Soleil," that of frequently giving undue prominence to the researches made at the observatory where the author was working.

The English edition now before us is not a mere translation. Not only has it been brought up to date by the addition of the results of observations published since 1890, and in some cases even by the insertion of results of American work not yet published elsewhere, but Prof. Frost has evidently been anxious to be more fair in dealing with older work of non-German astronomers, and to bear in mind that all spectroscopic researches do not bear the stamp, "Made in Germany." No attempt has been made to distinguish the portions so added from the original text, except in a few cases where Dr. Scheiner requested it, and where the additional matter is put in brackets. At the end of the preface Dr. Scheiner has inserted a number of notes on various points, as to which he differs from the views of the translator.

The first part (110 pp.) deals with "Spectroscopic Apparatus," beginning with the effect of imperfect achromatism of the telescope objective on the spectrum, and the means it furnishes of testing the achromatism of an object-glass. Harkness, Vogel, and Young have applied this method in various ways; but it may be mentioned here that the method is much older, and has been used by d'Arrest and others. The next paragraphs discuss the passage of light through prisms and prism-systems, the loss of light by reflection and absorption, the curvature of the spectral lines, the properties of the cylindrical lens, and the effect of atmospheric disturbances on spectroscopic observations. A lengthy account follows of all the various spectroscopes and spectrometers which have been brought into use from about the year 1817 (not 1823), when Fraunhofer designed the objective-prism spectroscope, and down to the present day, the theories and modes of adjustment of the instruments being fully considered. The translator has here added accounts of Rowland's construction and use of concave gratings, and of Michelson's and Morley's application of interference methods to spectroscopic measurements; he might also in this chapter have inserted a description of the bolometric methods of observation, which have yielded such splendid results (they are partly mentioned in the chapter on the sun, but the instrumental arrangements should have been given in detail). In the paragraph on photographic spectra the Potsdam spectrograph is chiefly considered, but the translator also describes Hale's spectroheliograph.

The second part of the book (pp. 111–150) on "Spectroscopic Theories" is divided into two chapters on Kirchhoff's Law of the ratio between the absorptive and emissive power, and on Doppler's principle. Prof. Frost states in the preface, that in view of the contradictory results of recent investigations upon the emission of light by gases, he has not thought it wise to make any additions to the chapter on Kirchhoff's Law. It seems, however, strange that he should not have drawn attention to these investigations, and pointed out their immense importance for the interpretation of celestial spectroscopic observations, though a careful reader will not fail to see, even from the short account given of E. Wiedemann's researches, how great a *rôle* "luminescence" phenomena are likely to play in future theories of the nature of celestial bodies. The chapter on Doppler's principle deals fully with the theoretical aspect of this important matter and the various objections which have been raised from time to time, while the splendid practical results are deferred to a chapter at the end of the book.

The third and largest part (pp. 151–360) is devoted to the "Results of Spectroscopic Observations." In the German original all wave-lengths were based on the Potsdam system of Müller and Kempf, and were expressed in millionths of a millimetre, but the translator has reduced them all to Rowland's system of 1893, and has adopted the tenth-metre as his unit, in accordance with the practice of most British and American spectroscopists. The chapter on the sun describes first the various methods of investigating the ultra-red spectrum, and includes an account of Langley's unpublished method. By this the invisible spectrum is moved by clockwork across a bolometer strip, the passage of the lines being recorded by a sensitive reflecting galvanometer, the point of light from which falls on a photographic film, also moved synchronously by clockwork in a direction at right angles to the plane of the mirror's movement, thus automatically producing an energy curve. This is subsequently converted into a linear spectrum containing dark lines corresponding to the cold spaces in the invisible spectrum. The ultra-violet spectrum is next shortly described, and lists of elements present in the sun are given. In the paragraph on the atmospheric lines, the translator has substituted Cornu's list of these for those of Angström and Vogel, which Dr. Scheiner had preferred; but we miss references to Dr. L. Becker's investigation of the low-sun spectrum and (curiously enough) to Dr. Müller's spectroscopic observations on the Säntis, although the latter were published more than a year and a half ago in the Potsdam publications. More remarkable than these omissions is, however, the brevity with which the spectra of sun-spots, faculæ, and the chromosphere are treated in only twenty-one pages. In the preface, the author accounts for this by pointing out that the present state of our knowledge of the constitution of the sun is unsatisfactory, and that we have "a large mass of observational data, although for the most part unscientifically discussed; and on the other hand, an indefinite number of hypotheses and solar theories, which are, with few exceptions, radically wrong at the start, and often contradictory to the most simple physical views of to-day." He therefore felt unwilling to undertake the task of discussing and sifting these theories. No doubt an author has a perfect right to decline an uncongenial task, but it certainly detracts from the value of the book that it gives comparatively scant information about our central luminary, on which spectroscopists have spent so much labour; and in the succeeding chapters Dr. Scheiner has by no means been adverse to dealing with "hypotheses and theories." It is, of course, as impossible to discuss the results of spectroscopic observations without attempting to interpret them, as it was for our forefathers three hundred years ago to discuss the motions of the planets "without any hypothesis." And notwithstanding his caution, the author has not been able to keep clear of questionable hypotheses on matters connected with the sun, as when he, for instance, suggests that the unsymmetrical broadening of lines in spot-spectra might arise from the metals entering into combinations with the metalloids. This idea is also afterwards brought in to account for the same phenomenon in star-spectra of Type III*a*, but Dr. Scheiner seems lately to have abandoned it, as he in a note to p. 308 concludes from recent observations that the unsymmetrical broadening is due to accidental "clustering" of fine lines. With regard to the spectra of sun-spots, we notice that all the work done at South Kensington is completely ignored.

While the chapter on the spectra of the planets, as to which not much work has been done of late years, is naturally somewhat meagre, that on comets is very full and interesting, and includes an account of the important laboratory work of Hasselberg. The evident dependence of the spectrum on the distance of a comet from the sun is duly emphasised, but the account of the two most remarkable comets of 1882 might have been more lengthy, as we, for instance, do not find any reference to the dark absorption lines seen with more or less certainty by several observers, and which (if really existing) are of very great importance for the interpretation of the changes in the heads of comets about the time of perihelion passage.

In the chapter on Nebulæ, a complete list of gaseous nebulæ is given, as well as one of the minute planetary nebulæ found with the spectroscope by Pickering and Copeland, and it is interesting to see how this latter class of objects, like the older gaseous nebulæ, cling to the Milky Way. A list is also given of all the lines observed in the spectra of nebulæ. It might have been mentioned that the line at 4472 (which also occurs in some stars of Type I*a* and in Nova Aurigæ) is probably identical with a well-known chromospheric line, associated with D$_3$ and the hydrogen lines, as suggested by Mr. Lockyer. The author does not express any opinion as to whether the temperature of nebulæ is high or low, but he remarks that the comparative simplicity of the spectrum points to the conclusion that the density of these bodies is extremely low.

In the lengthy chapter on the spectra of the stars, the classification of Vogel is followed, apparently somewhat reluctantly on the part of the translator. So long as the system is not supposed to represent the gradual evolution of a star, there can, of course, be no objection to it; but in the light of the results obtained from temporary stars, and the detection of dark lines in spectra of Type I*c*, it certainly looks doubtful if the bright line stars can properly be divided among the two first classes (I*c* and II*b*).

The account of spectra of Type I*a* includes a list of ninety-one lines measured by the author in the photographic spectrum of Sirius, and an account of the harmonic relations between the hydrogen lines. That the stars of this class are the hottest of all, is generally conceded, and the confirmation of this view, which Dr. Scheiner (in a note on p. vii.) finds in the appearance of the magnesium line at 4481, was indeed found many years ago by Mr. Lockyer (*Proc. R.S.* xxx. p. 29), who first called attention to the fact that this line can only be produced by a high tension spark, and is indicative of very high temperature. In the spectrum of *a* Cygni (Type I*b*) it is the strongest of all lines. Notwithstanding this the author concludes from the fact that only the fainter iron lines occur, that a very different temperature must prevail in stars of Type I*b* from that in stars of I*a*. Yet the possibility does not seem to be excluded that this may arise from different conditions as to density. Under the heading "Spectra of Type I*c*," the translator gives a detailed account of Belopolsky's investigation of β Lyræ, with regard to which Dr. Scheiner remarks in a note that, in view of recent observations made at Potsdam, he cannot believe the phenomenon to be nearly as simple as Belopolsky's observations would indicate. "There is great probability that more than two bodies are concerned in the case of β Lyræ."

Passing to the Type II*a*, we find a catalogue of 290 lines measured by the author on Potsdam photographs of the spectrum of *a* Aurigæ. While the author justly considers this a complete proof of the absolute agreement between the spectrum of this star and that of the sun, he takes a very pessimistic view of the measures of the visual spectrum of *a* Tauri by Huggins and Vogel, whose identifications of lines with metallic lines he seems, with few exceptions, to consider worthless. Many readers will probably dissent from this view, as the agreement between the two observers is really good (as also conceded by the author), and this somewhat sweeping condemnation would apparently, if consistently applied, wipe out many conclusions drawn from spectroscopic observations.

In the section "Spectra of Type II*b*" the translator has put together a large amount of information not to be found in the original, by giving a list of fifty-five stars of this class (which are with few exceptions in or close to the Milky Way), and a list of bright lines in the visual spectra of thirty-one of them, recently observed by Campbell at the Lick Observatory. The existence of a large envelope of incandescent hydrogen about one of these stars (D.M. + 30°, 3639) seems to be proved by Campbell's latest observations, according to which the F line, observed with a narrow slit, is a long line extending to a very appreciable distance on each side of the continuous spectrum, and with an open slit is a large circular disc about 6″ in diameter. The same appearance is noticeable in the faint $H\gamma$ and very faint $H\alpha$ lines, but not in other lines.

The section on Temporary Stars has also been very considerably extended by the translator, by the addition of a detailed account of the observations of Nova Aurigæ and of the various theories which have been proposed to account for the manifold phenomena exhibited by this object. The difficulties in the way of accepting any one of these hypotheses as fully satisfactory are pointed out, and it seems impossible to deny that there must have been more than two bodies in action. The complete transformation of the spectrum at the revival of the star, so strikingly similar to that discovered by Copeland in the case of Nova Cygni, is also an awkward fact to deal with, and one that cannot be avoided by merely denying that we have here "a star turned into a planetary nebula." The interpretation of the nebulous appearance of the star as caused simply by the chromatic aberration of the blue hydrogen rays, when the telescope is focussed for the most intensive rays of the chief nebular line 5002, seems untenable, as so experienced and sharp-sighted an observer as Prof. Barnard has recently declared himself to be absolutely sure, that the nebulous appearance is not a mere telescopic effect (*Astr. Nach.* 3238). And why should we think it impossible for the object to *look* like a nebula, when it has the unmistakable spectrum of one, and when we remember the above-mentioned observation by Campbell of D.M. 30°, 3639? The objects which caused the outburst in December 1891 probably left the scene of the catastrophe a few months after, leaving behind them masses of gas both visually and spectroscopically seen as a nebula. But, as pointed out by Prof. Frost, the most difficult facts to explain are the enormous relative velocities of the objects.

The study of the spectra of Type III*a* has, during the last few years, produced results which have very much lessened the supposed similarity between these spectra and those of sun-spots, and the development of bright lines in many spectra of long-period variables at their epochs of maximum obliges us to give up the ideas which formerly prevailed with regard to these variables. Here, as in the case of Nova Aurigæ and β Lyræ, we have evidently to do with very complex phenomena. The translator refers in a few words to the theory advanced by Mr. Lockyer, that the long-period variables may be systems of two swarms of meteorites revolving in elliptical orbits, and he dismisses it with the objection (which is not new) that the conditions in a system of this kind could not be permanent, as with successive collisions the smaller swarm would become spread out into a ring, thus causing the variability to cease. This objection is, however, not a serious one, as our own Leonids, though spread out into a ring, have for many centuries exhibited a very strongly marked maximum.

After describing the spectra of Type III*b*, the translator gives a summary of Pickering's statistical examination of the Draper Catalogue. He has omitted the short notice of the Meteoritic Hypothesis which Dr. Scheiner had inserted at the end of this chapter, and which hardly gave a fair idea of the hypothesis. The two remaining chapters are devoted to the spectra of the Aurora and Zodiacal Light, and the displacements of spectral lines as caused by the rotation of the sun, the motion of stars in the line of sight, or by spectroscopic binaries. A useful addition is given in the shape of a reprint of Campbell's formulæ and tables for the reduction of observations of displacement.

The fourth part of the book (pp. 361–426) contains a very valuable set of spectroscopic tables, viz. Rowland's new table of standard wave-lengths (*Astronomy and Astrophysics*, April 1893), Abney's wave-lengths of lines in the ultra-red spectrum, Kayser's and Runge's arc spectrum of iron, a catalogue of stars of classes III*a* and III*b*, and, lastly, an unpublished partial revision of the chromospheric lines by Young. Finally, on pp. 427–472, a bibliographical list is given of books and papers relating to astronomical spectroscopy. This list is unfortunately very incomplete, and glaringly so with regard to solar phenomena. We have, also, in several cases missed references to papers quoted in the body of the book, and in others only found references to short notices in NATURE, instead of to original memoirs.

On the whole, this English revised edition is a great improvement on the original, valuable as the latter undoubtedly was, and it forms both an excellent text-book for the student and a useful book of reference to workers in spectroscopy. J. L. E. DREYER.

AGRICULTURAL ZOOLOGY.

Agricultural Zoology. By Dr. J. Ritzema Bos, Lecturer in the Royal Agricultural College, Wageninen, Holland. Translated by J. R. Ainsworth Davis, B.A. With an introduction by Eleanor A. Ormerod. (London: Chapman and Hall, 1894.)

AGRICULTURISTS will be misled by the title of this book, if they expect to find any reference in it to farm animals which especially interest and concern them, such as horses, cattle, sheep, and pigs. There are no descriptions of these animals in this work upon agricultural zoology, although after having enumerated the thirteen orders of mammals, Dr. Ritzema Bos says he shall "deal only with those of agricultural importance," and forthwith leaves out all references to cattle, horses, sheep and pigs. But, on the other hand, such animals as wild boars, deer, otters, golden eagles, nightingales, herring-gulls, and grebes, having no connection with agriculture, are treated of at some length, and figures of them are given. Cuttle-fishes and star-fishes also seem out of place in a work entitled "Agricultural Zoology," which should rather have been styled "Zoology, or the Elements of Zoology."

Among the insects the migratory grasshopper (*Acridium migratorius*) and the Colorado beetle (*Doryphora decemlineata*) figure, though these are not British insects, nor are they likely ever to gain a foothold in this country. A work upon British Agricultural Zoology is much wanted that would give the cultivators accurate information upon all the animals that are in any way, directly or indirectly, serviceable to them, and all those that are harmful to them, directly or indirectly. Dr. Ritzema Bos just touches the fringe of this subject with regard to the larger animals, though, it must be admitted, he goes into rather more detail concerning insects. Knowledge of the inner life of animals is most desirable, and should be spread through the whole of the country districts by the Technical Education Committees of County Councils, by means of competent lecturers, in the absence of any standard text-book on the subject. There is a capital book on Agricultural Zoology in France, compiled by Dr. Brocchi, entitled "Traité de Zoologie Agricole," in which detailed descriptions are given of all the animals that are useful and injurious to cultivators. Their habits (*mœurs*) are first detailed, then their use (*utilité*), or the harm (*dégâts*) occasioned by them, so that one may see at a glance those that may be counted upon as friends or foes. It might be supposed naturally that in a treatise upon Agricultural Zoology, Dr. Ritzema Bos would have dealt at some length with, for instance, such a useful bird as the kestrel (*Falco tinnunculus*), which must be held to be one of the best friends of the farmer, for it feeds upon mice, rats, and cockchafers. Swallows, martins, and swifts are dismissed with exceedingly short notices, and their indescribably good services to cultivators are unfairly depreciated in the following inconsistent passage :—

"Swallows fly quickly and catch insects while on the wing. The insects on which they prey are generally unimportant to agriculture and forestry; but they may also do good by catching crane-flies (Tipula) and ribbon-footed corn-flies (Chlorops), which often fly about our fields in enormous swarms in order to lay their eggs."

It must be strenuously denied that the insects on which they prey are unimportant to agriculture, as they are known to be especially fond of aphides, and many hop-planters believe that the far greater frequency of the attacks of the *Phorodon* (*aphis*) *humuli* upon hop-plants in the last five years is due in a degree to the scarcity of swallows and martins. There is no doubt, also, that these birds clear off the Hessian fly, *Cecidomyia tritici*, and others of the *Cecidomyidæ*, and as they live entirely on insects, and especially on the smaller and most dangerous insects, they are of inestimable benefit, and should therefore be preserved with religious care. It is much to be lamented that swallows, martins, and swifts are so ruthlessly massacred in the sunny climes in which they pass the winter seasons. Plovers, too, whose value to farmers is inestimable, are not alluded to. This is an unfortunate omission, as it is desirable to clearly point out that these birds should be encouraged, and that the general raids upon their eggs, to satisfy the appetites of gourmets, should be stopped.

In his large, valuable work, "Tierische Schadlinge und Nutzlinge fur Ackerbau, Viehzucht, Wald- und Gartenbau,' published at Berlin in 1891, Dr. Ritzema Bos, like Dr. Brocchi, gives full accounts of all animals in any way connected with the field, forest, and garden, and this might have been liberally epitomised and translated for the benefit of British agriculturists with far more advantage to them than the unsatisfactory *réchauffée* now before us. Insects are Dr. Ritzema Bos's strong point, as all are aware who know his labours in this direction, so that it is not surprising to find considerably more than a third of the contents of "Agricultural Zoology" devoted to them. But it is rather strange that some very important insects are not mentioned, and that others are dismissed with a short account of their habits. In some cases methods of prevention and remedies against insect attacks are suggested, but they are generally given in the briefest possible manner. Thus for the pea-weevil (*Sitones lineatus*) the remedy prescribed is "rational rotation," which will convey little or no meaning to the perplexed pea-grower.

For the ravages of the Diamond-back Moth (*Plutella cruciferarum*), no remedy whatever is mentioned, although the caterpillars of this insect occasionally do serious harm to many species of the Brassica, as in 1891, when many thousands of acres of turnips, rape, and cabbages were ruined by their action.

Another instance of a curious remedy may be given in the paragraph upon Cockchafers (*Melolontha vulgaris*) in which it is recommended that the grubs that are turned up during ploughing should be collected, and that the cockchafers should be caught. "This is very expensive, since it has to be done very energetically if most of them have left the pupa case. A part of the expense may, however, be recouped by using the cockchafers as manure." This "part of the expense," it is thought, would be absurdly infinitesimal.

Again, for the Red Spider (*Tetranychus telarius*), most destructive to many crops of the farm, garden, and glass-house, no modes of prevention or remedial measures are hinted at, although economic entomologists have pointed out that as moisture is most obnoxious to these mites, washing or spraying infested plants frequently is an efficacious remedy against them. One of the best parts of this volume is that devoted to the *Anguillulidæ*, or eelworms, which are most injurious to a number of crops, and in many cases are quite unsuspected enemies.

With regard to the insects omitted, it will be seen that none that are injurious to fruit crops have been included, though fruit-growing forms an important feature of British land culture. As in Holland and Germany, the Winter Moth (*Cheimatobia brumata*) is terribly destructive to the apple crops in this country, and the Codlin Moth (*Carpocapsa pomonella*) is almost equally injurious in some seasons to apple-trees in Great Britain, the Continent, and the United States and Canada. Both these are unnoticed, as well as several other moths, and many weevils and sawflies, that attack apple, pear, and plum trees, gooseberry and currant bushes, and raspberry-canes, against whose onslaughts fruit-growers would only be too thankful to have some practical advice from an expert of the reputation of Dr. Ritzema Bos.

In a few instances valuable remedies are recommended against insects, as, for example, the remedy adopted for the Silver Y Moth (*Plusia gamma*), by fastening together by laths several long troughs with steep inner walls, at distances equal to those between the adjacent furrows, and the caterpillars are swept by besoms fixed to the laths into the troughs, from which they are collected in sacks at the end of the furrows. With this cheap machine about twelve acres per day can be cleared. This is a practical remedy, and is derived from Taschenberg, the most practical and able of all economic entomologists, who has done more for cultivators in the way of describing insects, and prescribing methods of prevention and remedial measures against them, than any other entomologist; and whose store of information many writers upon economic entomology have calmly used without acknowledgment. His "Praktische Insekten-Kunde" is a model of what a work upon baneful insects should be.

The 149 illustrations in "Agricultural Zoology" are good, especially those from Taschenberg, which are very clear, and some of these form very pretty pictures. It would be a great assistance to readers if an index had been supplied, for it is difficult to find references that are required.

Upon the whole we cannot congratulate Prof. Ritzema Bos upon his last production. If he had reproduced parts of his larger work, "Tierische Schadlinge und Nützlinge," without alteration, it would have been far better than boiling it down and entitling the result "Agricultural Zoology."

OUR BOOK SHELF.

Progress in Flying Machines. By O. Chanute, C.E. (London: Messrs. Sampson Low, Marston, and Co., 1894.)

This book is a reissue of a series of twenty-seven articles which appeared in *The Railroad and Engineering Journal* (now re-designated as *The American Engineer*) of New York City. It gives a very complete account of the many experiments that have been performed by various experimenters with details of the machines used, and clear reasons why so many of them have failed. After a short statement of general principles the author describes the machines in which wings and parachutes were used; then those in which screws were used to lift and to propel. The author believes that the true function of aerial screws is to propel and not to lift (page 72); but Lord Kelvin, in the discussion on aerial navigation at the British Association in Oxford, last August, stated his belief in screws working round a vertical axis for the latter purpose. The greater part of the book is devoted to a description and discussion of aeroplanes. The whole subject of aerial navigation resolves itself into ten problems or conditions:

(1) The resistance and supporting power of the air.

(2) The motor, its character and its activity.

(3) Selection of the instrument to obtain propulsion.

(4) The form and kind of the apparatus for sustaining the weight—whether flapping wings, screws, or aeroplanes.

(5) The amount of the sustaining surface required.

(6) The best materials to be employed for the framing and for the moving parts.

(7) The maintenance of the équilibrium, which is the most important, and perhaps the most difficult of solution, of all the problems.

(8) The guidance in any desired direction.

(9) The starting up into the air under all conditions.

(10) The alighting safely anywhere. Safety in starting up, in sailing, and in coming down is essential.

All these problems are fully and fairly discussed in this volume. There are eighty-two diagrams, and an excellent index, which add greatly to the value of the book.

Fertilisers and Feeding Stuffs; their Properties and Uses. By Bernard Dyer, D.Sc. (Lond.) (London: C. Lockwood and Co., 1894.)

This little book, which is a handbook for practical farmers, and is not addressed to the agricultural student, is issued opportunely. It contains the full text of the Fertilisers and Feeding Stuffs Act 1893, and the Regulations and Forms of the Board of Agriculture relating to the same, and also some useful notes on the Act, by Mr. A. J. David, Barrister-at-Law. Dr. Dyer's notes were first published in the form of newspaper articles, and have been reprinted by request; they will prove very useful to the class to whom they are addressed, containing as they do short descriptions of the origin, composition, and uses of farmyard manure, artificial manures, and of purchased feeding stuffs, all of a practical nature. The notes on the new "Fertilisers and Feeding Stuffs Act" will also be useful to those who wish to put this Act into use; but these, we anticipate, will be few.

Heat treated Experimentally. By Linnaeus Cumming, M.A. (London: Longmans, Green, and Co., 1894.)

The companion volume to this—"Electricity treated Experimentally"—is known to most teachers of physics. The present work aims at giving (1) an elementary account, with easy experiments, of the general laws of heat; (2) a brief account of the classic researches of Regnault, Joule, and other eminent investigators; (3) a description of the theory of heat comprehensible to students whose mathematical range does not extend beyond elementary trigonometry. This laudable design is satisfactorily realised. Mr. Cumming writes clearly; in other words, he knows what to say and how to say it. The experiments described are all workable and well arranged, hence the book is one which may be used in science classes with confidence and pleasure.

Ways and Works in India. By G. W. Macgeorge, M.I.C.E. (Westminster: Constable and Co., 1894.)

An account of the public works in India from the earliest times up to the present day should be useful, if only as an outline for a precise and detailed history of Indian Public Works. The materials for the compilation before us have been collected by the author from various official publications, and the facts are arranged in a satisfactory manner. The subjects treated are the trigonometrical survey of India; roads; irrigation works; railways; water-supply of towns; internal telegraphic system; and sea and harbour works. The data referring to these matters will be valuable to all interested in the progress of India. The work does not appeal to a large public in England; nevertheless, it presents, in a readable form, much useful information on the engineering works which will stand for many years as monuments to British rule in India.

Manual Pratique de L'Aéronaute. By W. de Fonvielle. (Paris: Bernard Tignol.)

In this book of 246 pages, M. de Fonvielle, a well-known writer on aeronautical matters, contrives to compress a mass of information of use to the aeronaut. We recommend the book to practical aeronauts, meteorologists, and the numerous amateurs who are interested in ballooning and its possibilities. Seventy figures illustrate the text. It has been said that the development of the art of flying has been retarded by the balloon; but even if this is conceded, M. de Fonvielle's book shows that science has gained a little from ballooning.

Fruit Culture for Profit. By C. B. Whitehead, B.A. Pp. 68. (London: Society for Promoting Christian Knowledge, 1894.)

In view of the recent correspondence in the *Times*, on fruit culture, this book appears very opportunely. Fruit-growing is now recognised as a valuable branch of agriculture, and English producers are becoming alive to its importance. The Royal Agricultural Society and the Board of Agriculture have encouraged fruit-growing by publishing articles and pamphlets upon the subject. These publications, and Mr. Whitehead's little volume, should be obtained by all who are interested in the profitable production of fruit.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Wilde's Theory of the Secular Variation of Terrestrial Magnetism.

SOME prominence is given in NATURE of August 9 to a letter of L. A. Bauer, a magnetic computer of the United States Coast and Geodetic Survey, on the above subject. Absence from home and other circumstances have prevented me from replying to this letter before now. It is not my intention to engage in controversy with a critic who roundly condemns my theory and experiments without reason, and at the same time naïvely announces that, by means of formulæ established by himself, he has succeeded in representing the observations many times better than the magnetarium results.

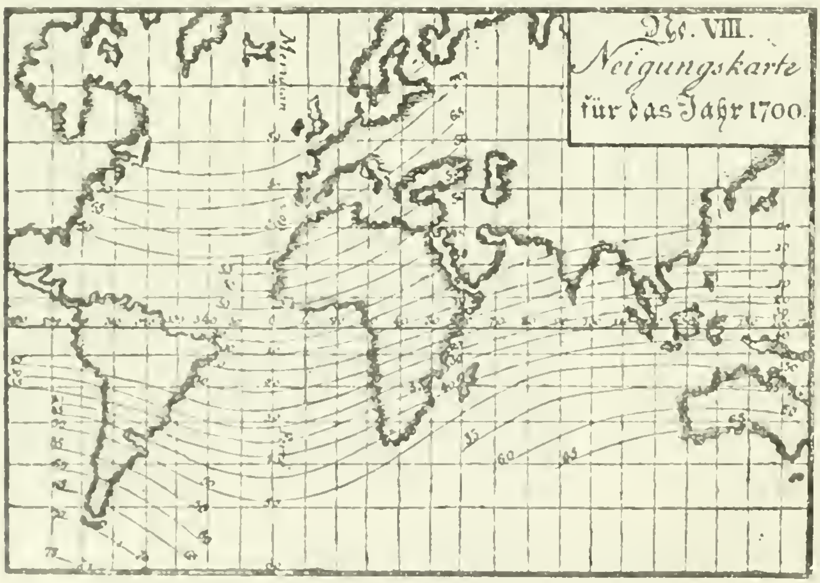
My principal object in writing is to correct an error I have made in stating that no observations had been made on the dip at St. Helena previous to the year 1825. The error is all the more inexcusable as I have in my possession Hansteen's "Magnetismus der Erde," with its valuable atlas-folio of charts of the magnetic variation, from which L. A. Bauer has derived his information of the dip at St. Helena for the epoch 1700–1780. Had I said that no *reliable* observations had been made before 1825, the statement would hardly have called for any notice. It is well recognised by magneticians that observations of the dip, up to the early part of the present century, were much more difficult to make than those of the declination, on account of instrumental imperfections and the unrecognised influence of vertical masses of ship's iron and local geological formations. Sabine, in his "St. Helena Observations," vol. 2, p. lxv., shows a difference of between 2° and 3° at Longwood and Sister's Walk, from the latter cause, and this illustrious magnetician did not venture to give observations of the dip further back than the epoch 1825.

I regret to observe that L. A. Bauer, in his intolerance of the magnetarium results, has inserted in his table guesses of his own for observations, which are very wide of the truth.

In order that my remarks on the dip at St. Helena may be better understood, I will, by your permission, reproduce the table of L. A. Bauer, although that of Sabine and the Admiralty chart are more in agreement with my results.

Date.	Observer.	Observed inclination.	Wilde inclination.	Observation Theory.
1700	Hansteen chart	11·5 S.	3·9 N.	−15·4
1754·3	La Caille	9·00	0·5 S.	−8·5
1771·4	Ekeberg	13·00	3·5	−9·5
1775·4	Cook	11·42	4·0	−7·4
1780	Hansteen chart	10·5	5·1	−5·4
1825·0	Duperry	14·93	14·7	−0·2
1840·1	Ross	18·27	18·5	+0·2
1842·3	Belcher	17·00	19·0	+2·0
1846·8	Smyth	19·39	20·5	+1·1
1890·1	U.S.C. & G.S.	29·65	33·8	+4·1
,,	,,	31·18	33·8	+2·6

It will be observed that for the epoch 1825–1890, the dip increased no less than 16°·25, or fifteen minutes annually. Hansteen's great work was published in 1819, and his curve of the inclination for the epoch 1780, showing 10°·5 S., at St. Helena, was laid down from the observations of Ekeberg, La Perouse, and Cook, which indicate a diminishing dip for the epoch 1771–1775. Hansteen's chart of the inclination for 1700 is exquisitely drawn, but on a scale so small that St. Helena is not shown thereon. The position of the island is, however, easily found from the latitude 15° 55′ S., and long. 5° 43′ W., or 12° E. of the meridian of Ferro.



As Hansteen's historical work on the magnetic variation is very rare, I have had his chart of the inclination for the epoch 1700 reproduced by a photographic process, with the position of St. Helena dotted thereon, for the benefit of your readers.

It will be seen from the chart that the magnetic equator, or line of no dip, is about 1° north of St. Helena, so that the amount of south dip would not be more than 2° for the epoch 1700. Hansteen would appear to have laid down his curve of the dip for 1700 from the previous observations of Ekeberg and La Caille, which indicate a decrease, reckoning backwards, from 1771 to 1754; but he nowhere states in the text of his work, that his curve was drawn from an observation made at St. Helena in 1700.

The amount of dip, 11°·5, shown by L. A. Bauer for 1770, is the same as that observed by Cook in 1775, and is an obvious blunder in his reading off the position of St. Helena 1° below the isoclinal of 10° south, instead of from the magnetic equator.

I shall leave others to judge how far any statements of L. A. Bauer on the subject of terrestrial magnetism in general, and on the magnetarium in particular, are entitled to credit when he places his erroneous computation under the heading of observed inclinations standing against the distinguished names set forth in his table.

It may be of interest to magneticians to know that the secular changes shown in my tables of the declination and inclination at London, Cape of Good Hope, St. Helena, and Ascension Island are obtained conjointly on the magnetarium without change of resistance in the secondary circuit; together with the great eastern and western lines of no declination, the Asiatic oval of small westerly declination, the oval of small easterly declination in the Pacific, the magnetic equator, and many other agreements with the observations, all for the epoch 1880.

I regret that I have not been able to accomplish more; but in reply to the remark of L. A. Bauer that although I possess the records of secular variation stations in the United States, I have made no published attempt to reproduce them, I may say that two years ago I presented a magnetarium to the United States Coast and Geodetic Survey, at considerable cost and trouble to myself, with full instructions for working it, and have no doubt that the department will make good use of the instrument.

Alderley Edge, September 28. HENRY WILDE.

The Newtonian Constant of Gravitation.

I SHOULD be obliged if you would allow me to make a correction in my lecture at the Royal Institution, published in NATURE, Aug. 2, 9, and 23, on page 331. I have stated that in pieces of apparatus geometrically similar but of different dimensions, the disturbances due to uncertain convection currents are likely to be in the proportion of the seventh power of the linear dimensions. Having discussed this at some length lately with Prof. Poynting, I find that I was in error, and that in reality the disturbances would be proportional to the fifth power of the linear dimensions if the circulation of the air were so extremely slow as to be steady. If, however, its velocity were sufficient to give rise to unsteadiness, the rate at which momentum would be given to the suspended portion of the apparatus would depend on the square of the velocity, at least in part, and as the part depending on the square increased in importance the disturbance would gradually rise to the eighth power. So long, therefore, as the apparatus is small enough to prevent terms involving the square of the velocity from being appreciable, the ratio of the disturbance to the couple to be measured or the stability is the same whatever the size; but as soon as the apparatus exceeds this, then the disadvantage of size very rapidly becomes evident.

Of course the objection due to the great increase of time which must elapse between the handling of apparatus and its being fit for observations to be made, which accompanies increase of size, remains.

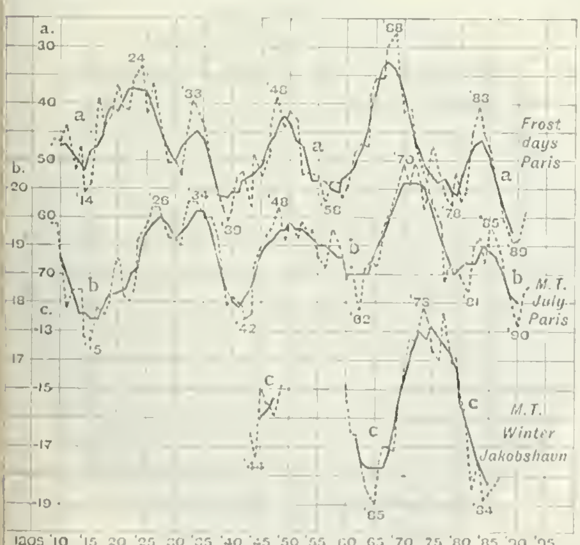
As the consideration of the relation between disturbance and couple to be measured, and its variation with linear dimensions, is a matter of great importance in the design of most instruments in which the movements of a suspended system supply the means of measurement, there is an additional reason for correcting in these columns the error that I made.

C. V. BOYS.

On Some Temperature-Variations in France and Greenland.

THE relations indicated in the diagram sent herewith are, I think, instructive; and they might perhaps be found to contain some useful clues to coming weather.

This diagram has two kinds of curves, dotted line, and continuous. Both are *smoothed* curves. In the former, the actual



values have been smoothed with averages of five; and in the latter, those averages have, in their turn, been treated in the same way. High points in all the curves denote heat; low points cold.

The first pair of curves (a) show, by averages, the variation in the number of frost days in Paris in October to April of each cold season since 1806. (I designate each cold season by the year in which it *ends*; 1806 meaning 1805 6, &c.). These are *inverted* curves, the numbers increasing downwards. They present a succession of (say) five obvious waves, which, with regard to the crest intervals, are neither wholly regular nor wholly irregular, the intervals of the smoother curve being, in series, 12, 15, 18, and 17 years.

The second pair of curves (b) show the variation in mean temperature of July at Paris during the same period; and we may perceive in these a general correspondence to the first curves, with, however, a distinct tendency to lag somewhat.

There is a good deal of general similarity, of course, between the weather of Paris and our own, and between the longer waves of variation of July and those of the whole summer. Hence we find, *e.g.*, that a once-smoothed curve of mean temperature of summer at Greenwich presents obvious minima in the years 1814, 1839, 1862, and 1881. Compare this with the Paris July curve.

It is known that in our climate a severe winter tends to be followed by a cool summer; but the facts here presented are, it will be perceived, of a somewhat different order, and wider scope.

The third pair of curves (c) relate to Jakobshavn, on the west coast of Greenland, and show the smoothed variations in mean temperature of winter (December–February) for a series of years. These curves are short compared with the others, and are interrupted at one part; but so far as they go, they seem to present a similar variation, with further lag; so that, as compared with the Paris frost curve, we find the phases have come to be nearly opposite. Our European winters, indeed, seem to be generally opposite to those of Greenland. This is pointed out, as regards Vienna, by Dr. Hann in the paper from which those Jakobshavn figures are obtained. (*Met. Zeits.* 1890, p. 113.)

By way of comparing these curves, it may be useful to note the lowest points of the three once-smoothed curves; and the intervals between those of the same curve and of different curves. (The intervals, in years, are given in brackets.)

Paris, frost,	1814 (25),	1839 (17),	1856 (22),	1878 (11),	1889
	(1)	(3)	(6)	(3)	
Paris, July,	1815 (27),	1842 (20),	1862 (19)	1881 (9),	1890
		(2)	(3)	(3)	
Jakobshavn, winter,		1844 (21),	1865 (19),	1884.	

The fact of this lagging correspondence would appear to suggest that the general variations of our winter seasons are, in some measure, a key to those of approaching summers, and also, if the Jakobshavn correspondence were confirmed by a longer series of data, to those of approaching winters in Greenland.

An explanation of these curious facts may perhaps be supplied by those who have a comprehensive knowledge of polar meteorology and its relations.

A. B. M.

New Element in the Sulphur Group.

DR. B. BRAUNER, of Prag, in 1888 made a careful investigation of the atomic weight of tellurium, an account of which will be found in *C. S. J.* 320, p. 382. In accordance with Messrs. Newland's and Mendeléef's Periodic Law, tellurium should have, if pure, an atomic weight of 125, or even lower.

Prof. D. Mendeléef takes Sb = 122, Te = 125, I = 127. Taking the latest numbers for antimony and iodine (Sb = 120, I = 126·8), Dr. Brauner proceeds to investigate the atomic weight of Te, for which he finds by a great number of experiments the number 127·65. As is only to be expected from such a staunch advocate of the Periodic Law, he at once came to the conclusion that neither himself nor former experimenters (Berzelius, in 1812, 1818 and 1832; von Hauer, in 1857, &c.) had been dealing with the pure element. As he puts it, tellurium is not an element.

Tellurium prepared from the dibromide gave the high atomic weight of 130. Prepared from the tetrabromide, which latter was distilled in vacuo, the resulting element being distilled in a current of hydrogen, Te = 127·65. Under these circumstances, he says, no doubt one constituent of "tellurium" partly escapes, thus reducing the atomic weight. He terms tellurium the gadolinium of the sulphur group.

In the following year, 1889, Prof. Mendeléef predicted (Faraday Lecture, *C. S. J.* 323, p. 649) an element with atomic weight 212, which he calls Dvi-(= Bi-) tellurium, for which he suggests the symbol Dt, and predicts the following characters: it will be capable of forming an oxide RO_3; its hydride, if it exists, will be even more unstable than tellurium hydride; its compounds will be easily reduced; it will form definite alloys with metals; and have the specific gravity of about 9·3. Since then Prof. W. Preyer, in his "Genetisches System der chemischen Elemente," Berlin, 1893, p. 100, among unknown elements, gives one in the sulphur group, thus predicted by Mendeléef. He goes into further details, representing the atomic weight as 213; specific gravity, 8·6; atomic volume, 24·7; specific heat, 0·03; electro-negative, divalent, diamagnetic.

A. Grunwald (Bl. 1891, 5, p. 21) appears to have seen the spectrum of this element, whilst observing spectra of tellurium, copper and antimony.

Norwegium is considered by some chemists to be this missing element; Dr. Preyer is not of that opinion, regarding the claims of norwegium to be considered an element to be insufficiently supported.

In consideration of Dr. Brauner's work on the atomic weight of tellurium, and the priority of his suggestion of the existence of an accompanying element of higher atomic weight, coupled with his excellent work generally in furthering the claims of the Periodic Law (notably in the cases of beryllium and of the cerium, lanthanum and didymium series), I would suggest that this new element, when isolated from its close union with tellurium, be called Bohemium, in his bonour.

C. T. Blanshard.

Bright Meteors.

A pretty bright meteor crossed the eastern sky here on Saturday evening last, at about 7.54 p.m. I saw only the flash of light which it cast on the ground and in the sky towards the east, like a momentary weak red flash of lightning. "A shooting-star," said a bystander close to me, who saw it fairly well, and who gave me, roughly, this description, by the stars, of its apparent course: From about R.A. 340°, Decl. + 25°, to about 336°, + 12°. It described this course of 12° in about a second, and was red in colour, and broke up at last with a red flash, leaving no train of light or of sparks along the track which it had traversed, so long as for a second or two in which I had time to look towards the direction where he pointed. Tree-tops intercepted his view beyond the point of this disruption, but the light's sudden extinction there made a much further extension of the track unlikely.

About an hour afterwards, at about 8.49 p.m., I chanced to see another rather fine shooting-star, of about the brightness and colour of the planet Mars at present, descending some 16° or 18° across the northern sky in one and a-half or two seconds, from R.A. 47°, Decl. + 70°, to 100° + 69°, beginning and disappearing rather suddenly, and of nearly uniformly bright appearance all along its course. It projected no sparks, and, like the earlier meteor, left no train of light or enduring sparks along its track to mark its course.

Prolonged backwards the apparent paths of these two meteors diverge from near α Cassiopeiæ, and it may perhaps be that a shower of bright, ruddy meteors from the direction of Cassiopeia was in progress on that date, of which the two meteors here described may have been bright enough members to have been generally noted. The above observations, although those of the brighter meteor are only of rather slender accuracy, will perhaps be useful, in that case, to serve for comparison with other records which, at least of the larger meteor of the two, may not impossibly have been noted and preserved elsewhere.

A. S. Herschel.

Observatory House, Slough, October 1.

Tan-Spots over Dogs' Eyes.

Can any of your readers explain the meaning of the tan-spots seen so commonly over the eyes in black-and-tan dogs of most breeds?

When in Melbourne last year, I went carefully over all the dogs in a show, with one of the stewards, and we found the spots in all the black-and-tan terriers, foxhounds, deerhounds, collies, lurchers, &c; but I could get no information regarding them from the experts.

In some of the highly-bred toy dogs, as the small black-and-tan terriers, I found on inquiry that these spots, formerly so very conspicuous, were being bred out, and had *nearly* disappeared. Their persistence through so many strongly-marked varieties, except those of late date, is singular, for there is fairly good proof that when first domesticated the dog was red or bright brown, like the pariah, dingo, &c.

As far as I can see, we do not find the spots white on a black or dark ground; nor yet black or dark on a white or light ground. My explanation is that they have arisen as a permanent marking after the dogs "sported" to black under domestication, and have been preserved and developed through natural selection. Possibly they are protective, and simulate *eyes*.

One morning, just at dawn, I had occasion to go out into the garden, and while stooping to examine some flowers, near a fence partly covered with creepers, I suddenly saw an animal's head looking through, and what seemed to be two black, and seemingly large, eyes glared at me. Suspecting that a black leopard was about to spring over, I started back, clapped my hands, and shouted. To my relief, however, I saw a tail wag, and found that the spectator was a coolie's dog I knew very well, and which recognised me. The use of the tan-spots—in this case at least—then occurred to me.

May it not be that the spots thus serve a protective purpose, and have often saved the lives of dogs (black dogs) from their enemies, the smaller felines, such as the clouded leopard, &c.? Perhaps the matter is not new; but if it is, it seems worth looking into.

I have several dogs about here now with black bodies and heads; the tan-spots, rather pale, are of the size of a shilling. I have shot one, keeping the skin of the head as a curiosity.

Sibsagar, Asam, September 7. S. E. Peal.

Flight of the Albatross.

At the request of several friends, I enclose, for your inspection, a snap-shot of a northern albatross, which I took *en route* from Victoria, British Columbia, to San Francisco.

The photograph gives the bird in a position in which the human eye is incapable of seeing it. Strangely enough, the flight of the bird which I photographed had been during the whole course of the morning the subject of much discussion: none of us could imagine how the force which enabled it to fly at such

great speed was generated. I remembered having seen some discussion in the papers on the subject, and stated that the matter had been settled to the satisfaction of scientific people, and did my best to explain the theory.

I chose the moment for my photograph when the bird was about fifteen feet from the camera, and sailing alongside of the steamer. The stretch of the wings was estimated by the captain of the ship at between eleven and twelve feet, and the indicator on the camera showed these wings apparently at full stretch at the instant that I pressed the button. The result is certainly somewhat astonishing, and I shall be glad to know whether it is worth comment in your paper; to me it certainly seems to entirely upset the accepted theories as to the flight of this bird. A. KINGSMILL.

Stanmore, October 10.

ON THE DOCTRINE OF DISCONTINUITY OF FLUID MOTION, IN CONNECTION WITH THE RESISTANCE AGAINST A SOLID MOVING THROUGH A FLUID.[1]

III.

§ 11. THE accompanying diagram (Fig. 1) illustrates the application of the doctrine in question, to a disk kept moving through water or air with a constant velocity, V, perpendicular to its own plane. The assumption to which I object as being inconsistent with hydrodynamics, and very far from any

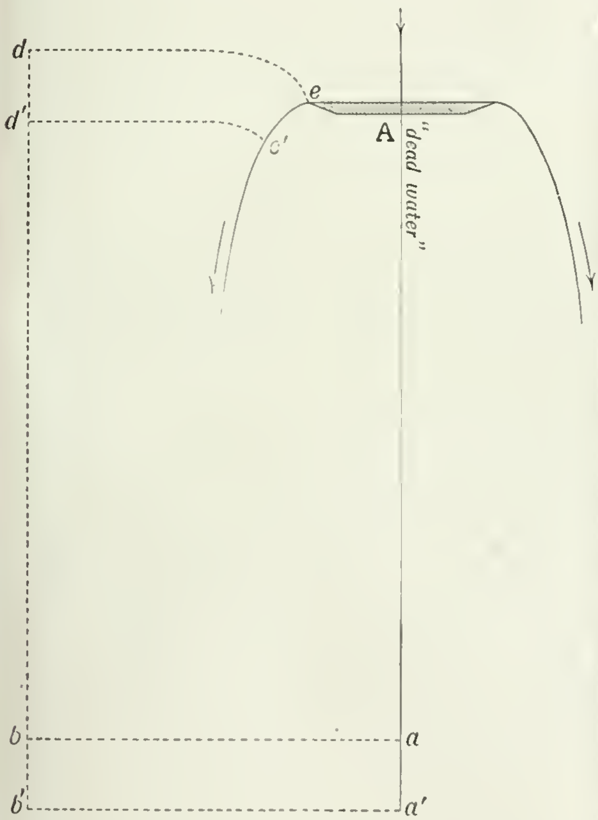


FIG. 1.

approximation to the truth for an inviscid incompressible fluid in any circumstances, and utterly at variance with observation of disks or blades (as oar blades) caused to move through water; is, that starting from the edge as represented by the two continuous curves in the diagram, and extending indefinitely rearwards, there is a "surface of discontinuity" on the outside of which the water flows, relatively to the disk, with velocity V, and on the inside there is a rear-less mass of "dead water"[2] following close after the disk.

[1] Continued from p. 549.

[2] This is a technical expression of practical hydraulics, adopted by the English teachers of the doctrine of finite slip between two parts of a homogeneous fluid, to designate water at rest relatively to the disk.

§ 12. The supposed constancy of the velocity on the outside of the supposed surface of discontinuity entails for the inside a constant pressure, and therefore quiescence relatively to the disk, and rearlessness of the "dead water." How such a state of motion could be produced? and what it is in respect to rear? are questions which I may suggest to the teachers of the doctrine, but happily, not going in for an examination in hydrokinetics, I need not try to answer.

§ 13. But now, supposing the motion of the disk to have been started some finite time, t, ago, and considering the consequent necessity (§ 9) for finiteness of its wake, let ab, bd be lines sufficiently far behind the rear, and beyond one side, of the disturbed water, to pass only through water not sensibly disturbed. We thus have a real finite case of motion to deal with, instead of the inexplicably infinite one of § 11. Let us try if it is possible that for some finite distance from the edge, and from the disk on each side, the motion could be even approximately, if not rigorously, that described in § 11, and indicated by the diagram.

§ 14. Let v be the velocity at any point in the axis, Aa, at distance y from the disk, rearwards. Draw ed perpendicular to the stream lines of the fluid, relatively to the disk supposed at rest.

The "flow"[1] in the line ed is 0;
" " " db " $V \times db$;
" " " ba " 0;
" " " aA " $-\int_0^{Aa} v dy$;
" " " Ae " 0, by hypothesis.

Hence for the "circulation"[2] in the closed polygon $edba$Ae, we have

$$V \times db - \int_0^{Aa} v dy.$$

Similarly, for the circulation in the same circuit[3] at a time later by any interval, τ, when the line ba has moved to the position $b'a'$, and ed to $e'd'$, we have

$$V \times db - \int_0^{Aa} v' dy.$$

where v' denotes, for the later time, $t+\tau$, the velocity in Aa, at distance y from A. Hence the circulation in edaAe gains in time τ an amount equal to

$$-\int_0^{Aa} (v' - v) dy;$$

which is the same as

$$-\int_0^{\infty} (v' - v) dy,$$

This, by the general theorem of "circulation,"[4] must be equal to the gain of circulation in time τ, of all the vortex-sheet in its growth from the edge according to the statement of § 11. Hence, with the notation of § 10,

$$(\Sigma\kappa)' - \Sigma\kappa = -\int_0^{\infty} (v' - v) dy.$$

§ 15. Remarking now that the fluid has only continuous irrotational motion through a finite space all round each of the lines ed, db, ba, aA; and all round Ae except the space occupied by the disk and the fluid beyond its front side, we have, for the velocity-potential of this motion, relatively to the disk,

$$Vy + \phi(x, y, z, t)$$

where ϕ denotes the velocity-potential of the motion

[1] "Vortex Motion" (Thomson), *Trans. R.S.E.*, 1869.

[2] *Ibid.*

[3] Remark that the circulation in $abb'a'$ is zero, and therefore the circulation in $edb'a'$Ae is equal to that in $edba$Ae.

[4] "Vortex Motion," *Trans. R.S.E.*, 1869.

relative to the infinitely distant fluid all round: and we have

$$v = \mathrm{V} + \frac{d}{dy}\phi(o, y, o, t).$$

With this the equation of § 14 becomes

$$(\Sigma\kappa)' - \Sigma\kappa = \{\phi(o, o, o, t+\tau)\} - \{\phi(o, o, o, t)\}.$$

Hence, by taking τ infinitely small,

$$\frac{d}{dt}\Sigma\kappa = \frac{d}{dt}\phi(o, o, o, t).$$

§ 16. Now in the time from t to $t + \tau$, there has been, according to the supposition stated in § 11, a growth of vortex sheet from e, at the rate $\frac{1}{2}$V, being the mean between the velocities of the fluid on its two sides,[1] and the circulation, per unit length, l, of the sheet thus growing is lV. Hence the vortex-circulation of the growing sheet augments, in time τ, by $\frac{1}{2}\mathrm{V}\tau \times \mathrm{V}$: and therefore, by § 15,

$$\frac{d}{dt}\,\phi\,(o, o, o, t) = \tfrac{1}{2}\,\mathrm{V}^2.$$

§ 17. Now, if Π denotes the pressure of the fluid at great distances, where its velocity, relative to the disk is V, and p the pressure at any point of the rear side of the disk, being the same as the pressure at A, we have, by elementary hydrokinetics,

$$p = \Pi + \tfrac{1}{2}\,\mathrm{V}^2 - \frac{d}{dt}\,\phi\,(o, o, o, t)$$

because the velocity of the fluid at every point of the rear side of the disk is zero according to the assumption of "dead water." Hence, by § 16,

$$p = \Pi,$$

which, being the same as the pressure on the rear side given by the unmitigated assumption of an endless ever broadening wake of "dead water," proves that our substitution (§ 13) of a finite configuration of motion conceivably possible as the consequence of setting the disk in motion at some finite time, t, ago, instead of the inconceivable configuration described in § 11, does not alter the pressure on the rear side of the disk.

§ 18. Hence were the motion of the fluid for some finite distance from the disk, on both its sides, the same, or very approximately the same, as that described in § 11, the force that must be applied to keep it moving uniformly would be the same, or very approximately the same, as that calculated by Lord Rayleigh from the motion of the fluid supposed to be wholly as described in § 11.

§ 19. But what reason have we for supposing the velocity of the fluid at the edge, on the front side of the disk, to be exactly or even approximately equal to the undisturbed velocity, V, of the fluid at great distances from the disk? None that I can see. It seems to me indeed probable that it is in reality much greater than V, when we consider that, with inviscid incompressible fluid in an unyielding outer boundary, the velocity, in the case considered in § 14, is equal to V at even so far from the edge as 1/5 of an inch, and increases from V to 63·7 × V between that distance from the edge, and the edge with its 1/2000 of an inch radius of curvature.

§ 20. And what of the "dead water" in contact with the whole rear side of the disk which the doctrine of discontinuity assumes? Look at the reality and you will see the water in the rear exceedingly lively everywhere except at the very centre of the disk. You will see it eddying round from the edge and returning outwards very close along the rear surface, often I believe with much greater velocity than V, but with no steadiness: on the contrary, with a turbulent unsteadiness utterly unlike the steady regular motion generally assumed in the doctrine of discontinuity.

[1] Helmholtz, Wissenschaftliche Abhandlungen; vol. i., foot of p. 151

§ 21. We may I think safely conclude that on the front side the opposing pressure is less than that calculated by Rayleigh. That this diminution of resistance is partially compensated or is over-compensated by diminution of pressure on the rear, is more than we are able to say from theory alone, in a problem of motion so complex and so far beyond our powers of calculation: but we are entitled to say so, I believe, by experiment. Rayleigh's investigation of the resistance experienced by an infinitely thin rigid plane blade bounded by two parallel straight edges, when caused to move through an inviscid incompressible fluid, with constant velocity, V, in a direction perpendicular to the edges and inclined at an angle i to the plane, gives a force cutting the plane perpendicularly at a distance from its middle equal to

$$\frac{3\cos i}{4(4 + \pi \sin i)}$$

of its breadth, and gives for the amount of this force in gravitation measure,

$$\frac{2\pi \sin i}{4 + \pi \sin i}\,\mathrm{PA},$$

where A denotes the area of one side of the blade, and P the weight of a column of the fluid of unit cross-sectional area, and of height equal to the height from which a body must fall to acquire a velocity equal to V.

§ 22. The assumption (§ 11) on which this investigation is founded admits no velocity of fluid motion relatively to the disk greater anywhere than V. It gives velocity reaching this value only at the edges of the blade; and at the supposed surface of discontinuity; and in the fluid at infinite distances all round except in the infinitely broad wake of "dead water" where the velocity is zero. It makes the pressure equal to Π all through the "dead water," and makes it increase through the moving fluid, from Π at an infinite distance and at the "surface of discontinuity," to a maximum value Π+P attained at the water-shed line of the disk. If the fluid is air, and if V be even so great as 120 feet per second (1/10 of the velocity of sound)[1] P would be only 7/1000 of Π. The corresponding augmentation of density could cause no very serious change of the motion from that assumed: and therefore in Rayleigh's investigation air may be regarded as an incompressible fluid if the velocity of the disk is anything less than 120 feet per second.

We may therefore test his formula for the resistance, by comparison with results of careful experiments made by Dines[2] on the resistance of air to disks and blades moved through it at velocities of from 40 to 70 statute miles per hour (59 to 103 feet per second).

§ 23. Dines finds for normal incidence the resistance against a foot-square plate, moving through air at m British statute miles per hour to be equal to ·0029 m^2 of a pound weight.

This, if we take the specific gravity of the air as 1/800, gives according to our notation of §21,

$$1{\cdot}16 \times \mathrm{PA}$$

as the resistance to a square plate of area A. At the foot of p. 255 (*Proc. R.S.*, June 1890) Dines says that he finds the resistance to a long narrow blade to be more than 20 per cent. greater than to a square plate. For a blade we may there take

$$1{\cdot}34 \times \mathrm{PA}$$

as the resistance according to Dines' experiments. This is 1·52 times the resistance calculated from Rayleigh's formula (§ 21 above), which is

$$\cdot 88\ \ \mathrm{PA},$$

for normal incidence.

§ 24. For incidences more and more oblique, the dis-

[1] Or $\frac{1}{2}\mathrm{V}^2 \div g\mathrm{H}$, where H is "the height of the homogeneous atmosphere."

[2] *Proc. R.S.A.*, June 1890.

crepancy is greater and greater. Thus, from curves given by Dines (p. 256) showing his own and Rayleigh's results, I find the normal resistance to a blade moved through air in a direction inclined 30° to its plane, to be 1·82 times that given by Rayleigh's formula. And by drawing a tangent to Dines' curve at the point in which it cuts the line of zero pressure, I find that, for very small values of *i*, it gives

$$3{\cdot}25 \times \sin i \times \text{PA}.$$

This is rather more than double the value of the force given by Rayleigh's formula for very small values of *i*, which is

$$\tfrac{1}{2}\,\pi \sin i.\text{PA}.$$

It is about three and a half per cent. greater than that given by my conjectural formula (NATURE, August 20, p. 426, and September 27, p. 525; and *Phil. Mag.*, October 1894) for very small values of *i*, which is

$$\pi \sin i \cos i.\ \text{PA}.$$

My formula is, however, merely conjectural; and I was inclined to think that it may considerably under-estimate the force. That it does so to some degree is perhaps made probable by its somewhat close agreement with Dines; because the blade in his experiments was 3*i* broad and ⅜ of an inch thick in the middle with edges "feathered off." An infinitely thin blade would probably have shown greater resistances, at all angles, and especially at those of small inclination to the wind.

(*To be continued.*)

OBSERVATIONS ON YOUNG PHEASANTS.

THE pheasants which formed the subjects of the following observations were hatched out in an incubator from eggs kindly given me by Sir Cecil Miles. The eggs were taken from the hen and transferred to the incubator a few days before the young birds were due to emerge.

The accuracy of pecking and seizing was found to be about the same as that of newly-hatched chicks. For example: two pheasants were hatched out at about 3 p.m.; that evening, at about 6.30, finely chopped egg was placed before them, but they showed no signs of pecking at it; nor did they peck at grain or sand next morning at 11 a.m. At 4 p.m. they began to peck, but seized very little. One struck repeatedly at a crumb of egg on the other's back, but failed to seize it, though the other bird was quite still. On the following morning they pecked at sand and grain (chiefly canary seed) with fair aim. One seized, at the first stroke, a grain of boiled rice at the end of a long steel pin. Another pheasant was hatched out in the night. At about 12 noon, I offered him some egg-bread on the end of a tooth-pick. He struck at it and missed, struck a second time and seized, swallowing some. He could not be induced to strike again. Later he picked up some ants' "eggs," striking with fair accuracy, but did not swallow any. At 4 p.m. he pecked some egg-bread off the end of the tooth-pick, and swallowed. He also pecked at an ant's "egg," but failed to swallow it; then at a second, and swallowed it. Further details would be merely wearisome. One may say that the co-ordination for pecking and swallowing is inherited in a condition such as to ensure fair but not complete accuracy; and that some individual experience is necessary to bring it to perfection.

The young pheasants took no notice whatever of water placed before them in a shallow vessel. When I gave them water on the tip of my finger, they seemed to enjoy it, and one in particular drank eagerly from the end of a tooth-pick, so that an association was established between the sight of the tooth-pick and the satisfaction of drinking. But when I lifted this bird and others, and placed them in the shallow vessel, they made no attempt to drink from it. They learnt to drink from the vessel through pecking at grains of food lying on the bottom. They drank, however, less freely than chicks.

The little birds showed no sign of fear of me. They liked to nestle in my warm hand. My fox-terrier was keen to get at them, much keener than with chicks, probably through scent-suggestion. I placed two of the young pheasants, about a day old, on the floor, and let him smell them (under strict orders not to touch them). He was trembling in every limb from excitement. But they showed no signs of fear, though his nose was within an inch of them. When the pheasants were a week old, I procured a large blind-worm and placed it in front of the incubator drawer in which the birds slept at night. On opening the drawer they jumped out as usual, and ran over the blind-worm without taking any notice of it. Presently first one, then another, pecked vigorously at the forked tongue as it played in and out of the blind-worm's mouth. Subsequently they pecked at its eye and the end of its tail. This observation naturally leads one to surmise that the constant tongue-play in snakes may act as a lure for young and inexperienced birds; and that some cases of so-called fascination may be simply the fluttering of birds round this tempting object. I distinctly remember when a boy seeing a grass-snake with head slightly elevated and quite motionless, and round it three or four young birds fluttering nearer and nearer. It looked like fascination; it may have been that each hoped to be the first to catch that tempting but elusive worm! Presently they would no doubt be invited to step inside.

Another incidental observation is worth recording here. I gave the young birds some wood-lice. These were frequently caught when they were moving, and eaten. But if one had time to roll up, and was thus seized, it was shot out to a distance by the pressure of the bill, just as a fresh cherry-stone is shot from between the finger and thumb of a school-boy. The protective value of the round and slippery form was thus a matter of observation.

I have not observed in the young pheasants the crouching down, which is seen in young chicks when an unusual sound startles them. They appear under such circumstances to stand motionless. For example, when two of them were walking about, picking up all the indigestible odds and ends they could find on my carpet, a high chord was sharply struck on the violin. Both stopped dead. The gentle piping noise they were making ceased. One of them was just lifting his leg, and remained in this position quite still, with neck stretched out, exactly as if he had been suddenly fixed in the attitude in which he chanced to be when the sharp sound fell on his ears. Thus he remained for half a minute. Then he took a few steps and again stopped, remaining quite still for about the same period. (Age 13 days.)

The method of tackling a worm appears to be a matter of inherited co-ordination. So soon as the worm is seized, it is shaken and battered about. There seems to be, also, an inherited tendency to run away with it to some distance before eating it. At all events, of two little pheasants, one of which was weakly, the stronger always bolted off with his worm, though his weakly brother or sister seldom or never chased him. He sometimes tried to bolt with one of his companion's toes by mistake, when one or both of the birds would topple over.

Two notes or sounds, one loud and distressful, the other soft and contentful, appear from the first to be clearly differentiated. A third sound, more gentle than the soft note and double, was occasionally heard when one caressed the birds in one's warm hand. It closely resembles a similar note uttered under similar circumstances by the chick. The note expressive of danger, alarm, or anger, was occasionally heard after about the sixth day. For example, as the little pheasant was bolting with his worm, I seized it with a pair of forceps. This alarm or anger note was at once uttered, and the little fellow bridled up and seemed ready to show fight.

The birds when fresh run about with little short spurts or dashes, as do also chicks. They have a dislike to being confined. When they were surrounded with wire netting, although the space inside was ample for all their needs, they squeezed through the meshes, and did so very cleverly when four or five days old. At about this age or earlier they preen their down, and the incipient feathers of the wing, often tumbling over from imperfect co-ordination. They also peck persistently at their toes. They scratch the ground much less than chicks.

More difficulty was found in rearing the pheasants by hand than in the case of chicks. Several died apparently from constipation. None were reared beyond the fifteenth day. The coldness of the season was against them, and unfortunately, through an accident, the incubator drawer in which they slept was allowed to get cold, and this caused the death of the last two, one of which was quite healthy. I hope to repeat the observations, next year, on these and other young birds under more favourable conditions. Such as they are, however, they serve to confirm the conclusions based upon the study of newly-hatched chicks and ducklings, which I briefly set forth in *Natural Science* for March 1894, and which are considered at greater length in my "Introduction to Comparative Psychology," to be published this autumn in the Contemporary Science Series.

C. Lloyd Morgan.

SCHOOLS OF METEOROLOGY.

In your issue of September 13, p. 481, you correctly state that one reason for the small number of meteorologists is the want of a training school. This is a defect in our University curricula that I have frequently pointed out and sought to remedy. You will agree with me that meteorology is worthy of a generous and profound treatment. It should be recognised as a possible major course in all large Universities. Laboratories should be provided where all questions bearing on the atmosphere and its motions can be experimentally elucidated.

I append a sketch of the four years' course of study and work that I hope to carry out with my own students. The necessary laboratory conveniences have not yet been provided, but we are looking forward hopefully.

I shall be glad if your publication of this course contribute in any way to the proper study of meteorology by the young physicists of the British Empire.

Cleveland Abbe.

Washington, September 24.

Columbian University.

Department of Meteorology.

The series of courses in the Department of Meteorology is designed to give a complete review of the present condition of that science, and is therefore necessarily extended through four years; but the series of lectures is so arranged that each of the four divisions is complete within itself; each course presents a view of a branch of the subject such as may be desired by a large number of students who need this information in connection with other branches of knowledge to which they are specially devoting themselves.

Students who intend to take the degree of Ph.D. in meteorology, and who therefore make this the major subject in connection with several other minor courses, must pursue the whole four years' course. Those who desire merely to enter the service of the United States Weather Bureau will probably find the first year's course sufficient to enable them to pass the necessary Civil Service examinations. Those who desire to do work in climatological study should also take the second year. The third year's course is designed for those who wish to perfect themselves in methods of making local weather forecasts. Finally, the fourth year's course will serve as an abundant introduction to the present state of our knowledge of the mechanics and physics of the atmosphere. In addition to the lectures, the instructor will give one hour a week to a quiz-class, in which, by question and answer, he will seek to remove any difficulties that remain.

(1) *Observational Meteorology.*—The methods of observation; the simpler instruments, their errors, corrections, and reductions; the use of self-registers; the forms of record and computation; personal diary of the weather.

Time.—About eighty lectures, or two hours a week, as also eighty other hours of personal investigation of instruments, especially self-registers.

Algebra and trigonometry are necessary preliminaries to this course. Elementary laboratory physics, as illustrated by Hall and Bergen's text-book, is desirable as a preliminary, but may be pursued as a concomitant study. The German language is earnestly recommended as a concomitant. The differential and integral calculus will be needed as preliminary to the Graduate Course in Meteorology.

(2) Climatology, both local and general; empirical meteorology, generalisations, averages, periodicities, irregularities. The relation of climate to geology, to vegetation, to animal life, and to anthropology.

Time.—About forty lectures and four hours weekly given to the investigation of special problems proposed in each lecture.

Students should be familiar with the use of logarithms; the method of least squares; the laws of chance; the details of physical geography, orography, geology, and ocean currents; the physiology of plants and animals; the distribution of species; physical astronomy, especially that of the sun, earth, and moon; terrestrial magnetism; the chemistry of the atmosphere; the biology of atmospheric dust. Physical laboratory work on radiation, conduction, and absorption of heat, and on condensation and evaporation of vapour, and on elementary electricity, is recommended, while German, the calculus and analytic mechanics should be continued as preliminary to the Graduate Course.

Graduate School of Meteorology.

The following scheme of studies in meteorology, subject to arrangement between the teacher and his pupils, is offered for the degree of Doctor of Philosophy:—

(1) Practical meteorology; the daily weather chart; the empirical laws of weather changes as depending on meteorological data, and the arrangement of continents, plateaus, mountains, oceans, &c.; weather types and typical weather charts; prediction of daily weather and seasonal climates; verification of predictions.

Time.—About forty lectures and at least five hours a week additional, in verifying old laws and studying new ones, in making and verifying predictions.

Concomitant Studies.—Methods of chart projection; experimental laboratory work in both steady and discontinuous motions of fluid and gases; mathematical and experimental electricity; the laws of refraction and interference of light; elementary hydrodynamics and thermodynamics; differential equations and definite integrals; the German language.

(2) Theoretical meteorology. Insolation. The absorption, conduction, and radiation of heat by the air and the earth. The thermodynamics of the atmosphere; the graphic methods of Hertz and Bezold. Convective equilibrium, as applied to the atmosphere of the sun by Lane, and to that of the earth by Sir William Thomson

(Lord Kelvin) and his successors. Motion on a rotating globe; Ferrel's and other simple approximate relations between baric gradients and the wind and temperature; Ferrel's general circulation of the atmosphere and his cyclones and pericyclones and tornados. Galton's cyclone and anticyclone. Fourier's most general equations of gaseous motions. Oberbeck's general circulation. Helmholtz's horizontal rolls. The investigations of Diro Kitao, Guldberg and Mohn, Marchi, Boussinesq, A. Poincaré, Sprung, Siemens, Moeller, Ritter, and others into the motions of the atmosphere. Viscosity and discontinuous movements. The possible special solutions of the general equations of fluid motions that apply to the true atmospheric circulation, both on the earth and on the other planets. Atmospheric tides; theories of Laplace, Ferrel, Rayleigh, Margules, A. Poincaré. Theories of atmospheric electricity.

Time.—Eighty lectures and an additional four hours a week given to special reading and investigation, and to the preparation of the final thesis, as closing the four years' course.

Concomitant Studies. — Riemann's "Differential Gleichungen"; Auerbach's "Hydrodynamics"; Lamb's "Fluid Motions" (new edition); physical laboratory work in gaseous motions, optical and electrical phenomena.

THE ROYAL PHOTOGRAPHIC SOCIETY.

SIR H. TRUEMAN WOOD, the new President of the Royal Photographic Society, delivered an address at the opening meeting of the present session on Tuesday. After briefly tracing the development of the Society, he said:

"Turning aside from the consideration of the affairs of our own Society, to the general condition of photography, we find cause for nothing but congratulation. It is not so very long since photography occupied a very subordinate position in the world alike of science and of art. Scientific men looked on photography as a mere art, artists regarded it as a mere science. About twenty years ago, when I suggested that some improvement in a photographic process—I forget now which—ought to be brought before the Physical Section of the British Association, I was told that there was nothing scientific about photography, that it was a mere empirical pursuit, unworthy the attention of serious students of science.

"And to a large extent the reproach was well deserved. Though the list of the earliest workers in photography contains many illustrious names, yet it is true that a large proportion of the most important contributions to photographic knowledge were not made by scientific workers, or by men who worked in scientific methods. They were obtained by practical men, seeking for results; often, indeed, seeking for them successfully by methods which would not have commended themselves to men better equipped with scientific knowledge. Of course this was the consequence of the fact that photographic science was early associated with photographic practice; and the same remark holds good of other sciences, electricity for instance, in which theory and application to practical use advance with equal steps; but I think it applies more to photography than to any other.

"At the present time we have indeed reached a very different condition of things. All the most striking of the recent advances in the science are the result of elaborate scientific research. The most recent improvements in lenses were the fruit of long and laborious investigation into the optical properties and the chemical nature of certain sorts of glass. The increased speed of modern plates, and their improved power of rendering colour values more truly, have only been obtained by minute knowledge of the condition of the problem to be solved, and by careful application of the most recent results of chemical and physical research. If the old photographic crux, the reproduction of colour, has been solved, or, at all events, if a possible method has been indicated for its solution, it was not by haphazard experiment, but by careful adjustment of means to secure an anticipated result. Nowadays, we can only hope for improvement by utilising the advance of scientific knowledge.

"But if the present position of photography is due to progress in the kindred sciences, how amply has she repaid the debt! There is not a single branch of science in which photography is not largely used. There are many whose progress is now absolutely dependent on the power of the camera to observe more accurately, more independently, more minutely, more rapidly, more permanently, than the human eye. If, as appears to be the case, we have reached the limits of human vision, aided by the most delicate instruments that can be constructed, it is difficult to imagine what limits need be set to photographic vision, can we but construct instruments of accuracy sufficient to allow its full powers to be utilised.

"I imagine that the first application of photography to a scientific purpose must have been when Dr. Draper in New York photographed the moon. Whether the pictures he obtained were of any astronomical value, I do not know; certainly those taken a little later, in 1852, by Dr. Warren De la Rue, were, and they were the precursors of the long series of astronomical photographs culminating in Dr. Common's nebula of Orion, and in the great work of charting the heavens by photography which is now in progress.

"The advantages of the 'retina which never forgets,' and it might be added which never tires, which accumulates weak impressions and stores them up till they become one strong one, were long since recognised by De la Rue, and I suppose it will not be very long before, for astronomical purposes, eye observations are entirely superseded by photographic. The photographic camera is now an indispensable adjunct to every large telescope, if indeed it would not be equally correct to say that the telescope is an adjunct to the camera, since the astronomical telescope tends more and more to assimilate to the form adopted long since by Mr. Rutherford, in which the visual rays are treated of but slight importance, and the chief attention is given to the accurate utilisation of the more chemically active rays at the violet end of the spectrum.[1]

"In his recent address to the Photographic Convention at Dublin, Sir Howard Grubb, than whom nobody is better qualified to speak on the subject, dwelt on the services which photography has rendered to astronomy, and gave several striking illustrations of those services. Indeed, if one not qualified to speak on such matters with any authority might hazard an opinion, it would almost seem as if the power of recording observations had already outstripped the capacity for examining the observations, and drawing conclusions from them. When we are told that a photographic plate has recorded 10,000 stars in an area not containing a single visible star, one may be excused an expression of wonder as to how the human mind is ever to grapple with problems of such infinite complexity, to turn to useful account observations dealing with such enormous multitudes.

"But if the telescope has lately become one of the most important of photographic appliances, the spectroscope may be said to have held that position almost since its introduction. Mr. Norman Lockyer, in his well-known text-book, "Studies in Spectrum Analysis," attributes to

[1] A good illustration of the telescope of the future would appear to be the 24-inch photographic refractor with an 18-inch visual telescope, now being constructed at the expense of Mr. McLean for the Cape Observatory.

Sir John Herschel the first suggestion of spectrum photography, and we find that in 1839 the latter pointed out that the way to investigate sensitiveness was to photograph the spectrum. In the following year he read a paper describing his results of spectrum photography. A little later, in 1842, Becquerel and Draper were both at work photographing the solar spectrum. Twenty years later (in 1864) Miller was turning to practical account the power of photography to record the parts of the spectrum beyond the limits of human vision, and from that date nearly all spectroscopic work has been photographic work. Whether applied to astronomical observation or chemical research, the spectroscope has always been combined with the camera, and it is by the combination of the two instruments that such wonderful results have been attained. And as photographic methods have improved, so have fresh facilities been afforded to the spectroscopic worker. Mr. Lockyer's earlier work was of necessity done with wet plates, but with the plates now available he is producing star spectra on a scale comparable with the solar spectra of twenty-five years ago.[1] Rutherford's recent maps of the solar spectrum could not have been produced without the use of colour-sensitive plates, while in one of the most recent attempts to employ spectroscopic analysis for purposes of practical metallurgy[2] Prof. Hartley tells us that he also used orthochromatic plates, specially prepared, and that after trying various developers he found hydroquinone the best.

"As an automatic recorder of scientific observations, photography seems to have been utilised in the Royal Observatory about 1847, under the superintendence of the venerable ex-president of this Society, Mr. Glaisher, who has been kind enough to furnish me with particulars of the methods originally devised by Mr. Charles Brooke, and successfully worked for many years by Mr. Glaisher and his staff.

"The method was first applied to record magnetic variations and the movements of the barometer and thermometer. In the case of the former, a ray of light reflected from a mirror carried by the magnet was focussed on the surface of a cylinder covered with sensitised paper.[3] The cylinder was rotated by clockwork, the result being, of course—in the way now commonly employed for such automatic records—to give, when the image was developed, a record of the movements of the magnet. A base line was given by an invariable spot of light, and by intermissions of this light a time record was provided. Similar results were obtained in the case of the barometer by using a float with a small perforation through which the light passed, and with the thermometer by simply allowing the mercury itself to screen the light from the sensitive surface.[4]

"Later on, in 1865, similar means were used by Mr. Glaisher for the automatic record of earth-currents, and they have consequently been continuously observed since that date at Greenwich.

"To the best of my knowledge but little alteration has been made in the original system, the only improvement being in the sensitive surface employed. When gelatino-bromide paper was introduced, it was tried and adopted at Greenwich, and by its means superior results were obtained.

"I have ventured to dwell at some little length on this part of the subject, not because what I have said can be novel to any of you, but because I think this first application of photography to automatic observation has considerable historical interest, and also because this application was carried out by one so long and so honourably connected with this Society.

"The principle thus first applied at Greenwich has received numerous other applications, and indeed it is now a matter of course that photographic methods should be used to register the movements of any instrument of whose indications it is desired to preserve a record. Instances are of course numerous in which no other method is possible. Hardly any but a photographic method could register the movements of the light spot of a reflecting galvanometer, and thus enable the physicist who, like Langley, is measuring the heat radiated from celestial bodies, to record the minutest differences of temperature; the chemist, like Dewar, who is producing hardly imaginable cold, to record temperatures approaching absolute zero; the metallurgist, like Roberts-Austen, who is dealing with the melting points of metals, to register by a photographically traced curve variations in high temperatures which but a short time ago could not be accurately measured at all. It is interesting to read the testimony of the last named, given at the recent conference of the Camera Club, to the effect that he could not conceive of any method which would give such results in the same space and time. Equally interesting is it to note the Professor's suggestion for a practical method of recording continuously the temperature of the air-supply of a blast furnace, a matter of great importance to the iron manufacturer, of which he says:—'If we had no photography it would be impossible to get a record which would be anything like so true.'

"Numerous other instances will occur to many of you in which photography has been or might be—indeed I may say will be—applied to similar purposes. I will only refer to one, because it appears to me so excellent an instance of the delicacy of the method. At the last (the Oxford) meeting of the British Association, Mr. Burch showed to the newly-formed Physiological Section photographic records taken with the aid of the capillary electrometer of electrical currents produced by speaking into the telephone. The letter *z* produced a complicated curve in which oscillations of current lasting only 1/3000 sec. were visible with a lens.

"It seems hardly worth while to trouble you with the details of many of the other services which photography has rendered to science, and if I were to attempt to produce an exhaustive list, there are many present to-night who could supplement it out of their own knowledge. The meteorologist has been enabled by its aid to study the form and nature of clouds, the shape and character of the lightning flash. The zoologist has been taught much about animal motion. The microscopist has long learnt to rely on the camera as the only accurate means of reproducing the objects of his studies. The physicist has by photographic methods investigated many phenomena in which the changes are too rapid for the human eye to follow them. By such means Lord Rayleigh and Prof. Boys have obtained long series of pictures of occurrences which all took place within a fraction of a second, thus almost analysing time as the chemist analyses matter.

"The uses of photography in ethnology, geology, geography, natural history, archæology, are too obvious to need mention. They and many other applications may be summed up in the remark that whenever the observer of natural phenomena requires to make an accurate record of his observations, photography supplies the means. It also supplies the means of showing to a room full of spectators what could otherwise be seen by but a single observer at one time, and has thus rendered to the popularisation of science no less a service than it has lent to its advancement. This universal use of photography for purposes of demonstration must certainly not be forgotten in however brief a summary of its applications."

[1] "Photographic Spectra of some of the Brighter Stars." *Phil. Trans.*, [illegible]

[2] "Flame Spectra at High Temperatures." *Phil. Trans.*, vol. 185, A., p. 161 *et seq.*

[3] The method employed was a form of the old calotype process. Paper [illegible] with potassium [illegible] was afterwards sensitised with [illegible] nitrate. The development was by gallic acid.

[4] For a full account of the apparatus reference may be made to an addendum to the introduction to the Greenwich magnetical and meteorological observations for 1847.

The services of photography to art were next touched upon by Sir H. T. Wood, who afterwards went on to say:

"The interesting investigations of Buchner and Marshall Ward into the action of light on bacteria can hardly with justice be admitted as adding to the list of photographic materials, though we must certainly claim the 'photobacteriograph' as an advance in our science and as suggesting new directions for photographic work.

"The question of sensitometry has exercised the minds of many of our most active workers for some time, but I think I may say without as yet any positive result. I believe I may put it as the opinion of those best qualified to express an impartial judgment on the subject, that while we have certainly obtained a means of roughly gauging the comparative sensitiveness of plates, and have got a guide of great practical use to the makers and users of plates, we are as far as ever from an absolute standard, and that the attainment of such a standard must await the attainment of a standard of light, a problem the solution of which is of importance not to photographers alone.

"It would obviously be unreasonable to expect that the increase of photographic knowledge should grow *pari passu* with the number of those who practise the art, but I think it is certainly a matter for regret that of the many thousands who have taken up photography as a pastime, so very few pursue it in a serious way, or in a scientific spirit. The popularisation of photography has indeed to my mind been a drawback to real progress. The process of picture-making has been rendered so easy that it has been deprived of much of its interest, even to the merest amateur in science, and the attention of those who might have pursued photography seriously has been diverted to other branches of science. Still we are fortunate in having, even among the younger workers, a considerable band of capable and active students who are adding slowly but surely to our knowledge of the scientific principles of the art.

"In photographic optics there is, I think I may say, a very distinct advance now going on. The expectations of opticians have long been fixed on the productions of the Jena manufactory, and those expectations are, according to the best information at my disposal, now in a fair way of being realised. The qualities of glass that are to be obtained commercially from Jena have provided the opticians with new possibilities for the improvement of photographic lenses. Both in this country and in Germany opticians are availing themselves of these possibilities. Great credit is certainly due to Messrs. Ross, who have carried out the work of Dr. Schroeder, and have produced from his calculations the lens which they have termed the 'concentric' lens. The double anastigmat of Goerz, described last year to the Society by that gentleman, is another new lens, the outcome of the Jena improvements in glass, which ought at least to receive mention.

"Mr. Dallmeyer has also made considerable advances, both theoretical and practical, in his 'telephotographic' lens, an instrument which produces results appealing at once to all who take any interest in photographic matters, and one which, in the opinion of competent authorities, is likely to have important practical applications for astronomical and other branches of scientific photography."

WILLIAM TOPLEY, F.R.S.

A GREAT gap has been made in the ranks of active geologists by the death of William Topley, which took place on the night of Sunday, September 30, at his house at Croydon. He was taken ill, with gastritis, probably from the use of contaminated water, in Algiers, during a short visit, made in reference to its geology; and he fell, therefore, in the fighting line of those who apply their scientific knowledge for the good of mankind.

He was ill whilst travelling home, and though after a time he began a slow recovery, a relapse came on Saturday, September 29, which soon proved fatal.

Born at Greenwich in 1841, he had reached an age when, though the physical powers may have begun to wane, yet the mental powers are reinforced by stores of knowledge and of experience, and the value of a scientific life is high.

His scientific education was at the Royal School of Mines, Jermyn Street. Soon after his student-life was ended, he joined the Geological Survey (early in 1862), and his future career was identified with that Survey, of which he was one of the oldest and best-known officers at the date of his untimely death.

For many years his work lay in the counties of Kent, Surrey, and Sussex, in the investigation of the great district of the Weald and its surroundings, with which his name will ever be linked.

He made his mark as a good observer of facts and an able reasoner from them in 1865, by the paper, read to the Geological Society, "On the Superficial Deposits of the Valley of the Medway, with Remarks on the Denudation of the Weald," which was written jointly with his then colleague, Dr. C. LeNeve Foster. This is a most important essay, in which the general question of inland erosion is discussed, and the special question of the processes of denudation that had acted over a definite tract, on which much had been written, may be said to have been practically settled, an achievement of no small merit.

In 1866 Mr. Topley supplemented his knowledge of our Wealden deposits by a visit to the Boulonnais, a tract that really contains the severed eastern end of the Weald, a visit in which the writer had the pleasure of accompanying him, and the results of which were given to the Geological Society in 1868.

He soon turned his attention to the bearings of geology on other branches of knowledge, and in 1871 the Royal Agricultural Society published a paper by him, "On the Comparative Agriculture of England and Wales," followed, in the next year, by another, "On the Agricultural Geology of the Weald."

In 1873 a paper was printed by the Anthropological Institute, in which he treated of the relation of parish boundaries to great physical features. This was illustrated chiefly from parts of the Weald and its borders: but references were made to other parts, and amongst them to Northumberland, to which county he had been transferred from the south.

In 1874 he gave the Geological Society a very suggestive paper "On the Correspondence between some Areas of Apparent Upheaval and the Thickening of Subjacent Beds," in which he pointed out that an apparent dip (over a large tract) may be partly owing to the thinning of beds underground.

In 1875 appeared the work by which he will probably be best known, and in the writing and compiling of which he may be said to have raised his own monument. The Geological Survey Memoir on the Weald is noted, not so much for local details (of which, however, there are many) as for the thorough way in which the literature of the subject is treated, for the full discussion of the subjects of physical geology, scenery, and denudation, and for the attention given to many branches of applied geology. The parts mentioned indeed take up more than half of the text, adding greatly to the interest of the book.

Naturally the important work of the Sub-wealden Boring was not done without Mr. Topley's help.

In 1876, he used his northern experience in the field in joining his friend Prof. Lebour in a paper to the Geological Society, on the intrusive nature of the Whin Sill, published the following year.

Since that time he contributed papers to various societies, other than those already mentioned, and to various journals These are chiefly on questions relating to economic geology, such as water-supply, petroleum, and coal in south-eastern England; and are too many to be noticed here. His name also appears, of course, as author, or part author, on many sheets of the maps and sections of the Geological Survey.

It is not only, however, by his published works that Mr. Topley is known—in science his was a public life. He took a marked part in the work of the British Association, and was secretary of its Geological Section for no less than fifteen years—one of the longest of such secretarial lives. He also served on some committees, and was secretary of that on coast erosion, the reports of which owe much to him. He served on the councils of the Geological Society and of the Geologists' Association for many years, and was president of the latter body for two years (1885-7). He took part in most of the international geological congresses, and worked hard for the great one in London, of which he was a secretary, in 1888. He was also for some time a sub-editor, and afterwards editor, of the *Geological Record*.

In his latter years, his presence at the Geological Survey Office, for a period of about fourteen years, brought him into contact with many people, who benefited by his knowledge and by his readiness in imparting it. Amongst engineers and others he was widely known as an expert of the most trustworthy kind on questions of water-supply, and of other subjects in which geologic knowledge comes in.

Happy in his domestic relations, of a kindly, cheerful disposition, good-natured and hospitable, he was always ready to help his brethren of the hammer, as well as all those who went to the Survey Office for information; indeed, a former colleague has said of him, to the writer, that his one prominent fault was excessive amiability.

He will be greatly missed by his colleagues, and his loss will be felt over a much wider circle—in fact, by all who knew him. W. W.

NOTES.

Two letters of Charles Darwin are published for the first time in the *Bulletin* of the Royal Botanic Gardens, Trinidad, No. 22, April 1894. These letters were addressed, before the completion of Darwin's book on the fertilisation of orchids, to the late Dr. Herman Cruger, who was Government Botanist at Trinidad for some years, asking him to observe if possible the fertilisation of certain species of the Melastomads. In the first letter he expresses a suspicion that the flowers which have the singular projections, or horns from their anthers, may be visited by small insects which penetrate one of the horns of the anther with their proboscis, to obtain the fluid contained in them. In the second letter he admits that this suspicion is quite groundless, and asks for information with regard to any instances of "bud variation" in plants from the warmer regions cultivated in the West Indies.

THE Botanical Society of America is about to try the experiment of admitting working naturalists only to its full fellowship. By a unanimous vote the Society has adopted a new constitution providing that none but American botanists engaged in research, who have published work of recognised merit, shall be eligible to active membership. Candidates for active membership must be recommended by three active members of the Society, but any nominee may be objected to by any member, and if ten members object, the name will not be considered by the Council. Nominees may be rejected by two negative votes in the Council, which numbers seven members, or by one-fifth of the votes cast after the name has been approved. The President of the Society for the present year is Prof. W. Trelease; the Vice-president, Prof. N. L. Britton; the Secretary, Mr. C. R. Barnes; the Treasurer, Mr. J. Donnell Smith.

DR. T. LAUDER BRUNTON, F.R.S., will deliver the annual Harveian oration at the Royal College of Physicians, on Thursday, October 18, at 4 p.m.

Two new wings of the Durham College of Science were inaugurated on Tuesday. The wings include apartments to be devoted to the study of engineering and the fine arts.

ON Friday last, the Duke and Duchess of York opened the new medical school, erected at a cost of £40,000, in connection with the Yorkshire College, Leeds, and also a new central hall and library, which have been added to the College at a cost of £20,000.

THE Essex Field Club will hold its annual cryptogamic and botanical meeting on Saturday, October 13. The headquarters for the meeting is the "King's Oak" Hotel, High Beach, Epping Forest.

THE opening meeting of the Royal Microscopical Society will take place on Wednesday, October 17, at 8 p.m., when Mr. F. Chapman will read a paper "On the Foraminifera of the Gault of Folkestone"; and Dr. H. Stolterfoth will give some notes on the genus *Corethron*.

A MEETING of the Institution of Mechanical Engineers will be held on Wednesday evening, October 24, and Thursday evening, October 25. The following papers will be read and discussed, as far as time permits:—"The Manufacture of Standard Screws for Machine-made Watches," by Mr. Charles J. Hewitt (Wednesday); "Drilling Machines for Cylindrical Boiler Shells," by Mr. Samuel Dixon (Thursday).

IT is reported that a violent storm passed over the town of Little Rock, Arkansas, at the beginning of last week. Though the storm or tornado only lasted three minutes, eight persons were killed during that time, and several were seriously injured, while property was damaged to an amount estimated at £200,000. The direction of motion of the disturbance was from south-west to north-east, and the width of the path traversed was only about two hundred yards. The storm was accompanied by heavy rain, and was followed by brilliant lightning.

ONE of the most valuable and extensive botanical libraries in the country, that collected by Prof. Lindley, has been for many years deposited in the rooms of the Royal Horticultural Society, under the care of trustees. It is now proposed to increase the value of the Lindley Library by forming, in connection with it, a library fund, to be administered by the trustees in connection with the Council of the Royal Horticultural Society. The money would be expended in cataloguing the library, and in the purchase of new books, for which the income at present at the command of the trustees does not suffice. Donations of horticultural and botanical works are also desired.

THE Berlin correspondent of the *Times* reports:—"The death is announced of Prof. Pringsheim, the well-known German botanist, at the age of seventy-one. As early as his thirty-third year he was elected member of the Berlin Academy of Sciences in appreciation of his researches and writings, which dealt especially with the processes of fructification and germination in the family of the Algæ. From 1864 to 1868 he filled the post of Professor of Botany at Jena, where he founded the first Institute for Vegetable Physiology, and this example was soon followed in other parts of Germany. Prof. Pringsheim returned to Berlin in 1868 and established a private laboratory, in which he carried out valuable investigations on the sexual life of the lowest vegetable organisms."

MR. H. J. MACKINDER commenced a course of lectures on the History of Geography and Geographical Discovery, at Gresham College, on Monday evening. The course, which will consist of twenty-five lectures, has been arranged for jointly by the Geographical Society and the London Society for the Extension of University Teaching.

PROF. RICHTER, of Graz, has been engaged for some time in making a careful bathymetrical survey of the Lake of Garda. By the use of an unusually light and compact wire-sounding machine he has been able to obtain rapid soundings, even in the greatest depths (364 metres) with a lead weighing only 800 grammes, and he is preparing a contoured map of the lake-basin.

EFFORTS were made this summer by several expeditions to ascertain the fate of the Swedish naturalists, Björling and Kalstennius, but no information has yet been received. The *Falcon* called at the Carey Islands, Clarence Head, and Cape Faraday, but found no trace of the unfortunate young men, while the most careful inquiries amongst the Eskimos of the Greenland coast elicited no news. There is no farther probability of their survival.

THE Arctic exploring parties at work during the season just past have not been by any means so successful as might have been expected. The weather seems to have been exceptionally unfavourable, and to have greatly hampered the movements of even the best equipped and most experienced Arctic travellers. Lieut. Peary has not felt justified in returning to America, although Mrs. Peary and her baby came back in the ship sent for their relief. Mr. Peary started on his main journey, after wintering at Bowdoin Bay, on March 6, with eight men, twelve sledges, and a large number of dogs. The cold encountered was very great, the thermometer falling to $-60°$ F., and very high wind was occasionally experienced. The expedition pushed on for twenty-seven days in the direction of Independence Bay, but only succeeded in travelling 220 miles when the death of most of the dogs from cold, and the disablement of some of the men, made it necessary to return, and Bowdoin Bay was regained on April 18. Thus Peary was unable even to reach the starting-point he had fixed upon as the base whence to push northward, and he had to content himself with making a detailed survey of Bowdoin Bay and the neighbouring coast of Inglefield Gulf during the summer. The *Falcon* arrived to his relief on August 20, and after landing a year's provisions, left him determined to make another resolute attempt to reach the new land beyond Independence Bay next spring.

THE Report of the Australian Museum, Sydney, for the year 1893, shows that the Government retrenchment scheme has caused the museum to suffer severely. There have been no funds to purchase specimens, nor to publish the results of investigation. At the commencement of the year there were thirty three officers and workmen on the staff, but owing to the necessity for retrenchment twelve of these were discharged, and the salaries of most of the others were reduced by amounts varying from £5 to £50. The amount voted for the ordinary service of the museum in 1892 was £7150, while in 1893 it was reduced to £3862. The trustees point out that it will be difficult to carry on the institution efficiently out of the reduced vote. It appears that in the parts of the museum open to the public, there are not hands enough now to keep the outside of the cases free from dust, although the specimens in them are duly cared for, and are in good order; the windows have not been properly cleaned for months, and the grounds are being over-run with weeds. Dr. E. P. Ramsay has recently retired from the directorship, owing to ill-health, and has been succeeded by Mr. R. Etheridge, jun.

PROF. A. KLOSSOVSKY, director of the observatory at Odessa, has published an interesting paper on the annual distribution of thunderstorms over the globe, accompanied by a coloured map showing their intensity in different localities. The question has hitherto been but little studied, as it is necessary to have a long series of observations in order to arrive at satisfactory mean values. He points out that a high temperature, a certain degree of humidity, and a considerable amount of rainfall, are the principal agents which favour the development of thunderstorms. The map shows that a zone of electric activity of great intensity exists on both sides of the equator, and this is also the zone of greatest rainfall. This zone is divided into three sections: (1) That embracing Asia and Oceania, Indo-China and the Sunda Isles to New Guinea, the yearly average amounting to ninety or one hundred storms. (2) The zone starting from the west coast of Africa, between 5° and 10° N. latitude, and 10° to 15° S. latitude. (3) The tropical regions of America, where the mean annual number of storms exceeds one hundred between 20° and 22° N. latitude. To the north of the zone which he terms the electric equator the number of storms decreases, we reach the deserts of Africa, Egypt, Persia, and Central Asia, where rainfall is scanty. To the north of the zone of deserts, especially over the continents of Europe and Asia, the electric activity is somewhat increased. For the high latitudes of the southern hemisphere, the principal data refer to the Falkland Islands, where the average number of storms is four. The sketch is necessarily very imperfect, but the subject is worthy of consideration and further investigation; and the author points out that, in his opinion, the solution of many meteorological phenomena is connected with atmospherical electricity.

A BRIEF account of the great Constantinople earthquake of July 10 has been already written by M. D. Eginitis, director of the Observatory of Athens (*Comptus Rendus*, vol. cxix. pp. 480-483). It occurred at 12h. 24m. p.m. Constantinople mean time. The earthquake consisted of three violent shocks, separated by very short intervals, and lasting altogether seventeen to eighteen seconds. The first and slightest was horizontal; the second, by which most of the damage was done, vertical and rotatory; and the third, undulatory and towards the end horizontal. The epicentral area, that of greatest damage, is in the form of an elongated ellipse; the major axis is 175 km. long, and extends from Tchataltza to Ada-bazar along the Gulf of Ismed; the minor axis is situated between the villages of Katirly and Maltépé, at the mouth of the gulf, and is 39 km. in length. At all parts of the epicentre the three shocks had approximately the same direction, nearly perpendicular to the major axis. The intensity was greatest in the islands of Halki and Antigoni. The fissures are few in number, the most important being at Ambarly, a village built on alluvial soil. This one is 3 km. long, 0·08 m. in maximum breadth, and runs east and west, *i.e.* parallel to the neighbouring sea-coast, which is 300 m. distant. The Kartal-Dardanelles cable was cut in several places, as if by a knife. The sea was greatly agitated along the epicentral coast. In some parts, it was observed to retreat for about 200 m., and after some oscillations to return to its normal condition. The depth of the seismic focus was found by Dutton and Hayden's method to be 34 km., and this agrees closely with the value obtained by M. Lacome from the observed times of the shock at different places. The shock travelled to Paris, Pavlovsk and Bucharest, with velocities of 3, 3·5 and 3·6 km. per second, respectively (see NATURE, vol. l. pp. 450-451).

THE *Zeitschrift für Instrumentenkunde* contains some particulars of the new method, adopted by Signor G. Guglielmo, for the exact measurement of differences of pressure. Instead of enlarging the displacement of the mercury column in the manometer or barometer by means of a capillary filled with oil, or containing an air-bubble, the new method is based upon the principle of readjusting the level to a fixed mark by the addition or subtraction of mercury, the quantity added or subtracted being weighed or measured with a burette. If the sectional area of the burette is one-hundredth of that of the manometer tube, a displacement in the former of 1 mm. will indicate a difference of pressure of 0·01 mm. To make the method sensitive it is best to use water as the manometer liquid, and to add or subtract mercury, which is more easily measured. The chief desideratum is a simple method of adding or subtracting, which is best done by attaching a sucking-tube to the top of the burette. A pointer is fixed inside the manometer tube opposite the centre of the meniscus. By observing the reflection of the pointer in the surface, and the depressions or elevations produced by the pointer, the observer is able to fix upon the mark to within 0·001 mm. If mercury is used, an electric contact is desirable. For barometer readings, pointers can be mounted in both branches of the tube, and measurements taken for both. Signor Guglielmo has also constructed an absolute electrometer based upon this principle, in which the level of mercury in a flat dish communicating with another is disturbed by a charged disc, and readjusted by adding or subtracting mercury.

WE have received from Dr. Luigi Palazzo, of the Meteorological Office at Rome, an account of a small portable unifilar magnetometer which he has designed, and which is being employed in the study of local magnetic disturbances in Italy. Signor Palazzo does not claim any special novelty in the general design, which in many respects resembles the Kew form of portable unifilar. The instrument is designed for observing the declination and horizontal force at strings of stations at one of which the elements have been determined by means of one of the more accurate and cumbersome forms of instrument. For the purpose in view it was of importance to have an instrument which should combine extreme lightness with portability, so that the different sets of observations along a line of stations might be quickly taken, and thus, to a certain extent, the effects of disturbances minimised, since there does not seem to be a self-recording magnetograph in the district under investigation, from the photographic records of which the disturbances could be eliminated. The azimuth circle has a diameter of 8 cm. and carries the graduations on the rim, a method of graduating the circle which, unless the tripod is very high, and therefore unstable, renders the reading of the verniers a matter of difficulty. The magnet employed is a hollow cylinder, as in the Kew instrument, carrying a photographic scale at one end and a lens at the other. The mirror which is used for illuminating the scale, as well as for reflecting the rays of the sun when determining the geographical meridian, is composed of a piece of parallel-sided plane unsilvered glass mounted on trunnions which are carried in V's of the ordinary form. The whole instrument packs into a box 28 × 12 × 18 cm. and only weighs four kilograms. The author does not say with what accuracy the horizontal component can be measured, but from some figures given it would appear that the declination can be determined to within about three minutes of arc; which, considering the small size of the instrument, is remarkably good. In order to facilitate the measurement of the bearing of landmarks, the telescope is supported on horizontal trunnions, so that it can be tilted in a vertical plane about 10° on either side of the horizontal.

THE "Proceedings of the Royal Physical Society of Edinburgh," Session 1893-94, is now ready, and may be purchased at the Society's rooms, George-street, Edinburgh.

PROF. J. SHIELD NICHOLSON'S lecture on "Historical Progress and Ideal Socialism," delivered at the Oxford meeting of the British Association, has been published in handy volume form by Messrs. A. and C. Black.

WE learn from the *Journal of Botany* that the monograph of the Mycetozoa, on which Mr. Arthur Lister has been engaged for some years, founded on the collection in the herbarium of the British Museum, will shortly be published.

UNDER the title "Nomenclator Coleopterologicus," H. Bechhold, of Frankfort-on-Maine, has published, for Herr S. Schlenkling, an etymological index, together with a list of species and their varieties, of the beetles of German districts. The book should be extremely useful to students of Coleoptera.

MR. BERNARD QUARITCH, Piccadilly, has issued a list of choice and valuable books he has for sale, including the library of the late Warren De la Rue. Many important works on physics, chemistry, astronomy, electricity, mathematics, photography, and microscopy are contained in the catalogue.

WE have received from the Skandinavisk Antiquariat, Copenhagen, a catalogue of books, ancient and modern, of Iceland and Scandinavia, which they have for sale. The catalogue, which will be sent free to all applicants, contains particulars of books relating to bibliography, periodical literature, the languages of the north, runology, mythology, archæology, topography, &c.

CHILL October has come, and with it a new number of "The Country Month by Month," in which Mrs. Owen and Prof. Boulger describe the characteristics of the plant-world and bird-life during the month. The entomologist's main occupation in October is digging up subterranean pupæ, so the authors give a brief account of insect metamorphosis. The chapter on bird-life deals with the autumnal migration of our birds in a very interesting manner.

THE Zoological Society of Germany has conferred a great boon upon students of natural history by editing a reprint of the tenth edition of Linnæus' "Systema Naturæ." The first volume, dealing with the animal kingdom, has lately been published by Wilhelm Engelmann, Leipzig. It is well printed, and will be very acceptable to those who are not the fortunate possessors of a copy of the original tenth and standard edition of Linnæus' work.

THE sixteenth edition of their "Catalogue of Minerals and Mineralogical Subjects" has been issued by Messrs. G. L. English and Co., New York. The illustrations are all new, and a complete revision of all Messrs. English's systematic collections has been made. The species are classified according to Dana's new "System of Mineralogy" (1892). The index to the catalogue is particularly valuable, for it enumerates all species, and refers to the proper species all important synonyms and varieties.

A REMARKABLE new substance, obtained by the action of ordinary alcohol upon peroxide of sodium, is described by Prof. Tafel in the current *Berichte*. When alcohol is poured upon sodium peroxide, about half of the latter disappears to form a strongly alkaline solution which contains practically no active oxygen, while the remaining half undergoes a complete change. The pale yellow colour of the commercial peroxide becomes changed to pure white, and the substance assumes the nature of a fine granular powder, totally different from peroxide of sodium. This substance is soluble in water, but with much less rise of temperature than the peroxide. While the latter compound is stable up to a high temperature, evolving no oxygen when pure below red-heat, the new substance evolves large quantities of oxygen upon gently warming, and if rapidly heated in a tube closed at one end explodes with violence and production of flame. The powder behaves very curiously if touched in one place with a heated rod; the particles are set in rapid whirling motion by the escaping oxygen, and the rise of temperature is so great as frequently to terminate in local combustion. This unusual phenomenon gradually extends throughout the whole mass, oxygen being copiously and continuously evolved in an almost perfectly dry state. When much more strongly heated the substance melts and then evolves water vapour, the residue consisting of ordinary sodium hydrate. Analyses indicate that the substance possesses the composition $HNaO_2$. Its production from sodium peroxide and alcohol in all probability occurs in accordance with the following equation, sodium ethylate being the secondary product:

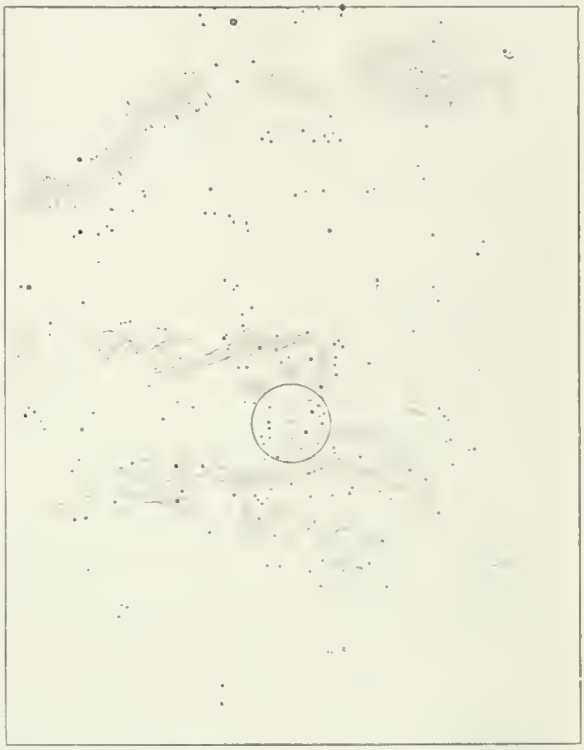
$$Na_2O_2 + C_2H_5OH = C_2H_5ONa + HNaO_2.$$

The probable existence of this new sodium compound was pointed out by Prof. Tafel in a previous communication concerning the action of alcoholic mineral acids upon sodium peroxide, and he has now been able to isolate it. He considers it to be the hydrate of a trioxide of sodium Na_2O_3. It dissolves in ice-cold water without decomposition, but at temperatures very little higher the solution slowly evolves oxygen. If alcohol is added to this solution the evolution of gas is considerably augmented and the solution deposits after some hours crystals of Mr. Vernon Harcourt's hydrate of sodium peroxide, $Na_2O_2.8H_2O$. Hydrochloric acid converts it into sodium chloride, hydrogen peroxide, and gaseous oxygen. In order to prepare the new compound, twelve grams of sodium peroxide and two hundred cubic centimetres of ice-cold absolute alcohol are convenient quantities to take; they should be well shaken together in a closed flask, the liquid and the fine white sandy product separated from any undecomposed lumps of peroxide, rapidly filtered, the white sand-like substance washed with cold alcohol and ether, and stored in a desiccator.

THE additions to the Zoological Society's Gardens during the past week include a Diana Monkey (*Cercopithecus diana*, ♀) from West Africa, presented by Mrs. Collcutt; a Mozambique Monkey (*Cercopithecus pygerythrus*, ♀) from East Africa, presented by Mr. H. J. Clowes; a Macaque Monkey (*Macacus cynomolgus*, ♂) from India, presented by Mrs. Morris; a Leopard (*Felis pardus*) from East Africa, presented by Mr. Thomas E. Remington; a Two-spotted Paradoxure (*Nandinia binotata*) from West Africa, presented by Dr. Sydney W. Thompstone; a Moose (*Alces machlis*, ♂) from Sweden, presented by Mr. Guy Nickalls; a Bennett's Wallaby (*Halmaturus bennettii*, ♂) from Tasmania, presented by Captain G. W. Brook; two Horned Screamers (*Palamadea cornuta*) from Para, presented by Mr. H. A. Astlett; a Banded Parrakeet (*Palæornis fasciatus*, ♀) from India, presented by Mr. Thomas Hodgson; a Green Turtle (*Chelone viridis*); a Hawks-billed Turtle (*Chelone imbricata*) from the East Indies, deposited; a Mexican Guan (*Penelope purpurascens*) from Central America, two American Wigeon (*Mareca americana*) from Brazil, a Short-tailed Parrot (*Pachyrus brachyurus*) from the Upper Amazon, purchased; two Raccoons (*Procyon lotor*); a Persian Gazelle (*Gazella subgutterosa*, ♂), born in the Gardens, three Bar-tailed Pheasants (*Phasianus reevesii*), an Amherst Pheasant (*Thaumalea amherstiæ*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

NEBULOSITIES NEAR THE PLEIADES.—For many years, says Prof. E. E. Barnard in the *Astronomische Nachrichten*, No. 3253, he has known of a vast and extensive nebulosity north of the Pleiades. This is not to be confounded with the nebulosities round the cluster revealed by photography during the last ten years, and all of which are included within the circle on the accompanying illustration. The wisps and patches of nebulous matter outside the circle are shown upon a photograph taken by Prof. Barnard with the Willard lens which he has rendered famous, the plate being exposed for ten hours, fifteen minutes.



The curved and streaky streams of celestial mist in the illustration are apparently connected with the Pleiades, though some of them extend irregularly for several degrees each side of the cluster. Prof. Barnard hopes to obtain still clearer pictures of the nebulosities by extending the time of exposure.

SCIENCE IN THE MAGAZINES.

EAST and west, as everyone knows, are merely relative terms. Elisée Reclus, in the *Contemporary*, traces the normal line of separation between the two halves of the ancient world which best deserve these names, considering the matter from an historical point of view. The true and natural partition between east and west of the ancient world is a transverse zone running from north to south between the Arctic Sea and the Gulf of Oram. This almost uninhabited zone begins just west of the plains of the Lower Indus, in the desert tracts of Lower Beluchistan, and ends in the barren reaches between the Obi and the Yenisei. Such a zone divides the world into two halves having continental masses of nearly equal size. The evolution of humanity was worked out differently on the two sides of this line, and the two developments are traced in the article referred to.

A very exhaustive article is contributed by Mr. John Rae to the same review, under the title "The Work of the Beer Money." The author describes what the County Councils have done for technical education since the passing of the Local Taxation (Customs and Excise Act) of 1890, when funds for the purpose of furthering such instruction became available. To those who expected great things, the survey will be disappointing; for it shows that in many cases the moneys have been expended almost uselessly. Better results, however, could hardly be expected, for it must be remembered that the County Councils had to create the machinery with which to carry on the work. On this account many mistakes have been made, "but," says Mr. Rae, "they [the Councils] have gone about matters in a practical way, and when they have made mistakes they have shown themselves quick to repair them. Much of the work was necessarily tentative, and that indeed is part of its value. Each local authority has started the work in its own way, according to its own circumstances, industries, and resources; so that the country has for two years been one great experimental station, with some hundreds of separate plots of educational varieties." The sums spent upon the erection of important technical schools during the last six or seven years will astonish many people. To quote Mr. Rae: "Bolton has built a technical school at a cost of £15,000; Bury, at a cost of £16,000; Blackburn, of £40,000. Oldham and Rochdale are now spending £12,000 each in building one; Halifax and Derby are spending £20,000 each; Bath, £21,000; Worcester and West Ham, £40,000; Birmingham, £48,000; and Manchester, on a site worth £100,000, is erecting a technical school estimated to cost £130,000 more, the most elaborate and magnificent product of the whole movement." So far as we can gather from the article, the work which has been done shows good promise of practical fruit. It is pointed out that the grant should be secured permanently for education by statute, and this should be done as soon as possible. Mr. Rae thinks that the worst deficiencies which the experience of the past three years has revealed are (1) the startling illiteracy of the men and the lads who have passed the standards of elementary schools, and (2) the general want of the means of good secondary education. These are the deficiencies which must prevent the effectual diffusion of technical instruction. Mr. Rae's article should certainly be read by everyone interested in the progress of technical instruction.

Another article in the *Contemporary* is entitled "Joseph Priestley in Domestic Life," by Madame Belloc. The mother of the authoress was taught to read by Priestley, and she gave her daughter a very clear idea of his personality. The article thus contains a description of the investigator as he really was according to the last echo of oral tradition. And though it deals chiefly with Priestley's private life, students of the history of chemical science will find parts of it interesting. The *Contemporary* also contains an article by Mr. Herbert Spencer, whose theme is "Weismannism Once More." Mr. Spencer harks back to the original points of discussion between Prof. Weismann and himself, in order to show (1) that certain leading propositions having been passed by unnoticed, remain outstanding; and (2) that when leading propositions have been dealt with, the replies given are invalid.

In the *National Review*, Mr. F. W. H. Myers writes on "The Drift of Psychical Research." Wonderful things are told of telepathy and kindred powers, and the author is very sanguine as to future developments. He recognises that men of science fight shy of the "gloom researches," and are ever ready to put their fingers upon the weak points in psychical reasoning and investigation. This dislike is accounted for by the rude approximate character of the work carried on by its votaries; but, on the other hand, Mr. Myers holds that psychology is a new science, and has, therefore, to grope its way up to the exactness of older branches of knowledge. He inclines to the opinion that the methods of science cannot at present be extended to the realm in which he is an explorer. After Mr. Myers' article, and as an antidote to it, one contributed by Mr. Ernest Hart to the *Century* should be read. Mr. Hart's paper should convince every even minded person of the imposture widely practised under the names of hypnotism, spiritualism, telepathy, "spookism" in its various manifestations, Mahatmism, Matteism, and other phenomena of an occult character. The same magazine contains the conclusion of the series of articles, "Across Asia on a Bicycle," contributed by Messrs. T. G. Allen and W. L. Sachtleben; and Mrs. C. L. Franklin gives a short biography of Sophie Germain, whose mathematical works and philosophical writings gained for her such a high reputation at the beginning of this century.

Sir Robert Ball continues his articles on "The Great Astronomers," in *Good Words*, the subject this month being Galileo. He handles the matter of Galileo's trial for heresy very carefully, and does not give vent to the feelings which every astronomer must experience when describing the events which led up to the abjuration which the founder of physical astronomy was forced to pronounce. Mr. T. Munro combines imagination with science in an article, "Sun-rise or the Morn," in *Cassell's Family Magazine*. The Mammoth Cave of Kentucky is the subject of an article, by Prof. W. G. Blaikie, in the same magazine. Under the alliterative title, "Seers of Science," Mr. Munro shows, in the *Leisure Hour*, how poets and story-tellers have anticipated some of the discoveries of science. It would have been strange if, in all the vague speculations which have been given to the world, some coincidences of the kind referred to had not been found. Salt, and sleeplessness are the subjects of two other articles in the *Leisure Hour*.

An extremely interesting account of "Tarahumari Dances and Plant Worship" is given by Dr. Carl Lumholtz in *Scribner*, with illustrations from photographs by the author. Another article of ethnographical importance is "Customs connected with Burial among the Sihanaka," by the Rev. J. Pearse, in the *Sunday Magazine*, which also contains a paper entitled "A Thousand Miles up the Irrawaddy," by the Rev. W. R. Winston. *Chambers's Journal* contains, as usual, a number of short and popular articles on more or less scientific subjects. Among those we note a description of some remarkable artesian wells, and a paper on the utilisation of waste products. Mr. Grant Allen writes pleasantly on "The Night Jar," in the *English Illustrated*, and Colonel Howard Vincent describes the scientific measurement and identification of criminals.

In addition to the magazines mentioned in the foregoing, we have received the *Fortnightly*, *Longman's*, and the *Humanitarian*, neither of which, however, contain articles that call for comment here. The first number of the *Phonographic Quarterly Review* has also been sent to us. The *Review* is edited by Mr. T. Allen Reed, and it bids fair to take a permanent stand among phonographic literature. Some of the articles have been furnished by phonographers, and others by well-known writers, the writings of the latter having been transcribed. The editor evidently recognises the importance of a knowledge of science to the shorthand writer of the present day, for among the articles we note "The Native Tribes of East Africa," by Dr. J. W. Gregory; "Experiences of a Naturalist," by Dr. A. S. Murray; "The Myths of the Unicorn and the Griffin," by Sir Henry Howorth; and "The Formation of Flints," by Canon Bonney. The publication of articles of this kind will help on the time when scientific lectures will be reported without being caricatured.

MEASUREMENTS OF PRECISION.[1]

MORE than two thousand years ago there lived in the far East a philosopher who established his claim to the possession of a good measure of both wisdom and wit, when he wrote: "Avoid even the appearance of evil: do not stop to tie your shoe in the melon patch of an enemy."

Suppressing the humour but not the sentiment of the Oriental teacher, it is easy to see that Confucius meant to impress upon his followers the importance of taking care that, even in the performance of trivial acts, the time and place should be such as would give rise to no suspicions as to motive or design.

I am honoured by being permitted the freedom of your academic groves to-day. I realise that the opportunity of defending a theme under such circumstances is not to be lightly esteemed, and I wish, in the beginning, to make terms with everybody, by declaring that in bringing before you a proposition so simple as to need no argument, I am innocent of ulterior motive or deep design.

My desire to give formal expression to this proposition grows out of the frequency with which it has presented itself in the course of official duties during the past few years.

I wish to consider "Precise Measurement" as one of the agencies through which man has advanced from a condition of savagery to his present state; and the metrology of any age as an exponent of the civilisation of that age.

The brief time during which I can venture to ask your attention to this subject fortunately releases me from all obligations to consider literary excellence or rhetorical ornamentation, and compels me even to deviate in some degree from the logical order of presentation. It is safe, however, to take liberties with an audience so largely composed of those who are not only familiar with the facts to be presented, but who are accustomed to arrange, digest, and put in orderly sequence materials which are found in a more or less chaotic condition.

The first form of measurement to which primitive man resorted was undoubtedly simple enumeration. In narration or barter the number of units in a group was alone considered, regardless of differences among individuals. The recognition

[1] An address delivered at the Johns Hopkins University, Baltimore, by Prof. T. C. Mendenhall.

of the fact that one quantity is greater or less than another is not measurement. Measurement implies the ability to represent numerically, so that ratios can be accurately expressed. Among primitive races measurement by enumeraton is very restricted. Tribes bordering on savagery at the present time are often found to be unable to enumerate beyond three or four. This statement is quite positively made by competent authorities, in spite of the fact that the ability to enumerate the number of fingers on at least one hand would appear to be necessary to even the lowest order of intelligence. It is curious to note in this connection that experiment has apparently proved that four is the maximum number of objects whose accurate enumeration is possible *at a single glance* and without *counting*, by the most highly cultivated man.

As man emerges from savagery his powers of enumeration increase. He soon discovers the necessity for units of a higher order which themselves represent a collection, and easily finds such units provided by nature in the groups of fingers on his two hands. Thus the decimal system of arithmetic is invented; not in one place or by one people, but everywhere and whenever man finds that somewhat extensive enumeration is desirable or necessary. It is a singular exception to this general rule, however, that the Greeks failed to invent a decimal arithmetic.

With systems of notation capable of indefinite extension, measurement by enumeration becomes rigorously exact; that is, barring blunders, which can always be discovered and avoided, the number of units in a group, if capable of being counted at all, can be counted with absolute accuracy. Thus, the cash in the Treasury of the United States may be more than a hundred million dollars, that is more than ten thousand million cents, and the exact quantity can be ascertained to a single cent. By simple enumeration, therefore, this quantity of money is measured so accurately that the error cannot be as much as one part in ten thousand millions, and this might be extended in any degree, if only the cash is there to be counted.

At a comparatively early stage, therefore, this kind of measurement was perfected, but there are two systems or methods of measurement derived from it that are worthy of brief comment. The first includes that variety of mensuration in which the numerical value of a magnitude cannot be obtained by simple counting, but is derived by calculation based on rigorously exact relationship. This is of a distinctly higher order than that just considered, and it is only found among highly intelligent people, those, in short, who have cultivated a knowledge of pure mathematics. A very simple illustration is the determination of the area of a triangle when its base and altitude are known. In this and similar cases a rigorously accurate result is attainable when the data are absolutely correct, but simple counting would be impossible. There are cases, however, and these constitute another step along the line in which we are travelling, in which an absolutely accurate evaluation is impossible, but in which any *desirable degree* of accuracy, however high, may be reached. Perhaps the best known example of this is the determination of the circumference of a circle when its diameter is known. The ratio of the former to the latter, which cannot be exactly expressed, has been determined with a degree of approximation by modern computers, which makes it possible to reduce the outstanding error to an inconceivably small quantity. An attempt to illustrate this may not be without interest.

In a display of mathematical genius which has perhaps never been surpassed, Archimedes more than two thousand years ago discovered the first real approximation to the value of this constant. The accuracy of his result may be shown in the fact that if the diameter of a circle be exactly one inch, its circumference as determined by the value of the constant found by Archimedes will not be in error more than the thickness of a human hair. If the value of the constant is more accurately known, it will be possible to compute the circumference of a proportionately larger circle so that the error shall not exceed a hair's-breadth. Let us go at once from the circle one inch in diameter to one having a radius equal to the distance from the earth to the sun and a circumference of nearly 600 millions of miles. It is difficult to form any adequate conception of the enormous stretch of 93 millions of miles which separates the earth from the sun. The immensity of it is in some degree realised on reflecting that if it were possible for a child to extend an arm across this space, and plunge his hand into the white hot layer of the sun from which light is radiated, he might grow to youth, manhood, old age, and unless he lived through the almost unprecedented period of 125 years, death would come before he would feel the pain of burning, so great is the distance through which the sensation must travel. But even this circle, of 600 millions of miles in circumference, is almost immeasurably small in comparison with the one for which we are seeking. Multiply it by a million; a million million; a million, million million; in fact multiply it by a number expressed by the word million repeated 98 times, and we reach a circle of utterly inconceivable dimensions; yet so precisely do we know the ratio of the circumference to the diameter of a circle, that having given the diameter of such a circle, its circumference can be determined within the breadth of a hair. For all ordinary, practical purposes this is sufficient.

A very modern and an extremely important species of measurement involving only enumeration is to be found in the statistical method of treating certain classes of problems in which the object is to follow the fortunes of a group rather than an individual. It has long been advantageously applied to social, political, and economical questions, and within a few years, in the hands of such men as Clerk Maxwell, Boltzmann, and others, it has proved to be a powerful agent in physical investigations.

It depends in great measure on what may be called the principle of the "long run," which is, that phenomena of apparently the most accidental and lawless character will, *in the long run*, occur with regularity and obedience to law, to such an extent as to render their prediction quite possible. At least one great railroad system in this country has so tabulated and investigated all accidents happening to its employés and patrons that it is able to foretell with a good degree of accuracy the number of people who will, during the next year, meet with death on its line; how many will lose a foot, how many an arm, and so on; and its Board of Directors is thus always ready to weigh the cost of a new invention to add to the safety of travel, against the probable damages to be paid for fatal and other injuries which said invention might prevent.

Further argument is unnecessary to show that measurement by enumeration, the first to appear in the evolution of man and his accomplishments, has advanced with man and kept pace with his accomplishments; that it has contributed greatly to his advancement, and that at any given period it may fairly stand as an exponent of his condition.

But in a far greater degree is this true of the second of the two forms of measurement to which men have resorted, namely, that in which a conventional unit embodying the particular quality to be measured is compared to the magnitude to be evaluated. Nearly all operations ordinarily called measurements belong to this class, and its necessity must have followed closely upon the introduction of measurement by enumeration. Of the three fundamental measures, from which it is convenient to derive all others, namely, length, mass and time, the first and last were undoubtedly the earliest to receive attention, and it is more than likely that some rude system of time measurement constituted the earliest contribution to metrology. Nature is lavish in the number and variety of time units which she has furnished man, some of which satisfy the most rigorous demands of modern science. In the early stages of chronometric development the method of enumeration was alone available. By taking the solar day as the unit, counting the number of days in a lunar period furnished the month. The year was similarly obtained, at first from the mere cycle of the seasons, but in a somewhat more advanced stage of development, from more exact observations upon the sun. Before this, there must have existed a demand for the division of the day into smaller units of time. Much ingenuity and often genius of a high order was shown in the invention of chronometric devices. A remarkably clever determination of the angular diameter of the sun was made by the Chaldeans by the use of one of the earliest forms of time-measuring apparatus. At the moment the sun's disk appeared in the eastern horizon a fine stream of water flowing from the bottom of a vessel in which the level was kept constant, was caught in a small cup, into which it was allowed to flow until the lower limb of the sun was visible. The small cup being instantly withdrawn, another much larger receptacle was substituted for it, and into this the small stream fell during all the day and until the sun appeared in the east again on the following morning. It was found that the water in the large vessel was 720 times that in the smaller, from which it appeared that the apparent diameter of the sun was $\frac{1}{720}$ of the circumference of the heavens, or one-half a degree of arc.

It is impossible here to trace the evolution of time-measuring from the earliest period to the present, and it is unnecessary, because most of the steps are doubtless well known to you all. You are requested to reflect, however, upon the close relation of the various stages of this evolution to the progress of the human race from savagery to enlightenment.

Hardly anything is a more certain and sensitive index of the advancement of a people than the precision required in the time schedule of the ordinary events of life. Improvement in time-measuring instruments, watches and clocks, is in response to a demand for this precision, and not the cause of it, as is sometimes asserted. Watches are now regulated to seconds where formerly minutes were near enough, and the few remaining civilised people among whom the hour has been the smallest division of time in common use, are fast mending their ways in this respect.

Unfortunately in the development of systems of measurement of length and mass, we have not succeeded as well as with the measurement of time. The greater excellence of the latter is unquestionably due to the universality of the fundamental unit, which is everywhere the day. While there have existed some differences among different nations as to the divisions and multiples of this unit, certain natural phenomena have directed all, along nearly the same lines, and at this moment, in all essential particulars, the chronometric systems of nearly all civilised nations are identical. Although not the best that could have been devised had existing knowledge and experience been available in the beginning, the prevailing subdivisions of the time unit are not seriously objectionable, and as they are so nearly universal and so firmly established by long usage, they are almost certain to continue unchanged.

In measures of length and mass or weight, the tendency from the beginning, up to a very recent period, has been, as in the case of time, towards the selection of natural units.

Dimly comprehending the importance and necessity of invariable units of measure, primitive man looked to nature to find the invariable. The nomenclature of every system of measure known bears testimony to the original use of natural units. Of measures of length familiar to all may be mentioned the hand, foot, pace, fathom, cubit, ell and span, all of which are derived from the dimensions of the human body. The inch, as everybody knows, was originally the length of three barley-corns from the middle of the ear, placed end to end. At a later period among some of the Oriental nations the unit of length was the length of a bamboo pipe, which when blown would produce a certain musical pitch. This argues a reckless indifference as to units of length, or an extraordinary power of detecting variation in the pitch of musical tones.

Units of weight or mass also had their origin in natural magnitudes, although in this case much greater difficulty is experienced. Almost the only natural unit of mass that was suggested or used was the mass of a grain of wheat from the middle of the ear, and from this our use of the grain weight of to-day is derived.

But all men are not alike in stature, nor are grains of wheat of great uniformity in dimensions or mass. As might have been anticipated, under such conditions there grew up, not only in different parts of the world, but in different sections of the same country, a variety of systems of weight and measure having no exact relations to each other, or among themselves, and which developed, as intercourse between nations became easier and more general, into one of the greatest calamities ever visited upon mankind. Various efforts were made at various times by various nations, each to improve its own system, but little good resulted up to almost exactly one hundred years ago. At the close of the Revolutionary War the weights, measures and coins in use in this country were almost innumerable in kind. Although mostly inherited from our Anglo-Saxon ancestors, many other European systems had gained a foothold, and considerable diversity in names and values had grown up throughout the colonies. An opportunity was presented at that time which we shall never see again, and which was lost by what one is forced to call the moral cowardice of men in high places. No one appreciated this opportunity more thoroughly than Thomas Jefferson, perhaps the most scholarly man of his time; the patron and friend of science and scientific men.

Jefferson recognised the incongruities of existing systems of weight and measure, but not wishing to depart sensibly from the foot as a unit of length he offered ingenious suggestions for a perfected scheme of linear measurement in which the foot was to be related decimally to the length of a seconds' pendulum and was to be decimally subdivided.

The Constitution of the United States provides that Congress shall have power to coin money, regulate the value thereof, and to fix the standard of weights and measures. At an early day this power was wisely exercised to provide escape from the bondage of the unphilosophical pounds, shillings and pence of the mother country by the establishment of a decimal system of coin ratios, the use of which during the past hundred years has been a greater gain, as compared with the discarded system, than the value of all the money in the country at the time of its adoption.

The second prerogative, that of "fixing a standard of weights and measures," was not at that time and, as a matter of fact, has never yet been exercised by Congress; indeed, considering the great danger which continually existed that when Congress did act it would act wrongly, it is a matter of congratulation that legislation on this important matter has thus far practically gone by default. But the opportunity existing during the early days of our national life was great, for the reason that just at this time there was conceived and perfected on the other side of the Atlantic the most decided, the most important, and the most far-reaching advance in metrology that the world has ever seen.

It had its beginning in the wisdom and foresight of the distinguished Talleyrand, who in 1790, while still a bishop, impressed by the excessive diversity and confusion of the weights and measures then prevailing, proposed to the Assembly of France a scheme for their reformation. Realising that not only national but international reformation was desirable, other nations were invited to join in the development and execution of this magnificent scheme. The co-operation of the Royal Society of London and of the English Government was sought, but unfortunately the English were not then in the mood for giving support to the French.

For the preliminary steps, looking to the determination of the value of the fundamental units and their relation to each other, a committee of the French Academy, including the most eminent mathematicians of Europe, was appointed, among its members being Borda, Lagrange, Laplace and Condorcet. Others engaged in the various measurements necessary to this determination were Lavoisier, Coulomb and Delambre.

Throughout the stormy scenes that accompanied the great political and social changes which occurred in France during the last decade of the eighteenth century, these noble scholars steadfastly pursued the problem upon the solution of which they had set out. At one time Borda, Lavoisier, Laplace, Coulomb and Delambre were dismissed from this public service by Robespierre's Committee of Safety, because their political views were suspected of being not quite in harmony with those of the aggressive party in power. (That was a hundred years ago.) But Robespierre was ambitious as well as cruel, and the project was afterwards allowed to go on. Finally, on June 22, 1799, the two new perfected standards—a metre, the unit of length, made of platinum, and a kilogramme, the unit of mass, of the same metal, were presented with great solemnity at the bar of both houses of the National Assembly of France by the celebrated Laplace, who addressed the assembled legislators; and on the same day the two standards were deposited in the archives of France, destined to be, a century later, the accepted units of measure of more than half of the civilised world, and eventually to become universal. In a report filed just seventy-three years ago to-day, John Quincy Adams, then Secretary of State, says of this event: "The spectacle is at once so rare and so sublime . . . that not to pause for a moment, were it even from occupations not essentially connected with it, to enjoy the contemplation of a scene so honourable to the character and capacities of our species, would argue a want of sensibility to appreciate its worth." "This scene," he says, "formed an epoch in the history of man, and an example and an admonition to the legislators of every nation, and of all after-times."

Just one hundred years ago, in 1794, copies of the preliminary metric standards were sent to this country, and our Government was urged to join in this memorable undertaking. Then, and during the thirty years following, the question of our adopting a system of weights and measures in harmony with our admirable monetary system was much agitated; but the counsel of the timid prevailed, and the wretched system which we had inherited mainly from England, but which is not in harmony with the English, was allowed to fasten itself upon the industrial interests of the country. The report on the subject by John Quincy Adams, already referred to, is a monument of exhaustive research and philosophical discussion. Nowhere is the decimal system praised so highly as in this report. In it he says of this system that, "considered merely as a labour-saving machine, it is a new power, offered to man, incomparably greater than that which he has acquired by the new agency which he has given to steam. It is in design the greatest *invention* of human ingenuity, since that of printing." This is high praise, and it is difficult to understand how the author of this and much more like it, could lack the courage to recommend that his country should at once put itself in the way of sharing the benefits of so remarkable a reformation. The spirit of conservatism, which came from his ancestors along with the yard and the pound, led him to advise that it was better to await the action of other nations, especially Great Britain.

At the close of the last century, in different parts of the world, the word *pound* was applied to 391 different units of weight, and the word foot to 292 different units of length. Not only were no two of these identical, but in only a few cases were their relative values known with anything like precision. In the wonderful march of the nineteenth century, most of these have been swept away; until now, of the enlightened nations of the earth, only the English-speaking people cling to what Lord Kelvin has so felicitously characterised as our "brain-wearying and intellect-wasting system of weights and measures."

I must now return to a very brief consideration of the indirect influence of precise measurement upon the welfare of man. Thus far the development of exact standards has been considered in relation to man's convenience, as facilitating the transaction of business, by diminishing the uncertainty and labour involved in commerce and trade. But indirectly it has been even more powerful. The use of correct standards of weight and measure has been regarded from the beginning as necessary to and indicative of integrity and fair dealing, among nations as well as individuals. Ultimate standards of reference, even in the earliest history of metrology, were carefully guarded and usually considered a part of the paraphernalia or accessories of the king or ruler. Although these standards were, until a comparatively recent period, very rude in their construction, they represented in a large measure the integrity of the nation, and to depart from or modify them was regarded as akin to a crime. According to Josephus, when Cain had settled in the land of Nod, and built a city, he invented weights and measures. In the law as given to Moses it is declared, "Thou shalt not have in thine house divers measures, a great and a small." The renowned Chinese Emperor, Yeo, who flourished 4000 years ago, kept the weights and measures which were used in the markets in a part of his own palace. In many countries standards were deposited in temples, and priests were their custodians. One of the principal objects sought to be secured by the Magna Charta was uniformity of weights and measures throughout the kingdom, and the one small spot in the world to-day whose neutrality is secured by the joint agreement of all civilised nations, including even the United States and Great Britain, is a bit of land near Paris, where stands the building in which the international prototype metre and kilogramme are preserved.

But in a far greater degree has precise measurement influenced the character, condition and destiny of man through its relation to the development of modern science. Volumes might be written about this, although not much is necessary before an audience to many of whom it is almost a daily lesson, and before another, smaller, audience of those who have contributed so largely during the past quarter of a century to the advancement of science and the improvement of the art of measuring.

Precision in measures demands and produces precision in language, and exact language makes exact thinking possible.

One cannot but admire the genius which enabled some of the philosophers of a few centuries ago to triumph over the obstacles growing out of the lack of exactness both in language and experiment. When Newton was converting his theory of the spheroidal form of the earth into established fact, he could only ascertain the possible effect of change of temperature upon the period of a pendulum by means of comparisons of the length of an iron bar when exposed to the sun's rays on a hot summer's day, with its length on a frosty morning in winter. Even in the earlier Transactions of the Royal Society of London, one may find time measured in *misereres* and temperature in inches. In the wonderful progress that has characterised the present age, by which business methods and social life have been well-nigh revolutionised, exact science has been the dominant factor. It is impossible here even to mention the many interesting devices by means of which during the last half-century the precision of measurements has been enormously increased. They are to be seen in nearly every laboratory, and are familiar to you all. Their invention has made possible many brilliant and useful discoveries in science, and it is gratifying to know that on this line our own country has been and is well to the front. Many proofs of this might be given, but among the most notable contributions of modern times to the science and art of delicate and precise measurement, one cannot fail to note the splendid work of Rowland in his measurement of light wave-lengths, of Langley in his solar researches, and of Michelson in his determination of the metre in terms of the ether vibration. The glory of the nineteenth century is exact experiment and honest logic, and precision in measurement has done much to make both possible.

In the matter of the metrology of the affairs of daily life, however, it is humiliating to confess that we are still skulking in the rear. Our sixty millions of intelligent citizens are far less intelligent, and less fit for the responsibilities that rest upon them, than they might be, were they not continually wearying their brains and wasting their intellects in constant struggle with the difficulties inherent in the system of metrology to which we so blindly cling. I yield to no one in my appreciation of the accurate learning and profound scholarship of the gentlemen of the Faculty of the institution before which I have the honour of appearing to-day, but I unhesitatingly affirm that not one of them, not even all of them together, can correctly set forth the system of weights and measures in common use at the present time in this country. Let us hope that this burden will be lifted in the near future, and that the pound and yard with their innumerable and irrational derivatives, relics of the dawn of civilisation, will be replaced by the beautifully simple kilogramme and metre. We can then rest with the pleasing assurance that when the next cataclysm shall have passed, and the archæologist of the future shall be burrowing among the ruins of the present age, he will not be misled by the crudeness of our metrology to catalogue us along with earlier civilisations. At best he will exhume much which we could wish to remain for ever buried, but let us hope that the evidence of integrity and simplicity in commercial transactions, of delicacy and precision in scientific investigations, and especially of honest and independent thinking, will be such that he will be compelled to put us down as a race in which, to apply the eloquent words of Buckle, "the greatness of men has no connection with the splendour of their titles, or the dignity of their birth; it is not concerned with their quarterings, their escutcheons, their descents, their dexter-chiefs, their sinister-chiefs, their chevrons, their bends, their azures, their gules, and the other trumperies of their heraldry; but it depends upon the largeness of their minds, the powers of their intellect, and the fulness of their knowledge."

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 1.—M. Lœwy in the chair.—The mass of Mercury and the acceleration of the mean movement of Encke's comet, according to the recent work of M. O. Backlund. A note by M. O. Callandreau.—On the automatic transmitter of steering directions, by Lieut. H. Bersier. The alternating current from a Ruhmkorff's coil passes from the pivot of a compass through the aluminium pointer, and leaps from the extremity of this needle to one of six vertical plates placed at intervals round the inside of the compass-box. This alternating current has no effect on the magnet, but serves to work six corresponding relays, and hence to cause the illumination of corresponding signal lamps placed in various parts of a vessel, and to set in motion the steering apparatus. The least deviation from the set course is automatically and immediately corrected in this way. The course is altered by simply rotating the drum carrying the plates.—A description of a bundle of descending cerebral fibres disappearing in the olivary bodies (cerebro-olivary bundle), by M. Y. Luys.—Influence of low temperatures on the laws of crystallisation, by M. Raoul Pictet. The author shows the essential difference in the manner in which the crystallising body loses heat at the moment of solidification in the two cases where the substance is (1) adiathermanous and (2) diathermanous. All substances become diathermanous below −70°, and hence the true temperature of crystallisation is only obtained when the surrounding medium is maintained at a temperature very slightly below the solidifying point. Hence an explanation of the anomalies occurring in determinations of the crystallisation point of such substances as chloroform.—On the development of the latent image in photography by alkaline peroxides, by M. G. A. Le Roy. Aqueous solutions of alkaline peroxides or alkaline solutions of hydroxyl can be used as developers, but are inferior to the ordinary reagents.—Action of hydrogen phosphide on potassammonium and sodammonium, by M. A. Joannis. When hydrogen phosphide is passed into a solution of potassammonium or sodammonium in liquefied ammonia, it is absorbed with the production of the solid white substances PH_2K and PH_2Na. Heat destroys these compounds in accordance with the equation $3PH_2K = 2PH_3 + PK_3$. Water decomposes them with liberation of hydrogen phosphide. Nitrous oxide does not yield any substance corresponding with the salts of hydrazoic acid.—Researches on mercuric picrate, by M. Raoul Varet. The preparation and properties of mercuric picrate are described. Thermal data are given in detail, and from them it is seen that the picrate ranges itself along with the acetate rather than with the other soluble salts, the chloride and cyanide. Picric acid displaces hydrocyanic acid from its potassium combination with disengagement of + 10·7 Cal., whereas hydrocyanic acid completely replaces picric acid in the mercuric salt with liberation of + 12·2 Cal.—Action of picric acid and picrates on metallic cyanides. The isopurpurates. A note by M. Raoul Varet. When picric acid can replace hydrocyanic acid in its compounds with evolution of heat, isopurpurates are formed; when, as with the mercuric salt, the hydrocyanic acid replaces picric acid with evolution of heat, isopurpurates are not formed.—The antiseptic properties of the vapours of formaldehyde, by M. A. Trillat. The vapours of formaldehyde, produced by the incomplete combustion of methyl alcohol, have proved very efficacious in destroying germs in sick rooms, and have no action on metals or instruments, and but little action on dyed fabrics.—Observations on flours, by M. Balland.—On the anterior extremity of the dorsal cord in the superior vertebrates, by M. G. Saint-Remy.—Evolution of the sexual elements in the composite Ascidians, by M. Antoine Pizon.—On one of the Chytridineæ parasitic on the vine, by M. A. Prunet.—On the calcareous tuffs of the col de Lautaret (Hautes-Alpes), by M. W. Kilian. From this preliminary study of the Lautaret tuffs, it may be concluded: (1) That these tuffs are relatively recent, their disposition indicating that the present aspect of the surface is much the same as that obtaining at the time of their formation. They are more or less mixed with moraine deposits. (2) The vegetable débris contained in these tuffs, notably the cones and branches of *Pinus sylvestris*, indicate the existence at the epoch of their formation of a forest vegetation which has since abandoned these altitudes.—On the presence of carboniferous earth in the Sahara, by M. F. Foureau.—Thermometric observations on the summit of Ararat, by M. Venukoff. M. Gimmer visited the summit of Ararat on August 16, 1894, and found two thermometers left by M. Pastoukoff the preceding year in a tin-plate box. The maximum registered + 17·25° C., the minimum −40° C. Another minimum instrument, attached in the open air to a vertical object, indicated −38 C. At the time of the visit, the temperature of the air in the shade was + 3° C.—On an aerostatic ascension effected in Russia, by M. Venukoff.

THE OPTICS OF PHOTOGRAPHY.

Handbuch der Photographie: II Theil: Das Licht im Dienste der Photographie und die neuesten Fortschritte der photographischen Optik. By Prof. Dr. H. W. Vogel. (Berlin: Robert Oppenheim (Gustav Schmidt), 1894.)

THIS second part of Dr. Vogel's well-known handbook is the fourth edition, completely revised and enlarged, as we are informed on the title-page. With the index it runs to 367 pages, and is embellished with numerous figures and a coloured frontispiece illustrating the Vogel-Kurtz process of printing in three superposed colours. The result is very satisfactory, and the grapes, pineapple, lemon, and other fruit appear very natural. There should be a promising future for this chromo-lithographic development of photography, which, it may perhaps be not altogether unnecessary to state, has nothing to do with the great question of direct photography in natural colours.

It is difficult within reasonable compass to give an adequate notion of the wide range of subjects dealt with in the present work. Everything likely to be of use to the scientific and practical photographer is treated of with more or less completeness. While the first part, which we noticed in these columns some years ago (vol. xliii. p. 3), deals with the chemical aspect of the subject, the instalment under consideration is devoted to the optical aspect, using the term optical in the wide sense of comprising the general nature of light regarded as a chemically active natural force. The optics of photographic lenses finds a place in the present part in the form of an appendix covering some ninety odd pages, and copiously illustrated. The appendix covers all that is usually comprised in this country under the term "photographic optics," and it is treated in a manner intended to be generally understandable; the actual German heading is, "Gemeinverständliche Darstellung der Grundzuge der photographischen Optik." The seven chapters forming the appendix deal with the methods of forming images, lenticular refraction, faults of lenses, intensity of illumination and "field," differences in photographic objectives, the stereoscope, panorama apparatus, and the principles of photographic surveying. The seventh chapter is of especial interest because it deals with the latest advances in the construction of photographic objectives, and comprises, among other things, a description of the teleobjectives of Miethe, Steinheil, and Zeiss. The remarkable efficacy of this new addition to the resources of the photographer is shown by two pairs of reproductions of photographs of views taken from the same spot, one with an ordinary, and the other with the teleobjective.

We have called attention to the appendix first, not because we desire to follow the practice of certain readers of fiction who form an opinion as to whether a book is worth reading by beginning at the last chapter, but because it treats of that portion of the subject which we here are too apt to regard as comprising the whole of photographic optics. The main portion of the work under notice treats of subjects quite distinct from that of the properties and construction of lenses, but which are of equal importance in modern photography. This portion of the book consists of thirty-one chapters extending over 266 pages. A brief analysis of the contents will give the reader a general idea of the scope:—Intensity of light and Lambert's law, measurement of intensity, the optical photometer, standards of light, Weber's definitions, the brightness of transmitted and reflected light for different substances, the photographic photometer or sensitometer, photographic standards of light, Miethe and Michalke's law of photographic reciprocity in developed films, dependence of the transparency of the negative on the period of exposure and on the intensity of the illumination, the chemical intensity of day and sunlight (Bunsen and Roscoe), intensity under limited sky illumination, continuing rays and the effects of previous and subsequent illumination, sources of artificial light for photography, reflection, halation, composition of light and photography of coloured objects, chemical action and absorption, properties of optical sensitisers, action of colouring matters on collodion and gelatine plates, shifting of the maxima of photographic activity (Wiedemann's law), relations between sensitiveness to light and optical sensitisers of the eosin series, other optical sensitisers, action of simple and mixed optical sensitisers on sensitiveness, ray filters (*i.e.* colour screens), instruments for the study of the colour sensitiveness of photographic films (*i.e.* spectrographs), testing of colouring matters and films for colour sensitiveness, reproduction of natural colours by multiple photography, direct photography in natural colours, colour perception and complementary colours, observations on the colour transparency of the atmosphere.

To those who are acquainted with photography as a science,[1] the headings to the various chapters will give sufficient indication of their contents. There are, however, many topics of importance hidden away, as it were, among the mass of information contained in the book, and to some of these we may direct the attention of the general reader who, without being an expert, may wish to ascertain the present state of knowledge with regard to such subjects as are of physical or chemical interest beyond their immediate application to photography. Thus, with regard to the standards of light we learn that preference is given over all others to the amyl acetate lamp of Hefner-Alteneck—a preference which many in this country will no doubt be prepared to dispute. Then, again, with respect to the amount of light reflected from various surfaces (chapter v.), some useful measurements are given, partly from the author's observations and partly from determinations by Kirschmann. The photographic efficiency of various sources of light (chapter vii.) is also a subject of general interest, apart from its practical bearing. The enormous chemical activity of the light of burning magnesium is well known, but the results stated quantitatively will be startling to many. According to Eder (to quote a few examples) the light in a

[1] We are much in want of some term to distinguish the scientific student of photography from the ordinary camera-carrying picture-taker. The relationship between the two classes is much about the same as that between the bird and animal stuffer and the "naturalist" whose designation he adopts. The designation "luciscribe" is quite as applicable to those who practise the art only, but it does not seem sufficiently harmonious to suggest its adoption.

well-lighted studio expressed in normal candles) is 50,000–100,000; direct sunlight (October), 450,000; electric arc light of 8000 candle visual intensity, 100,000–300,000; flash light with four grammes magnesium powder, potassium chlorate and perchlorate, 10,000,000.[1]

The chapter on sensitometers is particularly good, and the critical discussion of the various systems in vogue will be found most useful. It is true that the author urges the advantages of his own "tubular photometer," but this does not prevent his doing justice to other forms. The discussion of the so-called law of photographic reciprocity according to Miethe and Michalke (chapters viii. and ix.) comes most opportunely at the present time. The relationship between the density of the silver deposit formed on development and the time of exposure, intensity and quality of light, &c., is a subject which has given rise to a great amount of discussion in this country lately. Strange to say, however, Dr. Vogel gives no reference to the work of Abney, Hurter and Driffield, and others who have taken part in the recent discussions. This is certainly an omission. It appears that Dr. Miethe undertook to investigate the accuracy of the law of reciprocity in order to ascertain whether photography could be applied to the measurement of the brightness of the stars. [*A priori*, one would have thought that the ordinary photographic plate would be inapplicable to this purpose because the photographic efficiency is dependent on the *quality* of the light emitted by a star, and this does not necessarily coincide with visual intensity.] Among other points brought out by his investigation is the fact that for very feeble illumination the law in question does not hold good, but when the light is about four times the intensity necessary to produce a visible result (on development) the relationship is true up to 1000 times this intensity. Other deviations from the law are discussed by Michalke in the paper which Dr. Vogel partly reprints, but enough has been said to indicate the importance of these two chapters.

The portions of the work to which those who have followed the recent developments of photography will naturally turn with great interest, are those dealing with the action of special sensitisers, a subject which will always be identified with Dr. Vogel as the discoverer to whom we are indebted for this advancement. The greater portion of the volume—viz. chapters xvi. to xxvii. inclusive—are devoted to this and related subjects. In connection with the sensitiveness of the silver haloids to the colours of the spectrum, the author brings out one point very clearly, and that is the futility of using the sun as a source of light in such experiments. It appears that the photographic transparency of the atmosphere is subject to such very great fluctuations, that the maxima of chemical activity are apt to be considerably shifted from day to day, so that concordant spectrum prints must not be expected from the solar spectrum in cases where accuracy is required. The action of organic colouring matters as special sensitisers receives very full treatment, and all the recent investigations on this subject are brought together. Of these the experiments of Dr. E. Vogel on the colour sensitiveness of the eosin colouring matters by themselves (chap. xx.), and on the special sensitising action of the *pure* colouring matters of this group on gelatino-bromide emulsion films (chap. xxii.), are of considerable importance. It appears now that the fugitive character of these colouring matters is due to photochemical reduction, and not oxidation (pp. 163–164); but the evidence on this point does not appear to the writer to be quite conclusive. It is shown, further, that the best of these colouring matters as special sensitisers are those which are by themselves the most sensitive to light—viz. tetraiodo- and diiodo-fluorescein—that the silver salts are better than the alkaline salts for this purpose, and that the sensitising power increases as the fluorescent power diminishes.

Other organic colouring matters are treated of in connection with this same photographic property, and the details, as given in the book, will be found well worthy of study. We may here call attention to the interesting work of Wollheim (chap. xxiii.) on chlorophyll, from which it appears that the efficient special sensitiser in the case of this substance is the phyllocyanin. The uncertain action of chlorophyll is well accounted for by these researches. Among recent work on the action of organic colouring matters, the author gives an account, almost verbatim, of that published by Mr. J. Acworth in 1890. This writer has made a detailed study of all the most efficient special sensitisers, and, as a general conclusion, confirms the view that the maxima of absorption and chemical activity do not absolutely coincide, but that a displacement occurs in accordance with a law which has been developed theoretically by E. Wiedemann. Figures of some of the absorption and photographed spectra are given (p. 192), and a plate giving Acworth's curves for the various colouring matters.

We might have dwelt upon many other topics discussed in the book; enough has been said, however, to show that photographic literature has been enriched by a work which will take rank among the classics in this subject. If, in concluding this notice, some defects are pointed out, it is not that the writer feels bound as a critic to find fault with something, but because in a work of high standard, such as this, small faults obtrude themselves and become great by contrast. In the first place, then, the author does not give sufficient recognition to work done in this country. One such omission has already been pointed out. Similarly the work of Abney on colour measurement, which is so closely related to the subject-matter of chapter xxx., is not referred to. Although J. J. Acworth's experiments on orthochromatic photography are given *in extenso* (because originally published in *Wiedemann's Annalen*?), the prior work of C. H. Bothamley is not described. In connection with the theory of direct photography in colours by the method of interference, Zencker alone is mentioned, and all reference to Lord Rayleigh's work on this subject omitted. But still more serious is the introduction of polemical matter into the work—in some parts to such an extent as to become an actual disfigurement. The whole of chapter xvii., on the history of the discovery of the action of special sensitisers, might very well have been omitted; what is the use of reprinting a series of polemical papers published twenty years ago, especially when one of the combatants (Schultz-Sellack) is dead?

[1] These numbers are referred to the *photographic*, not *visual* intensity of the standard candle.

Then, again, the passage of arms between the author and Dr. Neuhaus in this same chapter, and Herr Hruza (chapter xxviii.) and, above all, Mr. Ives (pp. 239-240), is conducted in a manner that in this country would be regarded as very bad form. Perhaps German notions of scientific literary taste differ from ours, but the writer of this notice has never yet come across a German work professing to be a scientific text-book, in which such bad taste is shown as in the introduction of the personalities which are here indulged in.[1] Discounting these imperfections, Dr. Vogel is to be congratulated on this second instalment of his book; it will be found valuable as a compilation, and still more valuable as embodying much original work. No scientific student of the subject can dispense with it, and beyond the domain of pure photography the chemist and physicist will find much in its pages worthy of consideration. R. MELDOLA.

THE MEASUREMENT OF ELECTRICAL RESISTANCE.

A Treatise on the Measurement of Electrical Resistance. By William Arthur Price, M.A., A.M.I.C.E. (Oxford: Clarendon Press, 1894.)

OF all electrical measurements probably that of measuring a resistance is the most important, since the resistance of many bodies is a permanent quality, and resistances can be compared by means of apparatus of comparatively simple construction, while the results obtained are much more accurate than in the case of any other electrical measurement. Most books on practical electricity contain more or less complete descriptions of the methods generally employed in the measurement of resistance, and in some cases give what may be called "diagrammatic" descriptions of the construction of the different forms of apparatus employed. The work under consideration, however, goes much further, for in it the mechanical details of the construction of the apparatus are described in a manner which shows that the author is practically acquainted with his subject.

The book may be roughly divided into two parts: in the first of these the materials used in the construction of resistances and the different methods of winding and mounting resistance coils are fully dealt with; while the second part contains full descriptions of the methods ordinarily employed in the measurement of resistances, both high and low.

The first chapter is introductory, and contains a definition of the term resistance, while the conditions to be fulfilled by a material suitable for the construction of standard resistances are shortly discussed. The properties of the different alloys employed in the construction of resistances are fully dealt with in the second chapter.

After referring to the artificial "ageing" of manganine wire, and to the extremely small value of the thermo-electric force between this alloy and copper, the author says that the electrical properties of this material seem to be quite permanent. This opinion, however, is at variance with the experience of most people who have tested this alloy, and it would be of interest to know whether any satisfactory experiments have been made to settle this point. Although it may be important in many commercial operations, where accuracy is not so much aimed at as simplicity and freedom from troublesome corrections, to make resistances of alloys having a low temperature coefficient, yet in any experiment where accuracy is necessary it is much more important to have a constant and linear function for the temperature correction than to have an extremely small but variable and uncertain one. A comparison of the curves for the variation of the resistances of the different alloys, which have been reproduced from Profs. Dewar and Fleming's paper, shows at once the fatal objection to manganine. Another objection to this alloy, as at present manufactured, is the extreme variation in physical properties between the different samples supplied.

Two very interesting chapters are devoted to the construction of resistance coil bobbins, and the methods employed for winding the wire. In connection with the question as to the best form to give standard resistance coils in order that the temperature may be accurately known, the author recommends that the coil be enclosed in a thick copper case, with a recess filled with mercury for the insertion of a thermometer, the whole to be covered in with a wooden case, to protect it from dust and draughts, instead of the usual thin case and water-bath. This method of securing a uniform temperature is very satisfactory when no heat is generated within the apparatus, but in the case of a resistance coil and a thermometer placed in a hole filled with mercury in the enclosing case, where the passage of the testing current heats the wire, the thermometer would probably "lag" considerably behind the wire; and the chief effect of the thick case would be to screen the thermometer from the changes in temperature of the wire.

The heat developed in a coil, and the rate at which the temperature rises, are shortly considered, data being given for calculating these quantities. It would be a great improvement, however, if in a subsequent edition a table were given showing at a glance the maximum current which can with safety be passed through the different coils of resistance boxes wound with the sizes of wire ordinarily used. Whether it would be possible to indicate this quantity on the boxes of coils as sent out by the makers, is perhaps doubtful; but if it could be done, it might perhaps stay the hand of the too venturesome student, who is continually trying to ruin any resistance boxes he may be using by passing an excessive current.

While the chapter on the Post Office and Dial forms of Wheatstone's Bridge is very complete, and contains a very useful table of the best resistances to be used in the ratio arms of a Post Office Bridge, that on the Slide Wire Bridge can hardly be said to be so. The only form of Slide Wire Bridge at all fully described and illustrated is of the ordinary design to be found in elementary physical laboratories. Although this is sufficient for teaching purposes, it is hardly suitable

[1] Out of consideration for those concerned, I refrain from giving specimens of the paragraphs complained of. Can it be that the style of discussion is incidental to the subject? Similar lucubrations are sometimes to be seen embellishing (?) the pages of photographic journals. In passing the above strictures it is to be understood that the question of the author or his antagonists being right or wrong is not raised: it is the style which is objected to– the transference of personal polemics from journals in which they might possibly be tolerated, to the pages of a text-book in which they are intolerable.

for very accurate work. No mention, either, is made of any form of switch-board, such as that designed by Prof. S. P. Thompson, for the interchange of the coils when using Carey Foster's method of comparing resistances. A good description, accompanied by several excellent diagrams, is, however, given of Kelvin and Varley's slide, and of Kelvin's apparatus for the comparison of low resistances.

The remaining chapters are devoted to the measurement of high resistances, of batteries, and of electrolytes. There are six appendices, in which the mathematical theory of the Wheatstone's Bridge, Lord Kelvin's method of measuring low resistances, and Manse's method of measuring the resistance of a battery are given, together with discussions on the E.M.F. of contact at the junctions of a metre bridge, on the discharge of a condenser through a high resistance, and on the electrostatic analogue of a Wheatstone's Bridge.

The work would have been more useful if its scope had been enlarged, and if it had contained a detailed description of some complete set of instruments used in the comparison of standard resistances, such as are used by the British Association Committee on Electrical Standards at the Cavendish Laboratory. Nevertheless, it is a good book, written by one who is practically engaged in the manufacture and testing of these instruments, and who, not content with rules of thumb, gives the reason for each point involved in the design and construction.

There is no doubt the book will be found of great use in every laboratory and testing-room, and is, as the advertisers of patents are wont to say, "calculated to fill a long felt want." W. W.

AN ASTRONOMICAL ROMANCE.

A Journey in Other Worlds; a Romance of the Future. By John Jacob Astor. With ten Illustrations. Pp. 476. (London: Longmans, Green, and Co., 1894.)

SINCE Jules Verne wrote his "Journey from the Earth to the Moon," many writers have tried their hands at similar productions, but none have excelled their prototype. A good grasp of the principles of science, a vivid imagination, and a brilliant descriptive power, are essential faculties in the man who proposes to give the public a view of the future as seen through his prophetic eye. We do not think the author is blessed with a bountiful share of these qualifications; nevertheless, he has been able to bring forth a book in which instruction and entertainment are happily combined.

Looking forward to the epoch A.D. 2000, the author saw that many things had come to pass which are undreamt of in the philosophy of this enlightened century. The incidents of the story are centred round a scheme for changing the obliquity of the ecliptic, and a machine in which trips are taken to Jupiter and Saturn. It is a source of regret to many people, and especially to those who are doomed to linger in an erratic climate like ours, that the earth's axis is not perpendicular to the ecliptic. If such a condition of things existed at the present time, it could truly be said, "Blessed are they that inherit the earth." Every latitude would have its own almost uniform temperature all the year round, and the slight eccentricity of the earth's orbit would be sufficient to awaken recollections of the succession of the seasons. Life would indeed then be one perpetual spring.

The idea of decreasing the obliquity of the ecliptic is only an incidental part of Mr. Astor's story. The greater part of the book is taken up by an account of a journey to Jupiter and Saturn. But, before passing to this section, we must point out that a certain looseness of expression is manifest in the previous one. The project of changing the obliquity is constantly referred to as one of "straightening the terrestrial axis." The impression that the general reader will obtain from such an expression is that the earth's axis is only "straight" when it stands bolt upright, as it were, in the plane in which our globe revolves round the sun. How the author came to use the word "straight" in the sense which he does, passes our comprehension. Another and really less important matter, is that the earth's axis is said to be "inclined to the ecliptic about $23\frac{1}{2}$ degrees." To be correct, the author should have said that the inclination to the ecliptic is $66\frac{1}{2}^{\circ}$, and that the angle between the axis and a perpendicular to the ecliptic is $23\frac{1}{2}^{\circ}$.

We come now to the flying machine. Jules Verne utilised known powers when he sent his imaginary car from the earth to our dreary satellite. Others who have followed in his wake have had to hypothecate their forces. *Apergy* is the force employed by Mr. Astor's characters. Similarly electrified bodies repel one another, argues he, then why may not matter exist in such a condition that gravitational attraction becomes apergetical repulsion? Given such a source of perpetual energy under control, and, heigh presto, away we can go into the realms of space, with concentrated extracts for food, and liquid oxygen for air supply. Three individuals undertook this kind of voyage in the year A.D. 2000; at least so the story goes. One is a learned bore who discourses sapiently on all and sundry circumstances of the journey. For instance, the information he hurls at his companions as Jupiter's largest satellite, Ganymede, is passed, is as follows. "This was discovered by Galileo in 1610. It is three thousand four hundred and eighty miles in diameter, while our moon is but two thousand one hundred and sixty, revolves at a distance of six hundred and seventy-eight thousand three hundred miles from Jupiter, completes its revolution in seven days and four hours, and has a specific gravity of 1·87."

This individual is brimful of knowledge which wells up at every opportunity, and, after a time, becomes very oppressive. His two companions, on the other hand, though assigned acute understandings and good educations by the author, listen in silence to these tiresome lectures on the most elementary facts of astronomy—an incongruity which is a very weak point in the story. Furthermore, the obtrusive dispenser of scientific scraps is much behind his time, for his astronomical knowledge does not go beyond that of the present day. If Mr. Astor were thoroughly conversant with astronomical investigations, he could have made his professor a much more interesting person. As it is, the man pours forth his spirit in and out of season, and is just the sort of individual that the majority of people are anxious to avoid.

We will pass over the little incidents of the journey to Jupiter. Suffice it to say that Mars and his moons were observed, that a few asteroids were met and a comet penetrated, and eventually the Callisto—that was the name of the car—was landed on a hard part of the planet's surface. Jupiter was found to be in the Palæozoic period; and a smattering of geological knowledge has enabled the author to conjure up multitudes of "extinct monsters," which quite eclipse those in Mr. Hutchinson's book.

Having passed through Saturn's ring, and seen for themselves that it was composed of meteoritic particles, the party arrived safely on the planet. Our belted brother was found to be an abode of spirits, upon the characteristics of which we are not competent to express an opinion. The height of the ludicrous is reached at a dinner given to the travellers by one of these airy nothings, who, we are gravely told, "took only a slice of meat and a glass of claret." The idea of a diaphanous bishop consuming meat and claret is very rich.

A word or two on the general character of the book may not be out of place. The author rightly terms his production a romance—that is, a story hung upon seeming impossibilities. There is no plot, and the characters are merely mechanical puppets used to expound didactic ideas, so the book cannot be called a novel. It is, in fact, little more than a reading-book suitable for beginners in astronomy. We doubt whether many people will read it through without skipping the prosy parts, but they who conscientiously do so will undoubtedly acquire a certain amount of more or less useful knowledge. The author is usually accurate in his astronomy; and this, considering that writers of romances generally play fast and loose with astronomical phenomena, is saying a good deal. We commend the book to readers who like instructive tales.

R. A. Gregory.

OUR BOOK SHELF.

Ueber die geometrischen Eigenschaften homogener starrer Structuren und ihre Anwendung auf Krystalle. Von W. Barlow. (Leipzig: Engelmann, 1894.)

This paper, which was recently published in the twenty-third volume of Groth's *Zeitschrift f. Krystallographie*, is an interesting contribution to the theory of crystal structure.

Mr. Barlow investigates the nature of a homogeneous structure, by which he means an arrangement of any material of constant form which is uniformly repeated throughout its whole extent. To every point in such a structure correspond other points homologous with it, and these must constitute one of the sixty-five regular assemblages of points as defined by Sohncke in his well-known treatise on crystal-structure. But the symmetry of the structure is not always identical with that of the assemblage of points derived from it, and it is sometimes necessary to extend the latter by a geometrical process of reflection or inversion in order to arrive at the symmetry of the structure. This process results in the addition of 164 possible homogeneous structures to the sixty-five already established. Incidentally it is shown that the assemblages of Sohncke are not in reality independent, but can all be regarded as compounded of one or other of ten assemblages belonging to the least symmetrical types in the various systems of crystallography. Fedorow and Schönflies have independently advanced a new theory, and agree in the result that there are 230 possible types of homogeneous structure. Since their methods are based upon Sohncke's definition extended by the principle of reflection or inversion, Mr. Barlow's investigation should lead to the same result. Now he finds 229 types, and expressly states that he is unable to account for a certain one of Fedorow's structures, so that his work is an absolute confirmation of the general accuracy of their calculations.

When this trifling question of 229 or 230 is settled, the problem of homogeneous structures, which was approached by Hauy 100 years ago, may be regarded as completely solved *from the purely geometrical point of view*.

Mr. Barlow's analysis of Sohncke's assemblages, and his laborious synthesis of the 164 new types, make the relations between the old and the new theory intelligible, and enable the reader to form a mental picture of all these complicated groupings: a task which is by no means easy from the writings of Fedorow and Schönflies without the aid of Mr. Barlow's tables.

H. A. M.

Theoretical Mechanics.—Solids. By Arthur Thornton M.A. Longmans' Advanced Science Manuals. (London: Longmans, Green, and Co., 1894.)

The manuals published in this series are written specially to meet the requirements of the advanced stage of science subjects, and the present book will be found a very worthy addition. It is not surprising to hear, as the author tells us in the preface, that in preparing this work he was confronted by the syllabus of this department. The range which these 400 odd pages then cover, can on this account be at once gathered: and it can safely be stated that the book includes all that is generally necessary for any school course. The order in which the subject has been treated is first kinematics, in which the geometrical science of motion is dealt with, then statics, and finally kinetics, in which force is treated in its relation to motion. In each part the author feels himself by no means bound up as regards the choice of proofs and definitions; and he places before the reader, in a well-arranged series of paragraphs, all the theorems and problems, illustrating them when necessary with clear figures. The real essence of the subject, that is, the "book-work," has had special attention devoted to it, and each chapter contains a special number of problems to be deduced directly from it. Stress has been laid, too, on the importance of solving problems from first principles, and not from a direct substitution in formulæ. Formulæ can easily slip the memory, if not totally, then partially, and it is for this reason that numerous methods and samples of solution have been given.

Examples of all kinds, and especially those introducing great diversity of style, are scattered throughout the work, some being original, while others are obtained from numerous well-known sources. A useful appendix, containing a brief summary of trigonometrical formulæ, and a short index, brings the book to a conclusion. For the convenience of those who are preparing the subject for special examinations, a short list is given of the portions which may be omitted.

The Earth: an Introduction to the Study of Inorganic Nature. By Evan W. Small, M.A. University Extension Series. (London: Methuen and Co., 1894.)

In this very acceptable addition to the well known University Extension Series, we have a set of chapters which are not intended to form a text-book on physiography, but to serve as a book containing a certain amount of accurate and definite knowledge for the general reader. Such being the case, the author has not dealt fully with any of the various branches, but has treated, in a sketchy manner, some of the more striking phenomena of the earth. The earth as a planet is first referred to, then the materials of which it is composed, which include the composition of the lithosphere, of the atmosphere, and of the hydrosphere. Next are discussed the laws of energy, and the past history of the earth as gathered from its present aspects, while the last chapter is devoted to the evolution of the earth, with sections on spectrum analysis, and theories of planetary origin. To anyone wishing to obtain a general survey of this many-sided subject, physiography, these pages should be of great service. As has been said before, the information in many cases is brief, and in some cases too brief for explanatory purposes. This is, however, counterbalanced to some extent by a number of useful references at the end of each chapter. An appendix, which may prove handy to teachers, gives a list of suitable lantern-slides for illustrating the subject-matter.

Songs of the Russian People. Collected in the Governments of Arkhangelsk and Olonetz, by Th. M. Istomin and G. O. Dütsch. (St. Petersburg, 1894.)

The northern provinces of Russia are the parts of the empire where the old popular songs are still kept in the memory of the people in their greatest purity. Elsewhere they are often forgotten, or are altered by the intrusion of modern music, very often of the music-hall type. In 1886 the Russian Geographical Society sent out a small expedition in order to collect the really old popular songs—religious, epic, wedding, and so on—and 119 of them are now published, both words and music, in the above-named collection. The words have been taken down by M. Istomin, and the music by M. Dütsch, who have both had a great deal of previous experience in that sort of work. Several songs of the collection are quite new, but the book's chief value is in the melodies of the epic songs (*byliny*), which now become known for the first time. It had always been supposed that the epic songs had no melodies, and were simply delivered in a sort of monotonous recitative; but it now appears that some of them have their special melodies, grave, most beautiful, and bearing the stamp of great antiquity. A map appended to the book shows the places visited by the expedition.

Visions of the Interior of the Earth, and of Past, Present, and Future Events. By H.R. and M.S.H. the Prince of Mantua and Montferrat. (London: Simpkin, Marshall, and Co., 1894.)

"Shadows to-night have struck more terror to the soul of Richard,
Than can the substances of ten thousand soldiers
Armed in proof, and led by shallow Richmond."

These lines are brought to mind by Prince Mantua's visions, which are calculated to produce a more or less terrifying effect upon the gentle reader. We cannot review the book seriously, for it is merely a record of what the author heard and saw while in a state of trance, and such revelations can hardly add to our knowledge of the earth's interior. Mr. Baxter, and the Society for Psychical Research, may find the volume interesting.

The Complete Poetical Works of Constance Naden. (London: Bickers and Son, 1894.)

In one of his essays, Macaulay, with his usual leaning to antithesis, holds that "as civilisation advances, poetry almost necessarily declines." His opinion was that science and poetry are antagonistic. The late Poet Laureate, however, showed that scientific facts and phenomena could be clothed in language at once poetical and impressive. Miss Constance Naden, who died at the end of 1889, won for herself a high place among poets of science and philosophy, and her admirers include many distinguished votaries of these branches of knowledge. Astronomy, geology, evolutionary ethics, and the nebular theory are a few of the subjects which inspired her to write, and that in a manner which commands admiration. She was a devoted disciple of Mr. Herbert Spencer, and, indeed, was a witness to the truth of his words: "It is not true that the cultivation of science is necessarily unfriendly to the exercise of imagination and the love of the beautiful. On the contrary, science opens up realms of poetry where, to the unscientific, all is a blank."

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Some New Facts with regard to "Bennettites."

The remarkable state of preservation of many Palæozoic plants, and some few Mesozoic forms, has raised palæobotany to a position of considerable importance in certain fields of botanical investigation. Endless synonyms, and specific determinations of more than doubtful value, have not unnaturally prejudiced botanists against the study of plant fossils. The scientific treatment of the mineralised tissues of extinct forms has, however, been productive of exceedingly important data towards the better understanding of the lines of plant evolution. Synthetic types and intermediate forms of plant structure are already fairly abundant, and the various suggestive facts revealed by a study of their remains are gradually assuming a more definite shape.

The genus *Bennettites* is an example of special interest among ancient plant types. This name was introduced by Mr. Carruthers in his important monograph of 1868, on the fossil Cycadean stems from the Secondary rocks of Britain.[1] The excellent preservation of the species *B. Gibsonianus* enabled this observer to give a detailed account of certain reproductive organs, which were embedded in the armour of the persistent petiole bases enclosing the plant stem. The affinities of this species have since been presented in a somewhat different light by Solms-Laubach,[2] and he is led to the conclusion that the *Cycadeæ* are the nearest known allies of the *Bennettiteæ*. There are, however, important differences between the two groups which preclude the idea that one has been directly derived from the other. The Marquis of Saporta and various other writers have contributed to the literature of *Bennettites*, and the speculations propounded as to its true position have been numerous enough.

We are indebted to the careful researches of Prof. Lignier, of Caen, for some recent additions to our knowledge of this genus, and his exhaustive monograph carries us a step further towards the solution of the Bennettites problem.[3] The specimen which forms the subject of Lignier's work was found by Morière, in 1865, in the Oxfordian beds of Vaches-Noires; two years later the fossil was described by its discoverer as part of a true Cycadean plant. In 1881, Saporta and Marion referred this Oxfordian fruit to the genus *Williamsonia*: and subsequent writers have assigned the fossil to various positions in the plant kingdom.

The specimen of *Bennettites Morierei* (Sap. and Mar.) described by Lignier is ovoid in form, and has a length of 55 mm., with a breadth of 35 mm. At the base a fractured surface reveals the existence of a slightly convex receptacle, from which is given off a compact cluster of long peduncles, each of which bears at its apex an oval seed. The seed-bearing peduncles are surrounded by several involucral bracts closely applied to

[1] *Trans. Linn. Soc.* vol. xxvi., 1870, p. 663.

[3] "Végétaux fossiles de Normandie. Structure et affinités du *Bennettites Morierei* (Sap. et Mar.)." With six plates. Octave Lignier. (*Mém. Soc. Linn. Normandie*, vol. xviii., 1894.)

the surface of the fruit. Unfortunately the fruit is isolated, and affords no clue as to the nature of the organ to which it was originally attached. Numerous thin lamellæ occur in association with the seminiferous peduncles; to these Lignier has applied the term interseminal scales. The seeds are arranged side by side close to the upper surface of the mass of peduncles and interseminal scales; the latter pass between and beyond the seeds, and their swollen distal ends form a protective covering to the blunt hemispherical apex of the fruit. In surface view, the upper part of the specimen appears to be made up of a large number of small projecting areas with polygonal bases and rounded summits. Here and there the projections arrange themselves in the form of rosettes round a small central cavity, marking the position of a seed.

Involucral Bracts.—Some important facts have been brought to light as the result of a detailed histological examination of these structures by means of a series of transverse sections. In section each bract has the form of an isosceles triangle with the base directed towards the surface of the fruit. The excellent preservation of the tissues affords indisputable evidence of the existence of stomata and numerous lamellar epidermal outgrowths, similar to certain structures described by Carruthers in *B. Gibsonianus.* The most interesting part, perhaps, of Lignier's account of the bract tissue, is the inference he draws from an examination of the course and structure of the several vascular strands traversing each bract. It would seem that the vascular bundles are far from their termination, and that the involucral bracts as shown in the specimen are merely the petiolar portions of leaf-structures, of which the pinnate or flabellate laminæ have not been preserved. Immediately underneath one of the scaly hairs of an involucral bract a section has cut through what is apparently a lenticel; in this case, suggests Lignier, lenticel development has probably taken place as the result of irritation consequent on the fall or decay of a hair.

Seed-bearing Peduncles.—The main portion of the fruit itself is made up of well-developed peduncles having a length of 30–45 mm., and a diameter of 1·5 mm. Each peduncle consists of fundamental tissue traversed by a single axial bundle, and surrounding the whole there is a very characteristic epidermal layer, which is gradually replaced towards the upper part of the fruit by a "tubular envelope" of variable thickness. This change is probably the result of the elongation of the peduncles, and of the epidermal cells which increased in length without undergoing transverse division, and thus became transformed into tubular elements. A similar alteration of epidermal cells occurs in *B. Gibsonianus*, but in that species its true nature was apparently not recognised by Carruthers and Solms-Laubach.

Seeds.—Each peduncle terminates directly in an orthotropous seed with a single integument; the seeds are elliptical below, and assume a tetragonal or pentagonal form towards their apices. In the neighbourhood of the seeds, the tubular envelope of the peduncles is reduced in size, and becomes differentiated into a small tubular, and a folded layer of cells. The former is prolonged to the apex of the seed; the latter retains its special character in the lower half, but towards the upper half of the seed its cells become radially elongated, and give place to a tissue described as the "assise rayonnante." Passing up to the micropylar canal the two layers undergo a further modification; the tubular envelope has now assumed the *rôle* of an ordinary epidermis, and the "assise rayonnante" passes into a simple sub-epidermal layer of cells. The inner face of the micropyle consists of narrow and radially elongated elements, which become isodiametric as we pass down to the pollen-chamber. The fundamental tissue of the seed-coat is divided into an external fleshy and an internal fibrous portion. In describing the cells of the fleshy part of the integument, Lignier points out that the thin cell walls show here and there numerous fine pits, and the cell cavity contains a dark substance which may possibly represent the remains of protoplasmic and other cell contents. In some cases the contracted protoplasm (*sic*) shows slender prolongations which appear to correspond to the pits in the cell wall; these are interpreted as strands which originally traversed the cellulose walls, and connected cell with cell. It is perhaps questionable how far the tissues of fossil plants will stand the strain of the minute descriptions which characterise the work of some French writers; but if protoplasmic continuity can be thus partially demonstrated in a fossil seed, it suggests possibilities beyond the wildest dreams of palæobotanical histologists! The greater part of the nucellus is occupied by a large embryo with two cotyledons. On the whole, the general disposition of the peduncles and seeds is the same as in *B. Gibsonianus*, but various differences in detail sufficiently establish a specific difference.

Interseminal Scales.—These may be compared to the scales in a pine cone; they are associated with the seminiferous peduncles, but extend beyond them, and form a continuous protective layer at the exposed surface of the fruit. External to the interseminal scales there are the so-called superficial scales, which have a fairly definite structure, and are not to be confounded with the external involucral bracts.

The above imperfect *résumé* conveys but a poor idea of the thorough and careful treatment of the fossil at the hands of Prof. Lignier.

In his concluding remarks as to the nature of *B. Morierei*, the author of the monograph expresses himself somewhat as follows:—Regarding the supporting trunk as an axis of the first order, the fruit-bearing axis is of the second order, and has its apex contracted in the form of a convex receptacle; the leaves below the receptacle are transformed into involucral bracts, the leaves inserted on the receptacle itself have become interseminal scales, and the seed-bearing peduncles are fertile leaves belonging to unileaved shoots of the third order.

The inflorescence of *Bennettites* is clearly distinguished from that of the Cycads in the following points:—(1) Ovules are terminal and erect; (2) each fertile bud is of a higher order and much reduced; (3) the inflorescence is compound, formed by the grouping together of several fertile shoots, with a supporting branch and its leaves, &c. "The *Bennettiteæ* are therefore posterior to the *Cycadeæ*, at least as regards the reproductive structures."

On the other hand, the inflorescence of *Bennettites* presents many points of agreement with the *Coniferæ*; *e.g.* in its compound nature, small seeds, unileaved fertile shoots with erect ovules, &c. The points of difference between *Bennettites* and the *Coniferæ* include (1) larger number of sterile leaves associated with the single-leaved buds; (2) the position of the fertile shoots, which is not perhaps strictly axillary, &c. Summing up the whole matter, Lignier says:—"I regard the *Bennettiteæ* as a family which has been derived with the Cycads from common ancestors, but not from the Cycads themselves. Of these common ancestors the two families have preserved the form of the trunk, the structure of certain tissues (large pith, gum canals, diploxyloid leaf-traces, and sclerenchymatous mesophyll), the foliar origin of the ovule, &c. But whilst the Cycads have retained a grouping of carpophylls on a single axis, and have acquired special characters, such as the complication of the leaf-trace and the lateral position of the ovules; the *Bennettiteæ* have retained the simple leaf-trace and have acquired a terminal position of the ovules, the reduction of the fertile axes to a single corpophyll, the grouping of these fertile reduced axes, and the modification of the neighbouring leaves as the result of *précurrence sexuelle*.[1] Perhaps the future will bring to light a greater affinity than is at present suspected between the *Bennettiteæ* and certain fossils referred to the *Cordaiteæ*."

A. C. SEWARD.

Science Teaching in St. Mary's Hospital Medical School.

MY attention has just been called to an article in the issue of NATURE of September 20, headed "Science in the Medical Schools." This article professes to demonstrate by means of a table, compiled from lists given in the students' number of the *Lancet*, the extent to which instruction in science subjects not purely medical is provided in the medical schools. According to this table, no instruction is provided in biology or zoology, botany, physics, practical physics, bacteriology, and hygiene, or public health, in this medical school. If you will refer to the prospectus of the medical school, which I forward with this letter, you will find that very complete courses of instruction are given in all those subjects here, and that the instruction includes lectures, classes, demonstrations, and laboratory work in all the subjects.

[1] In explanation of this term Lignier adds:—"Je designe sous le nom de *précurrence sexuelle* le phénomène par lequel certains organes soit porteurs de la glande sexuee soit voisins de celle-ci et formes antérieurement à elle, sont peu à peu englobés dans l'appareil sexuel à mesure que celui-ci se complique dans la généalogie des plantes. La précurrence sexuelle ainsi comprise se rencontre partout dans le règne vegétal."

I cannot help thinking, that before publishing such an article, it would have been but in accordance with common accuracy and equity if you had verified the list of subjects taught in this medical school, by reference either to the prospectus or to one of the officials, who would have been pleased to give you all necessary information. The list relating to St. Mary's Medical School, in the number of the *Lancet* from which you prepare your table, teems with inaccuracies and omissions. It is not a list issued with any authority from this school, nor is it submitted for revision or correction to any official of the school. The statement in your article, that "the table does not pretend to be complete," is one that I cordially endorse; but the subsequent statement, that "it will serve to show the kind of science subjects on which lectures are given to medical students," is one that, as regards the teaching at St. Mary's Medical School, is both misleading and untrue.

My colleagues concerned in the management of this school feel with me that such a reference to our science teaching in a paper of such wide circulation as that of NATURE, is calculated to be most damaging to the interests of our medical school, which we have used every endeavour, and spared no expense, to render efficient from the educational point of view. We therefore trust that you will publish this letter in full, and that you will take the earliest opportunity of correcting the erroneous statement in connection with the science teaching here that appears in your issue of September 20 last.

ARTHUR P. LUFF.

[The students' number of the *Lancet* contains lists of the "classes, lecturers, and fees" at the medical schools of Great Britain, for the session 1894–95. We assumed that these lists were fairly complete, and the table referred to by Dr. Luff was prepared from them. It occurred to us that our contemporary may have omitted some courses inadvertently, and this led us to state distinctly that "the table does not pretend to be complete," and, later on, "courses of lectures on bacteriology are advertised to take place at nine medical schools, but it must not be supposed that they are the only schools having facilities for carrying on this work." The table served its purpose of showing the kind of sciences taught in medical schools in addition to the usual professional subjects. It was not intended to be used as a criterion of the efficiency of the schools individually.—ED. NATURE.]

Gohna Lake.

THE notices in NATURE (August 30, p. 428, and September 20, p. 501), on the overflow of the lake dammed up by a landslip at Gohna, in the Kumaun Himalayas, leave the impression that the dam burst and the lake was completely drained. This is incorrect. The accompanying extract shows that Mr. Holland's forecast, an abstract of which, with illustrations, appeared in NATURE, July 5, was singularly accurate. The whole occurrence is of remarkable geological interest, and it is important the correct facts should be known.

W. T. BLANFORD.

Weyburn, near Godalming, October 9.

Mr. Michie Smith, the Madras Astronomer, referring to the Gohna Lake, writes to the *Madras Mail*:—"My excuse for writing to you again on this subject is that I have now received trustworthy information regarding the present state of the lake, which makes it possible to compare Mr. Holland's forecast with what has actually taken place. In Mr. Holland's official report, he laid stress on three main points. (1) That the dam would not yield until the water overflowed it. This, as is admitted, was correct. (2) That the water would overflow the barrier about the middle of August. This was the result of a very intricate calculation, the data for which were obtained with great difficulty; yet, as we now know, this estimate was within ten days of the actual time, and on the safe side. Both these points were of much practical importance for the purpose of making arrangements in the valley below, and Government accepting the conclusions allowed traffic to continue in the valley for 160 miles till August 15. (3) Mr. Holland held that it was probable that 'there will be preserved above a lake 3½ miles long and 1¼ miles wide, whose destruction by gradual erosion of the dam and silting up of the basin, though a matter of time geologically considered short, will be sufficiently slow for what historically may be called a permanent lake.' Now, what are the facts of the case? According to the latest trustworthy report from Gohna, a lake has been left which is over 3 miles long and 400 feet deep, and so far as it is possible to judge it will have the permanence predicted for it. I hold no brief for Mr. Holland, but it seems to me that his predictions, founded on careful research and accurate reasoning, have been fulfilled to a most remarkable degree, and that he has fully justified the confidence placed in him by the authorities."

Instinctive Attitudes.

DR. LIVINGSTONE makes this interesting observation: "Manyuema children do not creep, as European children do, on their knees, but begin by putting forward one foot and using one knee. Generally a Manyuema child uses both feet and both hands, but never both knees. One Arab child did the same; he never crept, but got up on both feet, holding on till he could walk." ("Last Journals," p. 381.) The last instance suggests arboreal survival, the Manyuema style being pure plantigrade, but rarely seen in civilised life. Creeping of infants as instinctive activity certainly throws light on human evolution, and it may be that racial differences will be revealed by investigation. It would also be interesting to inquire how far idiosyncrasy in walking is connected with peculiarity in creeping. Swinging the arms seems quadrupedal survival. Looking down from a high building on people walking below, their movements thus projected on a plane are strikingly suggestive of a quadruped, and the professional pedestrian who makes the utmost use of arm-swinging to accelerate gait suggests the rapid shuffle of a bear.

Again, the various attitudes instinctively assumed by persons for sleep are significant for the evolutionist. I know those who naturally dispose themselves flat on the stomach, with the limbs placed much like a dog asleep.

So far as habits of creeping, walking, and sleeping have not been taught, but are purely instinctive, they throw light on the history of man. It is very desirable that travellers and residents in all countries secure photographs of these attitudes, and deposit them with anthropological societies, where they would be of great use to the investigator. HIRAM M. STANLEY.

Lake Forest University, October 3.

The Tetrahedral Carbon Atom.

IN the letter which he has addressed to you on this subject, it seems to me that Dr. Turpin has not succeeded in justifying his position. Whether your reviewer is or is not acquainted with all that has been written on the subject, is not a matter of great importance, though reference to the *Proceedings* of the Birmingham Philosophical Society (vii. part ii. p. 264) will be sufficient to show that the views of Wislicenus and Wunderlich have not been overlooked. The question is whether the writer of a text-book bearing on its title-page the word "Elementary," is justified in presenting without preface, and almost without explanation, a bald statement such as that complained of, which represents not the deliberate conclusions of the majority, or even of a considerable body of chemists, but speculations still in the earliest stage of evolution. (Wislicenus himself says, in reference to his own views, "Ich lege ihnen keineswegs den Werth einer wissenschaftlichen Ueberzeugung bei und möchte nicht auf ihnen 'festgenagelt' werden." *Ber.* xxi. 584.) I hope and believe that this sort of thing is not commonly taught to beginners in organic chemistry, and it may be as well for Dr. Turpin and his pupils to note that tetrahedral carbon is not referred to in any way in the syllabus of the first stage of organic chemistry in the Directory of the Science and Art Department. W. A. T.

"Abstract Geometry."

I SEE your reviewer of Prof. Veronese's book on "Abstract Geometry" says: "Apparently this method" (that of pure geometry, free from axes, algebraic processes, &c.) "has not previously been applied to the discussion of space of more than three dimensions." Will you allow me to point out to him that this is a mistake? The case of four dimensions is discussed, and a general method indicated, in my "Foundations of Geometry," which was reviewed in your issue of April 6, 1891 (vol. xliii. p. 554). I have not yet read Prof. Veronese's book, but from your review I gather he treats the subject rather differently. EDWARD T. DIXON.

Cambridge, September 28.

ON THE DOCTRINE OF DISCONTINUITY OF FLUID MOTION, IN CONNECTION WITH THE RESISTANCE AGAINST A SOLID MOVING THROUGH A FLUID.[1]

IV.

§ 25. ANOTHER decisive demonstration that the doctrine of discontinuity is very far from an approximation to the truth, is afforded, in an exceedingly interesting and instructive manner, by Dines' observations of the pressures on the two sides of a disk held at right angles to a relative wind of 60 statute miles per hour (88 ft. per sec.), produced by carrying it round at the end of the revolving arm of his machine. The observations were described in a communication to the Royal Meteorological Society in May 1890. In his paper of June of the same year, in the Royal Society Proceedings already referred to, he states the results, which are, that at the middle of the front side an augmentation of pressure, and at the middle of the rear side a diminution of pressure, measured respectively by 1·82 i and ·89 i of water, were found. These correspond to heads of air, of density 1/800 of that of water, equal respectively to 121$\frac{1}{3}$ and 59$\frac{1}{3}$ feet. The former is in almost exact accordance with rigorous mathematical theory for an inviscid incompressible fluid; which gives 88· 64·4, or 122$\frac{1}{3}$ feet for the depth corresponding to the pressure at the water-shed point or points, of a solid of any shape moving through it at the rate of 88 feet per second. The latter shows that there is a "suction" at the centre of the rear side very nearly equal to half the augmentation of pressure on the front; instead of there being neither suction nor augmented pressure as taught in the doctrine of discontinuity!

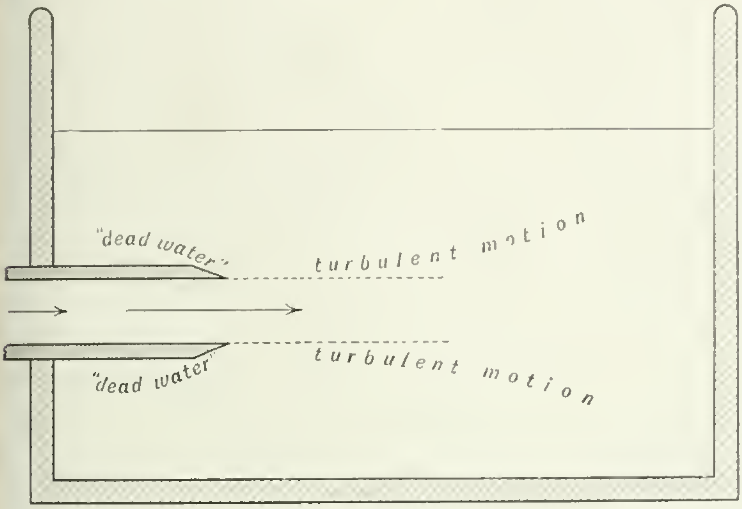

FIG. 2.

§ 26. The accompanying diagrams (2, 3, 4, 5) represent several illustrations of the doctrine of discontinuity in the motion of an inviscid fluid, less attractive to writers on mathematical hydrokinetics than that represented in Fig. 1, (whether as it stands, or varied to suit oblique incidence), because each is instantly soluble without mathematical analysis, and they do not, like it in the two-dimensional case, constitute illustrations of the beautiful mathematical method for finding surfaces of constant fluid velocity in prolongation of given surfaces along which the velocity is not constant, originated by Helmholtz,[1] developed in a mathematically most interesting manner by Kirchoff,[2] and validly applied to the theory of the "vena contracta" by Rayleigh.[3]

§ 27. A cylindric jet (not necessarily of circular cross-section) issuing from a tube with *sharp edge*, into a *very large* volume of fluid of the same density as that of the jet, is represented in Fig. 2. This case was carefully considered by Helmholtz,[4] both for the ideal inviscid incompressible fluid and for real water or real air. He gave good reason for believing that, with real water or real air, and at distances from the mouth as great as several times the diameter of the tube (or the least diameter, if it is not of circular cross section) the surrounding fluid is nearly at rest, and the jet is but little disturbed from the kind of motion it had in passing out of the tube: and therefore that the efflux is nearly the same as, other circumstances the same, it would be if the atmosphere into which the jet is discharged were inertia-less. This conclusion, which is of great importance in practical hydraulics, has been confirmed by careful experiments made eight years ago in the physical laboratory of the University of Glasgow by two young officers of the American Navy, Mr. Capps and the late Mr. Hewes. I believe it has been tested and confirmed by other experimenters.

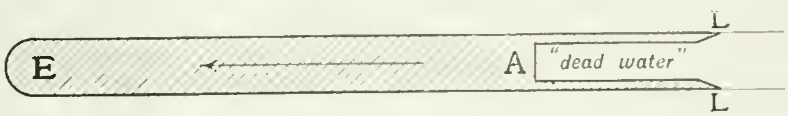

FIG. 3.

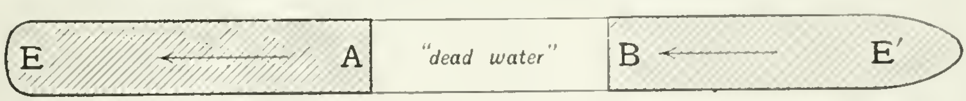

FIG. 4.

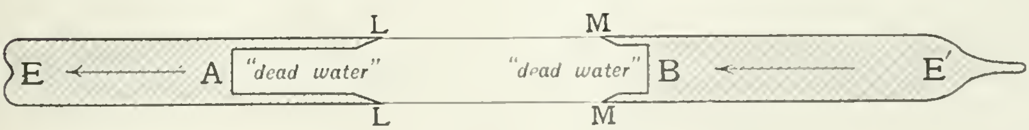

FIG. 5.

§ 28. The very simplest application of the doctrine of discontinuity to the theory of the resistance of fluids to

[1] Continued from page 575.

[1] "Wissenschaftliche Abhandlungen," vol. i. pp. 153-156.
[2] "Vorlesungen über Mathematische Physik," vol. xxi.

[4] "Wiss. Abh.," vol. i. pp. 152-153.

solids moving through them, is represented in Fig. 3, and the result is no resistance at all! Surely this case, requiring no calculation, might have been a warning of the extreme wrongness of the doctrine in connection with resistance of fluids against solids moving through them. The nullity of the resistance in the case represented by Fig. 3 according to the assumption of a wake of "dead water" having the same pressure, Π, as the distant and near water flowing uniformly in parallel lines, follows immediately from an easily proved theorem which I stated in the combined meeting of Sections A and G in Oxford last August, to the effect that the longitudinal component of the pressure on each of the ends, E, E′, in Figs. 3, 4, 5, whatever their shapes, and whether "bow" or "stern" provided only that it ends tangentially in a cylindric "mid-body" long in comparison with the greatest transverse diameter of the solid, is equal to ΠA, where A is the area of the cross-section of the cylindric part of the solid.

§ 29. Figs. 4 and 5 represent two varieties of a case wholly free from the inconceivable endlessness of Fig. 1, and carefully chosen as thoroughly defensible by holders of the doctrine of discontinuity if it has any defensibility at all. I venture to leave it with them for their consideration.

KELVIN.

PARACELSUS.[1]

"THEOPHRASTUS VON HOHENHEIM was adjudged by most eminent physicians to be a man of genius, indeed of superlative genius. . . . By others, who refused to follow him, he was thought to be less deserving than the cooks, the bellows-blowers, and the charcoal-burners." Thus spoke Lukas Gernler, Rector of the University of Basel, in 1660. Haser, in his "History of Medicine," says: "Probably no physician has grasped his life's task with a purer enthusiasm, or devoted himself more faithfully to it, or more fully maintained the moral worthiness of his calling, than did the reformer of Einsiedeln." And of this same reformer, Zimmermann, who was physician to Frederick the Great, wrote: "He lived like a pig, looked like a drover, found his greatest enjoyment in the company of the most dissolute and lowest rabble, and throughout his glorious life he was generally drunk."

As with these, so with others who have tried to form an estimate of the character of Paracelsus. Some praise him inordinately; others as inordinately abuse him. It is only men of power and character who are thus extolled and thus abused. You may neglect an ordinary man; you must either praise much, or anathematise more, a great man.

Even as regards the name of the "reformer of Einsiedeln" there are divergencies of opinion. Kahlbaum, in the pamphlet cited below, says that he never called, or signed, himself by the sounding name that was given him by some of his followers, who thought to awe the common people by styling their master "Philippus Aureolus Theophrastus Paracelsus Bombastus ab Hohenheim." For himself, Theophrast von Hohenheim was sufficient. On one occasion, says Kahlbaum, he used the name Aureolus, to distinguish himself from Theophrastus a disciple of Aristotle. The father of Paracelsus was a natural son of a member of the noble family of the Bombasts of Hohenheim, and he adopted their name as his own. In accordance with a fashion of the times, the name von Hohenheim was paraphrased into the classical tongues. *Paracelsus*, which may perhaps be rendered as "belonging to a lofty place," seems to be a kind of Græco-Latin form of von Hohenheim, the family name of Theophrastus. As von Hohenheim became *Paracelsus*, so Lieber became *Erastus*, and Schütz became *Toxites*; and in modern times the Jewish Neumann emerged from the baptismal font as *Neander*.

Paracelsus was born at Einsiedeln, in the canton of Schwyz, towards the end of the year 1493. He was educated for a time by his father, then by the monks of a convent in the valley of Savon, and then in the University of Basel. After leaving the University, Paracelsus studied under Johannes Trithemius, Abbot of Sponheim, and then under Siegmund Füger, a rich nobleman at Schwaz in the Tyrol. Both Trithemius and Füger were celebrated adepts and students of occultism, and from them Paracelsus may have imbibed the doctrines which he afterwards developed. Paracelsus was a great wanderer: he visited Tubingen, Heidelberg, Ingoldstadt, Vienna, Leipzig, Cologne, Toulouse, Paris, Salerno, and many other towns; he probably also spent some time in the East, and he is said to have received the stone of wisdom from an adept at Constantinople. Wherever he went he always eagerly sought fresh knowledge.

In 1527 he delivered lectures in the University of Basel, with the sanction of the Rector. Paracelsus attempted to institute a method of testing the apothecaries of the town as to their knowledge of the business of making drugs and determining the purity of the materials they dispensed. He spoke scornfully of the decoctions, tinctures, extracts, and syrups that the apothecaries delighted to prepare, calling them all "soup-messes" (*Suppenwust*). Of course the dealers in decoctions were up in arms against the man who attacked their trade. Paracelsus also roused the physicians. He taught that they should go to nature, and not to books, for their knowledge; he rebelled against the doctrine that was then held by almost every medical man, "the truth is to be found only in the ancients." He boasted that for ten years he had not opened a single book written by a follower of Galen, and he spoke of the Galenists as men who tried to hide their folly under red cloaks; and, worst of all, he delivered his lectures in German. The physicians and apothecaries of Basel could not stand these things. Paracelsus was abused not only publicly, but also in anonymous pamphlets; it is said that one of these productions was found on a Sunday morning affixed to the door of the Minster, with the superscription, "The Shade of Galen to Theophrastus, better called Kakophrastus." Of the attacks made on him Paracelsus exclaimed, "These vile ribaldries would raise the ire of a turtle-dove." Matters came to a head when a Canon of St. Clara, who had been cured by three laudanum pills, refused to pay Paracelsus the 100 florins he had promised, and sent six florins instead. Paracelsus sued the Canon for the money, but the court dismissed his suit. In his indignation Paracelsus seems to have put himself into the wrong; hearing that the magistrates had resolved to arrest him, on the advice of his friends he fled from Basel in 1528. After wandering about over a great part of Europe, Paracelsus found a resting-place at Salzburg, under the protection of the Archbishop Ernest. But he did not live long to enjoy the repose that had come at last. He died on September 24, 1541, after a short illness, in his forty-eighth year.

It is not possible to form a just estimate either of the character or the work of Paracelsus. The evidence is not sufficient, nor sufficiently trustworthy. Nevertheless we can draw some kind of picture of the man, and we are able to trace, in a hesitating way, the effects of his labours and his teaching on the progress of science. The pamphlet by Kahlbaum is concerned with dates, and the outward paraphernalia of the life of Theophrastus. Kopp gives a short account of the work of Paracelsus in

[1] "Theophrastus Paracelsus, ein Vortrag gehalten zu Ehren Theo[illegible] am 17 December [illegible] im Bernoullianum zu Basel." [illegible] 72 pp. [illegible]

chemistry, pharmacy, and medical chemistry. The essential doctrines inculcated by the cosmogonist of Hohenheim are put into the language of modern mysticism by Hartmann, in his "Life of Philippus Theophrastus, Bombast of Hohenheim, known by the name of Paracelsus; and the substance of his teachings," published in 1887. A collection of the works of Paracelsus was made by Dr. E. Schubert; that author, and also Dr. Karl Sudhoff, have thrown much light on the history of Paracelsus. A pamphlet entitled "Theophrastus Paracelsus, Eine Kritische Studie," was published by F. Mook in 1876; and a criticism of this critique, by Prof. Ferguson, of Glasgow University, appeared in 1877 with the title "Bibliographia Paracelsica."

The difficulty of estimating justly the influence of Theophrastus von Hohenheim on his age is enhanced by the fact that the greater part of the writings that go under his name was compiled after his death by his followers, from fragmentary manuscripts left by their master. Hartmann gives a list of the works attributed to Paracelsus in the edition published by Huser, at the request of the Prince Archbishop of Cologne, in the years 1589–90. The list contains the names of fifty works on medicine, seven on alchemy, nine on natural history and philosophy, twenty-six on magic, and fourteen on various other subjects. In 1893, Prof. Ferguson printed (privately) a very complete annotated catalogue of the different editions of the works of Paracelsus.

The preparation of an inflammable gas by the action of oil of vitriol on iron filings is usually attributed to Paracelsus. He also examined the differences between metals and substances that are like metals, and he asserted ductility to be the characteristic property of all true metals. The differences between the vitriols and the alums were referred by Paracelsus to the presence in the former of metals, and in the latter of earths. He introduced into medicine many new and potent drugs, notably laudanum; and he constantly sought to determine the medicinal effects of the chemical substances that he worked with. Paracelsus was the first to make medicinal use of preparations of mercury, lead, and iron. He held that substances that were poisonous when administered in quantity might have healing properties when given in smaller doses and under proper conditions. In his endeavour to obtain definite substances, freed from admixture with extraneous and unnecessary, or perhaps hurtful, materials, he made tinctures and essences of various plants, and used these in place of the sweetened decoctions of the entire plants that were generally employed at that time. Paracelsus asserted that the aim of chemistry should be not to make gold, but to produce healing medicines. Medicine was for him a branch of chemistry. He insisted that apothecaries ought to be acquainted with the chemical characters of the drugs they compounded, and that only by a knowledge of chemical reactions could the physician restore to the perturbed bodies of his patients that chemical equilibrium which is health.

It is evident that a man who held and practised such views as these could not pay much respect to the physicians of his own time, whose highest ideal was to do what Galen had done, and to administer this or that drug because Avicenna laid it down, on such or such a page, that the drug ought to be administered. What the authorities of the schools were to his contemporaries, nature was to Paracelsus: the supreme court of appeal. Surrounded by prejudices, separated from nature by the thick veils that mediæval philosophy had drawn over men's eyes, bound by the formulas of his age—as we are bound by those of our age—Paracelsus nevertheless knew that the sun was shining on the other side of the mist, and that could he and others break through they would find the light. We can surely sympathise with his struggle. We may perhaps even recognise the essential rightness of the daring claim of the man who felt that the vision of nature could alone give understanding:—"After me, you, Avicenna, Galen, Rhasis, Montagnana, and the others. You after me, not I after you. You of Paris, you of Montpellier, you of Swabia, of Meissen, and Vienna; you who come from the countries along the Danube and the Rhine; and you, too, from the islands of the Ocean. Follow me. It is not for me to follow you, for mine is the monarchy.'

But while we admire the audacity of the man, and even admit the force of his claim, we know that one who attacked the citadel of nature in this mood would dash himself to pieces before the outworks were carried. Yet he might make a breach through which a way for others should lie open. And Paracelsus succeeded in this; we are entering nature's strongholds by some of the ways he helped to open. With few appliances, with no accurate knowledge, with no help from the work of others, without polished and sharpened weapons, and without the skill that comes from long handling instruments of precision, what could Paracelsus effect in his struggle to wrest her secrets from nature? Of necessity, he grew weary of the task, and tried to construct a universe which should be simpler than that most complex order which refused to yield to his analysis.

The struggle is so arduous, nature is so infinitely complex, men are so easily led astray, that the giants alone keep to the quest, and they only go always forward to the goal. The syren-songs of the miracle-men are very soothing, and few escape. It is so pleasant to lie still and dream; it is so hard to get up and act. In the time of Paracelsus the air was filled with the soporific murmurings of industrious human bees. They were all busy secreting the wax of philosophising, that with it they might construct symmetric cells to be filled with the syrup of their own wisdom. Paracelsus, too, was obliged to become a wax-gatherer and a universe-maker. And a very remarkable universe he produced. The facts of nature that he sought were found so slowly that, in his impatience, he supposed the aim of science was to produce a completed scheme of things; and such a scheme he set himself to construct.

It would be out of place here to attempt more than the briefest sketch of the outlines of the Paracelsian conception of the order of nature. Paracelsus was essentially of the order of mystics. He would have adopted with enthusiasm the words of Blake: "I assert for myself that I do not behold the outward creation, and that to me it is a hindrance, and not action. 'What,' it will be exclaimed, 'when the sun rises do you not see a round disc of fire somewhat like a guinea?' Oh, no! no! I see an innumerable company of the heavenly host crying 'Holy, holy, holy, is the Lord God Almighty. I question not my corporeal eye any more than I would question a window concerning a sight. I look through it, and not with it." Paracelsus insisted on the unity of all things; he taught that in everything in nature there is an inner and essential principle, which is itself a part of the universal life. There was for him an absolute and attainable knowledge; and although he admitted that much is to be learned from external nature, he taught that this real knowledge must be discovered by each man in himself. "Each man has . . . all the wisdom and power of the world in himself; he possesses one kind of knowledge as much as another, and he who does not find that which is in him cannot truly say that he does not possess it, but only that he was not capable of successfully seeking for it." Chemistry was regarded by Paracelsus as a spiritual art; an art that deals with the spiritual principles of things. Everything in nature was thought of by him as having a threefold character.

as consisting of "a body and a soul held together by the spirit, which is the cause and the law." "To grasp the invisible elements, to attract them by their material correspondences, to control, purify, and transform them by the living power of the spirit—this is true alchemy." The pure, invisible, intangible, universal elements constituted the highest of the three orders of things; the second order was composed of "elements that are compounded, changeable, and impure, yet may by art be reduced to their pure simplicity"; and the third order contained the "twice compounded elements" which served as vehicles for drawing down the pure ethereal elements and fixing them in the substances of the second order. The laboratory was the place for learning the properties of the things of the second order; "for from these proceed the bindings, loosings, and transmutations of all things." Paracelsus speaks of the three substances of which all things are composed; these three things are "sulphur, mercury, and salt"; but he adds, "they are acted on by a fourth principle which is life." "These three substances," he says, "are not seen with the physical eye. . . . If you take the three invisible substances, and add the power of life, you will have three invisible substances in a visible form. . . . They are hidden by life, and joined together by life. . . . All things are hidden in them in the same sense that a pear is hidden in a pear tree and grapes in a vine. . . . A gardener knows that a vine will produce no pears, and a pear-tree no grapes"

I think it is possible from these extracts to construct, in a general way, the non-natural scheme of nature that was upheld by Paracelsus. A great deal may be said in its favour, if only we agree to construct the nature that is to be explained from our own consciousness with closed eyes. This certainly may be asserted in favour of the so-called spiritual science of Paracelsus and the mystics of his school, that their method is infinitely easier than the method of natural science, or, as it is called by the modern Paracelsians, materialistic and sceptical science. Whatever judgment may be passed on natural science when it is contrasted with supernatural mysticism, it is at any rate ludicrously erroneous to say that the former is proud, dogmatic, and conceited, while the latter is humble, suggestive, and ready to learn. The answer to the conception of the universe that Paracelsus framed is to be found in the history of science, and in the history of humanity, since the Middle Ages.

But however radically a modern naturalist may differ from the mediæval alchemist, he must recognise the great debt which those who to-day seek the knowledge of natural laws owe to the man of the sixteenth century who boldly declared against authority, and besought his followers to go to nature, who insisted on the interdependence of the various branches of natural knowledge, who taught the essential unity of the forms of matter and of the forms of energy, and who, by his discoveries in medicine, helped forward the blessed work of alleviating the miseries and soothing the sorrows of human beings. Whatever else he was, Paracelsus was certainly a true man; he lived earnestly; he was not regardful of the conventionalities of life; he received blows, and he returned them; he suffered much, and he bore his troubles on the whole with patience and some nobility. With his own words we may leave him:—"Have no care of my misery reader; let me bear my burden myself. I have two failings: my poverty, and my piety. My poverty was thrown in my face by a Burgomaster who had perhaps only seen Doctors attired in silken robes, never basking in tattered rags in the sunshine. So it was decreed that I was not a Doctor. For my piety I am arraigned by the parsons, for I am no devotee of Venus, nor do I at all love those who teach what they do not themselves practise."

M. M. Pattison Muir.

ON HOLLOW PYRAMIDAL ICE CRYSTALS.[1]

I. *The Lava Cavern of Surtshellir.*—The lava cavern of Surtshellir forms a long subterranean channel—over a mile in length—in the post-glacial lava-field which encompasses in a vast semicircle the ice-covered Eyríksjökull (Iceland). The farthest recess forms a chamber about 30 feet high, and from its floor and ceiling spring ice-stalagmites and stalactites of rare beauty. (Fig. 1.)

The north-western wall is gracefully draped by a long curtain of icicles resembling somewhat the pipes of an organ. From those parts of the vault not covered by icicles a thousand glitterings and sparklings are seen, at every movement of the candle, to be reflected from ice crystals which stud the walls.

The ice crystals have the form of hexagonal funnels, or hollow hexagonal pyramids. In size they range up to two inches long, with a hexagon side of half an inch. The triangular sides of the pyramids are built of most delicate steps of ice, arranged in the manner of a staircase.

The attachment is invariably by the apex, and the hexagonal bases turn trumpet-like towards the interior of the cave. (Fig. 2.) When these observations were made in June 1892, the temperature of the air in the cave was $+0.5^{\circ}$ C.

There are some minute cracks in the roof of the cave, through which water trickles scantily. At such places *icicles* are formed, but not crystals. The crystals are not formed from the water percolating into the cave, but from the moisture contained in the air, and as such they must be regarded as a kind of *hoar-frost*.

II. *Hoar-frost.*—During Christmas week 1892 an unusually fine hoar-frost prevailed over the North of England. In various parts of Yorkshire, Lancashire, and Cheshire, we found the rime to consist almost entirely of hexagonal "hopper" crystals. (Fig. 3, *a*, *b*, *c*.) The basal hexagons varied up to about ⅜ inch in diameter, and the majority of the crystals measured in height about twice the diameter. (Fig. 3, *a*.) Some, however, were more obtuse. (Fig. 3, *b*.) The forms were often obliquely truncated (Fig. 3, *c*), certain faces having grown more rapidly than others. A spiral arrangement was noticed in some cases, and occasionally a double spiral resembling the helix of an Ionic capital. (Fig. 3, *d*.)

There was a marked tendency for the simple pyramids to group themselves into compound forms. (Fig. 3, *e*, *f*.) The groups exhibited hexagonal outlines (Fig. 3, *f*), and the primary pyramids on the periphery were, as a rule, better developed than those in the interior. The secondary hexagons often measured more than 1½ inches in diameter. Even a tertiary grouping could be made out in a few cases. In a few rare instances the primary hexagons were studded at the corners with small hexagons resembling bastions. These bastions were either solid or hollow. (Fig. 3, *g*.)

III. *Crystals under Ice-Crusts.*—On January 3, 1894, we found in Cheshire, during a severe frost, similar hexagonal hoppers on the under-surfaces of ice-crusts covering hollow spaces over ruts in clayey soil, or covering ponds where an air-space divided the ice from the water. No ice crystals were found on the sides and bottom of the ruts, and there was no trace of *hoar-frost* on adjacent objects.

These observations suggested the idea that *hoar-frost might be made at will* on any cold night. We accordingly spread pieces of black cardboard and black velvet over grass, and on examining these after two days of hard frost we found the *under*-surfaces coated with an abundance of hollow pyramidal and other forms of ice

[1] From a paper read before the Royal Society, by Dr. Karl Grossmann and Joseph Lomas.

crystals. No hoar-frost formed on the upper surfaces of the velvet or cardboard, and none existed on the grass.

IV. *Artificial Hoar-frost.*—Experiments had been planned before Christmas 1892, for the artificial production of hoar frost It was thought advisable, before completing our arrangements, to search for any possible traces of hoar-frost in the refrigerating chambers used for the frozen-meat trade in Liverpool. This visit rendered experiments unnecessary, as it yielded a rich harvest of simple and compound forms of hollow pyramidal crystals. All the variations observed in natural hoar-frost were met with, and the details of the forms were registered by microphotographs taken with magnesium light The ice chambers were cooled down to -13° C.[1]

Very large and beautiful simple hoppers were obtained from ships used in the frozen-meat trade. During the four to six weeks of transit from the River Plate to Liverpool the hold is cooled down to about -5° C., and the enclosed air is perfectly calm.

On the occasion of a visit to Berlin, in June 1893, the large cooling cellars connected with the "Muenchener Brauhaus" were examined (by kind permission of Director Arndt), and small hopper crystals were discovered on the cooling pipes.

V. *Comparison with other Skeleton Crystals.*—The simple hollow hexagonal pyramids of ice naturally suggest comparison with the well-known cubic "hopper" crystals of rock salt and skeleton crystals of other substances.

In crystal-building there is always a marked tendency towards excessive growth along the diagonal axes of the crystal. At the angles of crystals there is, for a given area, a larger supply of material for growth than in the middle of a side. Beautiful skeleton crystals of potassium chloride can be formed by rapidly cooling concentrated warm solutions. First, a great number of micro-crystals are formed, which float about in the brine. Any of these may form a centre of attraction round which crystalline matter will aggregate. A small cube will form the centre, and from each solid angle a straight axial row of small cubes will arise.[1] The intervening parts will gradually get filled up if sufficient time is allowed.

This type of skeleton crystal is evidently due to *overgrowth.*

Quite differently formed, though with the same result, are the hopper crystals of sodium chloride. NaCl is almost equally soluble in cold and hot water. Unaffected by cooling, it will therefore crystallise out of brine most rapidly where the concentration becomes greatest through evaporation, viz. at the surface. Suppose, then, a single cube to be formed at the surface. Beginning to sink, there will be deposits of fresh cubes on the four upper edges of the cube in the form of a step. This goes on until we have a floating hollow pyramid, apex downwards. At the corners of these hoppers additional cubes are formed. (Compare the analogy with the hexagonal form, Fig. 3, *g.*) These skeleton crystals are due to *growth at the upper edges of floating crystals.*

A third type of hollow skeleton crystals we have in hoar-frost.

When crystallisation of atmospheric vapour takes place in absolute freedom, we find the crystals mainly

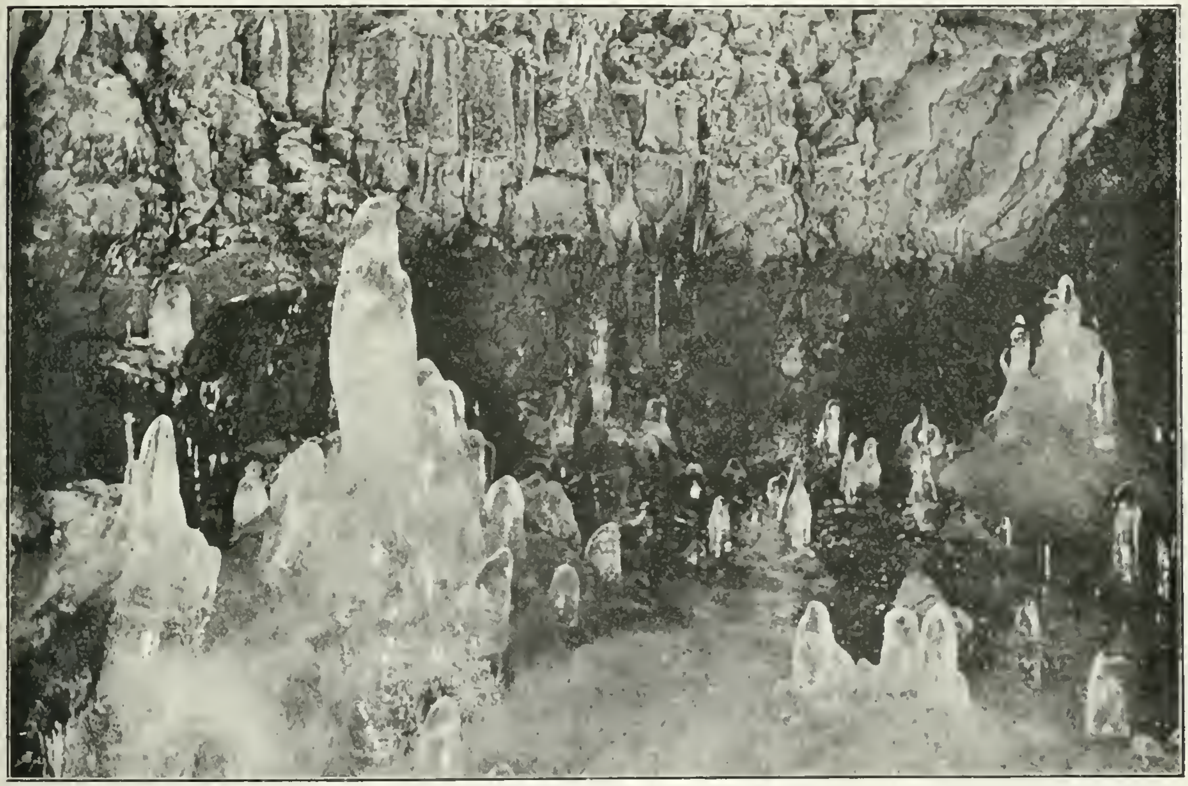

FIG. 1.—Ice Stalagmites in the Lava Cavern of Surtshellir (Iceland).

[1] Our thanks are due to Mr. Ward for permission to work in the chambers of the Sausineoa Company, and to Mr. Lintott, through whose help we were enabled to exhibit some of the ice crystals at the soirée of the Royal Society.

[1] See A. Knop. "Molekularconstitution und Wachsthum der Krystalle," p. 52. (Leipzig: 1867.)

developed in a plane perpendicular to the principal axis, as *flat* snow crystals. When, however, the atmospheric space is limited by a wall, first a small hexagonal disc of ice attaches itself to that wall. Then, as growth proceeds, in a calm or comparatively calm medium, the middle portion of the disc will be in contact with air

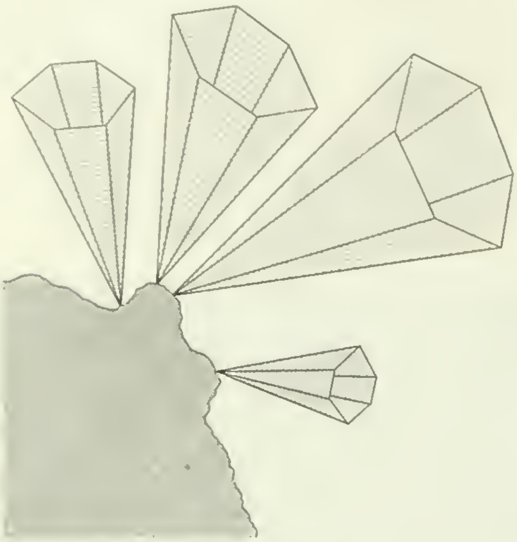

FIG. 2.—Hollow Hexagonal "Hopper" Crystals of Ice found in Surtshellir. (Natural size.)

robbed of its moisture, while the edges will grow outwards, the rate depending on the amount of food material. The open ends of the funnels will point towards the middle of the wall-bound air-chamber or cavern, or away from the wall; in the case of hoar-frost the funnels will be open towards the sky.

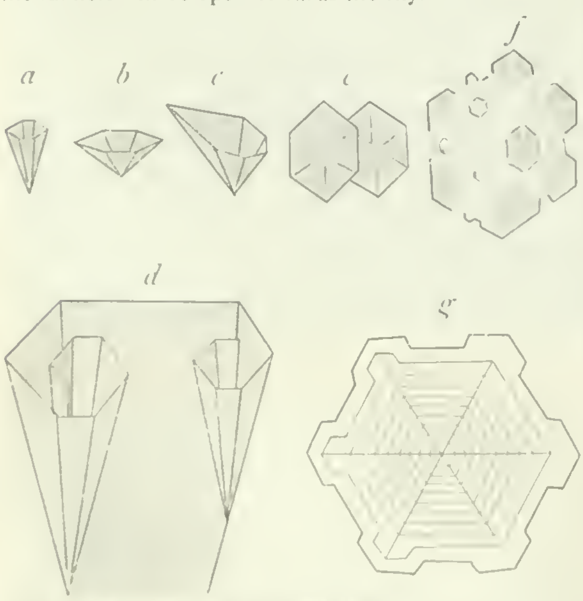

FIG. 3.—Natural Hoar-frost (Christmas [illegible]). (*a* and *f* natural size; *b*, *c*, *d*, *e* and *g* enlarged.)

This type of skeleton crystal may be termed *starvation crystal*.

By reflections from the steps seen on the triangular faces of the pyramids, we were able to show that they consist of combinations of faces of the hexagonal prism (∞ P) and the basal pinacoid (OP).

VI. *Literature.*—In 1697, Camerarius of Tübingen ("De figura nivis et pruinæ." *Misc. ac. natur.* Jenæ, Dec. 1697, p. 480) describes some hoar-frost on the lead bindings of windows as hexagonal discs, some of which had a central depression.

Dr. J. Krenner mentions, in his description of the ice cave of Dobschau ("A Dobsinai Jégbarlang." Budapest, 1874), flat hexagonal ice crystals, some depressed in the middle, or obtusely funnel shaped.

In a paper entitled "Eine Krystallgrotte" (Groth's *Zeitschr. fur Krystallographie*, 1888, xiv. p. 250), C. A. Hering mentions and illustrates fan-shaped ice crystals which probably are identical with those seen by Krenner, except that they are quite flat. On the upper surface of the fans some hexagonal hopper-shaped ice crystals were found.

VII. *Conclusions.*—(1) Water when changing direct from the gaseous into the solid state is highly crystalline.

(2) The tendency to crystallisation is so strong that in those cases where the area of supply is limited by a wall or other surface, skeleton crystals—hexagonal "hoppers"—are formed, growing away from the wall, even under circumstances of excessively slow growth.

(3) Calmness of air seems to be an essential condition for their formation.

(4) From our observations there can be no doubt as to the identity of the ice crystals of Surtshellir, of the refrigerating chambers and ships in Liverpool, and of the cooling cellars of the Berlin breweries, with natural hoar-frost.

THE GLACIAL SYSTEM OF THE ALPS.

ON the day following the close of the Sixth International Geological Congress an excursion, organised and conducted by Profs. Penck of Vienna, Brückner of Berne, and Dr. L. du Pasquier, left Lugano to visit the chief glacial deposits of the Alps. An excellent guide-book of permanent interest, entitled "Le Système Glaciaire des Alpes," had been prepared by the conductors of the excursion.

On the first day (September 17) the party, numbering thirty-five, took train to Sesto Calende, and descending the Ticino in boats, walked over the moraines of Lago Maggiore to Borgo Ticino. An excellent view of the morainic amphitheatre, which forms a loop round the southern end of the lake, and rises to 470 feet above its level, was obtained from the morainic Monte del Bosco. In the evening the party proceeded to Ivrea by rail.

Next day was spent in examining the celebrated moraines of Ivrea, which testify so eloquently to the size of the glacier that descended the valley of Aosta. From the northern morainic ridge (the Serra), which rises to a mean elevation of 1300 feet above the central depression, a good view of the great amphitheatre was obtained. Late at night Milan was reached.

On the 19th train was taken to Lonato at the southern end of the Lake of Garda, whence carriages were taken to Salò, on the western shore of the lake. On the way to Salò, most interesting evidence of three successive glaciations was seen. It is found that the moraines of the last glaciation show only a very thin weathered crust, whereas the moraines of the two previous glaciations are marked by a weathered crust called "ferretto," many feet thick, in which the pebbles, even of granite and gneiss, are so much decomposed as to be readily cut with a knife. The whole weathered crust has assumed a deep red-brown rust colour, whence the Italian name for it.

At Mocasina the unaltered lower part of a moraine of the second glaciation was seen overlying the much-weathered "ferretto" crust of a moraine of the first glaciation. At Benecco the unaltered moraine of the last glaciation overlies the "ferretto" crust of a moraine of the second glaciation. In the evening, Riva, at the head of the Lake of Garda, was reached by steamer.

On the 20th the party took train to Innsbruck. The following day was spent in examining the deposits at Hötting, close by the town.

The breccia of Hötting, considered by Penck a cemented cone of dejection or talus of rock-fragments, contains fossil plants (all but four of existing species). It overlies one moraine and underlies another, and is held to indicate an inter-glacial epoch.

On the 22nd Munich was reached, and some most interesting sections at Höllriegelskreut, seven and a half miles south of the city, were examined. Three successive fluvio-glacial deposits were seen, superposed one upon another, each corresponding to a separate glaciation. Here again the weathered (though not red) crust of the older fluvio-glacial deposits underlies the unaltered lower part of the succeeding deposit. The oldest of the three deposits (viz. the Deckenschotter, *alluvion des plateaux*) consists here almost exclusively of limestone pebbles, which are so solidly cemented together as to form a conglomerate used as a building stone.

The 23rd (last day of the excursion) was rainy, but the morainic amphitheatre of the Isar glacier around the Starnberger (Würm) See, near Munich, was examined as far as the weather would permit, and at the close of the excursion all members joined in an enthusiastic vote of thanks to its most excellent conductors.

B. Hobson.

NOTES.

A few weeks ago the Paris *Figaro* opened a subscription list in order to enable the Pasteur Institute to supply Dr. Roux's anti-diphtheria serum to all medical applicants. The appeal has resulted in a sum equivalent to about £10,000 being raised. It is hoped that institutes in which experienced physicians will administer the cure will soon be established. The Paris Academy of Medicine has reported in favour of Dr. Roux's treatment.

We learn with much regret that Mr. George Knott died at Cuckfield, Hayward's Heath, Sussex, on the 8th inst., at the age of fifty-eight. He was an eminent authority upon double and variable stars, to the observation of which he devoted his astronomical life. So long ago as 1861 he read his first paper before the Royal Astronomical Society, the subject being the variable star R. Valpecula. From that date to April 1892, when he communicated a series of observations of the magnitude of Nova Aurigæ, he contributed no less than twenty-four papers to the Society. In 1877 he completed a valuable series of micrometrical measures of double stars, taken by himself between 1860 and 1873. For many years he was a member of the Council of the Society. He was highly respected by his fellow workers, not only for his astronomical labours, but also for his sterling character. His death will be deeply regretted by all who were acquainted with him.

From a circular bearing the imprint of the University of Minnesota, Minneapolis, we learn that Mr. Clarke Barrows proposes to supply a complete up-to date reference to all zoological literature by means of a card catalogue arranged alphabetically by authors, and supplemented with a subject catalogue. It is proposed to begin the catalogue with the current volumes of the more important periodicals devoting the whole, or a portion, of their space to zoology, to print the new titles as they appear, and take up the back volumes as rapidly as possible. It is hoped that arrangements will soon be made to get the titles of all other important zoological writings, and thus a catalogue of all the zoological literature not recorded in the "Bibliotheca Zoologica" up to 1861 will be produced. Each card will have printed upon it the name of the author of a zoological paper, the full title of the paper, and the name and date of the periodical in which it was published. The cards will be punched so that they can be stacked in drawers with a wire through them. They should be of great assistance to curators of zoological libraries.

The Sunday Lecture Society will commence a new series of lectures next Sunday afternoon, at St. George's Hall, Langham Place, when Sir B. W. Richardson, F.R.S., will discourse on "Muscle and Athletic Skill."

The steam yacht *Windward*, with Mr. Jackson's party on board, which left Archangel on August 5, is reported by the captain of a Norwegian walrus-hunting vessel, but the news is vague, being without exact dates, and the ship does not appear to have been "spoken." She was first seen about the middle of August off Matochkin Schar, the strait separating the two islands of Nova Zembla, where the ice was very heavy; and again about the end of August in lat. 75° 45′ N., and long. 44° E., steaming up a clear lead through rotten ice in the direction of Franz Josef Land.

Mr. A. Trevor-Battye and Mr. Hyland landed on the island of Kolguef, south-west of Nova Zembla, at the end of last June, with the special object of studying the ornithology of the island. His companion, Mr. Powis, returned for him in the steam-yacht *Saxon* on August 6, but not finding him at the landing place considered further search unnecessary and returned. Another Arctic steam-yacht made a remarkably cautious attempt to reach the island at a later date, but returned unsuccessfully, and Mr. Trevor-Battye has been left behind to face the Arctic winter without an adequate outfit. It is probable that when the winter ice unites the island to the continent, he will be able to cross to the mainland, a distance of less than sixty miles, and thence travel overland to St. Petersburg by sledge. It is to be hoped that he will be able to bring back his collections, which should be of considerable scientific value. A rescue expedition is proposed by Captain Battye-Trevor, but it is doubtful whether it can be carried out by sea at this advanced date. There seems no reason for anxiety, as game is usually plentiful on Kolguef, and there are habitable houses used temporarily in summer by Russians and Samoyedes.

We have received a letter, written by Lieut. Peary to the President of the American Academy of Natural Sciences, which contains more detailed accounts of his expedition last season. When on the ice-cap in the spring of 1894, the average air-temperature experienced for forty-eight days was -31.5 F., and the average wind velocity for forty-three days 15·9 miles an hour. During the worst weather there were thirty-four hours with an average temperature of $-50°$ F. and a minimum of $-62°$, the average wind velocity being 48·1 miles per hour. The experience has convinced Mr. Peary that the human frame can stand any degree of natural cold without permanent injury. He intends to spend the coming winter in studying the Eskimo dog, and devising means to keep this invaluable animal alive and in health during extreme cold. There has evidently been some friction amongst the members of the exploring party, most of whom seem to have had enough of Arctic hardships, as the leader refers to the two men who remain with him as those who "decline to desert." The letter concludes: "You may rest assured that I shall not return until I have done everything that is possible for one who believes in ultimate success, and whose every fibre is in sympathy with and straining for the desired end."

We are always glad to welcome any journal having for its object the extension of scientific knowledge; hence we note with pleasure the publication of the first number of the *Agricultural Journal of the Leeward Islands*, edited by Mr. C. A. Barber, the Superintendent of Agriculture at St. John's, Antigua, West Indies. The journal will ensure the rapid and wide publication of the results of investigations of interest to West Indian planters. It will be the medium through which the work carried on in the Government laboratories, and in experimental and botanical stations of the West Indies, will be made public. But besides being the organ of the scientific officers of the Government, the journal will contain reports of the proceedings of the agricultural societies in the colony, and facts of interest connected with the agriculture, natural history, and meteorology of the different islands will be recorded. To the number before us, the editor contributes some notes on the nature of the irritating ticks from which the cattle of the West Indies suffer. The journal also includes an article on the planting of eucalyptus trees; one on hurricanes, by Mr. F. Watts; and a third, on coffee planting in the Leeward Islands. The editor hopes to keep the journal scientific throughout, although it must be made eminently practical. We hope and believe that this addition to periodical literature will take a permanent stand among the scientific journals of the tropics.

The current number of the *Comptes-rendus* contains a paper by M. R. Blondlot, on the propagation of electromagnetic waves in ice, and on the specific inductive capacity of this material. In a previous communication the author had shown that for turpentine and castor-oil the wave-length of the radiation given out by an oscillator, in these substances, is the same as in air; and enunciated the general law that the wave-length depends only on the dimension of the oscillator, and not on the medium in which the oscillator is plunged. There was, however, considerable doubt whether this law would be found to hold in the case of ice, for M. Bouty had found that the specific inductive capacity of ice was 78, that is enormously greater than in the case of any other dielectric. The apparatus employed consisted of two copper wires stretched horizontally and parallel at a distance apart of 80 cm. A resonator made of gilt copper, the same as that employed in the previous experiments on liquids (*Comptes-rendus*, July 25, 1892), was placed between these wires; the portion of the wires beyond the resonator pass through a wooden trough four metres long. This trough being empty, a bridge is moved along the wires beyond the resonator till the sparks disappear, the distance between the bridge and the resonator then being equal to the quarter wave-length of the resonator. The resonator is then surrounded with a water-tight bag filled with freshly-boiled distilled water, which is then frozen. The quarter wave-length is now found to be greater than before, in the ratio of 141 to 100 The trough is then filled with water which is frozen, and by breaking away the ice the place at which the bridge has to be placed in order to stop the sparking found. The wave-length under these conditions is exactly equal to that obtained when the resonator and wire are surrounded by air. The experiment was repeated four times, using resonators of different capacity, and in every case gave the same result. The results obtained can be utilised for calculating K the specific inductive capacity of ice, and give for K the value 2, which value the author considers correct to within about $\frac{1}{5}$. M. Blondlot having mentioned the above result to M. Perot, who, working by means of electric oscillations, had found a very high value for K in the case of ice, the latter examined his results, and found that he had made an error in the formula he employed. Having applied this correction to his results, he now obtains the value 2·04 for the specific inductive capacity of ice.

A recent number of the *Atti della Reale Accademia dei Lincei* contains a paper, by M. Ascoli and F. Lori, on the radial distribution of the induced magnetism in an iron cylinder. The authors have investigated this question experimentally, using cylinders of different lengths in magnetic fields of varying strength. The cylinders employed were composed of 127 iron wires, each of 0·095 cm. in diameter. These wires were regularly arranged round a central wire in layers containing 6, 12, 18, 24, 30, and 36 wires respectively. Between each of the layers was wound a coil of fifty turns of fine insulated copper wire. By means of a series of mercury cups either of these six coils could be connected to a ballistic galvanometer. The authors find that for long cylinders (50 cm.) the distribution is practically uniform, while in the case of shorter cylinders there is an increase in the induction as you pass from the axis to the circumference. This increase is particularly noticeable in the case of short cylinders (5 to 10 cm.), and is greater in the case of strong than of weak inducing fields.

In the *Journal* of the Scottish Meteorological Society (No. x. third series), Dr. Buchan has published a very valuable discussion of the mean monthly and annual rainfall of Scotland for the twenty-five years 1866 to 1890. He points out that of all the climatological elements, rainfall calls for the greatest number of years' observations in obtaining fairly approximate averages. The period of twenty-five years now dealt with, for a large number of stations, and for the same years, may well be accepted as a sound basis for discussion. In addition to the tables, and a discussion of the principal features of each month, the depth of rain for each month and for the year is shown on coloured maps. The part of Scotland where the rainfall is smallest is the low-lying district round the Moray Firth, where the annual amount varies from 23 to 26 inches, the absolutely dryest place being Nairn. Three parts of Scotland have an annual rainfall of upwards of 80 inches, viz. the south-western half of Skye, the highest mean annual fall being 92 inches, at Sligachan. To the west of the Caledonian Canal, in the central parts of Ross-shire and Inverness-shire and the north of Argyll, the average at some stations exceeds 100 inches; and to the south-east of the canal the averages are still larger, amounting to over 127 inches in Glencoe. The work will be referred to as the standard authority on the rainfall of Scotland, and when the publication of similar returns for the United Kingdom, now being prepared by the Meteorological Council, is complete, the distribution of the rainfall of these islands will be fairly accurately determined.

At a recent meeting of the Berlin Physical Society, Herr E. Pringsheim exhibited some examples of the application of photography to the deciphering of "palimpsest" manuscripts. A manuscript contained in the Royal Library at Berlin, on which the process was tested, showed the second writing intensely black, while the older writing, washed off as much as possible to make way for the new, was larger, and showed a yellow tint. The problem was to bring out in a photograph the feeble yellow writing without the later black manuscript, and this was accomplished as follows. A negative was first obtained through a yellow screen, using a long exposure and a flat development. This showed the older writing only very feebly, and the later very well. Another negative was taken with an ordinary bromide plate, was developed into a hard image, and used to obtain a diapositive. This transparency showed both writings with approximately equal intensity. The transparency was then placed upon the first negative so tha the two images coincided. In this case the background was dark in one case and light in the other, as was also the later manuscript. The latter therefore was imperceptible. But the older manuscript was dark in both cases, so that it appeared alone in the combination as an intensely black writing on a shaded ground. The greatest difficulty met with was that of obtaining two perfectly congruent negatives. An apparatus suitable for this purpose, in which the object and the camera were fixed in a definite position in an iron stand, was provided by Herr H. C. Vogel at the Potsdam Astrophysical Laboratory. But perfect coincidence was only obtained on taking the second negative through a glass plate of the same thickness as the yellow glass used for the first.

THE calendar of the University College, Nottingham, for the fourteenth session, 1894-95, has been published; and also the calendar of the University College of North Wales.

PART iii. of vol. vii. of the *Proceedings* of the Bristol Naturalists' Society has just been issued. It contains some of the papers read before the Society during the session 1893-94, and a portrait and short biographical notice of Dr. John Beddoe, F.R.S.

PROF. FRANK CLOWES and Mr. J. Bernard Coleman, of University College, Nottingham, have written a new work on "Elementary Qualitative Analysis," specially for the use of beginners. The book will be published by Messrs. Churchill, early in December.

MESSRS. LONGMANS AND CO. have just published "A Shilling Arithmetic," by J. Hamblin Smith, which is suitable as an introduction to the same author's "Treatise on Arithmetic." The book contains short explanations of arithmetical processes and a large number of simple examples.

MESSRS. MACMILLAN have in preparation a "Popular History of Celestial Photography," by Mr. R. A. Gregory and Mr. Albert Taylor. The book will be divided into twelve sections, each of which will trace the development of the application of photography to a particular branch of astronomical inquiry.

THE *Electrician* Printing and Publishing Co. has lately published the substance of the lecture on "The Work of Hertz," delivered by Prof. Oliver Lodge at the Royal Institution on June 1, and fully reported in these columns on June 7. Twenty-three illustrations have been introduced into the text, and abstracts of the work of some of Hertz's successors are given in appendices.

A MONOGRAPH of the land and freshwater mollusca of the British Isles, by Mr. J. W. Taylor, is in the press, and will shortly be issued. There will be two volumes, the first of which will be devoted to a general treatment of the subject, and the second to the treatment of species individually. Intending subscribers should communicate with Messrs. Taylor Bros., Sovereign Street, Leeds.

THE physical properties of soils are very inadequately described in most text-books. With a view of enabling teachers of agricultural classes to do fuller justice to this part of their subject, Prof. R. Warington, F.R.S., has drawn up a few "Brief Notes on the Physical and Chemical Properties of Soils" (Chapman and Hall). The notes will doubtless prove of great assistance to the science teachers for whom they are intended.

MESSRS. GEORGE NEWNES (Limited) announce that they propose to issue a series of little books dealing with various branches of scientific knowledge, and treating each subject in clear concise language, as free as possible from technical words and phrases. The following three volumes will be issued immediately: "The Story of the Stars," by Mr. G. F. Chambers; "The Story of the Earth," by Prof. H. G. Seeley, F.R.S.; "The Story of Primitive Man," by Mr. Edward Clodd.

STUDENTS of human anatomy should find Mr. Gordon Brodie's "Dissections Illustrated," the third part of which has just been published by Messrs. Whittaker and Co., an invaluable handbook. The dissections illustrated and described in the new part refer to the head, neck, and thorax. There are twenty remarkably fine coloured plates, drawn and lithographed by Mr. Percy Highley, and eight diagrams. The plates are drawn so clearly, and they are so large (five are full size and the rest two-thirds natural size), that the muscles, vessels, and nerves of each dissection can be found without any difficulty.

SHORTLY before the fifth international congress of geologists, a "Geological Guide-book for an Excursion to the Rocky Mountains" was prepared by a number of geologists familiar with the different parts of the region visited, and was edited by Mr. S. F. Emmons. This book has been extracted from the *Compte rendu* of the congress, and is now published separately by Messrs. Kegan Paul, Trench, Trübner, and Co. A number of illustrations have been added to the original, and also many bibliographical references. The result is a capital account of the chief points in the geology of one of the most interesting regions of the world.

A REPORT on meteorological observations in British East Africa for 1893, by Mr. E. G. Ravenstein, has been received. The meteorological records, of which a summary is presented in the report, refer to seven stations on or near the coast, and two in the interior. At all these stations the temperature, rainfall, and other climatological factors have been recorded, and in the case of five of them the records embrace at least one year. Observations of the rainfall only have been recorded at four other stations. Mr. Ravenstein recognises that the observations are as yet far too scanty and imperfect to enable the true means of the temperature, rainfall, and humidity to be deduced.

DR. HARRISON ALLEN has revised and brought up to date his valuable "Monograph of the Bats of North America." The original work was issued nearly thirty years ago by the Smithsonian Institution, and has remained the only work on the subject. The progress made in systematic zoology since that time, however, rendered it desirable to prepare a new edition. The monograph just distributed by the Institution is essentially new. Dr. Allen has added to the species, elaborated the descriptions, and introduced several novel features. These changes have increased the usefulness of a very important work, and they will be welcomed by students of what is recognised to be a difficult group of animals.

MR. GISBERT KAPP has revised and largely rewritten his work on the "Electric Transmission of Energy" (Whittaker and Co.), the fourth edition of which was published last week. Changes were rendered necessary on account of the enormous developments which have taken place in every branch of electric power transmission since the third edition was published. The author has omitted a large amount of the descriptive matter, and has given a greater amount of space to the theoretical part of his subject. Among the omissions are "the historical account of power transmission, detailed descriptions of plants, comparison of electric with other systems of transmission, underground cables, electric tramways, and telpher lines." Altogether the book, as at present constituted, is more scientific, and less a trade catalogue than formerly.

MESSRS. J. J. GRIFFIN AND SONS have recently published the third edition of their illustrated and descriptive catalogue of chemical apparatus. A few of the new instruments are worthy of notice. For instance, a new pattern of Tate's air-pump, described in the catalogue, has been designed with valves at each end of the barrel so that no air can exist between them and the pistons, hence, at each stroke, all the air contained in the barrel is expelled. Metallurgists will be interested in a new form of gas furnace capable of carrying on operations at a white heat without the aid of a blower; the power of the furnace may be judged from the fact that one pound of cast iron can be melted in thirty-five minutes. A cathetometer which enables the operator to turn the telescope in any direction without moving the instrument bodily, is another noteworthy feature. Arnold and Hardy's apparatus for the estimation of sulphur in steel and steel-making iron; benzoline blast furnaces attaining a temperature of 2100° F.; Prof. Roberts-Austen's electrical pyrometer; and many other pieces of apparatus, for use in teaching and research, have been introduced into the catalogue.

A CONSIDERABLE addition to our knowledge of the chemical history of hydrazine or diamide and its derivatives is contributed by Prof. Curtius, its discoverer, and his assistants, to the current issue of the *Journal für praktische Chemie*. An interesting account is given of the position of diamide as a salt-forming base, and its relations in this respect to ammonia and the fixed alkalies. Diamide itself, $\begin{matrix} NH_2 \\ | \\ NH_2 \end{matrix}$, is an extremely unstable substance, so much so that it is still doubtful whether the anhydrous gas has yet been obtained, or is even capable of separate existence. On the other hand, the liquid hydrate, $N_2H_4.H_2O$, is a very stable substance, as Prof. Curtius has long ago shown. It is interesting to note that this is the opposite of what is the case with ammonia, where the gas itself is stable and the hydrate particularly unstable. Moreover, while ammonia is a mon-acid base, diamide is di-acid; and just as we accept the idea of a hypothetical ammonium radicle NH_4, so we are bound likewise to admit the conception of a divalent radicle $\begin{matrix} NH_3 \\ | \\ NH_3 \end{matrix}$, which Prof. Curtius terms diammonium, in the hydrazine salts. Thus the normal chloride of hydrazine is $\begin{matrix} NH_3Cl \\ | \\ NH_3Cl \end{matrix}$ and the sulphate $\begin{matrix} NH_3 \\ | \\ NH_3 \end{matrix} SO_4$. Diammonium would thus seem to be analogous to the divalent metals of the alkaline earths, and the parallel would appear to be further justified by the sparing solubility of the sulphates and their inability to form alums with sulphates of the alumina group. On the other hand, diammonium exhibits properties which point to a close similarity to the alkali metals. For the hydrate behaves in by far the greater number of instances as a mon-acid base, like ammonium hydrate. The neutral chloride above mentioned, $N_2H_6Cl_2$, decomposes below 100° into hydrogen chloride and the chloride $N_2H_4.HCl$, which cannot be made to lose more hydrochloric acid without destruction of the base. The hydrate $N_2H_4.2H_2O_2$ is only capable of existence in solution; it passes on evaporation into the hydrate $N_2H_4.H_2O$, which latter substance boils without decomposition. Dry ammonia gas only displaces half the acid of the sulphate $N_2H_4.H_2SO_4$, and leaves the stable sulphate $(N_2H_4)_2H_2SO_4$. Moreover, Prof. Curtius has only succeeded in preparing one nitrate, $N_2H_4.HNO_3$, and one thiocyanate, $N_2H_4.SCNH$. Hence he concludes that diammonium is capable of acting both in a monovalent capacity as (N_2H_5), and as a divalent radicle (N_2H_6), the former resulting in the production of the more stable salts.

PROF. CURTIUS has succeeded in preparing a large number of double salts containing diammonium, and describes them in a separate memoir in conjunction with his assistant, Herr Schrader. Ammonium, as is well known, forms three classes of double salts containing sulphuric acid, namely, the alums, the double sulphates with $6H_2O$, and the peculiar and as yet little understood salts usually formulated as $R''SO_4.nNH_3$ in which the anhydrous gas is assumed to enter into combination with the metallic sulphate. All efforts to obtain alums containing diammonium sulphate, $N_2H_6SO_4$, have so far failed: but salts of the other two types, containing the more stable sulphate $(N_2H_5)_2SO_4$, are readily obtained. It is somewhat singular, however, that they contain no water of crystallisation, a fact which is possibly explained by the difficult solubility of the compounds. The divalent metals present may be copper, nickel, cobalt, iron, manganese, cadmium or zinc, but not magnesium. They are at once precipitated upon mixing concentrated solutions of the metallic sulphate and diammonium sulphate. It is further remarkable that the latter may be either of the two sulphates of diammonium; indeed, the solution may contain free sulphuric acid. Moreover, the sulphate $N_2H_6SO_4$ is difficultly soluble, while the more stable sulphate $(N_2H_5)_2SO_4$ is deliquescent, and yet the sparingly soluble double salts always contain the deliquescent diammonium sulphate. In addition to these, salts of the type $R''SO_4.2N_2H_4$ and $R''SO_4.3N_2H_4$ have been obtained; in those of the former type R″ may be zinc or cadmium, corresponding to the ammonia compounds $R''SO_4.4NH_3$, and in those of the latter type nickel or cobalt, these salts being analogous to the well-known compounds $NiSO_4.6NH_3$ and $CoSO_4.6NH_3$. In direct opposition to the ammonia compounds, the salts containing anhydrous hydrazine are almost perfectly insoluble in water.

THE additions to the Zoological Society's Gardens during the past week include two Pig-tailed Monkeys (*Macacus nemestrinus*, ♂ ♀) from Java, a Vervet Monkey (*Cercopithecus lalandii*, ♀) from South Africa, presented by the Rev. Sidney Vatcher; a Rhesus Monkey (*Macacus rhesus*, ♀) from India, presented by Mr. E. Logan; a White-backed Piping Crow (*Gymnorhina leuconota*) from Australia, presented by Miss Vincent; a Manx Shearwater (*Puffinus anglorum*) from Cornwall, presented by Mrs. E. S. Smith: two Robins (*Erithacus rubecula*), South European, presented by Mr. A. T. Binny; a Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mr. W. L. Strong; a Deadly Snake (*Trigonocephalus atrox*) from Trinidad, presented by Dr. A. Strading; a Yak (*Poephagus grunniens*, ♂), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

THE RIO DE JANEIRO OBSERVATORY. The Brazilian National Observatory, situated on the Morro do Castello, the most easterly hill of Rio de Janeiro, is to be removed. The *American Meteorological Journal* reports that the unfavourable situation of the Castello for astronomical observations has led to the selection of a site across the bay, near Petropolis, at an elevation of about 3500 feet. A road is now being built up the mountain, and it is hoped that the new observatory will be completed within two years. The sum of five hundred thousand dollars has been voted by the Government for the installation.

OBSERVATIONS OF MARS.—The current number of the *Observatory* contains a short article in which Mr. Stanley Williams directs attention to certain important features of Mars, which, it will be remembered, is in opposition on Saturday. With regard to the canals or channels, he remarks that a few points upon which observations are desirable are: "How far is the visibility of the canals in different parts of the planet affected by seasonal changes? Their duplication, when does it occur? How long does it last? How does it occur? And again, how far is it subject to seasonal changes?" Mr. Williams commenced observations in the latter part of August, and he found that the plainer canals were conspicuous, and even those of average distinctness could be seen without much difficulty. At the date of writing (September 18) he had observed about thirty of the canals, although only about two-thirds of the planet's face had been examined. *Ganges* was seen double on August 29, but not so clearly as in 1892. *Gehon* was also seen plainly double on the same date. Three other canals—*Eunostos*, *Cyclops*, and *Cerberus*—were found distinctly duplicated, and the germination of *Phison* was suspected. The observations were made almost exactly at the time of the summer solstice of Mars' southern hemisphere. Mr. Williams has observed a few small dark spots similar to the "lakes" detected by Prof. W. H. Pickering at Arequipa in 1892.

THE MASS OF MERCURY.—M. Backlund's recent researches on the mass of the planet Mercury, and the acceleration of the mean movement of Encke's comet, are described by M. Callandreau in *Comptes-rendus* of October 1. Encke's comet is interesting not only on account of the diminution of its period of revolution (about two hours from one apparition to the next), but also from the fact that its movement is disturbed by Mercury. A discussion of the seven apparitions of the comet between 1871 and 1891 has led M. Backlund to conclude that Mercury has a much smaller mass than has hitherto been ascribed to it. The value obtained is

$$\text{Mass of Mercury} = \frac{1}{9{,}647{,}000}.$$

It would, therefore, take about 9,700,000 bodies like Mercury to make up the mass of the sun.

To account for the acceleration of Encke's comet, it has been supposed that a resisting medium of some kind is uniformly distributed round the sun. M. Backlund, however, thinks that all hypotheses of a continuous resisting medium of uniform density ought to be discarded, and that the resistance is very probably met only in certain regions. This idea is a very plausible one, for, according to Laplace's hypothesis, in the formation of the planets from the solar nebula, all the substance of the rings would not be used up in the process, and some of it would without doubt travel along the planetary orbits as clouds of very light material. It is suggested that Encke's comet passes through nebulous clouds of this kind, and that the resistance they offer causes the observed acceleration of the mean motion.

BRORSEN'S COMET 1851 III.—This comet first appeared in the month of August 1851, moving in the constellations of Bootis and Draco. On forty-one evenings observations were made, besides numerous measures of position with micrometers, and many have been the attempts to deduce an accurate orbit. Among these may be mentioned Rumker (*Astr. Nach.*, No. 771), Vogel (*Astr. Nach.*, No. 774), Brorsen (*Astr. Nach.*, No. 775), and Tuttle (*Astr. Journal*, II.), who found parabolic elements, none of which satisfied the observations sufficiently. At a later date Brorsen obtained elliptical elements (*Astr. Nach.*, No. 782), which he compared with all the then known observations. In the communication before us, on a new determination of the orbit of this comet by Dr. Rudolf Spitaler (lxi. *Denkschriften der Math. Naturwiss. Classe der k. Ak. der Wissenschaften*), the writer makes use of some new observations and more accurate places for the camparison stars. To limit this note we will state in a few words the result he has obtained. The most probable parabolic elements after two or three "verbesserungen" were

$$\tau = 1851 \text{ August } 26{\cdot}2523 \text{ Paris Mean Time.}$$

$$\left.\begin{aligned} \pi &= 310^\circ\ 57'\ 23''{\cdot}7 \\ \Omega &= 223\ 40\ 21{\cdot}2 \\ i &= 38\ 12\ 57{\cdot}5 \end{aligned}\right\} \text{Eq. } 1851{\cdot}0.$$

$$\log q = 9{\cdot}9933272$$

An attempt to improve this led to elliptic elements as follows:—

$$\tau = 1851 \text{ August } 26{\cdot}249997 \text{ Paris Mean Time.}$$

$$\left.\begin{aligned} \pi &= 310\ 57\ 19''{\cdot}2 \\ \Omega &= 223\ 40\ 33{\cdot}9 \\ i &= 38\ 12\ 52{\cdot}9 \end{aligned}\right\} \text{Eq. } 1851{\cdot}0.$$

$$\log q = 9{\cdot}9933235$$
$$e = 0{\cdot}9999151$$

Both these elements give ephemerides which agree well with the observations, and can be looked upon as accurate within the limit of error of the observations.

M. PAPAVASILIORE ON THE GREEK EARTHQUAKES OF APRIL, 1894.[1]

THE earthquake series to which this abstract refers consisted of two principal shocks and a large number of minor ones, the former felt throughout all Greece and far beyond, but chiefly affecting the north-east region of continental Greece, and especially the province of Locris.

The first great shock occurred on April 20, and was registered by a seismoscope at the observatory of Athens at 6h. 52m. p.m., Athens mean time. The region in which much damage was done may be divided into three principal zones. (1) The epicentral zone, comprising the peninsula of Ævolymion (west of Cape Theologos). Three villages were completely destroyed; 180 persons were killed, and 27 wounded. (2) The zone in which nearly all the buildings were overthrown. This is in the form of an ellipse whose major axis is 28 km. long, and extends in a south-east and north-west direction from the Bay of Larymne to near Cape Arkitza; the minor axis is 8 to 9 km. in length. Nine villages were affected; 44 persons were killed, and 20 wounded. (3) The zone in which houses were much damaged or partially fell, also in the form of an ellipse. The major axis is 90 km. in length, directed south-east and north-west, and reaches from Dritza to near Molos. The minor axis is 65 km. long, and extends from Levadia to Mantoudi in the Island of Euboea.

During the night of April 20–21, the ground in the first and second of these zones was in a state of almost incessant disturbance, interrupted often by stronger shocks. For three days shocks were very frequent throughout all three zones; then they became more and more rare until, on April 27, a second great shock occurred, more violent than the first, and registered at the Athens Observatory at 9h. 21m. 6s. p.m., Athens mean time. The same continual disturbance of the ground followed as before.

This second shock disturbed a greater area than the first. The major axis of the second zone is 30 km. longer, especially towards the north-west; it reaches from the Bay of Scroponeri to St. Constantin. The major axis of the third zone is lengthened by about 22 km. to the town of Lamia. The minor axes of these zones are also several kilometres longer, especially on the south-west side. The same villages suffered, but the amount of damage was greater.

This earthquake was a remarkable one in several ways. At the moment of the shock, the sea rose in a wave which submerged the whole coast from the Bay of St. Theologos to St. Constantin. The water afterwards retired, except in the Plain of Atalante, where the greater part of the coast is now submerged for a distance of some metres. Several springs have ceased to run, while others have increased their flow. New thermal springs have started up at Ædipsos, near pre-existing ones, and similar in nature. Numerous fissures, occasionally some kilometres in length, have been formed.

But the most remarkable phenomenon of all is the production of a great fissure about 55 km. long. Its breadth varies from a few centimetres to three metres, according to the nature of the ground, being on an average about half a metre. It extends in a constant east-south-east and west-north-west direction from the Bay of Scroponeri through Atalante, until it disappears near St. Constantin. This fissure appears to be a fault, on account of (1) its extraordinary length and its parallelism to the Gulf of Euboea; (2) the constancy of its direction and its independence of geological structure; and (3) the existence of both a throw and horizontal displacement along the fissure, causing a lowering of the Plain of Atalante and a slight shift towards the north-west. The throw is generally very small, often zero on Cretaceous ground, reaching several centimetres on the Tertiary formations, and as much as 1½ metres on the alluvial beds of the Plain of Atalante.

M. Papavasiliore regards this fault as one of the series which, at the end of Tertiary or beginning of Quaternary times, gave rise to the Gulf of Euboea, and the recent earthquakes as due to orogenic movements by which the width of the gulf may in future be still further increased.

C. DAVISON.

[1] Abstract of two papers by M. S. A. Papavasiliore: (1) "Sur le tremblement de terre de Locride (Grèce) du mois d'avril 1894"; (2) "Sur la nature de la grande crévasse produite à la suite du dernier tremblement de terre de Locride"—*Comptes rendus*, vol. 119, 1894, pp. 112-114, [illegible]

THE AFFILIATED SOCIETIES OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

In the general report of the Brooklyn meeting of the American Association for the Advancement of Science, given in these columns on September 6, it was pointed out that a marked feature of recent meetings has been the increasing number of affiliated societies which hold meetings in connection with the Association. A useful purpose may be served by recording the communications made to these Societies.

The following papers were down in the programme of the American Mathematical Society:—Theorems in the calculus of enlargement, by Dr. Emory McClintock; on the expression of the roots of algebraic equations by means of series, by Dr. Emory McClintock; elliptic functions and the Cartesian curve, by Prof. Frank Morley; concerning the definition by a system of functional properties of the function $f(z) = \frac{\sin \pi z}{\pi}$, by Prof. E. Hastings Moore; Bertrand's paradox and the non-Euclidean geometry, by Prof. George Bruce Halsted; analytical theory of the errors of interpolated values from numerical tables, by Prof. R. S. Woodward; upon the problem of the minimum sum of the distances of a point from given points, by Prof. V. Schlegel; on the fundamental laws of algebra, by Prof. Alexander Macfarlane; about cube numbers whose sum is a cube number, by Dr. Artemas Martin; reduction of the resultant of a binary quadric and m-ic by virtue of its semicombinant property, by Prof. Henry S. White.

The Society for the Promotion of Engineering Education had papers and discussions upon a number of interesting matters. Promoters of technical education in Great Britain will see, from the following list of subjects, that the matter is considered from many points of view in America.

Among the subjects discussed were:—Entrance requirements common to all engineering schools, by F. O. Marvin; engineering education and the State University, by W. M. S. Aldrich; text-books considered as such and not as works of reference, by C. H. Benjamin; graduate and post-graduate engineering degrees, by Palmer C. Ricketts, Geo. F. Swain, and Robert H. Thurston; teachers and text-books in mathematics for engineering students, by Mansfield Merriman; teaching engineering specifications and the law of contracts, by J. B. Johnson; teaching mechanical drawing and lettering in engineering schools, by J. J. Feather; early instruction in physics and mechanics, by C. M. Woodward: some German schools of engineering, by Storm Bull; the organisation and conduct of engineering laboratories and the equipment of the laboratories at the Massachusetts Institute of Technology, by Gaetano Lanza; electrical engineering laboratories, by D. C. Jackson.

The Civil Engineering section of the Society had papers and discussions on:—Minimum laboratory work and equipment in a civil engineering course, by Dwight Porter; a few mistakes in the conduct of college field practice, by O. V. P. Stout; the teaching of structural engineering, by Edgar Marburg; relation of practical to theoretical work in civil engineering courses, by Olin H. Landreth: the education of civil engineers for railroad service, by C. Frank Allen.

The subjects brought before the Mechanical and Electrical Engineering section were:—Mechanical laboratory work at Ames, Iowa, by G. W. Bissell: amount and kind of shop-work required in a mechanical engineering course, by C. W. Marx; teaching machine design, by J. H. Barr.

The programme of the Society for the Promotion of Agricultural Science included the vitality of seeds of red clover and of seeds of weeds, by W. J. Beal; the Russian thistle in Nebraska, by C. E. Bessey; climate in its relation to rust, by L. H. Pammel; (1) a possible relation between blights and exceptional weather; (2) notes upon field experiments, by B. D. Halsted; crimson clover, some observations in reference to methods and times of seeding, by E. B. Voorhees; the growth of lettuce as affected by the physical properties of the soil, by B. T. Galloway; canaigre, its cultivation and preparation for market, by F. A. Gulley; the effect of different fertiliser constituents upon the composition and combustibility of tobacco, by H. J. Patterson; the oil of the black walnut, by W. E. Stone; nurseries as factors in the distribution of insect pests, by J. B. Smith; Bordeaux mixture as a remedy for flea beetles on potatoes, by L. R. Jones; an inquiry into the relation existing between the Burrill disease of corn and the so-called "cornstalk disease" of cattle, by V. A. Moore; a simple milk-sampling tube, by M. A. Scovell.

The following papers were read before the Geological Society of America:—The nickel mine at Lancaster Gap, Pa., and the pyrrhotite deposit at Anthony's Nose, on the Hudson, by J. F. Kemp; a connection between the chemical and optical properties of amphiboles, by Alfred C. Lane; on a basic rock derived from granite, by C. H. Smyth, jun.; the process of segregation as illustrated in the New Jersey Highlands, by Ralph S. Tarr; alunogen and bauxite of New Mexico, with notes on the geology of the Upper Gila region, by Wm. P. Blake; a study of the cherts of Missouri, by Edmund Otis Hovey; use of the aneroid barometer in geological surveying, by Charles W. Rolfe; platycnemic man in New York, by Will H. Sherzer; oil and gas in Kansas, by Erasmus Haworth; dislocations in certain portions of the Atlantic coastal plain strata and their probable causes, by Arthur Hollick; faults of the region between the Mohawk river and the Adirondack mountains, by N. H. Darton; reconstruction of the Antillean continent, by J. W. Spencer; evidences as to the change of sea-level, by N. S. Shaler; the extension of uniformitarianism to deformation, by W. J. McGee; Tertiary and early Quaternary base-levelling in Minnesota, Manitoba, and north-westward, by Warren Upham; departure of the ice-sheet from the Laurentian lakes, by Warren Upham; the drumlinoid hills near Cayuga, N.Y., by Ralph S. Tarr; drumlins in the vicinity of Geneva, N.Y., by D. F. Lincoln: channels on drumlins, caused by erosion of glacial streams, by George H. Barton; review of our knowledge of the geology of the Californian coast ranges, by Harold W. Fairbanks; the geological history of Missouri, by Arthur Winslow; the magnesian series of the North-western States, by C. W. Hall and F. W. Sardeson; the stratigraphy of the St. Louis and Warsaw formations in South-eastern Iowa, by Charles H. Gordon; the Permo-carboniferous and Permian rocks of Kansas, by Charles S. Prosser; the Trias and Jura of Shasta County, California, by James Perrin Smith; cenozoic history of a portion of the middle Atlantic slope, by N. H. Darton.

A number of papers were read before the Association of Economic Entomologists, and the president, Prof. L. O. Howard, delivered an address on "The Rise and Present Status of Official Economic Entomology."

Prominent among the Societies that met in connection with the American Association is the American Chemical Society, having a membership of nearly eight hundred. The following were among the papers read:—Recent progress in the detection of adulteration in lard, by H. W. Wiley; Ucuhuba fat, by Joseph F. Geisler; oxidation of non-drying oils by air, by Walter D. Field; a new and rapid method of estimating the total proteids in milk, by E. H. Bartley; inspection of cotton for use in gun-cotton manufacture, Chas. E. Munroe; ferric acid and the ferrates, by C. A. O. Rosell; some points in making molybdate of ammonia solutions for phosphorus determinations, by Charles B. Dudley; report on abbreviations of the names of metric terms used by chemists, by Wm. H. Seaman.

In the course of an interesting address delivered before the American Association of State Weather Services, Major H. H. C. Dunwoody, the acting chief of the National Weather Service, remarked that the three thousand voluntary observers who take observations of temperature and rainfall, and record miscellaneous meteorological phenomena, render it possible to supply, through the State Weather Service, climatological information for almost any locality in the United States. Nearly every county in the whole country is now provided with a station equipped with instruments of the Government standards, and if the work of establishing new stations continues during the next two years at the same rate as during the past two years, there will not be a county within the limits of America that will not have a meteorological station.

The weather crop service of the National Bureau now undoubtedly ranks next in importance to the work of making forecasts. The system of gathering reports upon which the weather crop bulletins are based has been so perfected in recent years, that further improvement in some States can scarcely be expected. The crop bulletins of the States have been improved, and are now more complete than at any previous time, and the increased circulation that these bulletins has attained amply attests their value. It is believed that there is no other class of information to which so much space is at present devoted in the public press of America.

More than 10,000 crop correspondents are to day co-operating with the National Weather Service through the State organisations; 3000 voluntary observers are furnishing monthly reports of daily observations of temperature and rainfall; and over 11,000 persons assist in the work of distributing the weather forecasts of the National Weather Service. This latter work has been more rapidly pushed during the past year than any other feature of State Weather Service work, and it is expected that during the ensuing year the already large number of communities receiving the Government weather forecasts will be further increased from 5000 to 6000. With a continuation of the present liberal policy of the Secretary of Agriculture and the Chief of the Weather Bureau towards these services, there will be in a comparatively short time no important agricultural community in the United States, with the proper mail facilities, that will not receive the benefits of the forecasts.

The monthly reports of many of the States are model publications of their kind. It is to be hoped that in those States where as yet the more approved methods of publishing meteorological data are not practised, means may be improved and raised to the standard attained where better facilities have been available. Uniformity in size, as far as practicable, and strictness as to tabular data, is very desirable. A daily record of temperature and rainfall for purposes of detailed investigation is most essential, and these should, if possible, form a part of each report.

The following papers were read before the American Forestry Association:—The forests of Alaska, by William H. Dall; the forests of the Shenandoah Valley, their origin and present condition, forestal areas in West Virginia, by Major Jed Hotchkiss; forests in New Jersey, by Prof. John C. Smock; the petrified forests of Arizona, by Horace C. Hovey; the Adirondack Forests, by Verplanck Colvin; the condition of our public timber-lands and forest reservations, by B. E. Fernow; what the people should learn about forestry, by Prof. Selden J. Coffin; tree-planting, by George H. Minier; forest fires in New Jersey, and some notes in methods of protection, by John Gifford; the prevention of forest fires, by General C. C. Andrews; prairie forestry, by Prof. L. H. Pammel; observations on the destructive effects of drying winds and the protection afforded by woodlands and wind breaks, by Prof. F. H. King; Does the rain-gauge settle the problem? by J. O. Barrett; the conservation of soil and water supply of hill countries in cultivated areas, by Thomas J. McKie; black walnut for economic tree-planting, by B. G. Northrup; Western pine timber-lands, by H. C. Putnam; economics in railway ties, by E. E. Russell Tratman; forest fungi and an anthracnose of the poplars, by Prof. Byron D. Halsted; the relation of insects and birds to certain forest conditions, by A. D. Hopkins.

B. E. Fernow called attention to the necessity of following up the policy begun through the efforts of the Association of reserving forest tracts of public timber-land with measures for a rational use of the same. Considerable discussion followed, resulting in the unanimous adoption of the subjoined resolution:

"Resolved, that the American Forestry Association desires to express again emphatically its approval of the efforts of the Public Lands Committee of the House of Representatives, and its chairman, the Hon. Thomas C. McRae, for the enactment of a law providing for the care and protection, not only, but for the rational use also, of the timber and other resources in the forest reservation, and on all public timber-lands. The policy of reserving can hardly be considered an advantage to the forestry interests unless followed up by an intelligent and efficient administration of the reservations, since deprived of the incidental protection. This Association emphatically denies that it advocates in the policy of forest reservations the unintelligent exclusion of large territories from actual use of the resources contained therein; but on the contrary, it reiterates that it conceives that by the reservations made for the purpose of their use—rational use—under restrictions and control which come from private interests in expectation of possible occupancy and uncared for by the rightful owner, the Government, the door is opened to greater destruction and depredation than before. We therefore desire to impress upon our representatives in Congress the urgency of making provisions for the better care of the public timber and other resources, as urged heretofore by this Association."

RECENT EXPLORATION IN BRITISH NEW GUINEA.

AT the ordinary monthly meeting of the Royal Geographical Society of Queensland, on August 20, the President (Mr. J. P. Thomson) read a paper on recent exploration in British New Guinea. The paper was a continuation of one read by the Governor at the Hobart meeting of the Australasian Association for the Advancement of Science in January, 1892. Since then several tracts of new country have been visited, and geographical knowledge of it has been increased by the detailed examination made by Sir William MacGregor of the extensive river systems of the Papuan Gulf, and his more recent exploration of the hitherto unknown parts of the north-east coast. The following extracts from Mr. Thomson's paper are reprinted from the *Brisbane Courier*.

For nearly half-a-century it had been known to geographers that several rivers existed in the neighbourhood of the Papuan Gulf. The Aird, especially, was noticed by the officers of H.M.S. *Fly* some forty-seven years ago, and more recently several channels were opened up by Mr. Theodore Bevan, whose investigations in British New Guinea were chiefly confined to this part of the country. Although these were nothing more than superficial surveys of a mere coastal fringe of the Gulf district they were the means of drawing attentioo to an exceedingly interesting and important part of the Possession. Here we are made acquainted with a tract of country north of the Fly estuary, cut up by almost bewildering labyrinths of tidal channels that constitute the mouths of several important rivers, which traverse enormous areas of rich agricultural as well as low, swampy, land. To intending settlers in British New Guinea this easily accessible region offers many inducements not readily met with in other parts of the Possession. Ample facilities for inland communication exist in several of the deep-water channels along the coast, while the recently explored Purari River flows through a region possessed of many attractive features of hilly and mountainous country. Along most of the watercourses native villages are thickly scattered, and these are inhabited by numerous tribes of powerful and warlike natives, who on several occasions have opposed the friendly advances of Europeans with formidable hostility. The houses, too, are truly remarkable for their large dimensions and massive architectural structure; dwellings of from 300 ft. to 400 ft. in length and over 100 ft. high being by no means uncommon. Next to the Fly the Purari is the largest river in the Possession. It enters the sea by several large channels. In the inland reaches above tidal influence it traverses some rough, hilly country, flowing almost parallel to and skirting the base of a mountain range 1500 ft. to 2500 ft. above sea level. This river was explored by Sir W. McGregor in January and December 1893. Its average width is about 250 yards. To the north lie a range of mountains 3000 ft. to 4000 ft. high, and southerly the country is greatly broken up by low rugged hills. To the westward the main range is visible at a distance of from fifteen to twenty miles, with its bold serrated perpendicular peaks. There is very little flat land here between the hills and the mountain spurs, although sago palms are more numerous than in some parts of the country lower down the river. The geological formation consists of sandstone associated with nodules of gray limestone. At the Aure junction, some eighty miles from the sea, the Purari receives its first considerable tributary. The width of this branch is from 80 to 100 yards, with a depth of one to two fathoms. Above its junction with the tributary the Purari maintains a general course along the main mountain range, the southern spurs of which it skirts very closely. Here the general character of the country, on the south side of the river, is a continuous succession of low sandstone hills, little more than 800 ft. high. These are rugged and precipitous, covered by dense forest. There are, however, no large trees. There was no appearance of any permanent native occupation in this district, and owing to its rugged nature the country did not seem adapted for European settlement. Several specks of gold were found in the bed of the river, and an important discovery of coal was also made near the island of Abukiru, in the main channel of the Purari River. As it is thought that the presence of coal in this district may greatly influence the future of the country, it has been proposed to arrange for a detailed examination of the locality. The people are bronze coloured, a few being lighter than the Port Moresby natives, and all lighter than those of the Purari delta. West of the Purari delta, between the mouths of the Fly and Aird Rivers, lie three important streams, the Omati, Turama, and Bamu. These traverse enormous areas of low-lying country. Concerning each of these rivers, Mr. Thomson gave some interesting details, the result of Sir William MacGregor's explorations. Continuing, he remarked: "The exploration of the lower Bamu basin, besides throwing a flood of light upon a hitherto unknown part of the country, reveals to us a condition of things not easily understood, and rarely met with in any other district of the Possession. Here no cultivated areas were seen, although the soil is exceedingly rich and abundantly watered. The people appeared to live entirely on sago. Bananas were growing wild amongst the rank forest vegetation, but there were no signs of sugar-cane or sweet potatoes. A fair idea of the richness of the land in this district may be obtained when it is stated that there is nothing to be compared with it in the Fly basin within 400 miles of the sea. It is high and dry and in every respect eminently suitable for extensive and systematic cultivation, there being a much larger area of good available agricultural land than Sir W. MacGregor had 'seen elsewhere in the Possession.' This district could no doubt be thrown open to European settlement without in any way infringing existing native rights." Mr. Thomson then dealt with some of the newly-discovered features on the north-east coast of the possession examined by Sir William MacGregor during the months of February and March last. "Recent detailed examination of some hitherto unexplored parts of the coast-line," said the writer, "has discovered the existence of several navigable streams of considerable importance, while a traverse of the coastal section between Ipote and Dako shows that there are numerous sheltered channels among many coral islands along the shore of the bay. These will be available for trading crafts in all kinds of weather. Passing on from this part of the coast-line, an examination was made of the mouth of a stream slightly north of the Clyde river, within the German territory. From observations of ten pairs of meridian stars the latitude of this stream was found to be 7° 58′ 30″ S., taken at the place where it enters the sea. It is a comparatively small watercourse, forty or fifty yards wide on the lower reaches. The natives here are of a dark bronze colour and quite naked. The hair is worn in ringlets, and removed from the face. Their ornaments consist of Job's tears, earrings of turtle shell, and head tuffs of cassowary feathers. They were armed with spears of palmwood, Gothic shaped shields nearly 3 feet long, and stone clubs. At first they were friendly, but afterwards appeared hostile. The next river to claim attention is called the Mambare. This is simply one of the mouths of a river known as the Clyde, of the Admiralty charts. It lies about two miles within the British territory, and in the lower part traverses some good alluvial land, abounding with remarkably fine fields of sago palms. The river was navigable by the steam launch for the first forty miles, where further progress was impeded by rapids, and some few miles farther the channel is simply a succession of deep pools. Below the rapids some extensive areas of very fine alluvial land were met with, and the forest trees so high that the birds on the upper branches bade defiance to the marksman's firearms. Above the rapids the country was broken, and little agricultural land was to be seen. The district possesses a very fine climate. Sandflies and mosquitoes were entirely absent, and the early morning atmosphere was decidedly cool and bracing. The people have well-cleared and cultivated gardens, in which they plant taro, sugar-cane, edible hibiscus, yams, and bananas; but there were apparently no tobacco, papaya, nor pumpkins. Several villages were located on the banks of the river, some of which are situated in the midst of beautiful groves of cocoanut and betel palms. The only ornamental shrubs met with consisted of a remarkably fine variety of light yellow crotons of great beauty. Ordinary watercresses were met with at one of the villages, but they were seen at no other place on the north-east coast. The men were profusely ornamented with shells, pigs' teeth, Job's tears, cassowary feathers, red seeds, and bones. Some of the women wore a necklace or two, others a narrow mat work belt, but they were clothed with nothing else. In this part of the country they use the password 'Orokaiva,' meaning 'man of peace.' They use an adze of basalt. Their pottery is not well prepared. It is without ornament, thick, and slightly conical in shape. The people seemed to be industrious agriculturists, growing food for the entire population. They possess a great number of canoes. Sir William MacGregor is of opinion that some good agricultural land could be obtained for European settlement without interfering with native occupation, and he further believes that the natives would welcome European settlers who would be prepared to treat them fairly." The next place visited was a small sluggish river, fifty to sixty yards wide, and two fathoms deep, called the Ope or Opera. The position of its mouth was found to be lat. 8° 18′ 16″ S., and long. 148° 11′ 25″ E. It is convenient for watering ships and of value to traders. Several villages were seen in the neighbourhood, and there was evidence of a large population of friendly natives. The men were nude, but the women were covered by a petticoat of native cloth. They were armed with spears and stone clubs, ornamented with wreaths of convolvulus and red hibiscus. They danced, sang, and shouted, but appeared to be very friendly. To the south of this district the Kumusi River flows into Holnicot or Gona Bay, in lat. 8° 28′ S., and long. 148° 16′ E. The mouth is obstructed by a bar, some four feet below the surface. Most of the land on the lower part of this river is low and unfit for European cultivation, although considerable areas of alluvial deposits are occupied by many native gardens, and there are fine fields of sago palms. The highest point reached was about forty-six miles from the sea, by traverse, or lat. 8° 35′ S. and long. 148° 0′ 20″ E., where further progress was barred by rapids. Here the country "was without exception the most attractive" Sir W. MacGregor had "seen in New Guinea." Extensive tracts of splendid alluvial land stretched far and wide along the river valley, covered by forest trees, and to all appearance above the reach of flood. These flats occupy what was formerly the river bed, as indicated by the sandy substratum. Some six miles from the river lay one of the central main mountain ranges, the intervening space being occupied by small mountain streams, numerous rolling wooded hills and flats. At night the air was pure and delightfully cool. Great reluctance was felt at having to leave such a district, where the scenery is of a very fine description. There is apparently a large population here, but the people would no doubt be friendly. When descending the river the steam launch *Ruby* collided with a treacherously concealed snag and foundered. This unfortunate accident compelled the party to travel down an open unprotected coast in the whale and river boats. The Kumusi natives were unusually interesting. They are from a light to a dark bronze colour, not remarkably powerful people, but of fair Papuan physique. Their foreheads are square and rather high, with hazel eyes of fair size, large mouth, small chin, and flat cheeks and chests. The nose resembles that of Port Moresby, only slightly shorter, and the nostrils rather coarser. Both sexes wear cloth of mulberry bark. They use stone clubs, the disc and the pineapple pattern, the palmwood spear with square-shaped sharp end and barbs on one side only, and small Gothic shields, with a few examples of the great shield of Orangerie Bay. The stone clubs and adzes are made of basalt. They have no tobacco growing in their gardens, and were ignorant of its use. Their canoes are similar to those on the Ikore and Mambare Rivers. It was found that a river of considerable size enters the sea at Cape Sudest, but unluckily a bar closes its entrance to navigation. The natives call it Tambokoro. The position of Cape Sudest was determined astronomically, and found to be in lat. 8° 44′ S. and long. 148° 25′ 30″ E. In Dyke Acland Bay three streams were discovered—Kevoto and Umundi Creeks and the Musa River. The mouth of the first of these lies in lat. 9° 4′ 55″ S. and long. 148° 33′ 20″ E. Both creeks are of little importance. The lower part of the Musa River traverses low, swampy country, covered by water when the river is flooded. When ascending this stream the Administrator passed within a few miles of the western peaks of Mount Victory. "It has three principal summits, the western one of which is at present quiescent." Ashy-looking deposits were observed among the rocks on the others, and several large fumeroles, out of which little spiral clouds of smoke were issuing. The highest point reached on the river was about thirty-five miles from the sea in lat. 9° 19′ 10″ S. and long. 148° 53′ 43″ E. Here the stream was about 100 yards broad, three fathoms deep, and the current two to three knots per hour. This place was evidently on the margin of a settled country. The banks of the river were beginning to rise, and the capacity of the channel was about sufficient to carry the water. The forest trees were very large. What the upper portion of the

Musa basin may be is at present unknown, but the lower part appeared to be of little value. Several villages occupy the flooded country on the banks of the river; the houses are built on stilts a few feet above the water. The natives were friendly, but naturally shy and suspicious. They excel in making native cloth, many specimens of which were obtained. Their dead are interred in the villages, the graves being covered with a neatly thatched cage. They use palmwood spears, stone clubs, and adzes of jade. Both sexes wear a native cloth. The men wear the hair long, hanging down the back. They cook their food in clay pots, and eat lime and betel nut. The men were fairly strong and of good physique, but many were suffering from ringworm and hydrocele. They were anxious to trade, and offered adzes, clay pots, and sago for plane-irons. Some very remarkable pottery was obtained on the north-east coast. The examples are bowl-shaped with outside raised designs, not previously seen in any other part of British New Guinea. Besides these explorations the discovery of Pennegwa Harbour in the extreme north-east of Rossell Island, and a safe anchorage at Mabudaun, which very greatly increases the value of the western portion of the Papuan territory, were described. Mr. Thomson, by means of a map, indicated the territory dealt with in his paper, and at its conclusion a few pictures appropriate to the occasion were thrown on to the screen by Dr. Thomson.

In the course of some remarks, Sir William MacGregor suggested that Mr. Thomson might follow up his paper with another. The one he had just read did not embrace all the latest work that had been done. His (Sir William's) dispatches had not all been printed; in fact, he questioned whether some of them had yet reached his Excellency the Governor. There was a great deal of information which might be included in such a paper. For instance, Mr. De Vis had been examining a number of new and interesting native birds; Baron Von Muller had got a lot of new plants; but perhaps the most interesting, because the most practical, was the work being done by Mr. Jack and Mr. Rands. The geological specimens he had brought from the Purari River indicated a very large district in which there were very rich coal formations. The fossils that were under examination would show very clearly, he thought, the age of the deposit.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—In the lists of lectures announced for the present term, the most noteworthy feature is the removal of the subject of Anthropology from the list of the Faculty of Natural Science, and its insertion under that of Literæ Humaniores. The titles of the Anthropological lectures are "The Intellectual Development of Mankind," by Dr. Tylor; "The Elements of Physical Anthropology," by Prof. A. Thomson; and "Primitive Musical Instruments," by Mr. H. Balfour. There does not appear to be any adequate reason for considering that these subjects should belong to letters rather than to Natural Science, but perhaps it is a sign that a day is approaching when all the subjects of Natural Science will be recognised as forming as much a part of *literæ humaniores*, that is, of indispensable culture, as Philosophy and Ancient History. In the departments of Natural Science there is no change of importance to chronicle. Professors, Lecturers, and Demonstrators are the same as in the past academical year, and the subject-matter of the lectures refers in each case to the examinations in the Honours School of Natural Science. Mr. R. T. Günther is in residence at Magdalen College as Science Tutor, and Mr. W. Garstang is in residence at Lincoln College, and will deliver a course of lectures as Lecturer in Natural Science to the College.

The examination for the Burdett-Coutts Scholarship will be held in the week beginning October 21.

The Vice-Chancellor has appointed Mr. William Holman Hunt the Romanes Lecturer for the year 1895.

A copy of the report of the Minister of Public Instruction in New South Wales, for the year 1893, has reached us. The work of the Technical Education Board for that year was carried on under very different conditions from those of previous years. The scheme for retrenchment of expenditure in the public service led to the reduction of the vote for Technical Education from £49,800 in 1892, to £25,367 in 1893. The field of operations had therefore to be confined within comparatively narrow limits. Only 187 classes were carried on throughout the whole year, and the total number of students was 7096. In addition to the ordinary class work, popular lectures on various subjects were given at different centres throughout the colony. The success of these lectures may be judged from the fact that the Rev. J. Milne Curran lectured in Geology and Mineralogy to audiences aggregating 13,360 persons, or an average of over 300 persons at each lecture.

The *Record of Technical and Secondary Education* completes its third volume with the current number. The journal was only started tentatively, but the experience gained during the last three years has shown that it is wanted, so it will be continued. The present number is full of information of use to promoters of technical education. It includes the reports of the technical instruction committees of Somerset, Hampshire, Isle of Wight, Staffordshire, and Worcestershire. Mr. W. E. Urwick gives a description of primary and secondary education in France, first tracing the progress of an imaginary boy from the primary school upward, and then detailing the means of transition from one school to another, the help offered by the State, and the method of procuring it. So many committees have had to confess that their schemes of agricultural education have, to say the least, been unsuccessful, that an article on the promotion of such instruction in Great Britain should be widely read. It is pointed out that elementary agricultural education must be founded definitely on science, though this may be elementary. The subjects likely to be of most use are chemistry, botany, and zoology. Mathematical subjects should, if only as a matter of education, engage earnest attention, and it is suggested that elementary physics, leading up to the construction of the steam engine, might replace botany or zoology in the curriculum. There must always be stations for field demonstrations and experiments, and this class of work is of a threefold nature. "First, there is the demonstration of the known action of certain elements of plant food when used in manures; it is this which is truly educational. Next comes what may fairly be called experiment, viz. the testing in each locality of the action of different manures on different crops or typical soils. Lastly, there is pure research into the unknown, a matter which can only be successfully carried out at special places, thoroughly well-equipped for this particular purpose. While, however, it is to be hoped that Rothamsted will always form the premier research station for the kingdom, there would seem to be no reason why stations such as that which the Royal Agricultural Society have at Woburn might not, within limits, be multiplied." In addition to the articles already referred to, the *Record* contains an illustrated description of the fine Technical College at Bradford.

The "Guide to Technical and Commercial Education," first issued by the Dundee and District Association for the Promotion of Technical and Commercial Education some five years ago, and the third edition of which has recently been published, has done good service. The object of the guide was to indicate the lines along which apprentices might with advantage be urged to a systematic continuance of their education in subjects bearing on their particular occupations. In point of fact, the aim of the Committee was to do for the apprentice architect, engineer, mechanic, or other craftsman, in the Technical School, what long ago in the Universities has been done for the professions by the institution of definite lines of study. Several Technical Instruction Committees have drawn up similar courses of study to be followed by young artisans in order to become efficient workmen; and when such schemes are properly drafted, they serve a very useful purpose.

SCIENTIFIC SERIALS

Quarterly Journal of Microscopical Science, vol. xxxvi. part 4, August.—In the first of a series of "Studies on the Nervous System of Crustacea," Mr. Edgar J. Allen gives the results of a careful investigation of the structure of the brain and ganglionic chain in lobster embryos. By the employment of Ehrlich's methylene blue method he has been able to demonstrate the course of the constituent nerve-fibres, both co-ordinating, motor, and sensory, with remarkable success. The author's observations agree with those of Retzius, Kölliker, and other recent investigators, as to the absence of any form of anastomosis between the fibres of different elements. Nervous discharges must, however, pass from one element to another by means of the finer terminal fibrils, which are shown to be frequently arranged in the form of distinct tufts, having a constant position relative to each other. On this account the author hazards the suggestion "that the nervous energy resembles a static electrical charge, in the fact that the discharge takes place most readily through points," the opposing tufts of fibrils of different elements being thus comparable to the "brushes" of an electrical machine. In the second and third of his "Studies," Mr. Allen deals with the Stomatogastric System of *Astacus* and *Homarus*, with the Beading of Nerve-fibres, and with End Swellings.—Other papers in the same number are by Mr. E. A. Andrews, on some abnormal annelids, and Mr. W. E. Collinge, on the sensory canal system of Ganoids. All these papers are admirably illustrated.

American Meteorological Journal, September.—On cloud formation, by Prof. W. von Bezold. This is a translation, by L. A. Bauer, of an address delivered in the "Urania" of Berlin, November 29, 1893, and published in *Himmel und Erde*, vol. vi. No. 5. We gave a brief notice of this valuable paper in vol. xlix. p. 508. Prof. von Bezold's explanations of the formation of fogs and clouds are exceedingly interesting and instructive, and the translation into English will be of great use to many readers who may be unacquainted with German. Several of the cloud views have been made in Berlin expressly for this article.—Summer hot winds on the Great Plains, by J. M. Cline, M.D. This paper has been reprinted from the *Bulletin of the Philosophical Society of Washington*, vol. xii. 1894, and contains an account of the hot winds observed from 1874 to 1892, and of the general meteorological conditions prevailing at the time of their occurrence, together with a description of the general characteristics of those hot winds, and conclusions as to their causes.—The meteorological services of South America, by A. L. Rotch. The countries in which meteorological observatories and central stations exist are Peru, Chile, Argentine Republic, Uruguay, and Brazil. Those dealt with in this article are Peru, in which is situated the observatory of *El Misti*, the highest station in the world, and Chile, of which the National Observatory is at Santiago, and was founded by the United States Transit of Venus Expedition in 1848.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 8.—M. Lœwy in the chair.—On the eccentricity of the orbit of Jupiter's fifth satellite, by M. F. Tisserand. If a be the great semi-axis, e the eccentricity, and ϖ_0 the longitude of perijove at a certain epoch (October 28, 1892), we have, as a first approximation,

$$a = 47''\cdot906,\ e = 0\cdot0073,\ \varpi_0 = -14^\circ.$$

—On the groups of transformations of differential linear equations, by M. Emile Picard.—Theory of flow on a weir without lateral contraction, when the bending liquid sheet is either depressed, submerged below, or adherent to the weir, by M. J. Boussinesq.—On the propagation of electromagnetic waves in ice, and on the dielectric power of this substance, by M. R. Blondlot (see Notes, p. 604).—Mean magnetism of the globe and "isanomales" of terrestrial magnetism, by M. Alexis de Tillo. The tables given show the mean value for the magnetic elements for parallels at 10° intervals for the years 1829, 1842, 1880, 1885.—M. Haton de la Goupillière informs the Academy that M. Cotteau has left his fine collection of fossil Echinoderms to the National School of Mines. This collection, combined with the Michelin collection, already at the School of Mines, will probably be the most complete of its kind.—On the dielectric power of ice, by M. A. Pérot. On recalculation of the results published on June 27, 1892, K assumes the value 2·04.—A study of the latent heats of vaporisation of the saturated alcohols of the fatty series, by M. W. Louguinine. The latent heats of vaporisation obtained are as follows: For ethyl alcohol, mean of eleven experiments, 201·42 cal.; Ramsay and Young's value, 206.4 cal., calculated by means of the formula

$$L = (s_1 - s_2)\frac{t}{I} \cdot \frac{dp}{dt},$$

where t = absolute temperature and I is the mechanical equivalent of heat, probably differs from the experimental value owing to accumulated errors of data entering into their formula.

Normal propyl alcohol, L = (1) 164·07 cal.; (2) 163·19 cal.
Isopropyl alcohol (Sp. Ht. assumed same as N. P. Alcohol), L = 159·72 cal.
Normal butyl alcohol, L = 138·18 cal.
Isobutyl alcohol (Sp. Ht. of normal alcohol used), L = 136·16 cal.
Fermentation amyl alcohol, L = 118·15 cal.
Dimethylethylcarbinol (Sp. Ht. assumed same as amyl alcohol), L = 110·37 cal.

All determinations were made at pressures between 745 and 755 mm.—On a particular case of the action of alkalies on glucose, by M. Fernand Gaud. The reaction of the alkali on glucose has been followed by means of different metallic oxides, capable of precipitating each of the products in turn, step by step.—On the production of gaseous formaldehyde for purposes of disinfection, by MM. R. Cambier and A. Brochet.—Manufacture of alumina from clays, by M. Joseph Heibling.—On the germination of oleaginous grains, by M. Leclerc du Sablon.—Experiments on the eggs of the mulberry silkworm, an annual race, by M. Victor Rollat. It is found that hatching may be produced at any desired time by submitting the eggs to the action of compressed air at the pressure of 6 to 8 atmospheres for a fortnight—M. J. Posno describes, in a note, the results obtained by a process of distillation of house refuse.—M. F. Larroque reports the ravages produced by anthrax in the higher pastures of the Pyrenees.

THURSDAY, OCTOBER 25, 1894.

TWO TEXT-BOOKS OF BOTANY.

A Students' Text-book of Botany. By Prof. S. H. Vines, M.A., D.Sc., F.R.S. (First half.) With 279 Illustrations. (London: Swan Sonnenschein and Co., 1894.)

The Students' Introductory Handbook of Systematic Botany. By Joseph W. Oliver. (London: Blackie and Son, 1894.)

WE are very glad indeed to welcome Prof. Vines' new book. It is the first English text-book of modern botany that has yet appeared. The book has grown out of the author's translation of Prantl's "Lehrbuch der Botanik," but, as Prof. Vines tells us in the preface, "though the form of Prof. Prantl's book is retained, and here and there paragraphs from the English edition have been inserted, it is essentially a new book, for which he alone is responsible."

The difficulties in the way of writing a good comprehensive text-book of botany are very great. Owing to the huge amount of material, much of it mere detail, which accumulates day by day, the work of selection becomes increasingly laborious to any writer who is anxious to produce a text-book which shall be of real value to the advanced student. Perhaps no botanist was so well fitted to undertake this work as Prof. Vines, and he has done the work carefully and well. Modern researches have been incorporated wherever possible, and the author has placed his facts before the reader in a very clear, but somewhat encyclopædic manner. We must protest against the terminology. The author has introduced a large number of new terms, many of which seem to be quite superfluous, and likely to render the study of botany unnecessarily confusing to the student. Added to this, the book is, unfortunately, not got up in a very attractive style; the illustrations are poor, and the majority of them will be familiar to the student of botany. They have appeared over and over again in all sorts of text-books, good and bad, and it is much to be regretted that an adherence to these old figures should have become traditional.

The volume before us is only the first half of the book. It is divided into three parts, which deal respectively with morphology, the intimate structure of plants (anatomy and histology), and the classification of plants; the latter includes the Thallophyta, Bryophyta, and Pteridophyta, the description of the Phanerogams being reserved for the second half of the book.

Part i. is divided into two chapters and an introduction. In the latter some fundamental points are considered, the meaning of the terms morphology and homology explained, and a general description given of polymorphism, or alternation of generations, as exemplified in the moss, which is taken as occupying a central position, of morphological equality in the two generations, in the vegetable kingdom.

The development of the body and its members is treated excellently. Holoblastic and meroblastic development are explained. The difference between homoblastic and heteroblastic embryology is discussed. The latter kind of development is seen most strongly marked in the Characeæ, Mosses, Lemanea, and Batrachospermum, where two distinct stages in the development of the gametophyte can be observed.

In chapter ii. the special morphology of the members, thallus, stem, leaf, root, &c., is treated in detail. The description given of the leaf is excellent. The form of the leaf and its various parts are first of all described, then the development of the leaf, its branching, heterophylly, bud scales, &c. The leaf is regarded, from Bower's point of view, as a branch system. In most plants the leaf undergoes differentiation or segmentation along its longitudinal axis or phyllopodium. The result is that we get in the most complete cases the phyllopodium differentiated into leaf base or hypopodium, mesopodium or petiole, and an apical part or epipodium. The epipodium is typically winged and forms the lamina, the mesopodium is rarely winged, the hypopodium more frequently so, forming the stipules or leaf-sheath. The branching of the leaf is commonly confined to the epipodium, and is like that of a stem or root, either dichotomous or lateral, but dichotomous branching is rare. The ribs of the lamina represent distinct axes of growth. In some cases the growth of these axes and their respective wings results in the production of leaves with an entire margin; in other cases the growth is more irregular, and lobed, or segmented leaves are produced.

The morphology of the reproductive organs is next considered, the vegetative, asexual, and sexual modes of reproduction being described in some detail. Bracts and perianth leaves are included under the common term hypsophylls. In connection with spore formation we think Prof. Vines has introduced an unnecessary distinction between spores which are produced on the gametophyte and spores which are produced on the sporophyte, especially as, in the cases where this is said to occur, the distinction between gametophyte and sporophyte is, to say the least, not well marked. When the spores are produced on a gametophyte they are called gonidia, the sporangia are called gonidangia, and he sporophores are called gonidiophores.

Part ii. deals with the intimate structure of plants, and is divided into two chapters, on the cell and the tissues respectively. The relation of multinucleated cells to uninucleate is explained. The multinucleate segment is regarded as a collection of protoplasmic units, *energids* (a term due to Sachs), and is termed a cœnocyte. But, as the author points out, true multinucleate cells are produced in some plants by fragmentation of the original nucleus, as in the internodal cells of Chara.

In connection with the minute structure of the cell, and the division of the nucleus, we find that many of the more important recent researches are included.

The important observations of Guignard on centrospheres are shortly described, and one or two of his figures are given in illustration. Here again the author's statement that "closely associated with the nucleus is a body called the centrosphere," appears to us to be too general, as centrospheres have not yet been discovered in all the groups of plants, although the observations which have been already made, lead one to the conclusion that they will ultimately be discovered in connection with all nuclei.

 D D

In chapter ii., under the heading of Tissues, the author describes the connection of the cells, intercellular spaces, the various forms of tissue, including "sieve tissue," glandular tissue, parenchymatous, strengthening, and tracheal tissue. The general morphology of the tissue system deals with the apical growth of plants, and the morphology of the stele. The researches of Van Tieghem are here included. The variations from the primitive monostelic structure of the stem are polystelic and schizostelic. The latter term, which corresponds to Van Tieghem's old term "astelic," is, in our opinion, a great improvement.

The fundamental tissue system or ground tissue is divided into extra-stelar and intra-stelar. In monostelic stems the limits of the extra-stelar tissue are the endodermis and the layer of cells immediately below the epidermis. In polystelic stems the extra-stelar tissue includes all the fundamental tissue outside the steles. The intra-stelar or conjunctive tissue includes the pericycle and pith.

A very good description is given of the secondary extra-stelar tissue. In the description of cork formation, the classification of Van Tieghem is adopted as regards the place of origin of the phellogen. We should like to have seen in this section some account of the conditions which, probably, determine the formation of special kinds of periderm. The chapter concludes with a short account of the formation of tissue in consequence of injury.

In the third part the classification of the vegetable kingdom into four groups, Thallophyta, Bryophyta, Pteridophyta, and Phanerogamia, is described. While recognising the general usefulness of such a division, we think it would have been better to separate the Bacteria and Cyanophyceæ to form another group—which has already been done by some writers—the Protophyta. The characteristics of the Bacteria are peculiar to themselves, and are such as to warrant their separation from the Fungi; and the same may be said of the Cyanophyceæ, and their connection with the Algæ.

The author adheres to the classification of the Algæ into four sub-classes: Cyanophyceæ, Chlorophyceæ, Phæophyceæ, and Rhodophyceæ. An excellent introductory account is given of the whole class, followed by a special description of each sub-class and its principal orders and families. The Chlorophyceæ is divided into five series: Protococcoideæ, Volvocoideæ, Siphonoideæ, Confervoideæ, and Charoideæ, a classification with which we cordially agree. It has been customary to place the Charoideæ between the Algæ and Bryophyta as a separate group, but we think their inclusion as a sub-group of the green Algæ is, in spite of the differences which exist between them, more in accordance with their structure.

A short but excellent description is given of the Phæophyceæ. The author includes the unicellular forms, Syngeneticæ and Diatomaceæ, in this group. This may be convenient, but few botanists will, we think, regard it as natural. A short general account of the red seaweeds, with a list of the orders and chief genera, concludes this portion of the book.

The next group dealt with is that of the Fungi. A general account is first of all given of the structure and methods of reproduction. The asexual formation of spores is of general occurrence. In accordance with the author's terminology, these are distinguished as gonida and spores, according as they are borne on the gametophyte or sporophyte. The ordinary mycelium of mucor, for example, is the gametophyte; on this are produced gonidangia and gonidia. On the other hand, the zygospores of some mucors produce a promycelium; this is regarded as the sporophyte, and its asexual reproductive organs are therefore sporangia and spores. Again in the Peronosporaceæ, "in those species in which the oospore gives rise to a promycelium, the promycelium is the sporophyte; in those in which the oospore gives rise to zoospores, the oospore itself represents the sporophyte, and finally, in those in which the oospore at once gives rise to a sexual plant, the sporophyte is altogether unrepresented." The ordinary mycelium is here also the gametophyte.

The book concludes with an account of the vascular Cryptogams. The classification adopted by the author is more in accordance with the known facts of morphology, and is a distinct advance in the right direction. One of the most striking changes is the complete separation of the Isoëtaceæ from the Selaginellaceæ, and its inclusion among the Eusporangiate Filicineæ. A useful table is given on p. 380, showing the relations of the various groups of the Pteridophyta.

In connection with the Lycopodiaceæ, Treub's important observations on the embryogeny of the sporophyte and the structure and development of the gametophyte are incorporated. This is the first time these important researches have been described in an English text-book.

In conclusion, English students have cause to be grateful to Prof. Vines for this excellent text-book, which puts before them so clearly and definitely the main facts and conclusions connected with the science of botany; and we look forward with great interest to the appearance of the second half of the book, which has been promised for the current year.

The second book before us is, the author tells us in his preface, designed for the use of students who have passed through an elementary course of botany. It is a compilation from several English works and Le Maout et Decaisne's "Traité Général de Botanique," and the author has been at some pains to select from them such portions as will be most useful to beginners. In this he has been fairly successful, and has placed his facts before the reader in a commendably simple form.

The author is not without hope that the book may be used for private study, but we could not recommend it for this purpose. It would be perfectly useless to place such a book in the hands of a private student, unless he were better acquainted with the elements of botany than the majority of students in elementary classes.

A little more than one-third of the book deals with Cryptogams, the remainder of the volume being devoted to a description of the structure and classification of the Phanerogams. We can heartily commend the author's lucid description of some of the types he selects to illustrate the various groups. On the other hand, many of the types are described by him in such a way as to give the student very little idea of the plant he is supposed to be studying.

The second part of the work deals with the Phanerogams. A very fair account is given both of the Gymnosperms and the Angiosperms. The major portion of this part of the book, however, is taken up with a description of the natural orders of the Angiosperms.

Though there are a few new illustrations in the book, the majority of them are the old familiar ones referred to in the foregoing. We notice that the author has sometimes forgotten to acknowledge the source from which his illustrations have been taken.

In conclusion, it may be said that the book is very well suited to those students who wish to pass a somewhat advanced examination, such as that of the Science and Art Department. We cannot help regretting, however, that there should be so large a demand for this kind of text-book.

HAROLD WAGER.

LIFE IN ANCIENT EGYPT.

Life in Ancient Egypt. Described by A. Erman; translated by H. M. Tirard. (London: Macmillan and Co., 1894.)

THE appearance of an English translation of Prof. Erman's work on the manners and customs of the ancient Egyptians is most opportune, for it comes at a time when the Egyptological world is still smarting under the loss, by death, of Prof. H. Brugsch, the last and probably the greatest of the little band of German Egyptologists of which Lepsius was such a brilliant member, and proves to us that there is in Germany, besides Dr. Wiedemann, one at least who may be expected to continue the great and good work which that veteran did so much to promote. Prof. Erman is well known to Egyptologists by his papers and books on Egyptian grammar, of which from the time of his appearance at the Congress of Orientalists in 1874 until the present year he has never ceased to labour. In 1878 he published some important observations on the formation of the plural in Egyptian ("Die Pluralbildung des Aegyptischen," Leipzig, 1878), which was followed in 1880 by his "Neuaegyptische Grammatik"; in 1890 he edited, with translation, commentary, &c., the stories from the Westcar papyrus ("Mittheilungen ans den orientalischen Sammlungen—Die Märchen des Papyrus Westcar"), and last year he published a good little Egyptian grammar. A portion of his time he has devoted to contributing articles to the *Aegyptische Zeitschrift*, of which he is now the editor, and to the *Zeitschrift* of the German Oriental Society. His work on the life of the Egyptians, which in an English form we owe to Mrs. Tirard, appeared in parts, which formed two volumes, between the years 1884 and 1887, and was then, and is now the only work of the sort in Germany. The large work by Ebers, "Aegypten in Bild und Wort," which appeared at Stuttgart in 1879–81, and of which an English translation by Clara Bell was published in London in 1881–82, attracted the popular mind chiefly by the many beautiful illustrations which it contained; references to original authorities were few and far between, but it nevertheless appealed to a large class of readers successfully. Our own countryman, Wilkinson, the author of the first guide-book to Egypt, was perhaps the first to recognise that the only trustworthy descriptions of the manners and customs of the Egyptians must be derived from the native records of sculptor, artist and scribe, and he spent many years in compiling his monumental work on the subject, which, as Mrs. Tirard says in her preface, has formed one of the main sources of supply for Prof. Erman. Wilkinson's knowledge of the inscriptions was somewhat hazy according to modern views, and the defects which occur in his work from this cause are conspicuous by their absence in Prof. Erman's book, which is of course, as was to be expected, a record of the Egyptians compiled from their own monuments and books. On many points we should like to have had his opinions, as for example, on the Hyksos, and on the Exodus; as for the Hittites, on which nation more than one reputation has been wrecked, he holds no strong view, but thinks they may have been identical with the Kheta of the hieroglyphics. In matters of chronology Prof. Erman differs greatly from Mariette and Maspero, for he places the sixth dynasty as late as B.C. 2500, while they date it at B.C. 3700 and 3300 respectively. There is no doubt that serious modifications in Egyptian chronology must shortly be made, and though they may take the form of reducing the antiquity of the periods of the dynasties from the twelfth downwards, yet it seems perfectly clear that the effect of the rearrangement ought to be either to lengthen the period of the duration of the earlier dynasties, or to admit boldly a more recent date for the beginning of historical Egyptian civilisation, and to proclaim a lengthy period of prehistoric civilisation which in all probability extended over thousands of years. Such considerations, however, affect Prof. Erman's book very little, for the reader will rely upon him not for speculations as to the original home of the Egyptians and the history of their descendants who are known to us, but for the descriptions of their life as depicted on their works; in this respect no more careful guide than Prof. Erman could be found. The tasteful form in which his book is printed and bound will, we believe, add to its intellectual attraction.

OUR BOOK SHELF.

La Géographie littorale. Par Jules Girard, Secrétaire-adjoint de la Société de Géographie (Paris). (Paris: Société d'Editions Scientifiques, 1895 [1894].)

M. GIRARD says very justly in his preface that geographers have not as yet given the coast lines of the world the attention to which these features are entitled. He accordingly prepared the present little book, which has appeared, chapter by chapter, in the *Revue de Géographie*. It is unquestionably a useful compilation, but it is far from complete in any part; and it has been so carelessly revised, that a number of printer's errors remain unnoticed. In the names of places outside France the letters *u* and *n* are frequently transposed. Bab-el-mandeb appears as *Bal-el-Mandel*, and an extraneous *r* creeps into several names beginning with G, *e.g. Granges* for Ganges, and *Gruppy* or *Grupy* for Guppy. More serious are blunders in statements of facts, such as describing the whirlpool of Corryvrechan as being near the island of "Scabra," *dans les lacs d'Ecosse*, the transference of the Grey Man Path from the north of Ireland to the west of Scotland, and the description of the Old Man of Hoy as the result of erosion in schistose rock, whereas it is a mass of horizontally stratified Old Red Sandstone. These examples might be considerably reinforced were detailed criticism necessary, but a graver defect is the way in which work done by others than Frenchmen has been ignored. Reference is certainly made to several British, German, Russian, and American writers, but rarely at first hand, and many works of the first importance have been entirely overlooked.

There are seven chapters dealing successively with the movements of water in the sea, coast erosion, the movements of sand (the two most satisfactory chapters), the origin of beaches, deltas, estuaries, and the evidence of movements of the land along the coasts, including the origin of fjords.

The treatment of estuaries is particularly inadequate. The Amazon and Congo are scarcely seriously touched on, the part of salinity in determining the *régime* of tides in an estuary is practically overlooked, and the relation of the volume and velocity of a river to the volume of its estuary is not worked out at all. Perhaps the most marked omission is Prof. Osborne Reynolds' magnificent experiments on the synthesis of sandbanks by tides, and the controlling relation of the configuration of the coasts to that of the banks.

But with many faults of execution, the plan of the book is sound, and the work supplies a framework for a treatise of great value, which might be furnished if the author would first prepare a bibliography of the subject, and then undertake a thorough and leisurely revision.

H. R. M.

The Mechanics of Hoisting Machinery. By Dr. Julius Weisbach and Prof. Gustav Herrmann. Translated from the second German edition by Karl P. Dahlstrom, M.E. (London and New York: Macmillan and Co., 1893.)

This book is a translation from Prof. Herrmann's revised edition of Weisbach's great work on engineering mechanics. Several volumes of this work are familiar to English readers. The present section, however, has not previously appeared in English print, although its value has long been recognised. Mr. Dahlstrom was induced to undertake the translation, because he felt that there was a want in our technical literature for a text-book suitable for the higher grades of mechanics of machinery.

As the title implies, the contents of the work are entirely concerned with hoisting machinery; commencing with the simple lever and screw-jacks, and going on with all kinds of pulleys and blocks, windlasses and lifts, as well as hydraulic plant, concluding with hoisting machinery for mines, cranes and sheers, excavators, and dredgers, &c.

The treatment of these subjects is such that criticism is nearly unnecessary. The examples and illustrations are nearly all taken from every-day engineering practice; some are, however, old-fashioned. Senior students will obtain many useful hints in this book, more especially on studying the methods of working out the examples through out the volume. The diagrams are very clear and to the point. One cannot help noticing that the illustrations have in many cases a decidedly foreign appearance, and the design would not be followed in this country; nevertheless, they serve the very useful purpose of illustrating theoretical constructions by means of every day objects. Fig. 65 represents the usual woodcut of the essential arrangement of an hydrostatic press. The ram of the force-pump is shown the full diameter of the cylinder, and therefore no passage exists for the water to pass from the suction to the delivery valve on the down stroke. Fig. 105 represents a two-cylinder geared steam winch, fitted with a peculiar slide valve. A description of this valve would have been interesting, because only one eccentric appears to be necessary, thus doing away with the noisy link motion, especially when badly worn.

The many references given add considerably to the value and usefulness of this work, while the able mathematical treatment of the more difficult examples leaves nothing to be desired. The translator may be congratulated on having added one more useful book to the library available to the student and engineer.

N. J. L.

An Elementary Manual of Zoology. By E. C. Cotes. Pp. 119. (Calcutta: Government Printing Office, 1893.)

The encouragement given to scientific instruction and research by the Indian Government is known to all who see the many interesting and important publications which issue from the different departments. Most branches of natural knowledge are fostered in India with a care which could be followed with advantage in the British Isles. The work before us is not a voluminous report, nor is it a richly illustrated monograph of the kind that often emanates from the various departments of the Government. In its way, however, it will do excellent service by providing a course of zoology suitable for the use of students at the Imperial Forest School, Dehra Dun. The author, who is lecturer on zoology in that school, and deputy superintendent of the Indian Museum, points out that the particular animals with which the Indian Forest officer is concerned are not treated in sufficient detail in the general text-books. His manual admirably supplies the requisite information, and furnishes a sound elementary course on the classification and habits of the commoner Indian animals. The work is divided into two parts, the first of which is a systematic course, while the second consists of directions for the dissection and examination of specimens. Theory and practice are thus each given a proper share of consideration. The book is a practical one, and the theoretical matter included in it is only such as is likely to be of use to the students for whom it has been designed. Little reference is therefore made to the fundamental theories of modern biology.

Preservation of Health in India. By Sir J. Fayrer, K.C.S.I., F.R.S. Pp. 51. (London: Macmillan and Co., 1894.)

The young European who is about to take up a long residence in India, could not do better than "read, mark, learn, and inwardly digest" what Sir Joseph Fayrer has to say about the preservation of health there. In this primer, so small that it will almost fit into the waistcoat-pocket, we find a good summary of information with regard to the physical characters and the climate of India. To obviate the deleterious action of the latter, and preserve health, the author lays down a few simple hygienic rules which must be observed. He describes the diseases and accidents in which immediate aid is required, and states briefly the antidotes to be employed in each case. Readers of the book will acquire, pleasantly and easily, a fund of useful knowledge on the most important points concerning health and possible sickness in our Eastern Empire.

First Principles of Building. By Alex. Black. Pp. 329. (London: Biggs and Co.)

They who build houses will find many matters connected with their occupation, presented in a practical light, in the book under review. The choice and preparation of a site, the planning of the dwelling, and the nature and use of the materials to be employed, are considered by the author from a technical point of view. The work is a practical handbook for architects and builders, and contains a mass of highly-compressed information on all points pertaining to the erection of residences.

LETTERS TO THE EDITOR.

The Inheritance of Acquired Characters.

IT may be of interest to your readers to know that two guinea-pigs were born at Oxford a day or two before the death of Dr. Romanes, both of which exhibited a well-marked droop of the left upper eyelid. These guinea-pigs were the offspring of a male and a female guinea-pig, in both of which I had produced for Dr. Romanes, some months earlier, a droop of the left upper eyelid by division of the left cervical sympathetic nerve.

This result is a corroboration of one series of Brown-Séquard's experiments on the inheritance of acquired characteristics. A very large series of such experiments are of course needed to eliminate all sources of error, but this I unfortunately cannot carry out at present, owing to the need of a special farm in the country for the proper care and breeding of the animals. LEONARD HILL.

"Rhynchodemus Terrestris" in Ireland.

IT is now nearly twenty-five years ago since Sir John Lubbock discovered this Land-planarian for the first time in England. Although it is very doubtful whether the two other species, viz. *Geodesmus bilineatus* and *Bipalium kurense*, can be looked upon as truly indigenous in Europe, it is not so with *Rhynchodemus terrestris*.

Since Müller's original discovery of this worm in 1774 in Denmark, it has been taken in the Balearic Isles, near Lille, and on the Mediterranean coast in France, and near Würzburg in Germany. Finally, Sir John Lubbock speaks of it as having been found in Shropshire and Kent in England. More recently Mr. Harmer discovered it near Cambridge, and I have now to add a new locality, having received some specimens from Black-rock, near Dublin. R. T. SCHARFF.

October 22.

Dr. Watson's Proof of Boltzmann's Theorem on Permanence of Distributions.

IN working over Dr. Watson's proof of Boltzmann's H-theorem (Watson, "Kinetic Theory of Gases," second edition, p. 43), it appeared that, probably through a slip, the reasoning given depends on an assumption palpably absurd, *i.e.* that the function whose vanishing defines the beginning or end of an encounter between a molecule belonging to a set with m degrees of freedom and one belonging to another set with n degrees of freedom *is a function of the coordinates of the last molecule only*, the one belonging to the n set. For while he takes the number of molecules of the n set whose momenta and coordinates lie between

$$p_1 \text{ and } p_1 + dp_1 \;\; . \; . \; . \; . \;\; q_n \text{ and } q_n + dq_n$$

as

$$f(p_1 \; . \; . \; . \; . \; q_n)\, dp_1 \; . \; . \; . \; . \; dq_n,$$

he also takes $q_n = 0$ as the condition of encounters between those molecules and others from a set whose coordinates are

$$P_1 \; . \; . \; . \; . \; Q_n.$$

I do not know Boltzmann's proof, but while I suppose it is all right, I find it very hard to understand how any proof can exist. *A priori* the only physical property assumed in Watson's proof is that

$$dp_1 \; . \; . \; . \; . \; dq_n = dp_1' \; . \; . \; . \; . \; dq_n',$$

together with the fact that the number of molecules about a configuration $p_1 \; . \; . \; . \; . \; q_n$ is

$$f(p_1 \; . \; . \; . \; . \; q_n)\, dp_1 \; . \; . \; . \; . \; dq_n;$$

and therefore it would, if true, apply to a system obtained by reversing the velocities when the permanent configuration had been very nearly reached. Such a system would retrace its path and go further and further from the permanent configuration.

Hence it would appear as if the whole conception of Dr. Watson's proof was founded on a mistaken idea of what can be proved, and that all that any proof could show is that, taking all the values of $\frac{dH}{dt}$ got from taking all the configurations which approach towards a permanent configuration of the molecules, *and* the configurations which recede from the permanent configuration (obtained by reversing velocities), and then striking some kind of average among them, the average $\frac{dH}{dt}$ would be negative.

Will some one say exactly what the H-theorem proves?

EDWD. P. CULVERWELL.

Trinity College, Dublin, October 12.

The Meteor-Streak of August 26, 1894.

SINCE the publication of my paper in NATURE of September 27, in which I discussed observations of the fireball of August 26 and its drifting-streak, I have received many additional descriptions which show that some of the earlier reports were not very accurate. The results I derived for the direction and rate of motion of the streak have therefore to be considerably amended to agree with the new materials.

From all the data I find that the height of the streak was fifty-four miles above a point seven miles north-east of Denbigh. From thence it travelled horizontally to south-east, passing successively over Ruabon, Denbighshire, and Wem and Wellington, Shropshire, finally becoming extinct six miles west of Wolverhampton, at just about the same height as at first. It traversed sixty-one miles in thirty minutes, which is equivalent to 176 feet per second.

This deduction differs from the previous one, which assumed the meteoric or cosmic cloud to have been rapidly ascending in the atmosphere during the time it remained visible. Mr. Wood, of Birmingham, obtained a similar result from the earlier observations. I feel certain, however, that no such upward movement of the cloud really occurred, but that it maintained, throughout its rapid drift to the south-east, a nearly uniform elevation of about fifty-four miles above the earth's surface.

Bristol, October 14. W. F. DENNING.

Flight of Oceanic Birds.

JUDGING from Mr. Kingsmill's photograph, it would appear that the bird is just in the position of the half-stroke of the wings when making a fresh start or a sudden spurt. While these birds generally sail about, yet at times they do flap their wings. The movement of the wings in all these oceanic birds is very deliberate. I might here be allowed to point out the interest attaching to such photographs as these; and as many have hand-cameras now, snap-shots of animal life at sea, or of any natural phenomena, would be valuable and interesting additions to our knowledge of sea life. D. WILSON BARKER.

Greenhithe, October 13.

A LONG-PERIOD METEOROGRAPH.

IN order to obtain a record of the principal meteorological variations at the summit of Mont Blanc, M. Jules Richard, of the well-known firm of scientific instrument makers, has constructed for Dr. Janssen a meteorograph which will run through the winter and spring without being re-wound.

The instrument (Fig. 1) is set in action by a weight of about ninety kilograms, which falls from five to six metres in eight months. This weight moves a pendulum, which regulates the movement of the various parts of the apparatus. It was essential that the motion of the pendulum should not be greatly affected by considerable variations of temperature. A modified form of Denison's escapement was therefore adopted by M. Richard (Fig. 1, A.). An advantage of this escapement is that it only requires a very minute quantity of oil. Denison was unable to detect any variation in the uniform motion of the pendulum when the oil had frozen to the consistency of tallow.

All the movements of the meteorograph are given to the respective instruments through a horizontal shafts

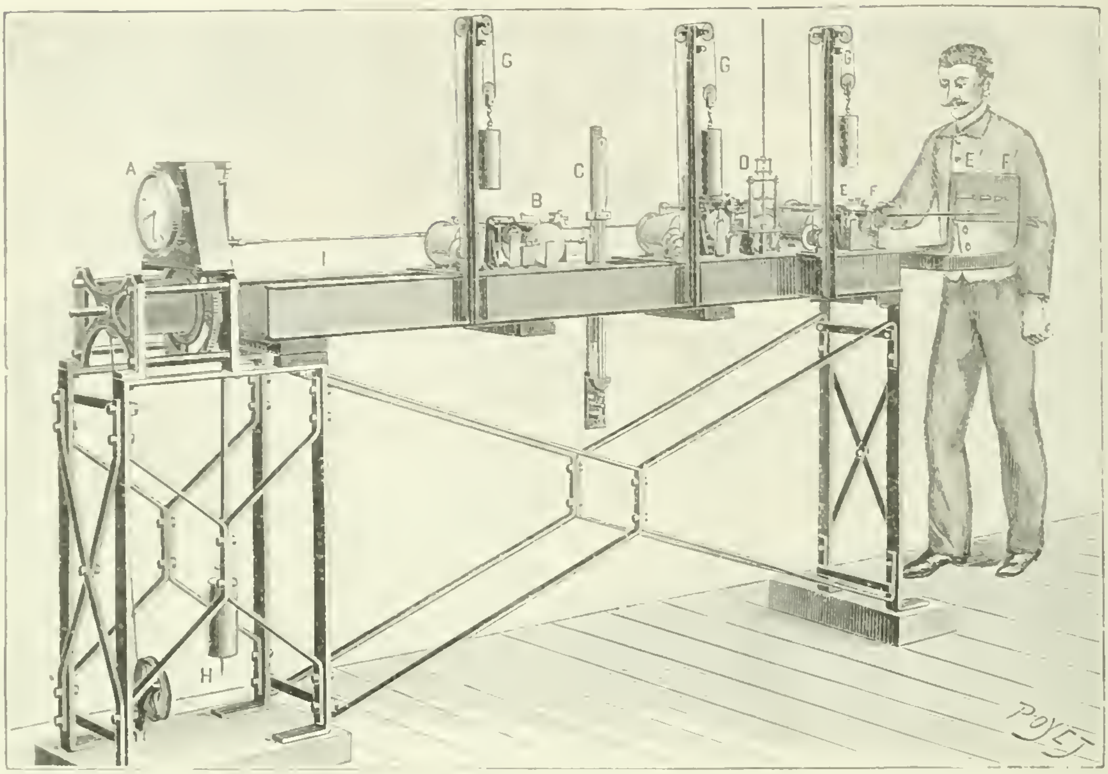

FIG. 1.—Long-period meteorograph for the Mont Blanc Observatory. A, clock to run eight months; B, barometric recording system: C, mercury barometer; D, registering anemometer and anemoscope; E, pen of thermometer; F, pen of hygrometer; E', reservoir of thermometer; F', hairs of hygrometer; G, G, G, counterpoises for ensuring the regular movement of the paper spindles; H, pendulum of clock; I, transmitter of the clock-movement to the different recording systems.

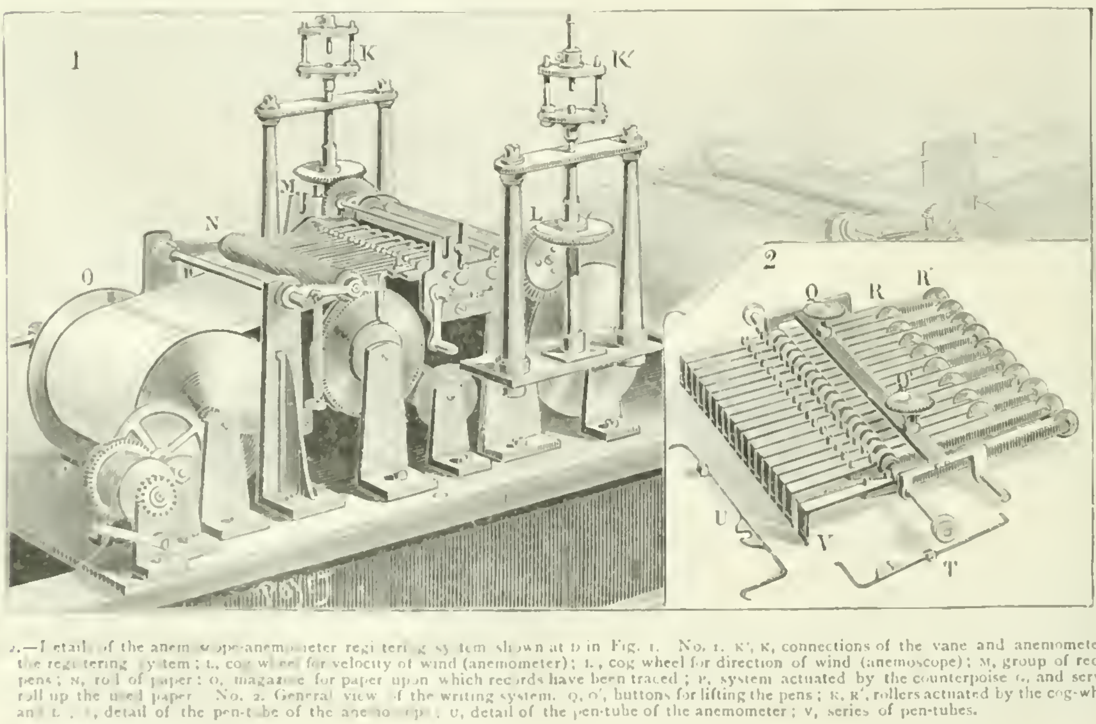

FIG. 2.—Details of the anemoscope-anemometer registering system shown at D in Fig. 1. No. 1. K', K, connections of the vane and anemometer with the registering system; L, cog wheel for velocity of wind (anemometer); L', cog wheel for direction of wind (anemoscope); M, group of recording pens; N, roll of paper; O, magazine for paper upon which records have been traced; P, system actuated by the counterpoise G, and serving to roll up the used paper. No. 2. General view of the writing system. Q, Q', buttons for lifting the pens; R, R', rollers actuated by the cog-wheels L and L'; T, detail of the pen-tube of the anemoscope; U, detail of the pen-tube of the anemometer; V, series of pen-tubes.

which is in connection with the pendulum. The shaft is completely rotated round its axis once in twenty-four hours, and this diurnal motion is communicated to the bobbins of paper belonging to the different registering instruments. The paper on these bobbins is unrolled with a different velocity for each instrument.

The instrument for registering variations of atmospheric pressure is shown at B, in Fig. 1. The marking needle records the movements of the mercury in the lower branch of a Gay-Lussac barometer having a very large cistern.

For recording variations of temperature, metallic reservoirs on the Bourdon system are employed, and for humidity a hair or Saussure's hygrometer is used. The velocity and direction of the wind are registered by a new arrangement devised by M. Richard, the principle being as follows :—A cylinder, carrying a certain number of cogs, arranged helically on its surface, is connected with a Robinson's anemometer, and acts by means of the cogs on an equal number of pens, each of which is lifted up in succession and made to mark the drum of paper so long as the cog acts upon it. For registering direction, the apparatus is provided with eight separate pens for the eight principal directions of the wind. For velocity, the cylinder carries ten cogs, which act successively on ten pens. Each pen is geared during one-tenth of a complete rotation of the cylinder, and, knowing the rate of movement of the cylinder, the velocity of the wind may be found from the length of the traces made by the different pens.

The descriptions beneath the accompanying illustrations, for which we are indebted to *La Nature*, tell the use of the different parts of the instrument. In spite of the many precautions which have been taken, Dr. Janssen recognises that the instrument is more or less tentative in character. But the question of long-period meteorographs for meterological stations at high altitudes is so important that the result of the experiment will be awaited with great interest.

NORTH AMERICAN MOTHS[1]

Many works on North American butterflies, and on some groups of moths also, have been published of late years, but the important family of the Noctuidæ has hitherto been much neglected. A great deal has been done in this direction, it is true, but the information is scattered broadcast through periodicals, and but little has been attempted to systematise it, the only existing guide being Grote's "List of North American Moths," which is limited to names of species, without even references to where they are described.

But to work at a group of insects without the aid of catalogues and monographs, is like attempting to study a language without the help of a grammar and dictionary. In the work before us, Prof. Smith has amply fulfilled the latter necessity, as far as regards the family of moths of which he treats. The Noctuidæ may be considered the most extensive family of the larger moths. We have 300 species in England, and Staudinger's last "Catalogue of the Lepidoptera of Europe, North Africa, Asia Minor, Siberia, and Labrador," published in 1871, enumerates 1040 species for those countries, and many have been added since ; and although Prof. Smith does not number the North American species, an examination of his index yields upwards of 3000 species ; and even after making the largest deductions for generic names and synonyms (perhaps too large an allowance), we may still fairly conclude that the Nearctic fauna considerably outnumbers the Palæarctic in this family, though it is not the case in the butterflies.

Prof. Smith has been accumulating materials for a monograph of the North American Noctuidæ for the last ten years. During the course of his studies, he visited London, and made a special study of the important series of type-specimens in the British Museum, which includes a large proportion of those described by Guenée, Walker, and Grote. Consequently he has been able to clear up a good deal of hitherto doubtful synonymy. He has also visited several of the more important museums on the continent, and of course the principal collections in North America had previously been examined by him ; therefore his work is not a mere compilation (though even in this case it would have been of great value), but it represents a large amount of original study.

A rather important question discussed by Prof. Smith in his preface, is that of "types." He remarks :—"Dr. Hayen holds that every specimen named by an author of a species described by himself is a type. Mr. Morrison was yet more liberal, and marked as 'type' a number of specimens of species described by Mr. Grote, having presumably compared them with the actual type. Mr. Grote's practice seems to have been to mark all specimens before him when writing his original description, as 'type,' and I think Mr. Grote is right." Our own opinion is that greater precision is necessary, and that no specimen can be considered a type which was not before an author when he drew up his description. Even so, he should always label one individual specimen, which he considers to represent his species best, as "type," and, properly speaking, there cannot be more than two such "types" of a species, male and female. The remainder of the series should be regarded not as "types," but as "co-types," and specimens which are afterwards compared and considered to agree with them, whether compared by the author of the species himself, or by some other person, should simply be labelled "compared with type." Too much precaution cannot be exerted in these matters. Among other subjects noticed in the preface, are the contents of the various collections consulted by Prof. Smith, the dates of Hübner's works (in which he hardly seems to us to be fully acquainted with the published information), and explanations respecting the manner in which he has arranged the details of his book, in quoting references and localities, &c. All the species contained in the United States National Museum at Washington are marked with an asterisk. A useful index to authors and works cited follows the preface, and the general index, which closes the volume, fills twenty-six pages of small print in double columns.

Great differences of opinion exist between Prof. Smith and other American and European entomologists respecting the classification of the Noctuidæ, and sometimes also respecting the identification of various species cited. This is unavoidable, and in no way interferes with the value of his work. In most cases, Prof. Smith indicates where the type specimens of each species are to be found, and frequently adds valuable notes on identification and variation. Transformations are omitted, owing to the late Mr. Harry Edwards having issued a complete catalogue of the early stages of North American Lepidoptera (*Bulletin* No. 35 of the National Museum).

In conclusion, we may venture to express a hope that it may not be very long before Prof. Smith's promised "Monograph of North American Noctuidæ" is ready to see the light. A catalogue is good, but a monograph is better, and we shall be very pleased to see a work of such magnitude and importance carried to a successful conclusion.

W. F. Kirby.

[1] *Bulletin* of the United States National Museum, No. 44. A Catalogue, bibliographical and synonymical, of the Species of Moths of the Lepidopterous Superfamily Noctuidæ, found in Boreal America, with critical notes by Dr. John B. Smith, Professor of Entomology in Rutger's College. (Washington, 1893.)

NOTES.

REUTER'S correspondent at Amsterdam reports that, according to a telegram received from Batavia, there has been an eruption of the volcano of Galoenggoen, near Garoet, in the Preang Regency. Several native villages are said to have been destroyed. The great eruption of this volcano in 1822 involved an enormous loss of life and property.

A SEVERE shock of earthquake is reported by the Central News correspondent at Tokio as having occurred on Monday night in the province of Akita. The centre of the disturbance was apparently the town of Sakata, which was almost entirely destroyed.

WE regret to note the death of Mr. Charles Carpmael, the Director of the Meteorological Service of Canada. He died at Hastings on Saturday. The death is also announced of General Robson Benson, whose work in connection with the development of the Botanic Gardens at Madras and Rangoon earned for him the esteem of all botanists; and of Mr. Edwin Clark, the engineer. Mr. Clark was a Fellow of the Royal Astronomical and Meteorological Societies.

WE learn from the *American Naturalist* that the Salt Lake Literary and Scientific Association has recently given sixty thousand dollars for the endowment of a chair of Geology in the University of Utah. The chair has been named the Deseret Professorship of Geology, and Dr. J. E. Talmage has been appointed to it.

A CORRESPONDENT informs us that he recently tested two samples of oxygen supplied for the use of lanternists, and found them to be mixtures of sixty-five per cent. oxygen and thirty-five per cent. nitrogen. Persons who use compressed oxygen should therefore obtain, from the dealer who supplies the gas, some kind of guarantee that it is up to a certain standard of purity.

A VERY fine auroral display was observed in New Zealand and the south-eastern parts of Australia on August 20. Mr. H. C. Russell writes to us, that at Sydney the south-eastern sky assumed a peculiar green tint at 6.35 p.m. Clouds interfered with his view of the display, and finally blotted out the auroral light and streamers at 8.33 p.m. In New Zealand, the aurora is said to have been very brilliant.

THE London and Provincial Ornithological Society will hold their ninth annual show at the Royal Aquarium, Westminster, on Tuesday, Wednesday, and Thursday, October 30, 31, and November 1. The extent of the show may be judged by the fact that over one thousand British and foreign birds will be on view.

THE following strange incident is described in the *Times* as having occurred in the reptile-house of the Zoological Society's menagerie, the scene being one of the compartments in which the boa-constrictors are confined. Two large boas occupied the chamber, one snake being nine feet and the other eight feet long. When the house was opened in the morning only one boa was found in this cage; the other had disappeared. Though the survivor was only a foot longer than the other snake, there was no reason to doubt that it had completely swallowed its companion. It was so distended that the scales were almost separated, and it was unable either to coil itself or to move. There is every reason to believe that in accomplishing this almost incredible feat the snake acted by mistake, and that it devoured its companion by what deserves to be called an accident. The larger boa was fed with a pigeon before the house was closed for the night. It swallowed the bird, and the other boa was then given a pigeon, which it had begun to swallow when the snakes were left for the night. It is believed that the larger snake then caught hold of the part of the pigeon which projected from the other's mouth, and gradually enveloped, not only the bird, but the head of the other snake. Once begun, the swallowing process would go on almost mechanically. As the swallowed snake was only one foot less in length than the swallower and of nearly equal bulk, weighing about fifty pounds, the gastric juices must have dissolved the portion which first entered the snake's stomach before the remainder was drawn into the jaws. Though still rather lethargic, the surviving boa is not injured by its meal. It coils itself up without difficulty, and its scales have the beautiful iridescent bloom peculiar to the skin of snakes when in perfect health.

THE Committee of the Bexley Cottage Hospital are to be commended for their enterprise. They have induced Mr. Hiram S. Maxim to consent to exhibit his flying machine to the public on Saturday afternoon, November 3, at Baldwin's Park, Bexley, and to give an account of its history, construction, and future. The machine will be run along its track at a high velocity, so there will be an opportunity of judging of its capabilities. Mr. Maxim's workshop will be open to visitors, and his scientific apparatus will be on view. There will also be a practical display of the Maxim automatic machine guns. This method of obtaining funds for hospital work is worth developing. We hope it will meet with the success it deserves. Perhaps the time will soon come when the public will take as much interest in a scientific invention as it does in a good picture.

TWO Russian Kalmuks from the lower Volga, one of them a Buddhist priest, have recently spent some time in Thasa, and the *Comptes-rendus* of the Paris Geographical Society expresses the hope that they may be able to make public some interesting facts about the sacred city, from which all Europeans have been rigidly excluded for the last half-century.

THE provisional programme issued by the Royal Geographical Society for the Session 1894–5 shows that the Society is responding to the more general interest now being taken by its Fellows in the serious study of geography. The rooms of the Society have been altered and greatly improved, better accommodation being provided for the large collection of maps to which the public has free access, and for the library. A large room has been added to the library for the use of Fellows who wish to carry on special study undisturbed. A new series of technical meetings is to be instituted, at which important papers may be discussed by specialists, and the investigation of the scientific aspects of geography encouraged. It has long been felt that the evening meetings did not serve this purpose, the lateness of the hour and the presence of a large general audience preventing anything like technical discussion or detailed criticism. The new afternoon meetings are intended for specialists only, and they will take place in the map-room of the Society as frequently as occasion arises.

EVENING lectures will continue to be a prominent feature of the activity of the Royal Geographical Society, and the Session will be opened on November 12 by Mr. H. H. Johnston, C.B., who will speak of the British Central Africa Protectorate, of which he is Administrator. The two following meetings will also be devoted to Africa, Mr. Walter B. Harris giving an account of his recent visit in disguise to the oasis of Tafilet in Southern Morocco, and M. Lionel Decle describing his adventurous journey from the Cape to Uganda. Papers are also promised by Mr. Basil H. Chamberlain on the Luchu Islands, Mr. O. Howarth on the Sierra Madre of Mexico, Mr. D. G. Hogarth on recent explorations in Asia Minor, Mr. G. G. Dixon on North-west British Guiana, Mr. S. Butcher on Luristan, Mr. H. Weld-Blundell on Cyrenaica, Mr. W. M.

Conway on the Alps, their limits, structure, and physiognomy, and Mr. C. Raymond Beazeley on a new Periplus of the Erythrean Sea. Mr. J. Theodore Bent, who starts immediately on a new journey from Oman to Aden across Arabia, hopes to return in time to give an account of his travels. The Christmas lectures to young people will be continued, the lecturer this year being Dr. H. R. Mill, and the subject "Holiday Geography."

WE have received a new instalment of the "Annals" (Ejegodnik) of the Russian Geographical Society, vol. iii. 1894, which is on the same high level as the preceding issues of the same series. It contains a review of astronomical, geodetical, and cartographical work done in the year 1892 by the geodetists and topographers of the Ministry of War, and of the hydrographic work done in 1891 by the officers of the Navy. The meteorological and hydrological observations made by officers of the Russian Navy are discussed by P. A. Mordovin; and also the work of the officers of the Ministry of Ways. E. E. Leist gives a review of the work done in the domain of terrestrial magnetism, magnetic anomalies, and magnetic perturbations in Russia; S. N. Nikitin sums up the progress of geological exploration in the Russian Empire; B. Y. Sreznewski deals with the progress of Russian meteorology; and N. I. Kuznetsoff gives an elaborate review of the work done in the domain of botanical geography in Russia, and partly also in West Europe. All these papers are supplied with full bibliographical indexes.

IN the same "Annals," M. Nikitin, who is undoubtedly the highest authority on the Glacial period in Russia, sums up our present knowledge as regards the supposed inter-glacial deposits in East Europe. In his well-known work on the glaciation of Russia, published in 1886, he pointed out that the theory of a double glaciation is utterly inapplicable to that country, and that, if a second glaciation really has existed in Europe, it did not exist in Russia, which must have been free of ice during the period when the ice is supposed to have invaded Europe for a second time. True, a young geologist, M. Krischtafowitsch, announced, in 1891, the discovery of inter-glacial deposits about Moscow, and his article had been quoted in West Europe as a confirmation of the double glaciation theory; but the following year, when his observations were made with greater accuracy, he hastened to recognise that he had too rashly built up his theory. M. Nikitin's opinion is, therefore, that, although the whole question cannot yet be considered as finally settled, there are no facts whatever which the theory of an inter-glacial period in East Europe might be built upon; on the contrary, the facts point to a single glaciation.

THE gradual but somewhat tardy recognition of the part played by motor elements in consciousness in the localisation of objects in space, forms an interesting chapter in the history of the progress of psychological interpretation. A valuable contribution to this subject is to be found in a paper on the localisation of sound, by Prof. Münsterberg and Mr. A. H. Pierce, in the current number of the *Psychological Review*. It is based on a careful experimental investigation, and goes far to establish Prof. Münsterberg's theory, that the assigning of direction to sounds rests upon the union of sensations of sound and motor sensations, the latter originating from actual or intended movements of the head in the direction of the sounding body. The paper, which well illustrates the value of experimental research in psychology, deserves the careful attention of all those who are interested in the psychological aspect of the problems of space.

AN investigation that furnishes a new point of view from which to consider the undoubted Arachnid affinities of that morphological puzzle, the American king-crab, *Limulus*, is described in the *Zeitschrift f. wiss. Zoologie*, vol. lviii. part 1 issued last July. The author is Dr. A. Jaworowski, of Lemberg, and he has traced out the development of the so-called "lung" in a spider, *Trochosa singoriensis*. He finds that this organ does not arise directly as such, but is formed in ontogeny by the secondary modification of a true trachea, which consists at first of a funnel-shaped external or stigmatic chamber, a common tracheal stem, and a bundle of delicate terminal tubules, penetrating some distance into the body. The tracheal tubes gradually atrophy, and on the walls of the external chamber or air-sac, which considerably enlarges, arise a number of parallel lamelliform folds, at right angles to the course of the common tracheal stem. From these structures, which in their early stages recall the appearance presented by the transverse striations of the tracheæ in insects, the respiratory lamellæ of the "lung" are derived. Development thus establishes the Tracheate origin of the Arachnida, and opposes the view that the lungs of spiders have arisen as modifications of the gill-books of a *Limulus*-like ancestor; though Dr. Jaworowski holds that the converse of this proposition—that the gill-books of *Limulus* have been evolved by the modification of Arachnid lungs—is very probably true. Simroth's view that *Limulus* is essentially a land animal, secondarily adapted to a marine existence, is thus confirmed; and Dr. Jaworowski does not hesitate, after a discussion of the nature of the Crustacean gill, to derive the whole phylum Crustacea from the Tracheate stem.

HERREN KOHLRAUSCH and Heydweiler appear to have approximated more closely to the preparation of absolutely pure water than any previous observers. In a paper on the subject, published in the current number of *Wiedemann's Annalen*, they describe the manner in which they prepared and tested the samples of pure water. Water distilled in air shows, even with the greatest precautions, an electric conductivity of $0{\cdot}7 \times 10^{-10}$ at 18°C., mercury being the unit. Distillation in a vacuum of about 0·01 mm. reduces this conductivity to $0{\cdot}25 \times 10^{-10}$, but into this value the solubility of the glass enters as a disturbing factor. A glass vessel employed for the purpose ten years ago had been constantly kept filled with water, with the result that the value for the conductivity found with what was now practically insoluble glass was as low as $0{\cdot}04 \times 10^{-10}$. This value was greatly influenced by changes of temperature, being about 0·014 at 0°, and 0·18 at 50°, but this behaviour had been predicted by the theory of dissociation. The authors now endeavoured to find the true conductivity of absolutely pure water by extrapolation, on the basis of the change of the temperature coefficient with increasing impurity, as given by the theory of dissociation. The value thus obtained for the conductivity of absolutely pure water at 18° C. was $0{\cdot}036 \times 10^{-10}$. It will be seen that the extrapolation only amounted to 10 per cent. The amount of residual impurity was estimated at a few thousandths of a milligramme per litre, which is 10,000 times less than the amount of air normally absorbed from the atmosphere. A curious phenomenon observed in the course of these measurements was the temporary increase of conductivity of the water when the current was of any considerable duration, an increase which sometimes amounted to 100 per cent. The amount of dissociated hydrogen in a cubic metre of water at 18° is calculated to be 0·08 milligrammes, at 0° only 0·036 milligrammes, and at 100° 0·85 milligrammes. Small as are these numbers, they still mean thousands of millions of atoms to the cubic mm., *i.e.* intervals between neighbouring atoms of the order of wave-lengths of light. In our conception, and even in microscopic vision, these free atoms of hydrogen would still appear to fill space continuously. That Ohm's law still holds for such a solution is not surprising.

IN a paper contributed to *L'Eclairage Electrique*, Signor L. Palmieri gives an account of the results he has obtained during the last few years in his study of the earth-currents at the Vesuvius Observatory. One of the earth-lines used terminates in a large copper plate buried in a well at the little village of Resina at the base of the mountain, and follows the direction S.W.–N.E. to the Observatory, where it is taken almost vertically down from the observing room and connected with the lightning-conductor. A shorter line has been tried in several azimuths, but has finally been permanently fixed in a N.W. direction from the Observatory. At first an ordinary astatic galvanometer with rather long magnetic needles was used, but it was found that the powerful currents which passed during thunderstorms often demagnetised the needles, or even magnetised them in the reverse direction. The ordinary form of suspended coil D'Arsonval galvanometer was also found to be subject to the objection that if the metallic suspension was sufficiently fine to allow of the small currents ordinarily obtained being recorded, then the large currents sometimes obtained fused the suspension. Finally the author, after consulting with Marianini, designed an instrument which essentially consists of a small electro-magnet the coils of which are connected to the earth-line and a magnetised needle suspended above this magnet. After more than a year of continuous observation, the author had come to the conclusion that the earth-currents were always from the lower station to the higher; but towards the end of August 1893, the currents commenced to vary in direction, and finally settled down in the opposite direction to that they had taken since 1889, when observations were first started. The change in the direction in the earth-currents occurred at a period when the volcano was more than usually active; but in January and February 1894 the volcano became much less active, and the earth-currents first decreased in intensity and then resumed their old upward direction. The activity, however, broke out again, at the central crater this time, and the earth-currents again changed their direction. In every case it has been found that when the volcano is quiescent the earth-currents ascend, but when the volcano's activity increases, the earth-currents at once change their direction and pass from the higher station to the lower. On June 7, 1891, when the lava made its first appearance, it was noticed that the needle of the astatic galvanometer at that time employed was continually in movement; and this movement was very irregular, the needle often behaving as if it had received a sudden blow.

A BRIEF summary of the analytical work required for the practical examinations in inorganic chemistry of the Science and Art Department is given in "A Laboratory Guide and Analytical Tables," by Mr. James Grant (Smith and Wood, Manchester).

THE October number of the *Proceedings* of the Physical Society of London (vol. xiii. part i.) has been published. It contains thirteen papers and six plates. The *Journal* of the Royal Microscopical Society, for October, has also just been issued.

MESSRS. WILLIAMS AND NORGATE have issued the sixtieth number of their scientific book circular, in which are catalogued new scientific publications, mostly of foreign origin, offered for sale by them. A similar catalogue has been received from Mr. J. H. Knowles, Lavender-hill, London, S.W.

THE *Electrician* Printing and Publishing Company are just issuing "Electric Lamps and Electric Lighting," by Dr. J. A. Fleming, F.R.S. The same publishers also announce, as ready shortly, "Electric Motive Power," with chapters specially dealing with the use of electricity in mines for lighting, haulage, pumping, coal-getting, &c. This latter work is by Mr. Albion T. Snell.

UNDER the title "Régularisation des Moteurs des Machines Electriques," M. P. Minel has completed a series of four volumes, which he has written for the Encyclopédie scientifique des Aide-Mémoire, on electricity and its applications to navigation. This new work has recently been published by MM. Gauthier-Villars, and also a volume on "Fortification," by Lieut.-Colonel Hennebert.

MR. ELLIOT STOCK has published a cheap edition of "A Manual of Exotic Ferns and Selaginella," by Mr. E. Sandford. The book comprises descriptions of more than one thousand species and varieties, and upwards of six hundred synonyms, as well as notes on the history, culture, and management of the plants considered. Amateur, and also professional, horticulturists will find the volume useful.

THE Geographical and Geological Commission of São Paulo, Brazil, has for some years published useful climatological data for that province. The last we have received is for the year 1892, and contains monthly and yearly means for twelve stations, and also for Rio de Janeiro, with a good general discussion, of the data for each place, by Sr. Schneider. As this State forms part of the coffee-growing region of Brazil, the publication of these summaries is of interest, both from scientific and commercial points of view.

FOUR lectures on biology, delivered by Dr. R. W. Shufeldt, before the Catholic University of America, in January 1892, have been reprinted from the *American Field*, and published in pamphlet form. The lectures deal with the history and present domain of biology; the relation of biology to geology; the value of biological study; and the growth and future influence of biology. They caused considerable stir at the time, for Dr. Shufeldt did not mince matters in presenting an account of the bearing of Catholicism to early scientific investigation. Nothing can be found in them, however, that is not sustained by the best of evidence.

DR. BÉLA HALLER has revised his numerous researches upon the morphology of Prosobranchiate molluscs, and has incorporated them in the form of a handsome quarto monograph entitled "Studien über Docoglosse und Rhipidoglosse Prosobranchier nebst Bemerkungen über die phyletischen Beziehungen der Mollusken untereinander," published by Engelmann, of Leipzig. The student of molluscan morphology will find there a lucid and admirably illustrated exposition of anatomical data, and will not fail to be stimulated, if only to opposition, by Haller's peculiar views on the phylogeny and inter-relations of the different molluscan groups.

EVERY student of physical chemistry unfamiliar with the German language will welcome a "Manual of Physico-Chemical Measurements" (Macmillan and Co.), translated by Dr. James Walker from Prof. W. Ostwald's standard work. The German edition was reviewed in these columns at the beginning of this year (NATURE, vol. xlix. p. 219), and it was then remarked that the manual was the only guide to measurements in physical chemistry suitable for service in the laboratory. The book is not intended for the beginner, but for the chemist and physicist who desires to become practically acquainted with the region common to both of them. Dr. Walker's admirable translation will doubtless considerably increase the sphere of usefulness of Prof. Ostwald's work.

A SECOND edition of the late Thomas Laslett's classical work on "Timber and Timber Trees" (Macmillan and Co.), completely revised, with numerous additions and alterations, by Prof. Marshall Ward, has just been published. The arrangement of the work has been completely altered, and the numerous advances that have been made in our knowledge of timber and its properties since 1875, when the first edition was published, have been taken into account. The work now consists of four parts. The first part deals with timber in general; in part ii. the timbers of Dicotyledonous trees are considered; part iii. deals with Coniferous timber trees; and the fourth part chiefly consists of tables showing the results of experimental investigations on the physical properties of timber. The book has been of valuable service to the shipwright and carpenter from the time it first appeared; and Prof. Ward's revision has certainly given it a new lease of life.

THE appearance of a second edition of Lord Rayleigh's "Theory of Sound" (Macmillan and Co.) reminds us that the first edition was reviewed in these columns by that eminent investigator, Hermann von Helmholtz, nearly seventeen years ago. Much additional matter has been included in the new edition, and the subject is carried to the limits of the present state of knowledge. Two new chapters have been interpolated, devoted to curved plates or shells, and to electrical vibrations. It was the author's original endeavour to produce "a connected exposition of the theory of sound, which should include the most important of the advances made in modern times by mathematicians and physicists." This object has been borne in mind in the preparation of the new edition. Lord Rayleigh naturally inclines to physical methods of investigation, but purely mathematical solutions are not entirely eschewed. The work has been recognised as a masterly exposition of a difficult subject ever since it first appeared, and the second edition maintains the high standard of the original.

AN important memoir concerning nitrogen trioxide, nitrous anhydride, N_2O_3, is communicated by Prof. Lunge and Herr Porschnew to the current issue of the *Zeitschrift für Anorganische Chemie*. It is claimed that the investigation, whose results are now published, finally disposes of all doubt as to the existence of this much discussed oxide of nitrogen. The main conclusion derived from the work is that nitrogen trioxide is a well characterised individual substance, which is readily formed under ordinary atmospheric pressure below the temperature of $-21°$ by the union of nitric oxide NO and nitrogen peroxide N_2O_4, and constitutes an indigo-blue liquid. It is stated to be perfectly stable at and below this temperature; but at a temperature slightly superior to this, even under pressure, it commences to decompose, and the dissociation is almost complete upon the conversion of the liquid into gas. Nitrous anhydride in a condition of purity thus appears to be incapable of existence in the gaseous state, while forming a comparatively stable liquid at temperatures below $-21°$. The gaseous product of dissociation, a mixture of nitric oxide and peroxide, exhibits similar chemical properties to those which might have been expected of gaseous nitrogen trioxide, hence of course the difficulty which has been experienced in deciding the question. It is pointed out, however, that the absolute incapability of existence of gaseous molecules of nitrogen trioxide is not proved, and the results of the investigation would appear to indicate that a residue of such molecules does escape dissociation upon the passage of the liquid into the gaseous state, and exists side by side with the molecules of the decomposition products. The experiments upon which these conclusions are based are mainly the following. It was first established that nitric oxide and nitrogen peroxide exhibit only the very slightest inclination to unite chemically at the ordinary temperature and at temperatures up to 100°. It was next found that at the temperature of $-21°$ the two oxides combined in practically exactly molecular proportions to form the indigo-blue liquid. The exact amount of N_2O_3 present in one of the specimens analysed is stated to have been 98·3 per cent. The well known work of Ramsay and Cundall upon this subject is, of course, quoted, and it is stated that the apparently small amount of absorption of nitric oxide by liquid nitrogen peroxide, corresponding to only 3·5 per cent. of N_2O_3, observed during that investigation, was due to the loss of weight by mechanical removal of a portion of the nitrogen peroxide in the stream of issuing nitric oxide. It was further demonstrated that the product of the action of oxygen upon nitric oxide gas behaves, particularly towards sulphuric acid, precisely like a mixture, which it probably is, of nitric oxide and nitrogen peroxide. Moreover, the vapour derived from liquid nitrogen trioxide is not stable towards oxygen, but becomes further oxidised until it is almost pure peroxide. The memoir will be found to include an admirable summary of the literature of the subject, together with the views of Prof. Lunge concerning the bearing of the main conclusions of the investigation upon the theory of the sulphuric acid manufacture.

THE additions to the Zoological Society's Gardens during the past week include a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, presented by Mr. Seymour Willoughby; a Pig-tailed Monkey (*Macacus nemestrinus*) from Java, presented by Mr. H. M. Vincent; a Tiger (*Felis tigris*) from Amoy, China, presented by Mr. Robert Bruce; a Tiger Cub (*Felis tigris*) from Burmah, presented by Mr. John Halliday; a Ring-tailed Coati (*Nasua rufa*) from South America, presented by Mr. J. E. Symonds; two Brazillian Caracaras (*Polyborus brasiliensis*) from South America, presented by Lord Lilford; two Grey-breasted Parrakeets (*Bolborhynchus monachus*) from Monte Video, presented by the Inns of Court Hotel Company; an Egyptian Jerboa (*Dipus ægyptius*) from Egypt, a Patagonian Conure (*Conurus patagonus*) from La Plata, two Brazilian Cariamas (*Cariama cristata*) from South-east Brazil, deposited.

OUR ASTRONOMICAL COLUMN.

TRIANGULATION OF SIXTEEN STARS IN THE PLEIADES.—In addition to the great interest that has always been attached to this bright group of stars, the Pleiades, as can be gathered from the numerous myths (NATURE, vol. xlix. p. 366) which have been handed down to us, their value to the practical astronomer has been by no means small. In most astronomical measurements, observations have first to be made on stars the positions of which are accurately known, in order to determine the instrumental constants: thus, for instance, the pitch of micrometer screws, ring micrometer constants, &c. The Pleiades, as they consisted of a group of bright stars suitable for such determinations, were constantly used for these purposes, and this necessitated a previous complete knowledge of their positions and motions.

At the present day, however, the stars in the Pleiades group are rather of too bright a nature and too varied in magnitude for very accurate determinations of instrumental constants, and the tendency is now to turn to that group of stars in Perseus, which is more suitable in many respects. A recent triangulation of this region has lately been undertaken by Prof. Wilhelm Schur at Göttingen, with the large heliometer, the results of which appeared in the *Proceedings of the Royal Society of Sciences of Göttingen*. The triangulation to which we wish to refer is of sixteen stars in the Pleiades, and has been made by Dr. Leopold Ambronn at the Göttingen Observatory (*Astronomische Mittheilungen von der Königlichen Sternewarte zu Göttingen*, Bd. xxxix. 3 part).

The instrument employed, a good illustration of which is given, was the small Fraunhofer heliometer, which in earlier times was used in the two Venus Expeditions of this century. It might at first sight seem superfluous to attempt this triangulation with such a small instrument, when we are already acquainted with the results obtained from larger heliometers.

The value of this investigation lies, however, in the very minute determinations of the instrumental constants, and these would be interesting even if nothing more were attempted.

Dr. Ambronn has, however, after making these instrumental constant determinations, measured the positions of sixteen of the Pleiades stars, and compared them with the results obtained from Elkin's new computed values of Bessel's measures made with the Konigsberg heliometer. The following table is of interest, as it brings out the great accuracy of the Gottingen observations, and leads to suggestions regarding the grouping of the stars in numerous systems.

Stars.	Gottingen.—Konigsberg		Relative proper motion for 50 years in	
	R.A.	Decl	Magnitude.	Direction.
g	+0″·06	+0″·09	0·13	29·0
b	+0·20	+0·42	0·46	23·2
m	−0·66	−0·18	0·63	253·3
e	+0·49	+0·12	0·47	75·1
c	−0·52	+0·07	0·49	81·1
k	−0·01	+0·13	0·14	4·4
l	−0·09	+0·16	0·18	26·6
d	−0·35	−0·06	0·33	259·5
12	−0·60	−0·01	0·55	268·9
η	—	—	—	—
28	+0·12	+0·22	0·25	26·6
[illegible]	+1·30	−0·76	1·42	122·5
f	−0·04	−0·16	0·17	194·1
h	+0·04	−0·03	0·05	53·1
34	0·60	+0·23	0·60	67·3
40	+0·44	+0·50	0·64	38·7

Dr. Ambronn points out that the proper motions appear to show, just as those of Elkin's indicated, that the stars form not one but several systems. As will be seen from the table, *g*, *b*, *k*, *l* (and 28) appear to group themselves together, so also *e* with *c*, and the three stars *m*, *d*, 12, with one another. For a more definite opinion on this point it is suggested that the number of stars observed must be greatly increased.

The result of the triangulation shows, however, that by a suitable determination of the instrumental constants and due care in arranging the measures for reduction, small heliometers can give results, especially with regard to distances, which compare very favourably with instruments of much larger size.

The Fifth Satellite of Jupiter.—A series of micrometrical measures of the fifth satellite of Jupiter, made during the opposition of the planet in 1893, is contributed to the *Astronomical Journal*, No. 325, by Prof. E. E. Barnard. From numerous observations, Prof. Barnard is confident that the satellite is not brighter than the thirteenth magnitude. Its sidereal period appears to be 11h. 57m. 22·618s. Filar-micrometer measures of the diameters of Jupiter were made in the course of the work, the following values being obtained:—

Equatorial diameter .. ... 90,190 ± 56 miles.
Polar diameter .. . ... 84,570 ± 75 miles.

The polar compression obtained from these measures is 1/15·98. The mean of measures of east elongations of the satellite, made from September 1893 to January 1894, correspond to a distance of 111,910 miles. But on account of the eccentricity and revolution of the orbit of the satellite, the elongation distance is a varying quantity. M. Tisserand was led to conclude, a short time ago, that the major axis of the satellite's orbit must make a complete revolution in about five months. He returns to the subject in *Comptes rendus* for October 8, having used Prof. Barnard's new measures to make another determination of the eccentricity and the longitude of perijove at a given epoch. His discussion of the observations has led to the following results:—Semi-major axis, 47″·906; eccentricity, 0·0073; longitude of perijove at the epoch October 28, 1892, 14°.

THE PAST SUMMER.

An examination of the meteorological results for the six months from April to September exhibit some features of interest by way of showing how the several elements of temperature, rainfall, and sunshine combine to make up what is commonly called weather, and how, as in the case of the summer in question, the absence of sunshine can mar the season. In some summers the character of the weather varies considerably in different parts of the kingdom, but during the recent summer there was a great similarity in the conditions over the whole of the British Islands, and consequently the principal facts in the following summary, deduced from observations in the neighbourhood of London, will, to a great extent, be an index for other parts of the kingdom.

Table showing the Temperatures at Greenwich for the several Months and for the whole Summer.

	Mean.	Diff. from average.	Mean of all highest.	Diff. from average.	Mean of all lowest.	Diff. from average.	Warm days.	Cold days.
April ...	51·9	+3·8	61°·8	+4°·6	41°·9	+3°·0	26	4
May ...	51·8	−2·1	61·1	−3·1	42·5	1·2	10	21
June ..	59·8	−0·6	69·2	−1·7	50·4	+0·5	11	19
July ...	63·6	0·0	73·0	−1·0	54·1	+1·0	13	18
August..	61·4	−1·5	69·2	−3·6	53·6	+0·6	5	26
Sept. ...	55·2	−3·0	62·2	−5·1	48·1	−1·0	6	24
Summer	57·3	−0·6	66·1	−1·6	48·4	+0·4	71	112

The averages used in the above comparison are for the 50 years 1841 to 1890. A warm day is one on which the mean daily temperature is above the average, and a cold day is one on which the mean daily temperature is below the average.

It will be noticed that the mean maximum temperature is below the average, except in April; while the mean minimum temperature is in excess of the average, except in May and September. The highest day temperatures at Greenwich only reached 70° or above on 51 days, and they were distributed as follows throughout the summer:—April, 3 days; May, 2; June, 12; July, 21; August, 12; and September, 1. There were in all only 7 days with a temperature of 80° or above; they occurred as follows:—June, 3; July, 3; and August 1. For the last 50 years, 1845–1894, there have been on the average 75 days with a temperature of 70° and above, and 15 days with a temperature of 80° and above. The summers of 1860, 1879, and 1888 each had a fewer number of hot days than the summer which has just passed, while 1846, 1857, 1858, 1865, 1868, and 1893 each had double the number of hot days. Last year the mean temperature for the whole summer was more than 3° in excess of the mean for the summer this year, but the summer last year was warmer than any during the last half-century, although it was only 0°·2 warmer than in 1868.

The following table gives the rainfall and sunshine at Greenwich, and the sunshine values at Westminster, for the several months and for the whole summer:—

	Rainfall.			Hours of bright sunshine.			
	Rainy days.	Total amount.	Diff. from average of 40 years.	Greenwich.	Westminster.	Diff. from average of 10 years.	Sunless days.
		ins.	ins.				
April	14	1·45	0·21	123	122	− 2	4
May	15	1·53	0·54	137	152	− 32	2
June	11	2·02	0·03	127	155	− 19	2
July	19	3·27	+ 0·87	149	166	− 9	2
August	16	3·04	+ 0·55	114	125	− 39	4
September ...	13	1·27	− 0·98	60	83	− 29	9
Summer	88	12·58	− 0·34	710	803	− 130	23

The above figures show that rain fell with great frequency, but the amount was by no means excessive, and, with the exception of July and August, the monthly falls were below the average. A slightly different result is obtained if the comparison is made with the last 50 years, 1845 to 1894, the average total fall in summer for that period being 12·66 inches, which gives a deficiency of 0·08 inch only for the recent summer. During the whole period of 50 years, the summer falls have been deficient in 32 years, and in excess in 18 years; but the amounts in excess are much larger than the amounts in defect. The driest summer was 6·80 inches in 1870, and this was followed by 7·39 inches during the summer of last year, while the wettest summer was 22·03 inches in 1879.

The sunshine, it will be seen, was very largely deficient; and this was the principal feature of the period, the sun being screened by cloud far more than usual throughout the summer. The smaller amount of sunshine at Greenwich in comparison with Westminster is very pronounced.

The following table gives various elements in connection with the weather for the several districts of the United Kingdom, the results being for the six months, April to September, or a period of 26 weeks.

	Cold weeks.	Wet weeks.	Rainy days.	Total rainfall.	Hours of sunshine.
				ins.	
Scotland, N. ...	10	11	100	16·8	829
Scotland, E. ...	12	11	97	15·8	842
England, N.E. ..	11	11	103	13·3	856
England, E. ...	13	15	102	14·9	923
Midland Counties	14	11	89	12·5	860
England, S. ...	13	14	95	15·0	1003
Scotland, W. ...	16	11	93	15·9	946
England, N.W....	15	13	99	15·0	847
England, S.W. ...	13	11	103	18·2	1037
Ireland, N.... ...	15	13	110	15·0	814
Ireland, S.	14	13	98	18·6	859
Channel Islands...	11	15	107	18·6	1131

The frequency of rain is in excess of the average, except in parts of Scotland, and the amount of rain is in excess, except over the northern portion of the kingdom and in the Midland Counties, the total rainfall for the summer in the latter district being two inches short of the average.

The sunshine was generally deficient, although in the north of Scotland there was an excess of nearly 100 hours. The deficiency during the summer amounted to 186 hours in the Channel Islands, 141 hours in the east of England, and 119 hours in the south of England. CHAS. HARDING.

ON MODERN DEVELOPMENTS OF HARVEY'S WORK.[1]

THIS annual meeting in memory of Harvey is usually associated with feelings of pleasure and happiness, for it was intended by its immortal founder to commemorate the benefactors of the College and to encourage good fellowship amongst us.

Such commemoration of those who have benefited the College in the past, although it, necessarily, recalls many who have passed away, is, notwithstanding, on ordinary occasions pleasant instead of painful, because the feeling of loss through their death is completely overpowered by the recollection of the good they have done in their lifetime. To-day the case is very different, for the first thought that must needs occur to every one present here is that on this occasion last year our late President showed for the first time what seemed to be imperfect fulfilment of his duty to the College by being late in his attendance at the meeting. Perhaps nothing else could have shown more clearly his deep concern for the welfare of the College, and his thorough devotion of every faculty of mind and body to its interests, than the fact that no duty, no pleasure, and no press of occupation could tempt him to leave one iota of his work in the College undone. The only thing that did keep him back was the hand of Death, which, although at the last meeting he and we knew it not, was already laid upon him. Though his death was less happy than that of the great Harvey, inasmuch as he lingered on for days instead of hours after he was first struck down, yet their deaths were alike in this respect that, up to the time of the fatal attack, each was in the full possession of his faculties, each was in the enjoyment of his life. Like Radcliffe and Mead, like Halford and Baillie, and like many other distinguished Fellows of this College, the greatness of Clark is to be estimated not by the published works which he has left behind, but by the influence he exerted on his contemporaries. For the very estimation in which his professional skill was held, led to his whole time being taken up in giving advice, and prevented him from having the leisure to work out or record the results of the pathological and clinical observations which both his youthful publications and his later career showed him to be specially fitted to make. I might say very much more about him, but it has already been said much better than I could possibly do it by yourself, Mr. President, in your annual address, and in the eloquent and heart-stirring words which you addressed to the College on the occasion of your taking the presidential chair rendered vacant by the death of Sir Andrew Clark.

But while we are saddened to-day by the death of our late President, we hope to be gladdened by the presence amongst us again of one whom we all reverence not only as a former President of this College, but as one of the greatest leaders of clinical medicine in this century, Sir William Jenner. Like Harvey, Sir William Jenner is honoured by his College, by his country, by his Sovereign, and by the world at large. In times of trial and danger the lives of the Royal children were committed to the keeping of Harvey by his King; and to-day the care not only of her own life, but of that of her nearest and dearest, is committed to Sir William Jenner by his Sovereign, in the full and well-grounded assurance that in no other hands could they be more safe. The great clinician, Graves, wished to have as his epitaph "He fed fevers"; but Jenner has advanced much beyond Graves, and, by showing us how to feed the different kinds of fevers, has saved thousands of valuable lives. To-day this College is acknowledging his right to rank with Sydenham, Heberden, Bright, and Garrod, by bestowing upon him the Moxon medal for clinical research. In numbering Sir William amongst its medallists, the College honours itself as well as him, and in acknowledging the great services he has rendered, it is, on this occasion, acting as the mouthpiece of the medical profession, not only in this country, but in the world at large.

It was with the wish to keep green the memory of the benefactors of the College that this oration was instituted by Harvey, and not at all with the intention that it should be devoted to his own praise. But Harvey stands out so high above all others, that it is only natural that in the numerous orations which have been yearly given before the College of Physicians, the subject-matter should have been, to a great extent, confined to a consideration of Harvey and his works. On looking over many of these orations, I find that everything I could say about Harvey, his person, his circumstances, his character, and his works, has already been said so fully and eloquently that I could not add to it anything further, nor could I hope to express it even so well. I purpose, therefore, to consider to-day some of the modern developments of Harvey's work, more especially in relation to the treatment of diseases of the heart and circulation. There is, I think, a certain advantage in this also, inasmuch as one is apt by considering Harvey's work only as he left it, to overlook the enormous extent to which it now influences our thoughts and actions; and thus to comprehend its value very imperfectly.

As he himself says, "From a small seed springs a mighty tree; from the minute gemmule or apex of the acorn, how wide does the gnarled oak at length extend his arms, how loftily does he lift his branches to the sky, how deeply do his roots strike down into the ground!"[1]

How very minute is the gemmule from which has sprung everything that is definite in medical science, for this gemmule is no other than the idea which Harvey records in these simple words: "I began to think whether there might not be motion as it were in a circle."

Out of this idea has grown all our knowledge of the processes of human life in health and disease, of the signs and symptoms which indicate disease, of the mode of action of the drugs and appliances which we use, and the proper means of employing them in the cure of disease. In the works that have come down to us, we find that Harvey developed his idea physiologically in several directions. He discussed its application to the absorption and distribution of nourishment through the body, the mixing of blood from various parts, the maintenance and distribution of animal heat, and excretion through the kidneys. How far he developed it in the direction of pathology and therapeutics we do not know, as the results of his labours

[1] The Harveian Oration, delivered at the Royal College of Physicians, on October 18, by Dr. T. Lauder Brunton, F.R.S.

[1] "The Works of W. Harvey," Sydenham Society's Edition, p. 320.

on these subjects have, unfortunately, been lost to us by the destruction of his manuscripts during the Civil War.

We are proud to reckon Harvey as an Englishman by birth, but he is far too great to belong exclusively to any country; men of various nations and scattered all over the face of the earth acknowledge him as their teacher, and have played, or are playing, a part in developing his discovery in its various branches of physiology, pathology, pharmacology, semeiology, and therapeutics. Americans, Austrians, Danes, Dutchmen, French, Germans, Italians, Norwegians, Russians and Swedes have all shared in the work, and so numerous are they that it would be impossible for me to name them all. Stephen Hales, however, deserves special mention, for he was the first to measure the pressure of blood in the arteries, and the resistance offered to the circulation of the blood by the capillaries was investigated by Thomas Young, a Fellow of this College, who ranks with Harvey, Newton, and Darwin as one of the greatest scientific men that England has ever produced, and whose undulatory theory has been as fertile of results in physics as Harvey's idea of circulation has been in physiology and medicine.

Harvey's desire that those who had done good work should not be forgotten was founded upon his knowledge of mankind, and of the tendency there is to forget what has already been done by those who have gone before us. The opposite condition often prevails, and the past is glorified at the expense of the present. But sometimes the present is wrongly glorified at the expense of the past, and past work or past benefits are forgotten.

Good examples of this are afforded by physiological views regarding the action of the vena cava and pulmonary veins and the causation of the cardiac sounds. Harvey appears to have thought that the vena cava and pulmonary veins were simply dilated passively by the passage of blood into them; but the fact that they possess a power of independent pulsation was known to Haller,[1] and was brought prominently forward by Senac,[2] who regards the vena cava as the starting-point of the whole circulation. He says: "The vena cava is therefore the first motor cause which dilates the cavities of the heart; it fills the auricles, and extends their walls in every direction."

These observations appear to have been almost forgotten until they were again made independently a few years ago,[3] and in one of the latest and most accurate physiological treatises which now exist, the description of the cardiac cycle is nearly the same as that given by Senac. "A complete beat of the whole heart, or cardiac cycle, may be observed to take place as follows:—

"The great veins, inferior and superior venæ cavæ and pulmonary veins are seen, while full of blood, to contract in the neighbourhood of the heart; the contraction runs in a peristaltic wave toward the auricles, increasing in intensity as it goes."[4]

The pulsation of these veins, however, cannot be a constant phenomenon, or it would have been noticed by such a keen observer as Harvey.

The sounds of the heart were discovered by Harvey, or at least were known to him, for he speaks of the sound caused in the œsophagus of the horse by drinking, and says: "In the same way it is with each motion of the heart, when there is a delivery of blood from the veins to the arteries that a pulse takes place and can be heard within the chest." This observation remained, as far as we know, without any further development until the time of Laennec, who introduced the practice of auscultation; but it was a Fellow of this College, Dr. Wollaston,[5] who first discovered that the muscles during contraction give out a sound; and although many observations were made regarding cardiac murmurs by Corrigan, Bouillaud, and Piorry, it was chiefly by Fellows of this College, Dr. Clendinning, Dr. C. J. B. Williams, and Dr. Todd, that the question was finally settled, and the conclusions at which they arrived are those now accepted as correct, viz. that "the first or systolic sound is essentially caused by the sudden and forcible tightening of the muscular fibres of the ventricle when they contract; and that the second sound which accompanies the diastole of the ventricle depends solely on the reaction of the arterial columns of blood in the semilunar valves at the arterial orifices."[1]

Yet in recent discussions regarding the origin of cardiac sounds, little mention has been made of the work of this committee; and, indeed, I first learned of the value of the work from a German source, Wagner's "Handworterbuch der Physiologie."

The importance of these observations in the diagnosis of heart disease it would be hard to over-estimate. But diagnosis alone is not the aim of the physician, whose object must be to prevent, to cure, or to control disease. A knowledge of physiology may greatly help us to prevent disease, not only of the heart and vessels, but of every member of the body. The control and cure of disease may also be effected by diet and regimen, but it is undoubtedly in many cases greatly assisted by the use of drugs, and is sometimes impossible without them. Harvey knew that drugs applied externally are absorbed and act on the body,[2] so that colocynth thus applied will purge, and cantharides will excite the urine; but the action of drugs when injected into the blood appears to have been tried first by Christopher Wren, better known as the architect of St. Paul's than as a pharmacologist. According to Bishop Spratt, "He was the first author of the noble anatomical experiment of injecting liquors into the veins of animals, an experiment now vulgarly known, but long since exhibited to the meetings at Oxford, and thence carried by some Germans, and published abroad. By this operation divers creatures were immediately purged, vomited, intoxicated, killed, or revived, according to the quality of the liquor injected. Hence arose many new experiments, and chiefly that of transfusing blood, which the Society has prosecuted in sundry instances, that will probably end in extraordinary success."[3]

The method originated by Wren, of injecting drugs into the circulation, was skilfully utilised by Magendie for the purpose of localising the particular part of the body upon which the drugs exerted their action, and he thus conclusively proved that the symptoms produced by strychnine were due to its effect on the spinal cord. His experiments showed that the rate of absorption from various parts of the body varied enormously, and, through the teaching of Christison, led to the introduction into practice by Dr. Alexander Wood of that most useful aid to modern therapeutics, the hypodermic syringe.

The first quantitative experiments on the effect of drugs upon the circulation were made, to the best of my knowledge, by James Blake in 1844, in the laboratory of University College, at the suggestion of the late Prof. Sharpey, with the hæmodynamometer of Poiseulle, which had then been recently introduced.

In speaking about the work of Blake and Sharpey, who are both dead, one requires to use the greatest care not to unduly detract from the merit of one by ascribing more to the other; but those who knew Prof. Sharpey's enormous range of knowledge, his readiness to put it all at the disposal of others, and the influence he exerted upon all who came in contact with him, as well as his unselfishness in making no claim whatever to what was justly his due, will at once recognise how greatly Blake was indebted to Sharpey. More especially is this the case when we consider that, although the credit for the observations themselves belongs to Blake, yet after the impetus which Sharpey gave him had passed away, he did very little more during the course of a long life. It seems all the more necessary to commemorate Sharpey on this occasion because he has left comparatively few writings behind him, and anyone who should judge by them alone of his influence upon physiological progress in this country would grievously underestimate it. For Sharpey was above all a teacher, and his work was written not with pen and ink on paper or parchment, but was engraved upon the hearts and minds of his pupils and friends. Upon two of these, especially, has Sharpey's mantle fallen, and to Burdon Sanderson and Michael Foster we owe a revival of experimental physiology in this country, a revival of the method which Harvey not only used in making his great discovery, but also employed to demonstrate the truth of it to the rulers of this land. By their writings, by their lectures, by their original experiments, by their demonstrations, and by the pupils they have trained, Burdon

Sanderson and Michael Foster, under the auspices of Acland and Humphrey, have diffused amongst the medical men of this country a knowledge of physiology so extensive and exact as could only be found, before their time, amongst those who had made a special study of the subject. Yet more than to them, more than to anyone else since the time of Harvey, do we owe our present knowledge of the circulation to Carl Ludwig. He it is who first enabled the pressure of blood in the arteries to record its own variations automatically, so that alterations could be noticed and measured which were too rapid or too slight to be detected by the eye. To him, also, we owe the plan of artificial circulation by which the changes in the functions of the organs and in the vessels which supply them can be observed, quite apart from the heart, lungs, or from the nervous system.

Like Sharpey, Ludwig is a great teacher, and like the great architects of the Middle Ages, who built the wonderful cathedrals which all admire, and the builder of which no man knows, Ludwig has been content to sink his own name in his anxiety for the progress of his work, and in his desire to aid his pupils. The researches which have appeared under these pupils' names have been in many instances, perhaps in most, not only suggested by Ludwig, but carried out experimentally with his own hands, and the paper which recorded the results finally written by himself. In the papers which have appeared under his pupils' names we find their obligations to the master recorded in such terms as "unter Mitwirkung." But no one, except those who have worked with him, can understand what such co-operation meant.

The graphic method introduced by Ludwig for the purpose of measuring the blood pressure, was adapted by Volkmann to the registration of the pulse in man, and the same method has been modified and rendered more easily applicable at the bedside by Marey and Chauveau, to whom we chiefly owe our knowledge of the modifications in the form of the apex beat, and of the pulse curve. It is to Ludwig and his scholars, however, that we owe the greater part of our knowledge of the mechanism of the circulation, and of the varying distribution the blood in various parts of the body.

The effect of emotion upon the heart was carefully noted by Harvey, who says: "For every affection of the mind which is attended with pain or pleasure, hope or fear is the cause of an agitation whose influence extends to the heart." [1]

Not only was Harvey well acquainted with the fact that the beats of the heart vary very much in strength and force, but he also knew that the circulation in various parts of the body may be very different at one and the same time. He says: "It is manifest that the blood in its course does not everywhere pass with the same celerity, neither with the same force in all places, and at all times, but that it varies greatly according to age, sex, temperament, habit of body, and other contingent circumstances, external as well as internal, natural or non-natural. For it does not course through intricate and obstructed passages with the same readiness that it does through straight, unimpeded and pervious channels. Neither does it run through close, hard, and crowded parts, with the same velocity as through spongy, soft, and permeable tissues. Neither does it flow and penetrate with such swiftness when the impulse (of the heart) is slow and weak, as when this is forcible and frequent, in which case the blood is driven onwards with vigour, and in large quantity."

"And what, indeed, is more deserving of attention than the fact that in almost every affection, appetite, hope, or fear, our body suffers, the countenance changes, and the blood appears to course hither and thither. In anger the eyes are fiery and the pupils contracted; in modesty the cheeks are suffused with blushes; in fear, and under a sense of infamy and of shame, the face is pale, but the ears burn as if for the evil they heard or were to hear; in lust, how quickly is the member distended with blood and erected." [2]

Harvey's great contemporary, Milton, though so violently opposed to him in politics, would certainly not remain in ignorance of Harvey's work, and he has noted the changes in the colour of the face produced by emotions. In describing the behaviour of Satan on his journey from Hell to Paradise, he says:—

> "Thus while he spake, each passion dimm'd his face,
> Thrice changed with pale—ire, envy, and despair;
> Which marr'd his borrow'd visage." [3]

But although these facts were known to Harvey so long ago, it is only in comparatively recent years that the mechanism by which they are brought about has been investigated, and it is only within the last decade that physiologists have begun regularly to believe that the cardiac muscle has a power of rhythmic pulsation independent of its nerves, although Harvey had noted that when the heart was cut into small pieces the fragments would still continue to pulsate. We may fairly, indeed, compare the movements of the heart, as regarded by physiologists of the present day, to those of a horse which is capable of going independently, although its pace may be slowed or accelerated by the reins or spur of the rider. The power of the vagus to act as a rein to the heart, and slow its movements, or stop them altogether, was first noted by Edward and Ernest Heinrich Weber, while the effect that it sometimes has of accelerating instead of slowing, like the effect of shaking the reins of the horse, was observed by Schiff, Moleschott, and Lister.

The accelerating nerves of the heart, and the position of the nerve-centre from which they spring, were more thoroughly investigated by von Bezold,[1] while the power of the vagus to weaken as well as slow the heart was observed by Gaskell. The position of the cardiac centre, which, like the rider, regulates the movements of the heart, was located in the medulla oblongata chiefly by Ludwig and his scholars. Like the heart, the vessels also are regulated in diameter by the nervous system in accordance with the wants of the body generally; and the effect upon the vaso motor nerves which, when cut, allow them to dilate, and when stimulated cause them to contract, was discovered by Bernard, Brown-Séquard, and by our countryman, Waller; while the power of other nerves to cause immediate dilatation was discovered by Bernard, Eckhardt, and Ludwig in the submaxillary glands, penis, and peripheral vessels respectively.

The heart, when cut out of the body, still continues to beat, and the transmission of excitation from one cavity to another was experimented on by Paget, although removed completely from the influence of the central nervous system, and the vessels have a somewhat similar power of independent contractility. The alterations produced in the circulation generally and locally by the contractile power of the vessels, and the changes caused in the vessels by the central nervous system, by peripheral stimulation of the nerves, or by variations in the quality of the blood, have formed the subject of a series of researches extending over many years; and though originated, and in many cases entirely conducted, by Ludwig, have appeared to a great extent under the names of his pupils. The starting-point of these investigations was an examination of the changes in the blood as it flowed through isolated organs, with the view of ascertaining in what manner the combustion by which the animal heat is maintained was effected in the body. While keeping up the circulation of blood through the vessels of muscles severed from the body, Ludwig and Sczelkow[2] observed variations in the flow which appeared to indicate contractile power in the vessels themselves. This research was carried on under Ludwig's direction by various of his scholars in succession, Alexander Schmidt, Dogiel, Sadler, myself, Hafiz, Lepine, A. Mosso, von Frey, and Gaskell. Their observations, as well as those of Cohnheim and Gunning, have shown that the muscular fibres of the arterioles, not only in the muscles but throughout the body generally, have a power of independent and sometimes rhythmical contraction and relaxation. Their contractility is, however, controlled by the central nervous system in accordance with the wants of the body generally. For the amount of blood contained in the body is insufficient to fill the whole of the vascular system at once; and when the vessels are fully dilated, as they are after death, we find that nearly the whole of the blood of the body may be contained in the veins alone. It is, therefore, necessary that when one part of the body is receiving a larger supply of blood, another should be receiving a smaller supply; and the functions of the vaso motor centres have been well compared by Ludwig to the turncocks in a great city, who cut off the water supply from one district at the same time they turn it on to another. Thus it is that when the brain is active the feet may get cold, and Mosso has shown this in an exceedingly neat manner by placing a man on a large board delicately balanced at its centre, and demonstrating that

[2] Ludwig and Sczelkow, "Henle and Pfeuffers Zeitschrift," 1863, vol. 17. p. 106 and *vide* p. 122.

whenever the man began to think, the increased supply of blood to his brain caused the head to go down and the heels to rise up. A similar condition was indicated by Mayow, who gave a different explanation. He said that the vital spirits were not able to be in the same place at once, and therefore it happens that if a man eats a heavy meal, he is apt to become drowsy, because the vital spirits descend from the brain to the stomach in order to carry on digestion; and, on the other hand, if a man thinks vigorously after dinner, the vital spirits have to leave the stomach to go to the brain, and consequently digestion is imperfectly performed. If we substitute the word blood for vital spirits, we have an exact expression of present physiological ideas.

Ubi stimulus ibi affluxus was an old doctrine and expressed a great truth. Wherever the need for increased nourishment or increased supply of oxygen exists in the healthy body, thither does the blood flow in larger quantities than usual. If the glands are active, their blood supply is greatly increased, as was shown by Bernard, and a similar occurrence takes place in the contracting muscle, as has been shown by Ludwig and his scholars. The vessels of the intestines and of the skin, with their numerous glands, have their calibre regulated by the vaso motor nerves which proceed from the centre in the medulla oblongata. This centre acts most readily upon the vessels of the intestine, and rather less readily on those of the skin. In consequence of this, when the centre is irritated, the vessels of the intestine contract and drive the blood through the skin, so that it is warmer than before, and it is only when the stimulation is very great that the vessels of both contract so that the skin receives less blood than normal, and becomes colder than before. But if the vessels of the skin and intestine are both contracted, where does the blood go? This question was put by Ludwig, and answered by the experiments which he made with Hafiz. It is evident that if the heart be stopped while the blood pressure is being measured in the artery of an animal, the pressure will fall regularly and steadily, because the blood is flowing out all the time through the arterioles and capillaries into the veins. One would naturally expect that if the arterioles were contracted by irritation of the vaso motor centres in the medulla, the fall of blood pressure would either not take place at all, or would be very much slower than before; but on trying the experiment, Ludwig and Hafiz found, to their surprise, that the blood pressure fell almost as quickly as when the vaso motor centre was left alone, and the vessels of the skin and intestine therefore remained uncontracted. In other words, the vessels which supply the muscles of the body and limbs are capable of such extension that when fully dilated they will allow the arterial blood to pour through them alone nearly as quickly as it usually does through the vessels of the skin, intestine, and muscles together. This observation, it seems to me, is one of the greatest importance, and one that has hardly received as yet the attention which it merits.

It is obvious that contraction of the cutaneous vessels, such as occurs upon exposure to cold, will drive more blood through the muscles, and as oxidation goes on more rapidly in them the result will be increased production of heat.

The experiments I have just mentioned show that the vessels of the muscles are not controlled by the vaso motor centre in the medulla oblongata in the same way as those of the intestine and skin. How far their vascular centres may be associated with those for voluntary movements, which have been so admirably localised by Ferrier in the cerebral cortex, still remains to be made out. The circulation through the muscles is indeed a complex phenomenon, and it was shown by Ludwig and Sadler to depend upon at least two factors having an antagonistic action. When a muscle is thrown into action, it mechanically compresses the blood vessels within it, and thus tends to lessen the circulation through it, but at the same time the stimulus which is sent down through the motor nerve, and which calls it into action, brings about a dilatation of the vascular walls, and thus increases the circulation through the muscle.

When the amount of blood is measured before, during, and after stimulation of its motor nerves, it is sometimes found that the flow is diminished, at others that it is increased, the alteration depending upon the comparative effect of the mechanical compression of the vessels of the muscles just mentioned, and upon the increase of their lumen by the dilatation of their walls. It invariably happens, however, that after the muscle has ceased to act, the flow of blood through the muscle is increased. This increase is quite independent of any alteration in the general pressure of blood in the arteries, and it occurs when an artificial stream of blood, under constant pressure, is sent through the muscle. The dilatation in the muscular vessels, as indicated by the increased flow of blood, and consequent change of colour in the frog's tongue, was observed by Lépine after stimulation of the peripheral ends of the hypoglossal and glossopharyngeal nerves, and the actual changes in the vessels themselves were observed microscopically by von Frey and Gaskell.

The dilatation of muscular vessels on irritation of peripheral nerves was thus brought into a line with the dilatation noticed in the vessels of the submaxillary gland by Bernard, and in the corpora cavernosa by Eckhart. It is evident that alteration in the size of such a huge vascular tract as the muscular arteries must influence, to a great extent, the blood pressure in the arteries generally, and it is equally evident that the changes induced in the condition of the blood pressure by muscular action may be of two kinds, either a rise or a fall. If the arterioles are compressed by the muscles so that the flow through them is impeded, the general blood pressure will rise. When this effect is more than counteracted by the dilatation of the arterioles themselves under nervous influence the general blood pressure will fall, for the blood will find an easy passage through the vessels from the arteries into the veins. We can thus see how readily a rise or fall in the general blood pressure may be induced by exercise of the muscles. If they contract suddenly or violently they will tend to compress the arterioles, and raise the blood pressure, while quite easy contraction will have little effect in compressing the arterioles, and these, becoming dilated, will allow the blood pressure to fall.

But there is still another factor which may tend to increase the blood pressure during severe muscular exertion, viz. a quickened pulse for stimulation of the nerve fibres extending from the muscles to the central nervous system greatly accelerates the beats of the heart. In this respect stimulation of the muscular nerves differs from that of the cutaneous and visceral nerves, inasmuch as the latter tend rather to slow than to quicken the pulse. The peculiar effect of the muscular nerves upon the heart would, indeed, appear to be a provision of nature for the purpose of maintaining an exceedingly active circulation during the active calls upon nutrition which violent exertions entail. Muscular exercise, therefore, has a special tendency to raise the blood pressure in the arterial system, and consequently to increase the resistance which the left ventricle has to overcome. Moreover, in the case of the intestinal vessels there is a special provision made for preventing their contraction from causing too great a rise of arterial pressure. This consists in the depressor nerve, which passes from the heart and tends to produce dilatation of the abdominal vessels, and thus prevent any undue pressure occurring within the heart from their excessive contraction.

In the case of the muscles, we have no such nerves. Its place seems to be taken by the dilating fibres which occur in the motor nerves. As I have already said, however, this effect of dilatation in the muscular vessels may be at first more than counteracted by mechanical compression at the commencement of exertion, and thus the blood pressure in the arteries, and the resistance which it opposes to the contraction and emptying of the ventricle, may be unduly increased.

As a general rule, the distension of any hollow muscular organ is attended with great pain. How great is the suffering when obstruction of the bowel prevents evacuation of its contents; or when a calculus, in its passage down the gall duct or ureter, forcibly distends their wall. One of the severest tortures of the Middle Ages was to distend the stomach with water, and the Emperor Tiberius could imagine no more awful punishment for those whom he hated than to make them drink wine, and, at the same time, by means of a ligature, to prevent the distended bladder from emptying itself. The heart is no exception to this rule, and distension of its cavities brings on most acute physical suffering. Its inability to empty itself is a question of relative, and not of absolute, power; for a strong heart may be unable to work only against enormously increased resistance in the peripheral arterioles, while the heart, weakened by degeneration, may be unable to empty itself in face of pressure little, if at all, above the normal.

When the contractile power of the heart is not, as it is in health, considerably in excess of the resistance opposed to it in vessels, but only nearly equal to it, a slight increase in the resistance may greatly interfere with the power of the heart to empty itself, and bring on pain varying in amount from slight uneasiness to the most intense agony in angina pectoris.

This is, indeed, what we find, for a heart whose nutrition has been weakened by disease of the arteries, and consequent imperfect supply of blood to the cardiac muscle, is unable to meet any increased resistance if this should be offered to it, and pain is at once felt. In such cases, unless they be far advanced, we find, precisely as we might expect, that walking on the level usually causes no pain, but the attempt to ascend even a slight rise, by which the muscles are brought into more active exertion, brings on pain at once. Yet here again we find, as we should expect, that if the patient is able to continue walking, the pain passes off and does not return. These phenomena would be inexplicable were it not for Ludwig's observations on circulation through the muscles, but in the light of these observations everything is made perfectly intelligible. Walking on the flat, by causing no violent exertion of the muscles, produces no mechanical constriction of the vessels, and thus does not increase the blood pressure. The greater exertion of walking up a hill has this effect, but if the patient is able to continue his exertions, the increased dilatation of the vessels—a consequence of muscular activity—allows the pressure again to fall, and relieves the pain.

As muscular exertion continues and the vessels of the muscles become dilated, the flow of blood from the arteries into the veins will tend to become much more rapid than usual. The pressure in the arterial system will consequently fall, but that in the veins will become increased, and unless a corresponding dilatation occurs in the pulmonary circulation, blood will tend to accumulate in the right side of the heart, the right ventricle will be unable to empty itself completely, shortness of breath will arise, and even death may occur. At first the right side of the heart is affected, and the apex beat disappears from the normal place and is felt in the epigastrium, but the left ventricle also becomes dilated, though whether this is simply through nervous influence tending to make it act concordantly with the right, or for some other reason, it is at present impossible to say. Severe exertion, even for a few minutes, may produce this condition in healthy persons,[1] and when the exertion is over-continued it may lead to permanent mischief. More especially is this the case in young growing boys, and it is not merely foolish, it is wicked to insist upon boys engaging in games or contests which demand a long-continued over-exertion of the heart, such as enforced races and paper-chases extending over several miles. Intermittent exertion, either of a single muscle or of a group of muscles, or of the whole body, appears to lead to better nutrition and increased strength and hypertrophy, but over-exertion, especially if it continues, leads to impaired nutrition, weakness, and atrophy. If we watch the movements of young animals, we find that they are often rapid, but fitful and irregular and varied in character, instead of being steady, regular, and uniform. They are the movements of the butterfly, and not of the bee. The varied plays of childhood, the gambols of the lamb, and the frisking of the colt, are all well adapted to increase the strength of the body without doing it any injury; but if the colt, instead of being allowed to frisk at its own free will, is put in harness, or ridden in races, the energy which ought to have gone to growth is used up by the work, its nutrition is affected, its powers diminished, and its life is shortened. The rules which have been arrived at by the breeders of horses ought to be carefully considered by the teachers of schools, and by the medical advisers who superintend the pupils.

In youth and middle age every organ of the body is adapted for doing more work than it is usually called upon to do. Every organ can, as it is usually termed, make a spurt if required; but as old age comes on this capacity disappears, the tissues become less elastic, the arteries become more rigid and less capable of dilating and allowing freer flow of blood to any part, whether it be the intestine, the skin, the brain, the muscles, or the heart itself. Mere rigidity of the arteries supplying the muscles of the heart will lessen the power of extra exertion, but if the vessels be not only rigid, but diminished in calibre, the muscles of the limbs and the heart itself will be unfit even for their ordinary work, and will tend to fail on the slightest over-exertion. This fact was noticed by Sir Benjamin Brodie, who, when speaking of patients with degenerating and contracted arteries, such as lead to senile gangrene, said: "Such patients walk a short distance very well, but when they attempt more than this, the muscles seem to be unequal to the task, and they can walk no further. The muscles are not absolutely paralysed, but in a state approaching to it. The cause of all this is sufficiently obvious. The lower limbs require sometimes a larger and sometimes a smaller supply of blood. During exercise a larger supply is wanted on account of the increased action of the muscles; but the arteries being ossified or obliterated, and thus incapable of dilatation, the increased supply cannot be obtained. This state of things is not peculiar to the lower limbs. Wherever muscular structures exist the same cause will produce the same effect. Dr. Jenner first, and Dr. Parry, of Bath, afterward, published observations which were supposed to prove that the disease which is usually called "angina pectoris depends on ossification of the coronary arteries. . . . When the coronary arteries are in this condition they may be capable of admitting a moderate supply of blood to the muscular structure of the heart; and as long as the patient makes no abnormal exertion, the circulation goes on well enough; when, however, the heart is excited to increased action, whether it be during a fit of passion, or in running, or walking upstairs, or lifting weights, then the ossified arteries being incapable of expanding so as to let in the additional quantity of blood, which, under these circumstances, is required, its action stops and syncope ensues; and I say that this exactly corresponds to the sense of weakness and want of muscular power which exists in persons who have the arteries of the legs obstructed or ossified."[1]

But the syncope and stoppage of the heart mentioned by Brodie are not the only consequences of impaired cardiac nutrition. The heart may be still able to carry on the circulation, but the patient may suffer intense pain in the process. The outside of the heart was found by Harvey to be insensible to light touches, but the inside of the heart appears to be much more sensitive either to touch or pressure.

A knowledge of the mode of circulation of blood through the muscles enables us to understand not only the pathology of angina pectoris, but the rationale of various methods of treating patients suffering from angina pectoris or other forms of heart disease. In most cases, our object is a twofold one—to increase the power of the heart, and to lessen the resistance it has to overcome. In some cases, we require also to aid the elimination of water which has so accumulated as to give rise to œdema of the cellular tissues, or dropsy of the serous cavities. In our endeavours to produce these beneficial changes in our patients, we employ regimen, diet, and drugs, and it is evident that as in one case the condition of a patient's heart may be very different indeed from that in another, the regimen which may be useful to one may be fatal to the other. We have already seen that sudden and violent exertion may raise the blood pressure, and so lead to intense cardiac pain or to stoppage of the heart and instant death; while more gentle exercises, by increasing the circulation through the muscles, may lessen the pressure and give relief to the heart.

The methods of increasing the muscular circulation may be roughly divided into three, according as the patient lies, stands, or walks. First, absolute rest in bed with massage;[2] second, graduated movements of the muscles of the limbs and body while the patient stands still; third, graduated exercises in walking and climbing.

The second of these methods has been specially worked out by the brothers Schott, of Nauheim, and the third is generally connected with the name of Oertel. It is obvious that in cases of heart disease where the failure is great and the patient is unable even to stand, much less to walk, where breathlessness is extreme and dropsy is present or is advanced, the second and third methods of treatment are inapplicable. It is in such cases that the method of absolute rest in bed, not allowing the patient to rise for any purpose whatever, hardly allowing him to feed himself or turn himself in bed, proves advantageous. The appetite is usually small, the digestion imperfect, and flatulence troublesome; and here an absolute milk diet, like that usually employed in typhoid fever, is often most serviceable, being easily taken and easily digested, while the milk sugar itself has a diuretic action, and tends to reduce dropsy. But while simple rest prevents the risk of increased arterial tension and consequent opposition to the cardiac contractions which might arise from muscular exertion, such benefits as would accrue from muscular exertion and increased circulation would be lost were it not that they can be supplied artificially by massage.

[1] Schott. Verhandl. des IX. Congresses in Med. zu Wien, 1890.

[1] "Lectures on Pathology and Surgery," by Sir Benjamin Brodie. (London, 1846, p. 360.)

[2] *Practitioner*, vol. li., p. 190.

This plan of treatment, although it has only recently been revived, was known to Harvey, who narrates the case of a man who, in consequence of an injury—of an affront which he could not revenge—was so overcome with hatred, spite, and passion that "he fell into a strange disorder, suffering from extreme compression and pain in the heart and breast, from which he only received some little relief at last when the whole of his chest was pummelled by a strong man, as the baker kneads dough."[1]

This was a very rough form of massage, but the same kneading movements which Harvey described have been elaborated into a complete system, more especially by Ling in Sweden, and made widely known in America and this country by Weir-Mitchell, and Playfair. One might naturally expect that kneading the muscles would increase the circulation through them in somewhat the same way as active exercise, but, to the best of my knowledge, no actual experiments existed to prove this, and I accordingly requested my friend and assistant, Dr. Tunnicliffe, to test the matter experimentally. The method employed was, in the main, the same as that devised by Ludwig, and employed by Sadler and Gaskell under his direction. The results were that, during the kneading of a muscle the amount of venous blood which issued from it was sometimes diminished and sometimes increased; that just after the kneading was over the flow was diminished, apparently from the blood accumulating in the muscle, and this diminution was again succeeded by a greatly increased flow exactly corresponding to that observed by Ludwig and his scholars.

The clinical results are precisely what one would expect from increased circulation in the muscles, and cases apparently hopeless sometimes recover most wonderfully under this treatment. For patients who are stronger, so that confinement to bed is unnecessary, and who yet are unable to take walking exercise, Schott's treatment is most useful, and it may be used as an adjunct to the later stages of the treatment just described, or as a sequel to it. Here the patient is made to go through various exercises of the arms, legs, and trunk with a certain amount of resistance, which is applied either by the patient himself setting in action the opposing muscles, or by an attendant who gently resists every movement made by the patient, but graduates his resistance so as not to cause the least hurry in breathing, or the least oppression of the heart. Perhaps the easiest way of employing graduated resistance is by the ergostat of Gartner, which is simply an adaptation of the labour crank of prisons, where the number of turns of a wheel can be regulated in each minute, and the resistance which is applied by a brake may be graduated to an ounce. The objection to it is the uniformity of movement and its wearisome monotony. Oertel's plan of gradually walking day by day up a steeper and steeper incline, and thus training the muscles of the heart, is well adapted for stronger persons, but when applied injudiciously, may lead, just like hasty or excessive exertion, to serious or fatal results. In Schott's method stimulation of the skin by baths is used as an adjunct, and this may tend to slow the pulse, as already mentioned. But in all these plans the essence of treatment is the derivation of blood through a new channel, that of the muscular vessels, and the results in relieving cardiac distress and pain may be described in the same words which Harvey employs in reference to diseases of the circulation: "How speedily some of these diseases that are even reputed incurable are remedied and dispelled as if by enchantment."[2]

There is yet another consequence of the circulation to which Harvey has called attention, although only very briefly, which has now become of the utmost importance, and this is the admixture of blood from various parts of the body. After describing the intestinal veins, Harvey says: "The blood returning by these veins and bringing the cruder juices along with it, on the one hand from the stomach, where they are thin, watery, and not yet perfectly chylified; on the other, thick and more earthy, as derived from the fæces, but all pouring into this splenic branch, are duly tempered by the admixture of contraries."[3]

Harvey's chemical expressions are crude, for chemistry as a science only began to exist about a century and a half after Harvey's death, yet the general idea which he expresses in the words which I have just quoted is wonderfully near the truth.

Two of the most important constituents of the blood are chloride of sodium and water. Chloride of sodium is a neutral salt, but during digestion both it and water are decomposed in the gastric glands, and hydrochloric acid is poured into the stomach, while a corresponding amount of soda is returned into the blood, whose alkalinity increases *pari passu* with the acidity of the stomach. Part of this alkali is excreted in the urine, so that the urine during digestion is often neutral or alkaline. Possibly some of it passes out through the liver in the bile, through the pancreas and intestinal glands into the intestine, where, again mixing with the acid chyle from the stomach, neutralisation takes place, so that neutral and comparatively inactive chloride of sodium is again formed from the union of active alkali and acid. But it is most probable that what occurs in the stomach occurs also in the other glands, and that it is not merely excess of alkali resulting from gastric digestion which is poured out by the liver, pancreas and intestine, but that these glands also decompose salts, pour the alkali out through the ducts, and return the acid into the blood.

We are now leaving the region of definite fact and passing into that of fancy, but the fancies are not entirely baseless, and may show in what directions we may search out and study the secrets of nature by way of experiment. For what is apparently certain in regard to the decomposition of chloride of sodium in the stomach, and probably in the case of neutral salts in the pancreas and intestine, is also probable in that important, though as yet very imperfectly known, class of bodies which are known as zymogens. Just as we have in the stomach an inactive salt, so we have also an inactive pepsinogen, which, like the salt, is split up in the gastric glands, and active pepsine is poured into the stomach. But is the pepsine the only active substance produced? Has no other body, resulting from decomposition of the pepsinogen, been poured into the blood while the pepsine passed into the stomach? Has the inactive pepsinogen not been split up into two bodies active when apart, inactive when combined? May it not be fitly compared, as I have said elsewhere, to a cup or glass, harmless while whole, but yielding sharp and even dangerous splinters when broken, although these may again be united into a harmless whole?[1]

This question at present we cannot answer, but in the pancreas there is an indication that something of the kind takes place, for Lépine has discovered that while this gland pours into the intestine a ferment which converts starch into sugar, it pours through the lymphatics into the blood another ferment which destroys sugar. Whether a similar occurrence takes place in regard to its other ferments in the pancreas, or in the glands of the intestine, we do not know, nor do we yet know whether the same process goes on in the skin, and whether the secretion of sweat, which is usually looked upon as its sole function, bears really a relationship to cutaneous activity similar to that which the secretion of bile bears to the functions of the liver. There are indications that such is the case, for when the skin is varnished, not only does the temperature of the animal rapidly sink, but congestion occurs in internal organs, and dropsy takes place in serous cavities, while in extensive burns of the skin rapid disintegration of the blood corpuscles occurs. It is obvious that if this idea be at all correct, a complete revolution will be required in the views we have been accustomed to entertain regarding the action of many medicines. In the case of purgatives and diaphoretics, for example, we have looked mainly at the secretions poured out after their administration for an explanation of their usefulness, whereas it may be that the main part of the benefit that they produce is not by the substances liberated through the secretions they cause, but by those returned from the intestine and skin into the circulating blood.

How important an effect the excessive admixture of the juices from one part of the animal body with the circulating blood might have, was shown in the most striking way by Wooldridge. He found that the juice of the thyroid gland, though it is harmless while it remains in the gland, and is probably useful when it enters the blood in small quantities in the ordinary course of daily life, yet if injected into the blood, will cause it to coagulate almost instantaneously and kill the animal as quickly as a rifle bullet. What is powerful for harm is, likewise, powerful for good in these cases, and the administration of thyroid juice in cases of myxœdema is one of the most remarkable therapeutic discoveries of modern times. Since the introduction by Corvisart of pepsine

[1] *Practitioner*, vol. xxxv. August 1885.

as a remedy in dyspepsia, digestive ferments have been largely employed to assist the stomach and intestine in the performance of their functions, but very little has been done until lately in the way of modifying tissue changes in the body by the introduction of ferments derived from solid organs. For ages back savages have eaten the raw hearts and other organs of the animals which they have killed, or the enemies they have conquered, under the belief that they would thereby obtain increased vigour or courage; but the first definite attempt to cure a disease by supplying a ferment from a solid non-glandular organ of the body was, I believe, made in Harvey's own hospital by the use of raw meat in diabetes.[1] It was not, however, until Brown-Séquard recommended the use of testicular extract, that the attention of the profession became attracted to the use of extracts of solid organs. Since then extract of thyroid, extract of kidney, extract of supra renal capsule have been employed; but even yet they are only upon their trial, and the limits of their utility have not yet been definitely ascertained.

But yet another therapeutic method has been recently introduced which bids fair to be of the utmost importance, the treatment of disease by antitoxins. The discovery by Pasteur of the dependence of many diseases upon the presence of minute organisms may be ranked with that of Harvey, both in regard to the far-reaching benefits which it has conferred upon mankind, and for the simplicity of its origin. The germ of all his discoveries was the attempt to answer the apparently useless question: "Why does a crystal of tartaric acid sometimes crystallise in one form and sometimes in another?" From this germ sprung his discovery of the nature of yeast and of those microbes which originate fermentation, putrefaction, and disease. These minute organisms, far removed from man as they are in their structure and place in nature, appear in some respects to resemble him in the processes of their growth and nutrition. They seem, indeed, to have the power of splitting up inactive bodies into substances having a great physiological or chemical activity. From grape sugar, which is comparatively inert, they produce carbonic acid and alcohol, both of which have a powerful physiological action. From inert albumen they produce albumoses having a most powerful toxic action, and to the poisonous properties of these substances attention was for a while alone directed. But it would appear that at the same time they produce poisons they also form antidotes, and when cultivated without the body, and introduced into the living organism, they give rise to the production of these antidotes in still greater quantity.

The plan of protection from infective diseases, which was first employed by Jenner in small-pox, is now being extended to many other diseases, and the protective substances which are formed in the body, and their mode of action, are being carefully investigated. The introduction either of pathogenic microbes or of toxic products appears to excite in the body a process of tissue change by which antitoxins are produced, and these may be employed either for the purpose of protection or cure. By the use of antitoxins tetanus and diphtheria appear to be deprived of much of their terrible power. But it seems probable that a similar result may be obtained by the introduction of certain tissue juices into the general circulation. It was shown by Wooldridge that thyroid juice has a power of destroying anthrax poison, and it seems probable that increase of the circulation of certain organs will increase their tissue activity, will throw their juices or the products of their functional activity into the general circulation, and thus influence the invasion or progress of disease. As I have already mentioned, we are able to influence the circulation in muscles both by voluntary exertion and by passive massage, and we should expect that both of these measures would influence the constituents of the blood generally; and such, indeed, appears to be the case, for J. K. Mitchell[2] has found that after massage the number of blood corpuscles in the circulation is very considerably increased.

Had time allowed it, I had intended to discuss the modifications of the heart and vessels by the introduction of remedies into the circulation, the power of drugs to slow or strengthen, to quicken or weaken the power of the heart, to contract or relax the arterioles, to raise or lower the blood pressure, to relieve pain or to remove dropsy; but to do this would require time far exceeding that of a single lecture. Moreover, the methods and results were admirably expounded to the College by Dr. Leech in his Croonian lecture, and I have therefore thought I should be better fulfilling the wish of Harvey that the orator of the year should exhort the Fellows and Members of the College to search out the secrets of nature by way of experiment by directing their attention to fields of research which have received at present little attention, but promise results of great practical value. Lastly, I have to exhort you to continue in mutual love and affection among yourselves; and it seems to me that the best way of doing this is to direct your attention to the examples of Harvey and of our late President, whose death we deplore to-day. They were beloved by their fellows while they lived, their loss was lamented when they died, and they have left behind them an example not only of goodness, but of courage. Harvey, seated speechless in his chair, distributing rings and parting gifts to his friends while awaiting the approach of death; or Andrew Clark, steadfastly determining to continue at work and die in harness, in spite of the hæmoptysis which seemed to threaten a speedy death, afford us noble examples which ought to encourage us to follow the directions of the venerable Longfellow, who, taking the organ Harvey studied to symbolise such courage as Harvey and Clark showed, says—

"Let us then be up and doing
With a heart for any fate.
Still achieving, still pursuing,
Learn to labour and to wait."

SCIENTIFIC METHOD IN BOARD SCHOOLS.[1]

AT the request of my friend and former pupil, Mr. W. M. Heller, I have undertaken to say a few words by way of introduction to the course which he is about to give here to assist a number of you who are teachers in schools in the Tower Hamlets and Hackney district under the School Board for London—a course of lessons expressly intended to direct your attention to the educational value of instruction given solely with the object of inculcating *scientific* habits of mind and *scientific* ways of working; and expressly and primarily intended to assist you in giving such teaching in your schools.

Nothing could afford me greater pleasure, as I regard the introduction of such teaching into schools generally—not Board Schools merely, but all schools—as of the utmost importance; indeed, I may say, as of national importance: and I now confidently look forward to the time, at no distant date, when this will be everywhere acknowledged and acted on. Personally I regard the work that I have been able to do in this direction as of far greater value than any purely scientific work that I have accomplished. At the very outset of my career as a teacher, I was led to see how illogical, unsatisfactory and artificial were the prevailing methods of teaching, and became interested in their improvement. My appointment as one of the first professors at the Finsbury Technical College forced me to pay particular attention to the subject and gave me abundant opportunity of practically working out a scheme of my own. I was the more anxious to do this, as I soon became convinced that if any real progress were to be made in our system of technical education, it was essential in the first place to introduce improved methods of teaching into schools generally, so that students of technical subjects might commence their studies properly prepared; and subsequent experience has only confirmed this view. Indeed it is beyond question, in the opinion of many, that what we at present most want in this country are proper systems of primary and secondary education: the latter especially. Now, most students at our technical colleges, in consequence of their defective school training, not only waste much of their time in learning elementary principles with which they should have been made familiar at school, and much of our time by obliging us to give elementary lessons but what is far worse, they have acquired bad habits and convictions which are very difficult to eradicate; and their mental attitude towards their studies is usually a false one.

The first fruits of my experience were made public in 1884, at one of the Educational Conferences held at the Health Exhibition. On that occasion, and again at the British Association meeting at Aberdeen in 1885, in the course of my address as president of the Chemical Section, after somewhat sharply criticising the methods of teaching in vogue, I pointed out what I conceived to be the directions in which improvements should be effected. Others meanwhile were working in the

[1] A revised address delivered at the Berners Street Board School, Commercial Road, London, E., on October [illegible], 1894, by Prof. H. E. Armstrong, F.R.S.

same spirit, and consequently, in 1887, a number of us willingly consented to act as a committee "for the purpose of inquiring into and reporting upon the present methods of teaching chemistry." This committee was appointed at the meeting of the British Association in York, and consisted of Prof. W. R. Dunstan (secretary), Dr. J. H. Gladstone, Mr. A. G. Vernon Harcourt, Prof. H. McLeod, Prof. Meldola, Mr. Pattison Muir, Sir Henry E. Roscoe, Dr. W. J. Russell (chairman), Mr. W. A. Shenstone, Prof. Smithells, Mr. Stallard and myself. A report was presented at the Bath meeting in 1888, giving an account of replies received to a letter addressed to the head masters of schools in which elementary chemistry was taught. In 1889 and 1890 reports were presented in which were included suggestions drawn up by myself for a course of elementary instruction in physical science.

Let me at once emphasise the fact that these schemes were for a course of instruction in physical science—not in chemistry alone. The objects to be accomplished by the introduction of such lessons into schools have since been more fully dwelt on in a paper which I read at the College of Preceptors early in 1891, printed in the *Educational Times* in May of that year. After pointing out that literary and mathematical studies are not a sufficient preparation in the great majority of cases for the work of the world, as they develop introspective habits too exclusively, I then said, in future boys and girls generally must not be confined to desk studies; they must not only learn a good deal *about* things; they must also be taught how to *do* things, and to this end must learn how others before them have done things by actually repeating—not by merely reading about—what others have done. We ask, in fact, that the use of eyes and hands in unravelling the meaning of the wondrous changes which are going on around us in the world of nature shall be taught systematically in schools generally—that is to say, that the endeavour shall be made to inculcate the habits of observing accurately, of experimenting exactly, of observing and experimenting with a clearly defined and logical purpose, and of logical reasoning from observation and the results of experimental inquiry. Scientific habits and method must be universally taught. We ask to be at once admitted to equal rights with the *three R's*—it is no question of an alternative subject. This cannot be too clearly stated, and the battle must be fought out on this issue within the next few years.

Well, gentlemen and ladies, you have the honour of forming part of the advanced guard in the army which is fighting this battle (for the fight is begun in real earnest, although as yet on a small scale); nevertheless, in this case, the small beginning *must* have a great ending.

I had long sought for an opportunity of carrying the war into the camp of elementary education, and this came about four years ago when my friend Mr. Hugh Gordon was appointed one of the Science Demonstrators of the London School Board. During at least three years prior to his appointment, Mr. Gordon had been doing research work in the laboratory of which I have charge at the City and Guilds of London Institute Central Technical College, where he had also taken part in our elementary teaching, and he was already an ardent advocate of the educational policy of which I am so strong a supporter. Under the London School Board, he achieved a marvellous success, and the work that he has done as a pioneer cannot be too highly appreciated. He secured your confidence and sympathy, and interested his pupils; and working in a most unpromising field, under conditions of a most unsatisfactory and often depressing character, he has proved that to be possible, even easy (to the competent and willing teacher), which my friends in higher grade schools have often scoffed at and declared to be impossible. In future, no public school will be able to excuse itself, except on the ground of want of will to give such teaching. I have often been told that our scheme was too costly, that much special provision must be made to carry it into effect, and that it requires so much time and such an increase in the teaching staff: my friend Gordon, with your assistance alone and no other addition to the staff, by successfully teaching, I believe, in seventeen of your schools, has given all these statements the lie. But I confess that as yet there are few who could accomplish so much; few equally well fitted and prepared for the work, so imbued with the right spirit, so convinced that the cause is a great and holy one, gifted with sufficient energy and enthusiasm to overcome the difficulties. The little book he has written, in which the first part of the course of teaching he adopted is broadly outlined,[1] although containing a few slight blemishes which mar its otherwise logical character—blemishes which will be very easily removed in a second edition—appears to me to be a most important contribution to educational literature, and will render great service to our cause. But I count as his greatest achievement the introduction of a proper balance—calculated to inspire confidence and respect—into the schools, for I believe the discipline of learning to weigh carefully and exactly to be of the very highest value to a child, and one of the most effective means of leading children to be careful and exact in their work generally. I envy my friend his success, as I have in vain tried to get proper balances introduced into schools of far higher grade in place of wretched contrivances costing but three or four shillings, *which can be of no service in forming character*, although I have no wish to deny that such may be made use of in illustrating principles.

Mr. Gordon, I believe, was appointed to teach mechanics under what I will venture to call an antiquated and wooden syllabus, but he had the courage to burst the bonds imposed upon him, and from the outset determined to teach what was likely to be of real service to his pupils. I have said that he gained the confidence and sympathy of the teachers with whom he was associated and whose work he was appointed to supervise and direct; but I believe that he did more, and achieved success in a task of greater difficulty—that he actually made converts of some of her Majesty's Inspectors whose sympathies had previously lain with literary studies.

I have thought it desirable thus to sketch the history of the introduction of our British Association scheme into School Board circles. Let me now further emphasise the importance of teaching *scientific method*, which after all is recognised by very few as yet. Let me endeavour to make it clear what I mean by scientific method.: that when I speak of scientific method, I do not mean a branch of science, but something much broader and more generally useful. We may teach scientific method without teaching any branch of science; and there are many ways in which we may teach it with materials always close to hand.

I have very little belief in the efficacy of lecturing, and it is always difficult to persuade those who are not already persuaded—I would therefore refer those of you who are not yet with me to a book from which they may derive much information and inspiration. I mean Herbert Spencer's "Essay on Education," the cheap edition of which, published by Williams and Norgate, costs only one shilling and elevenpence! It is a book which every parent of intelligence desiring to educate his children properly should read; certainly every teacher should have studied it thoroughly; and no one should be allowed to become a member of a School Board who on examination was found not to have mastered its contents. But as Herbert Spencer says—and the times are not greatly changed since he wrote—although a great majority of the adult males throughout the kingdom are found to show some interest in the breeding, rearing, or training of animals of one kind or other, it rarely happens that one hears anything said about the rearing of children. I believe the subject is seldom mentioned in School Board debates. Hence it happens that Herbert Spencer's book has had a smaller circulation than many novels, and that the 1893 edition is but the 34th instead of being the 340th thousand. After very fully discussing the question "What knowledge is of most worth?" he arrives at the conclusion that science is, and eloquently advocates the claims of the order of knowledge termed scientific. The following are eminently instructive passages in his essay:—"While every one is ready to endorse the abstract proposition that instruction fitting youths for the business of life is of high importance, or even to consider it of supreme importance; yet scarcely any inquire what instruction will so fit them. It is true that reading, writing, and arithmetic are taught with an intelligent appreciation of their uses. But when we have said this we have said nearly all. While the great bulk of what else is acquired has no bearing on the industrial activities, an immensity of information that has a direct bearing on the industrial activities is entirely passed over. For, leaving out only some very small classes, what are all men employed in? They are employed in the production, preparation and distribution of commodities. And on what does efficiency in the production, preparation, and distribution of commodities depend? It depends on the use of methods fitted to the respective natures of these commodities; it depends

[1] *Cf.* NATURE, 1893, xlix. 121.

on an adequate acquaintance with their physical, chemical, and vital properties, as the case may be: that is, it depends on science. This order of knowledge, which is in great part ignored in our school courses, is the order of knowledge underlying the right performance of those processes by which civilised life is made possible. Undeniable as is this truth, there seems to be no living consciousness of it: its very familiarity makes it unregarded. . . . That which our school courses leave almost entirely out, we thus find to be that which most nearly concerns the business of life. Our industries would cease, were it not for the information which men begin to acquire, as they best may, after their education is said to be finished. And were it not for the information, from age to age accumulated and spread by unofficial means, these industries would never have existed. Had there been no teaching but such as goes on in our public schools, England would now be what it was in feudal times. That increasing acquaintance with the laws of phenomena, which has through successive ages enabled us to subjugate nature to our needs, and in these days gives the common labourer comforts which a few centuries ago kings could not purchase, is scarcely in any degree owed to the appointed means of instructing our youth. The vital knowledge—that by which we have grown as a nation to what we are, and which now underlies our whole existence, is a knowledge that has got itself taught in nooks and corners; while the ordained agencies for teaching have been mumbling little else but dead formulas."

Some improvement there has been since Herbert Spencer wrote, but chiefly in technical teaching; and there is yet no national appreciation of what constitutes true education: fashion and vested interests still largely dominate educational policy.

Another advocate of the teaching of scientific method to whom I would refer you is Charles Kingsley, the celebrated divine, but also a born naturalist possessed of the keenest powers of observation, a novelist of the first rank, and a poet. Read his life, and you will find it full of inspiration and comfort. Study his scientific lectures and essays (vol. xix. of his "Collected Works," Macmillan and Co.), and you will not only learn why "science" is of use, but will have before you a valuable model of method and style. A friend—a member of the London County Council—to whom I happened to send some of my papers, noting my frequent references to Kingsley, remarked, "How very fond you are of his writings!" Indeed I am, for they seem to me to display a truer grasp of the importance of scientific method and of its essential character than do any other works with which I am acquainted. I recommend them because they are pleasant as well as profitable reading, and because our text-books generally are worthless for the purpose I have in view. Any ordinary person of intelligence can read Herbert Spencer's and Kingsley's essays and can appreciate them, especially Kingsley's insistent application of the scientific principle of always proceeding from the known to the unknown; but few can read a text-book of science—moreover, the probable effect of most of these would be to dissuade rather than persuade.

Kingsley's great point—and Herbert Spencer's also—is that what people want to learn is not so much what is, still less what has been, but how to *do*. And the object you must set before yourselves will be to turn out boys and girls who, in proportion to their natural gifts—for, as every one knows, you cannot make a silken purse from a sow's ear—have become inquiring, observant, reasoning beings, ever thoughtful and exact and painstaking and therefore trustworthy workers. To turn out such is the whole object of our scheme, which chiefly aims at the development of intelligence and the formation of character. In your schools information must be *gained*, not imparted. After describing how the intelligent mother trains her young child, Herbert Spencer remarks:—"To *tell* a child this and to *show* it the other, is not to teach it how to observe, but to make it a mere recipient of another's observations: a proceeding which weakens rather than strengthens its powers of self-instruction—which deprives it of the pleasures resulting from successful activity—which presents this all attractive knowledge under the aspect of formal tuition. . ." You must train the children under your care to help themselves in every possible way, and give up always feeding them with a spoon. Abolish learning lessons by rote as far as possible. Devote every moment you possibly can to practical work, and having stated a problem leave it to the children if possible to find a solution. Encourage inquisitiveness, but suggest methods by which they may answer their own questions by experiment or trial or by appeal to dictionaries or simple works of reference, part of the furniture of the schoolroom, and lead them to make use of the public library even: in after life you will not be at their elbows, but books will always be available, and if they once grow accustomed to treat these as friends to whom they can appeal for help, you will have done them infinite service and will undoubtedly infuse many with the desire to continue their studies after leaving school. Under our present system school books are cast aside with infinite relief at the earliest possible moment, and the desire for amusement alone remains. Teach history, geography and much besides from the daily papers, and so prepare them to read the papers with intelligence and interest, and to prefer them to penny dreadfuls and the miserable, often indecent, illustrated rubbish with which we are nowadays so terribly afflicted. At the same time, make it clear to them that the editorial "we" is but an "I," and that assertion does not constitute proof. If such be your teaching, and it have constant reference to things natural, you will also—as Herbert Spencer points out in a very remarkable passage—without fail be giving much *religious* culture, using the word in its highest acceptation, for, as he says, "it is the refusal to study the surrounding creation that is irreligious." As I have already said, one great—indeed the great—object of our teaching is the formation of character: and if you teach your pupils to be careful, exact and observant, and they become trustworthy workers, you are giving much training of the highest excellence; and if they have enjoyed such training, what does it matter what facts they know when they leave school?

But I hear you say that the inspectors will not allow all this. Gentlemen, do not fear the inspectors—they also are advancing; they also are learning that literary methods are insufficient, that desk studies must not absorb the entire attention of the scholars; that greater latitude must be permitted to the teachers, and especially in the direction of devising more suitable methods. And a new race of inspectors is coming into existence. Mr. Gordon, I know, had difficulties with the inspectors; but when they realised that he understood his business and learnt to appreciate his work, they soon became his supporters.

And with appreciative ministers like Mr. Acland at the head of affairs, we shall move far more quickly than heretofore, and shall be able soon to entirely throw off the cast-iron bonds of control by examination and payment on results—a refined method of torture affecting both teachers and taught most disastrously. We know that a holiday spent under healthy conditions at the seaside or in the country is of the greatest service. We are becoming accustomed to take care that our houses are properly ventilated and drained, and to rest satisfied that when this is the case their inhabitants may safely be left to themselves. In like manner, in future, we shall take care that our schools are fully provided with all necessary proper appliances—in which I include teachers—and we shall see that the teachers are working in accordance with a proper system; but we shall trouble ourselves little about the taught, feeling that if they have been placed under healthy conditions they cannot fail to have benefited, however little this may be apparent on the surface. In the days to come the work of the teachers will be directly criticised; they, not their pupils, will be examined: but always by competent and sympathetic inspectors who have become acquainted with the work and its difficulties practically, and are not mere theorists, whose main function will be that of guide, philosopher and friend—not that of inquisitor.

In the course that you are about to attend under Mr. Heller—the demonstrator upon whom has fallen the mantle previously worn by Mr. Gordon, and who is equally desirous of promoting and devising rational methods of teaching—you will in the first place devote your attention to exercises in measurement, including much that is ordinarily taught under mechanics and physics, the prime object of which is to teach accuracy of observation. You will then study a series of problems, mainly chemical, which have been arranged chiefly in order to cultivate reasoning powers and to teach the research method. In fact, what we want to do is, as far as possible, to put every scholar in the position of the discoverer. The world always has and ever will advance through discovery; discoveries, however, are rarely made accidentally—indeed we all pass from ignorance to knowledge by discovery, and by discovering how to do things that we have not done before we ever increase our powers of usefulness: we all require therefore to be taught how to discover, although we may never be called on to make original discoveries or have the opportunity. But as you proceed I trust that you will realise that the method which you are learning to apply is one which can be made use of in all your work—that the course has a broad educational value far transcending its special value as an introduction to physical science.

Lastly, I should like to take this opportunity of calling attention to the very great value to girls, as well as to boys, of teaching such as you are about to give. I fear that much that girls are being taught under the guise of domestic economy is of slight value educationally or otherwise, and that they are but having imparted to them little tit-bits of information which they are as likely as not to misapply. Nothing is done by way of increasing their intelligence and forming their characters. Lessons which would lead them to be observant, thoughtful and, above all, exact—lessons in method—would be of far higher and abiding value. They would then carry out their household functions with greater ease; there would be far less waste; less unhealthiness; far more comfort. I believe the need for such training to be indeed far greater in the case of girls than in that of boys. Boys are naturally apt in many ways, and even if neglected at school, perforce develop when they go out into the world; but girls are of a different disposition, and rarely seem to spontaneously acquire the mental habits which a training in scientific method can confer, the possession of which would be of inestimable value to them. Extraordinarily little has been done as yet on their behalf, and they have been cruelly sacrificed at examinations—for which, unfortunately, they appear themselves to have an insatiable natural appetite. It is to be hoped that the new Board will give the most serious attention to this matter, and that it will take steps to secure the teaching of scientific method in all the schools under its charge, whether boys' schools or girls' schools. Unhealthy buildings have attracted much attention; but the existence of a far more serious evil—the absence of healthy teaching suited to the times—has not even been noticed.

In these remarks, I have been able but briefly to bring before you a number of questions of importance—it must rest with you to seriously study the subject. It is a subject worth hard study, which will afford infinite opportunity and infinite satisfaction to the earnest worker.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following examiners for the Natural Sciences Tripos were appointed on October 25. Physics: L. R. Wilberforce and Prof. G. F. Fitzgerald, F.R.S. Chemistry: W. J. Sell and Prof. W. Ramsay, F.R.S. Mineralogy: Prof. Lewis and H. A. Miers. Geology: P. Lake and Prof. G. A. J. Cole. Botany: Prof. F. W. Oliver, F.R.S., and W. Gardiner, F.R.S. Zoology: W. Bateson, F.R.S., and Prof. S. J. Hickson. Human Anatomy: Prof. A. Macalister, F.R.S., and Dr. H. D. Rolleston. Physiology: W. B. Hardy and Prof. E. A. Schafer, F.R.S.

Prof. Bradbury delivered his inaugural lecture, as Downing Professor, on Wednesday, October 24, before a large audience. The subject was "Pharmacology and Therapeutics."

The University Lecturer in Geography, Mr. Yule Oldham, delivered a public lecture on the evening of October 24, on "A New Discovery of America." He will give during the present and the Lent terms a course on the "History of Geographical Discovery," on Thursdays at noon in the Chemical Theatre.

An election to the Royal Geographical Society's Studentship of £100 will be held in the Lent Term. The studentship is open to members of the University who have attended the lectures on Geography.

Of the Freshmen entered this term, 137 have announced their intention to study medicine at the University.

The period of five years for which Dr. Donald Macalister was elected as the University member of the General Medical Council expires on November 13. The Vice Chancellor gives notice that an election will be held in the Senate House on Friday, November 9, from 2.30 to 3.0, at which all members of the Senate may vote. Dr. Macalister is eligible for re-appointment.

Dr. Charles Rieu, late keeper of the Oriental MSS. in the British Museum, has been elected Sir Thomas Adams Professor of Arabic in succession to Prof. Robertson Smith.

The Council of the Senate have issued a second report o special degrees (Litt.B. and Sc.B) for advanced study an research, in which they call attention to the steps in the san direction taken by the University of Oxford, the Scotti Universities, the Gresham (London) University Commissioner and the University of Harvard. They propose that, as th bearings of the subject have greatly widened since their fir report on post-graduate study, the whole question should b referred to a special Syndicate, with power to confer with oth bodies and with the several teachers concerned.

WE have received an advance copy of the report on the wor of the Examinations Department of the City and Guilds London Institute for the session 1893–94. During this sessic the number of classes registered by the Institute was 853, vi 701 in Technology and 152 in Manual Training. The tot number of students in attendance was 25,718, viz. 22,703 technology and 3015 in manual training. At the examinatio this year, 11,631 candidates presented themselves, being 1377 excess of the number examined last year. The examiners f the Institute, like those of the Department of Science and Ar find that the Honours papers are the least satisfactory. It pointed out that Honours students should be taught in speci Honours classes. To quote the report:—

"It often happens that facilities for higher or advanced i struction are not provided at the schools, and that the canc dates for Honours seeking further teaching are only able attend the ordinary class a second session. This absence higher instruction is a matter to be carefully considered by th Technical Instruction Committees of County Councils. El mentary technical instruction is of little value unless it e courages the student to seek further knowledge; and effor should be made, even where the number of students is sma either to establish advanced classes, or to enable students pursue their studies at other institutions where such advanc instruction may be obtained."

MR. HERBERT TOMLINSON, F.R.S., has been appoint Principal of the South-West London Polytechnic Institut now in course of erection in Chelsea. The institute, which w be of the same dimensions and be conducted on somewhat t same lines as the Battersea Polytechnic, will, it is hoped, finished by April next.

IT is announced that Dr. William Peterson, who for the la twelve years has been the Principal of University Colleg Dundee, has been appointed to the post of Principal of McG University, Montreal, vacated by Sir William Dawson, F.R.S more than a year ago.

SCIENTIFIC SERIALS.

American Journal of Science, October.—The standardisati of potassium permanganate in iron analysis, by Charlotte Roberts. A simple and rapid method for standardising a pe manganate solution is to determine its strength, first, by co parison with electrolytic iron, and then by immediate titrati with ferric chloride to determine the exact amount of iron each cubic centimetre of the latter solution. This being asce tained, the ferric chloride solution can be employed at any tir for the standardisation of potassium permanganate.—T detection and approximate estimation of minute quantities arsenic in copper, by F. A. Gooch and H. P. Moseley. Th is a modification of Sanger's process for wall-papers, who application is rendered difficult by the fact that the presen of copper in the Marsh generator holds back the arseni The new process is based upon the simultaneous action strong hydrochloric acid and potassium bromide upon the su of arsenic.—Wave-lengths of electricity in iron wires, by C E. St John. A Lecher wire system was used in which th discs at the end towards the induction coil were left out, so as obtain a form depending more directly upon the principle electrical resonance. The indicator used was a bolometer adapted by Rubens. It was found that the self-induction iron circuits is greater than that of similar copper circuits and very rapid electric oscillations (115 million reversals p second). The difference in self-induction varies from 3 4 to 4 per cent., and increases with decreasing diameters. The i crease in self induction produces greater damping and a shorte ing of the wave-length of 1·5 to 2 per cent. The permeabili f annealed iron wires under this rate of alternation is about 85. For oscillations of the same period, the wave-length long parallel copper wires varies directly with the diameter of he wires, the maximum difference observed being 5 per cent. with wires of 0·03915 and 0·1201 cm. diameter respectively.—The present status of high-temperature research, by Carl Barus. To clear away the anomalies now existing in high temperature ata, either the boiling point of zinc must come down from 930 o 905°, or else the melting points of gold, silver, and copper must move up 30° or 40°, or both must move towards each ther by corresponding amounts.—The recent eruption in the rater of Kilauea, by L. A. Thurston. This is a description f the subsidence of the lava lake on July 11, when its level ell 250 feet.—On solutions of metallic silver, by M. Carey Lea. The solutions previously described are all colloidal, and t the same time absolutely transparent.

Wiedemann's Annalen der Physik und Chemie, No. 10.—On ure water, by F. Kohlrausch and A. Heydweiler. (See Notes.) —Magnetic experimental investigations, by Carl Fromme. This aper deals with the self-induction and the electrostatic apacity of wire coils and their influence upon magnetic henomena. Coils with bifilar winding are free from self-nduction, and also from electrostatic capacity as long as their esistance does not exceed 1000 ohms. At 2000 ohms their apacity is already very considerable. Coils wound by Chaperon's method, *i.e.* with the direction of winding changing with each round, are perfectly free from capacity, and their elf-induction is negligible. It is therefore quite feasible to determine their resistance by the alternate current method.—Examination of the Ketteler-Helmholtz dispersion formula, by Heinrich Rubens. The electromagnetic theory of dispersion, as eveloped by Herr von Helmholtz, is in complete accordance with the results obtained in the case of fluorspar, quartz, rock-alt, sylvine, and one of the heavy Jena silicate-flint glasses. The agreement extends over the whole region of the spectrum nvestigated, comprising 5½ octaves.—Bolometric investigations, by F. Paschen. This is a reply to Herr Angström's riticism of his work on the absorption spectrum of carbonic nhydride.—On the infra-red dispersion of fluorspar, by F. Paschen. The spectrum of the fluorspar prism employed was alibrated by Langley's grating method. The best source of adiation was found to be a small piece of platinum foil coated with oxide of iron. The region of the spectrum examined xtended from 0·8840 μ to 9·4291 μ, and the corresponding refractive indices ranged from 1·42996 to 1·31612.—Change f volume during melting, by Max Toepler. The author investigated the number of cubic cm. by which a gramme of arious elements expanded or contracted during melting. The st included eleven metals and five non-metals. He found that he coefficient of expansion of the elements in the solid state, nd their change of volume during melting, show a definite reation to each other.—The depression of the freezing-point of a olvent by electrolytes, by Harry C. Jones. In the case of a olution of phosphoric acid of concentrations 0·077 and 0·146, he numbers obtained, 2·52 and 2·31, are in fair accordance with those obtained by Arrhenius, but not with those of Loomis.

SOCIETIES AND ACADEMIES.

LONDON.

Entomological Society, October 3.—The Right Hon. Lord Walsingham, F.R.S., Vice-president, in the chair.—Mr. W. F. H. Blandford exhibited specimens of a sand-flea, chigoe r nigua, received from Mr. Szigetváry, of the Imperial Maritime Customs, China, who had found them in the ears of ewer-rats trapped at Ningpo. Mr. Blandford stated that the pecieswas allied to, but not identical with, the American species, *Sarcopsylla penetrans*, L., one of the most troublesome pests n Tropical America and the West Indies to man and various omestic and wild animals, the female burrowing into the skin, sually of the feet, but also of any other accessible region. He said that the distribution of the chigoe was recorded over Tropical America and the Antilles from 30° north to 30° south, nd of late years it had established itself in Angola, Loango, nd the Congo. Colonel Swinhoe, Mr. McLachlan, Lord Walsingham, Mr. Champion, Mr. J. J. Walker, Mr. Barrett, nd others, took part in the discussion which ensued.—Mr. F. C. Adams exhibited a specimen of *Mallota eristaloides*, a species of Diptera new to Britain, taken by himself in the New Forest on July 20 last. He said that the species had been identified by Mr. Austen, of the British Museum, and that he had presented the specimen to the National Collection. Mr. Verrall made some remarks on the species and on the distribution of several allied species in the United Kingdom. Lord Walsingham, as a trustee of the British Museum, expressed his satisfaction at the presentation of the specimen to that institution.—Mr. Tutt exhibited specimens of a form of *Zygæna exulans*, well scaled, and with the nervures and forelegs of a decidedly orange colour, collected during the last week in July by Dr. Chapman in the La Grave district of the Alps, at a considerable elevation; also specimens of the same species taken by Dr. Chapman near Cogne, and others from the Grison Valley, which were less well scaled. He also exhibited Scotch specimens for comparison, and stated that he was of opinion that the latter were probably as thickly scaled as the continental ones, but that, owing to the differences in the climate of Scotland and Switzerland, collectors had fewer opportunities of getting the Scotch specimens in good condition.—Mr. P. M. Bright exhibited a remarkable series of varieties of *Arctia menthastri* from N. Scotland, also series of *Liparis monacha* (including dark varieties) and *Boarmia roboraria* from the New Forest; *Zygæna exulans*, from Braemar; *Noctua glareosa*, from Montrose and the Shetlands; *Agrotis pyrophila*, from the Isle of Portland, and Pitcaple, N.B.; red varieties of *Tæniocampa gracilis*; and a specimen of *Sterrha sacraria*, taken at light, at Mudeford, in October, 1893; also living larvæ of *Eupithecia cribrum*.—Mr. J. J. Walker exhibited a living specimen of a large species of Pulex, which he believed to be *Hystricopsylla talpæ*, Curtis, taken at Hartlip, Kent. Mr. Verrall and the chairman made some remarks on this and allied species.—Mr. K. J. Morton communicated a paper, entitled "Palæarctic Nemouræ."—Lord Walsingham read a paper, entitled "A Catalogue of the Pterophoridæ, Tortricidæ, and Tineidæ of the Madeira Islands, with Notes and Descriptions of New Species." In this paper sixty-six species of Lepidoptera belonging to these families were recorded as occurring in the Madeiras, of which thirty were noticed as peculiar to the Islands, twelve as common to the Madeiras and Canaries, of which two were not known as occurring elsewhere, and one extends its range only to North Africa. Over thirty species were added to the list, and one new genus, seven new species, and two new varieties were described. Mr. Jacoby and Mr. Bethune-Baker made some remarks on the species and their geographical distribution.—Mr. Blandford read a paper, entitled "A Supplementary Note on the Scolytidæ of Japan, with a list of Species."

PARIS.

Academy of Sciences, October 15.—M. Lœwy in the chair.—The death of M. N. Pringsheim, on October 6, 1894, was announced to the Academy, and a short account of his work given by M. Bornet.—Determination, partly experimental and partly theoretical, of the inferior contraction of a bending fluid sheet, either depressed, submerged below, or adherent, on a weir having its up-river face vertical, by M. J. Boussinesq.—Observations of Gale's comet (1894, *b*) made with the great equatorial at Bordeaux Observatory by MM. G. Rayet, L. Picart, and F. Courty. A note by M. G. Rayet. The apparent positions of the comet on twenty-seven days between May 4 and July 31 are tabulated.—On the degree of incandescence of lamps, by M. A. Crova. The conclusions are given: (1) That the quantity of light emitted by a gas-burner per litre of gas used increases with the quantity of the combustible burnt per hour, whereas the degree of incandescence slightly diminishes, up to a maximum yield which should not be exceeded; (2) that, for lamps with incandescent substances, the maximum yield corresponds to the minimum amount of the combustible which must be burnt in order to obtain the maximum degree of incandescence.—Report on the memoir by M. Stieltjes, on "Researches on Continued Fractions." After a detailed consideration of the memoir, the report proceeds to say: "This work by M. Stieltjes is one of the most remarkable memoirs on analysis which has been written in late years."—Disappearance of the southern polar spot of Mars, by M. G. Bigourdan. The spot ceased to be visible on October 13.—First observations of the pendulum in the Alps of Dauphiny. The values obtained for the constant of gravitation are given below in column g_m, for comparison the values calculated for each place at latitude ϕ from the formula $g_\phi = 9{\cdot}78124(1 + 0{\cdot}005243 \sin^2\phi)$ are appended. The values of are corrected to sea level by means of the densities of subjacent formations taken from the most recent work.

	g_0	g_1
Paris	9·81013 ...	9·81030
Valence	9·80640 ...	9·80682
Grenoble	9·80603 ...	9·80705
La Bérarde	9·80530 ...	9·80682
Marseilles	9·80539 ..	9·80536

The variation of the observed from the calculated value at La Bérarde becomes less when a correction is made for the influence of the mass of the surrounding mountains, g_0 is then 9·80575.—On the infinitesimal transformations of the trajectories of systems, by M. Paul Painlevé.—On the reduction of the structure of a group to its canonic form, by M. E. Cartan.—Experimental researches on the congelation of sulphuric acid of different degrees of concentration, by M. Raoul Pictet. Four extensive series of experiments carried out on large volumes of the acid, in different ways and with all the precautions indicated by the study of the laws of crystallisation at low temperatures, yield concurrent curves which include the cases between pure H_2O and pure H_2SO_4. This curve crosses the line of zero temperature five times (including origin with pure H_2O). On descending parts of the curve the liquid contains a larger proportion of acid than the solid, on ascending parts the inverse is the case; at the summits of the curve the titre of the liquid is the same as that of the solid. The maxima and minima do not, in general, correspond to definite hydrates.—Application of Trouton's law to the saturated alcohols of the fatty series, by M. W. Longuinine. The author finds that Trouton's constant is constant only for groups of similarly constituted substances, and varies from group to group. If M be the molecular weight, r the latent heat of vaporisation, T the absolute temperature of the boiling point, $\frac{Mr}{T} = 26{\cdot}34$ for fatty saturated alcohols. Water gives the value 25·86, ethers 21, hydrocarbons about 20. Formic and acetic acids appear to be exceptions giving the values 12·82 and 13·03. Acetic acid, however, gives 25·9 if the heat required to bring the vapour to the normal condition of $C_2H_4O_2$ be added to the latent heat. Probably formic acid is a similar case.—Action of chloride of sulphur on the copper derivatives of acetylacetone and benzoylacetone, by M. Victor Vaillant.—On estimations of glucose by cupro-alkaline liquids, by M. Fernand Gand.—On pine tar, by M. Adolphe Renard. A new hydrocarbon $C_{14}H_{22}$ is characterised; it is probably a member of the aromatic series.—Action of the sands and waters of the Sahara on cements and hydraulic limes, by M. Jules Perret.—On the homarian origin of crabs, by M. E. L. Bouvier.—On a disease of Ailanthus in the parks and promenades of Paris, by M. Louis Mangin. This disease is characterised as fungoidal, but the species of fungus causing it has not yet been determined.

NEW SOUTH WALES.

Linnean Society, August 29.—Prof. David, President, in the chair.—On the Kuditcha shoes of Central Australia, by R. Etheridge, jun. The remarkable slippers described are in vogue among certain tribes toward the centre of the continent. They are made of human hair, interlaced with emu feathers, with a cementing medium of human blood in the sole. Their variously described functions—their use by the rain-maker, by the authorised agents in obtaining blood-revenge, and to disguise tracks when wife-hunting—were summarised and discussed; and it was pointed out that it is not improbable that their use was not so much to conceal tracks as to disguise the direction in which the wearer was travelling, the heel and toe being alike.—A list of exotic trees and shrubs which have become hosts for certain Australian parasitical plants, by Fred Turner. Indigenous members of the N.O. *Loranthaceae*, more particularly *Loranthus celastroides*, Sieb., *L. pendulus*, Sieb., and *Viscum articulatum*, Burm., were shown to have taken very kindly to certain exotic plants. Twenty-seven species, belonging to a dozen natural orders, serving as hosts, had come under the author's notice in New South Wales, the *Rosaceae*, as compared with other orders, supplying the largest number.—On the formation of a "Mackerel Sky," by A. H. S. Lucas. A description of the remarkable sky of this nature seen over Sydney on April 20, 1894, was given from the notes of Mr. Russell, the Government Astronomer. The author then proceeded to compare the arrangement of the clouds with that of the ridges of sand in ripple-mark, and showed how they are formed similarly, as a result of the wave-motion of layers of the air. He considered the condensation to be produced by rarefaction of the air in the ridges of the waves with consequent fall of temperature. The condensation into cloud thus rendered manifest the position of the wave-crests. He then referred to Prof. von Bezold's paper in the February number of "Himmel und Erde," which advances somewhat similar views as to the origin and importance of wave-clouds. He concluded by suggesting that the wave-cloud, or *Undulus*, should take its place in the classification of clouds by the side of the other elemental forms, *Cirrus*, *Cumulus* and *Stratus*.

BOOKS, PAMPHLETS, and SERIALS RECEIVED.

BOOKS.—Dissections Illustrated. C. G. Brodie. Part 3 (Whittaker).—Lectures on Biology: Dr. R. W. Shufeldt (Chicago).—Chemical Handicraft (J. J. Griffin).—From the Greeks to Darwin: Dr. H. F. Osborn (Macmillan).—On Preservation of Health in India: Sir J. Fayrer (Macmillan).—Manual of Physico-Chemical Measurements: Prof. W. Ostwald, translated by Dr. J. Walker (Macmillan).—Text-Book of the Diseases of Trees: Prof. R. Hartig, translated by Dr. W. Somerville (Macmillan).—University College, Nottingham, Calendar 1894-95 (Nottingham, Sands).—Reprint of the North American Zoology: George Ord, Appendix by S. N. Rhoads (the Editor, Haddonfield, N.J.)—Peru, 2 Vols: E. W. Middendorf (Berlin, Oppenheim).—A Manual of Exotic Ferns and Selaginella: E. Sandford: cheaper edition (Stock).—University College of North Wales, Calendar 1894-95 (Manchester, Cornish).—Leçons de Chemie: H. Gautier and G. Charpy: deux edition (Paris, Gauthier-Villars).—The Great Ice-Age: Dr. James Geikie, 3rd edit. (Stanford).—Electric Light and Power: A. F. Guy (Biggs).

PAMPHLETS.—A Laboratory Guide and Analytical Tables: J. Grant (Manchester, Smith and Wood).—A Discourse on Roses and the Odour of Rose: J. C. Sawer (Brighton, Smith).—Report on Meteorological Observations in British East Africa for 1893: E. G. Ravenstein (Philip).—Brief Notes on the Physical and Chemical Properties of Soils: R. Warington (Chapman).—On the Whirling and Vibration of Shafts (Philosophical Transactions of the Royal Society of London, Vol. 185 (1894) A, pp. 279-360: S. Dunkerley (K. Paul).—On Derived Crystals in the Basaltic Andesite of Glasdrumman Port, co. Down (Scientific Transactions of the Royal Dublin Society, Vol. v. series 2: Prof. G. A. J. Cole (Williams and Norgate).—Twelfth Annual Report of the Fishery Board for Scotland for the Year 1893, Part 2.—Report on Salmon Fisheries (Edinburgh).—The Slide Rule: C. N. Pickworth (Emmott).—Geschichte der Bibliothek und Naturaliensammlung der Kaiserlichen Leopoldinisch-Carolinischen Deutschen Akademie der Naturforscher: Dr. O. Grulich (Halle).

SERIALS.—Encyklopædie der Naturwissenschaften, Dritte Abthg., 22 and 23 Lief^g, Zweite Abthg., 83-85 Lief^g, (Breslau, Trewendt).—Engineering Magazine, October (Tucker).—American Journal of Science, October (New Haven).—Record of Technical and Secondary Education, October (Macmillan).—American Meteorological Journal, October (Ginn).—Proceedings of Bristol Naturalists' Society, 1893-94 (Bristol).—American Historical Register, No. 2 (Philadelphia).—Palestine Exploration Fund, Quarterly Statement, October (London).—Quarterly Review, October (Murray).
