"*To the solid ground*
*Of Nature trusts the mind which builds for aye.*"—WORDSWORTH.

THURSDAY, MAY 7, 1908.

## *LA HOUILLE BLANCHE.*

*Service d'Études des grandes Forces hydrauliques (Région des Alpes), Annales de la Direction de l'Hydraulique.* In two volumes. Vol. i., pp. 181; vol. ii., pp. 451; with maps and diagrams. (Paris: Imprimerie nationale.)

MOUNTAINOUS countries are ill adapted for convenience in travel and transport, but as some compensation for this drawback, Nature has endowed them with a signal benefit of another and equally important kind. She has placed at the disposal of the inhabitants a form of energy which is not only readily utilisable, but in the majority of instances is cheap and plentiful, and, it may be added, is also picturesque. The numerous streams of water which streak the mountain sides like veins of silver ore, or which

"like a downward smoke,
Slow dropping veils of thinnest lawn,"

spread themselves over the ledges of precipitous cliffs, possess a wonderful commercial value. They are, indeed, to be reckoned among the most utilitarian assets and resources of a country, side by side with coal, iron, and other such serviceable minerals, while they possess the additional advantage that their application to industrial purposes is readily effected, and is almost as unlimited in scope as the supply is, apparently, inexhaustible. The French have poetically referred to the latent wealth of these mountain streams as *la houille blanche* (white coal), and coal they surely are, to all intents and purposes, for when diverted into proper channels, do they not serve to actuate wheels and vanes, motors and turbines, setting in useful motion a wide range of plant and machinery as effectively as coal itself, without the complicated series of transformations required before the latter is converted into horse-power units?

The study, then, of so valuable a source of industrial energy is almost an obvious duty on the part of the countries thus enriched. Not until within the last fifteen or twenty years, however, has this duty become definitely recognised as a national obligation deserving of governmental support. At the present time in France, Switzerland, and Italy, three countries enclosing or bordered by lofty mountain ranges, there are organised commissions, subsidised by their respective Governments, for the purpose of collecting data and establishing records of the various changes in flow and level of mountain streams.

In Italy the initiation of systematic hydrographical research dates from 1890, when Zoppi was commissioned to study successively the Aniene, the Nera, the Velino, and their principal affluents. The Swiss hydrographical service was inaugurated by a federal decree of 1895. France did not recognise her obligation until eight years later, and the first of the two volumes under consideration opens with an account of how an instruction of the Minister of Agriculture, dated March 25, 1903, set upon a proper footing the study of questions affecting the assessment of hydraulic power in mountainous regions and the utilisation of the energy therein contained by the regulation of channels or of the water itself.

The hydrological service thus established was first allocated to the Alps, to be extended later to the Pyrenees, and ultimately, if it be considered desirable, to the whole country. Its programme comprises, first, the purely physical investigation of watercourses and their basins from a geographical, meteorological, and hydrographical point of view; and, secondly, the economical study of questions involved in the utilisation of the energy produced.

The first part of vol. i. is devoted to an account of the steps taken and the results achieved during the first year, or rather during the whole period prior to 1904. There is some reference to early attempts at gauging the Isère and the Durance, and a deduction, from these and similar experiences, of methods advisable to be pursued in the future.

Then follows a detailed account of the observations made and recorded during the years 1904 and 1905. Both this and the preceding section are arranged on common lines, and the subject is treated under several heads, comprising:—

(1) General organisation and programme of work.

(2) Gauging stations; methods adopted for measuring the discharge of streams.

(3) Pluviometry, nivometry, and glacial studies.

(4) Planimetry; surface measurement of basins.

(5) Levelling; determination of slope and fall.

(6) Publication of results.

The records are very full and complete. They abound in instances of local difficulties and the manner in which these were overcome. The work was carried out under the joint direction of M. de la Brosse and M. Tavernier. The former gentleman concerned himself more particularly with the basins of the Arve and the Isère, and the latter with the basins of the Durance and the Var.

There are a large number of appendices dealing with various matters of special interest, including some practical directions in the matter of gauge measurement, a note on the theory of screw calibration, a provisional estimate of the value of the hydraulic forces, a typical hydrological study of a mountain basin, and other cognate matters of importance.

The theoretical and mathematical investigations are of an extended and detailed character, and the volume forms a thoroughly complete and valuable guide for those who are engaged in hydrographical studies and experiments. A number of interesting photographs are reproduced, showing the actual operation of gauging as carried out at several places, and illustrating in a most effective manner the expedients described in the text for dealing with particularly difficult and almost inaccessible stations.

It is recorded that a good deal of very useful assistance was derived from voluntary workers, including those at power stations and industrial depôts. Help was also forthcoming from officers at military posts and from the staff of the conservators of waters and forests. Aid was rendered, too, by meteorological and geological departments, municipal and vicinal administrations, and by railway companies, notably the Paris-Lyon-Méditerranée. The coordination and instruction of all these various agencies, spread over an extended area, involved much care and attention.

The second volume is devoted almost entirely to a numerical record of the results of the work. It abounds in figures and data systematically collated and arranged, so as to be of immense value for reference purposes. It also includes a series of excellent maps of the various basins printed in colours, showing the subsidiary watersheds, and indicating the positions of the stations of observation. Altogether, the volumes are replete with information, and form a striking testimonial to the value and national utility of the Service d'Études des grandes Forces hydrauliques.

## SUBTERRANEAN STUDIES.

*L'Évolution souterraine.* By E. A. Martel. Pp. 388; with 80 figures. (Paris: Ernest Flammarion, 1908.) Price 3.50 francs.

IN France, the fascinating study of caverns—or, as it is now the fashion to call it, spelæology—has risen greatly in popular favour during the last twenty years, mainly through the energy and enthusiasm of M. Martel, one of the editors of *La Nature*. The scope of spelæology, in the course of its recent development, has become gradually enlarged until it now touches at one point or another almost the entire circle of the sciences. The work before us, which forms a volume of Dr. Gustave Le Bon's "Bibliothèque de Philosophie scientifique," extends, however, beyond the mere study of caves, though this forms its main theme. From caverns the author passes to the general phenomena of the underground world, and seeks to show how their study has a bearing on nearly all branches of knowledge, especially on the doctrine of evolution. The range of the work consequently comes to be extremely wide. Where the programme set before the writer is so ambitious, no reasonable reader can expect to find it worked out with thoroughness. Brevity often becomes imperative. The wonder is not that many of the subjects are touched with only a light hand; the wonder is rather that it has been found possible to crowd so much into a volume of such limited size.

Scattered through M. Martel's pages are many suggestions which seem to call for remark. Thus, with regard to the planes of rupture in the earth's crust, he suggests that the term "joint" should be limited to planes of stratification, whilst those fissures which run vertically or obliquely, and in stratified rocks across the bedding, should be called "diaclases"—one of the terms introduced by Daubrée in his system of nomenclature for divisional planes. No doubt it would be convenient to have some short word for a plane of bedding, but it will certainly require much persuasion to induce an English geologist to call it a joint, for this happens to be just the term that he is in the habit of applying to any plane other than that of stratification.

Our author does well to insist on the fact that the process of cave-making, so far from being due to a single agent, depends in most cases partly on mechanical erosion and partly on chemical corrosion. Which of the two processes is the more important is determined to a large extent by the character of the rock to be hollowed out. Moreover, the formation of these subterranean hollows has not been limited, as some Continental writers have supposed, to any particular geological epoch.

On the question of the supposed desiccation of the earth—a subject on which so much has been written—M. Martel holds very pronounced views. Whilst some writers who admit the progressive diminution of the earth's superficial waters believe that it proceeds too slowly to be recognised in historic time, our author holds that abundant evidence of the change may be cited within the range of human history. On the other hand, a compensating action may come into play if it be true, according to an opinion that has recently been gaining ground in certain quarters, that much of the water emitted as vapour by volcanoes is derived from the deep-seated magma of which it is an original constituent, so that its emission is a direct contribution to the surface-waters of the globe.

It was only to be expected that M. Martel would have much of interest to say on his favourite subject of the hygiene of potable waters. Those who are acquainted with his former writings will not be surprised at his warning that springs of apparently pure water are in many cases merely the outflow of surface-waters which have disappeared through fissures, carrying with them pollution from the soil and not undergoing purification during their passage through the rocks. Even chalk, according to the writer, is generally far from being a thoroughly effectual filter.

In glancing through M. Martel's work the reader will find, probably to his surprise, that the spelæologist is unquestionably a being of large discourse, looking before and after. In one part he discusses the origin of man and the cradle of his civilisation; in another he speculates on the probable future of humanity; in an early chapter he discourses on the hypotheses concerning the beginning of the earth; in the last chapter he carries the reader forward to the catastrophes likely to bring the history of our planet to a close. Notwithstanding the fact that the range of subjects is thus so wide and diverse, the book remains readable and informing throughout. M. Martel is always vivacious, sometimes impressive, and occasionally original—but never obscure. In fine, he has written a little book which may be described in the best sense of the word as popular.

---

## *CHEMISTRY OF PHARMACOLOGY.*

*The Chemical Basis of Pharmacology.* By Francis Francis and J. M. Fortescue-Brickdale. Pp. xii + 372. (London: E. Arnold, 1908.) Price 14*s.* net.

THE general scope of this work is indicated by the above title and the subtitle, reading "An Introduction to Pharmacodynamics based on the Study of the Carbon Compounds." Short general introductions to chemistry and physiology are first given, dealing with such subjects as valency, structural formulæ, isomerism, correlation of chemical and physiological properties, and the relationships between structure and action. Then follow chapters on the main groups of carbon compounds, for example, hydrocarbons, alcohols, purine bodies, and the alkaloids, their methods of preparation and properties, both chemical and physiological. The book contains a fund of information, from which many suggestions as to lines of research may be gathered, and is a genuine attempt to systematise our present knowledge of the chemistry of pharmacology. As such it should prove of great use, more particularly to physiological and pharmaceutical chemists rather than "to the practitioner who is daily brought in contact with the claims of new drugs," and whose chemical knowledge could hardly be expected to reach the standard required for the assimilation of the information given, however desirable such a state of things might be.

We agree with the authors that the student of organic chemistry will find in the work an introduction to a fascinating branch of applied chemistry, but think that the usefulness of the book, alike to the student of chemistry and manufacturer of synthetic drugs, would have been largely increased had more references to original papers been given. It is also to be regretted that more care has not been bestowed on the book during its passage through the press. The orthography is sometimes unusual in such words as "etherial," "radical," "Kekule," and the work contains innumerable press errors, and many which cannot be attributed to this cause. For example, the expression (p. 90)

$$C_2H_5.OH + HNO_2 = H_2O + C_2H_5ONO2 \text{ (Ethyl nitrite)}$$

is not an equation, nor is the formula for ethyl nitrite correct. Butyl chloral (pp. 79, 109) has not the formula $CCl_3.CH_2.CHO$, and trichloroethyl alcohol is not accurately represented as $CCl_3.COH$. Such faults are inexcusable.

A very deplorable aspect of modern chemistry in its application to pharmacy or physiology would appear to be the lack of system in nomenclature, and a consequent flood of synonyms. This point does not seem to have appealed to the authors, for we find them either ignorant of, or not in agreement with, the systems of nomenclature adopted by the Physiological and Chemical Societies, and in consequence confusion is rendered worse confounded by the adoption of any and every style of naming. We quote as examples "proteid or protein"; "methyl or methylic alcohol"; "sodic or sodium acetate"; "silver hydrate, aqueous potash, ammonium hydroxide"; "glycerol or glycerin"; "mannite or mannitol"; "oxybenzoic or hydroxybenzoic acid"; and "1-oxy-2-iodo-4-chlor-quinoline."

It could reasonably have been expected that the authors would have made a serious attempt to introduce order and method where chaos prevails by adhering strictly to those generally accepted principles of nomenclature which, though imperfect, materially help to build up an intelligible chemical literature.

## *TWO RECENT BOOKS ON EVOLUTION.*

(1) *A Picture Book of Evolution.* By Dennis Hird. Part ii. Pp. vi + 214. (London: Watts and Co., 1907.) Price 2*s.* 6*d.* net.

(2) *Darwinism To-day.* By Prof. V. L. Kellogg. Pp. xiv + 403. (London: George Bell and Sons; New York: Henry Holt and Co, 1907.) Price 7*s.* 6*d.* net.

WE cannot recommend anyone wishing to make himself acquainted with the present aspect of the problem of evolution to put himself under Mr. Hird's guidance. His treatment of the subject is crude and uncritical, nor does he give any evidence of familiarity with the evolutionary questions that are now chiefly engaging the attention of biologists. Putting minor inaccuracies aside, the book might have been of some service if published, say, forty years ago; at the present time it is to a large extent either misleading or superfluous. Opposition to the doctrine of species-formation by natural selection comes to-day, not, as the author seems to think (p. 25), from the "House of Lords or the pulpit," but from scientific men, both in this country and abroad; more particularly in Germany and America. While no educated person now disputes the fact of evolution, the Darwinian theory is being attacked more vigorously than ever; the assailants, however, belong to a very different class from Darwin's impetuous critics of the early 'sixties. Mr. Hird takes little or no notice of present-day problems, but writes as if the whole question of evolution still occupied the same position as in the mid-Victorian era. Within these limits he is fairly interesting; it is, however, unfortunate that he has admitted to his pages several inaccuracies that might with a little more care have been avoided. "Oasperm," "octoderm," are ugly misprints; "hermaphrodite" does not mean the same as "diœcious"; it is new to us that hæmatococcus "like the amœba, requires to be magnified some 900 times in order to be seen." Huxley can scarcely be ranked as a "discoverer of evolution"; he would certainly never have made such a claim for himself. The illustrations in Mr. Hird's volume have mostly been seen before. Many of them are good, but the connection of some with the text is remote.

(2) Prof. Kellogg's book is of a very different stamp. So far from ignoring the questions that have in recent years grown up around the central doctrine of evolution, he has devoted an immense amount of labour to collecting, arranging, and expounding the views of nearly all the recent writers on evolutionary subjects. His treatise thus contains a vast quantity of material, in large part consisting of copious quotations from English, French, and German authors, put together somewhat promiscuously, and discussed without much exercise of the critical faculty, but useful to the student as a storehouse of various and conflicting opinions. The author's own standpoint is not very easily discovered. He passes in review the tenets of Darwinians, Lamarckians, Mutationists, Nägelians, with much appearance of giving a fair hearing to all sides. But as he seldom seems to know his own mind for long together, the general result is unsatisfying, not to say irritating; his impartiality is the impartiality of the pendulum rather than that of the judge. The author rightly appreciates the constructive weakness of anti-Darwinian arguments, but greatly overestimates their destructive efficiency. He allows, for example, far too much weight to frivolous objections such as those raised by Wolff in his "Beiträge zur Kritik der darwin'schen Lehre."

In examining the assaults delivered from various quarters on the Darwinian position, one cannot help being struck with the fact that the efforts of objectors tend much more effectively, on the whole, to refute each other than to weaken the defence. It is also quite obvious that to many of these critics Darwin's own writings are practically a sealed book. One cannot suspect Prof. Kellogg of talking about Darwin without having read him; nevertheless he shows, like other writers, a strange confusion of mind with respect to the Darwinian view of the function of natural selection in evolutionary process. Why should it be considered a "weakness" of the Darwinian theory of natural selection that this principle has "no influence whatever on the origin and control of variations"? Darwinism never professed to be an "all-sufficient explanation of adaptation and species-forming" apart from the existence of variation, which fact it takes for granted. It is irrational to blame a theory because it does not explain one of the fundamental data from which it starts.

In at least one passage of his book, the author shows a distinct leaning towards the "orthogenesis" advocated by the school of Eimer. Theories, he thinks, of this general type "are directly in line with the spirit of modern biological methods and investigations." On this point, opinions will differ; we should be inclined to maintain the opposite. On a later page he advances what he considers to be "a logical proof for the introduction into phylogeny of adaptive ontogenetic changes," *i.e.* a proof of Lamarckism, for it is hard to see any distinction between this view and that of the French evolutionist.

"When species-differences and adaptations are identical with differences and modifications readily directly producible in the individual by varying environment, are we not justified," he asks, "on the basis of logical deduction, to assume the transmutation of ontogenetic acquirements into phyletic acquirements, even though we are as yet ignorant of the physicochemical or vital mechanism capable of effecting the carrying over?"

This question we should unhesitatingly answer in the negative. When rhetoric of the above description is dignified with the name of "proof," we are not surprised to find that the author's estimate of the true bearing of ascertained facts is feeble. It appears to cause him some astonishment that there still exist, "especially in England," thorough-going Darwinians who remain unmoved by the storm of criticism levelled against the theory of natural selection. That there are such stalwarts is undoubtedly the case, and the situation as maintained by them could not be better expressed than in the words, quoted without approval by Prof. Kellogg, of Sir E. Ray Lankester, at York, in August, 1906:—

"In looking back over twenty-five years it seems to me that we must say that the conclusions of Darwin as to the origin of species by the survival of selected races in the struggle for existence are more firmly established than ever."

F. A. D.

## OUR BOOK SHELF.

*Graphics, applied to Arithmetic, Mensuration, and Statics.* By G. C. Turner. Pp. ix + 388. (London: Macmillan and Co., Ltd., 1908.) Price 6s.

THIS work forms a valuable addition to the text-books on an important branch of mathematics, and, coming from a past student of Prof. Henrici, is especially welcome. Within the limits imposed by the author, the subject of graphics is very fully and ably treated. The first chapter, on graphical arithmetic, gives, at perhaps undue length, the geometrical constructions corresponding to the ordinary arithmetical processes, with the employment of scales and squared paper, and is followed by a very useful chapter on the graphical mensuration of plane figures. Vectors are then introduced, with examples of displacement, velocity, and acceleration vectors, and problems on mass centres—altogether a very interesting section. Experimental work is done in connection with concurrent forces in chapter iv., and in verification of the properties of the link polygon and the equilibrium of a general system of coplanar forces in chapter v.

The principles of graphic statics, having thus been well laid and amply illustrated, are further developed in the succeeding chapters by practical applications, such as to stress diagrams for bridge and roof trusses, loaded at the joints, at intermediate points, and under wind pressures; to bending moments and shearing forces in beams, and the action of travelling loads; and to problems involving friction and work done by constant and variable forces.

While the deductive reasoning is well sustained throughout and satisfying to the logician, the subject is everywhere exemplified by concrete examples, fully worked out, and at short stages the student is provided with exercises in abundance, with answers, the author having drawn freely from the examination papers of the University of London, the Board of Education, the Civil Service Commission, and similar sources.

The very fulness with which graphic statics is discussed and illustrated in this volume makes one regret that some space could not have been found (by omissions, if necessary) for the equally important subject of graphic dynamics, founded on the vector conception of Newton's second law, with the application of the hodograph, and illustrations drawn from the motions of machines, the leading idea being to develop the fundamental law that force is vector rate of change of momentum. The author rightly emphasises the need for good-sized figures, and uses fairly large set-squares, in conjunction with straight-edge, scale and compasses, but he seems content with this comparatively meagre equipment, the incompleteness of which must surely handicap a student who does much quantitative graphical work.

With these reservations the book is admirable, and should do much to encourage the teaching of a subject that ought to form an integral part of the mathematical training given in our secondary and technical schools.

*Man and his Future: A Glimpse from the Fields of Science.* By Lt.-Col. William Sedgwick. Pp. 256. (London: T. Werner Laurie, 1907.) Price 7s. 6d. net.

This book is a curiously naïve attempt to justify and interpret in the light of modern scientific discoveries a somewhat old-fashioned form of orthodoxy. "The whole universe is the scene of a conflict between two powers over the possession of atoms of matter." This conflict is waged by means of the $\alpha$- and $\beta$-rays of the physicist, which have respectively the power of "doing building work" with the atoms and of destroying the systems thus set up. Man is "a transgressing anthropoid ape" who, having wandered out of the regions where alone he could live in a state of nature, has purchased relief from his conditions by taking service with the Power of Repulsion destroying the forests of the earth for fuel, and analysing compounds (such as ores) for their useful elements. But the growth of his needs has led him from mere destruction to synthesis, and so into the service of the Power of Attraction. Nevertheless, his original transgression condemns him still to destroy on earth, so that his synthetic activities—shown, for example, in chemistry, physics, and engineering—must be regarded as really "a training in the art of Universe-building," to be applied seriously only when the present cosmic order makes way for the New Evolution. Thus death is "a recruiting agency for the staff" to be engaged upon this gigantic re-constructive operation, when they have re-clothed their "resting forms" in the protoplasmic garments for which the coal seams and the nitrate beds are perhaps intended to provide materials.

This work is so sincerely and modestly written that one regrets the necessity of saying that it can have but little value except to the student of the psychological history of discovery, who will note with interest and curiosity that, in connection with his "building-up" theory, Col. Sedgwick, in 1902, predicted the existence of non-valent elements having the atomic weights now actually assigned to the members of the helium group.

*Développement et Progrès de la Fabrication du Malt pendant les quarante dernières Années.* By Ed. Eckenstein. Pp. 212. (Paris: A. Hermann, 1908.) Price 5 francs.

This work gives an account of the development of methods of malting on the Continent from the time when the employment of mechanical appliances to supplement hand labour was first suggested to the present day, when, in some maltings, hand labour has practically disappeared. The author makes no attempt to discuss the progress of scientific knowledge in relation to malting, but confines himself almost entirely to a description of the manner in which the engineer has overcome many of the practical difficulties met with when attempting to deal with large bulks of germinating grain other than by hand labour. Problems such as the controlling of the heat generated by respiration of germinating grain in mass, and establishing an equal distribution of moisture throughout the individual corns of the mass, together with equal conditions of aëration, have to be solved. The solution of such problems by mechanical means is not easy, and there are still many competent critics, both in this country and abroad, who consider that the claim for success made by advocates of mechanical malting is not at present thoroughly well justified. However this may be—and the question is essentially a technical one—everyone interested in the progress of mechanical malting should read M. Eckenstein's book, the value of which is much enhanced by the numerous very excellent drawings and diagrams which it contains.

*The Romance of the Sky; the Story of Star-gazing and Star-tracing, being an Introduction to the Study of Astronomy.* By C. J. Griffith. Pp. viii+166. (London: George Routledge and Sons, Ltd.; New York: E. G. Dutton and Co.)

Mr. Griffith has undertaken to tell his story through the mouth of a mythical amateur astronomer, condemned to live through all the phases of astronomical science from pre-Ptolemaic days to the present. The method naturally introduces a great deal of reading matter that is not astronomy, but for non-astronomical readers the result, thus diluted, should prove of interest. A talk with Ptolemy, the enunciation of his great theory by Copernicus himself, the unfortunate reaction which delayed astronomical progress for centuries, and the final clearing of the mists by Kepler's results, occupy the first twenty pages. Then in rapid sequence Galileo, Newton, Halley, Herschel, and other notable workers in astronomy are interviewed, the volume concluding with discourses on the making of present-day observations and the deductions arising therefrom. The book is good, in parts, and the glossary of astronomical terms (chapter xxiv.), together with the excellent index, should not prove the least interesting or instructive to the beginner.

W. E. R.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Life on Mars.

IF the canals of Mars are structures made by intelligent beings, it is difficult to believe that these beings have not at their disposal appliances both for construction and survey. It is difficult to believe that some of these appliances are not made of metal. If made of metal, it is difficult to believe that the Martians do not use fire. There is strong evidence that friction was the source of the discovery of fire on the earth. But is it likely that fire would be discovered by friction on a planet the barometrical pressure of which is less than 4 inches of mercury, and the still atmosphere of which is believed to be free from thunderstorms and lightning flashes?

The obvious, and I think adequate, criticism of such an argument is that it is anthropomorphic. It interprets the conditions of life on Mars too much in terms of human experience. In the present state of our knowledge, may not the same criticism be made of the assertion that life on Mars is accompanied by an intelligence similar to our own? On the earth, life without any high degree of intelligence has been the rule. Life with a high degree of intelligence has been the exception, an exception confined to an insignificant fraction of the time during which mundane life has existed. Is it safe, without very cogent evidence, to assert that a similarly exceptional state of things exists on Mars? Can no other possibilities be suggested?

To be told that life exists on Mars tells us but little of its nature. It does not even tell us that living beings exist. Perhaps on Mars there is only one living being, a gigantic vegetable the branches or pseudopodia of which embrace the planet like the arms of an octopus, suck water from the melting polar snows, carry it to other parts of the planet, and are visible to us as the Martian canals. Lowell adduces the straightness of the canals as a proof that they are artificial products of intelligent beings. But they are certainly no straighter than the somewhat similarly interlaced pseudopodia seen in certain Heliozoa, Foraminifera, and Radiolaria.

That this idea is not excluded by anything necessarily inherent in the nature of living matter may be shown by considering the conditions that must have accompanied the origin of life, whether on the earth or on Mars. Parenthetically, it may be remarked that the existence of life on Mars is not without bearing on the problem of the origin of life on the earth, and Lowell's discovery may be regarded as adding reason to the hope that has been expressed that some day life may be artificially produced in our laboratories.

It is impossible to believe that life originated directly by a fortuitous concourse of atoms of the elements of which living matter consists. Organic compounds must first have come into existence as links between the living and the not living. Some clues as to the nature of these links possibly may be afforded by current researches on the fixation of atmospheric nitrogen. We may surmise that some stages in the evolution of living matter were amino-acids, polypeptids, and proteids. The fact that nowadays no such substances exist in natural water does not disprove this supposition, for had such compounds existed they must long ago have been destroyed by bacteria and similar organisms. We may surmise that gradually these primeval proteids became aggregated into larger and larger molecular complexes until they existed as a loose jelly of indefinite extent, that these complexes were subjected to a slow oxidation, that, if we may accept Pfluger's doctrine of the nature of respiration, these molecular complexes, under the influence of oxidation, acquired a certain molecular instability, but showed at first no other vital character than the power of combining with or assimilating other molecules of primeval proteid. However imperfect such a conception may be, there can be no doubt that the process of the origination of life was in the main a process of building up (one is tempted to use the word polymerisation) of small simple aggregates into larger and more complex aggregates. I can see no reason for believing that there was anything in the nature of this primitive living matter that would prevent this process of aggregation from continuing indefinitely. Or, in other words, we have no right to assert that there could have been anything in the nature of the primitive living matter itself to prevent it forming a scum of unlimited extent on the water in which it existed.

The fact that such indefinite growth either did not occur, or, if it did occur, was only a transient stage in evolution, may safely be ascribed to the effect of some external forces or conditions of the environment. An illustration may make this clear. Ice-crystals have the property of aggregating together to form snow-flakes. Owing to conditions and forces external to themselves, the process of aggregation does not continue indefinitely, but the snow-flakes cease to grow when they have reached a certain size. Under another set of conditions, ice-crystals may not form snow-flakes at all, but may cover a large extent of country in the form of hoar-frost. Similarly, the primitive living matter on the earth, owing to the action of some external forces or conditions, developed in the form of separate individuals that we may compare to snow-flakes. The possibility cannot be excluded that on Mars living matter developed in the form of a scum covering the seas of that planet, which scum would correspond to the hoar-frost of our illustration. What external force is there that would be likely to act on primitive living matter on the earth, but not on Mars? Could it be the action of tides and waves?

All I wish to assert is that it is possible and conceivable for a single vegetable organism to come into existence on a planet, and for it not to break up into separate individuals. In such a vegetable, parts unfitted for the environment might perish and be assimilated by other parts that were better adapted to the conditions that existed. Thus it might possess a power of adaptation to a changing environment, such as must have occurred, for example, in the drying up of the seas that once existed on Mars. No one who believes in "the continuity of the germ-plasm" will see any objection in the quasi-immortality of such an organism.

Another possibility may be suggested. Supposing, in the course of many millions of years, the earth was to follow the example of Mars and gradually to lose its water. Should this happen, a stage would be reached in which a few isolated lakes existed in the dried-up beds of the oceans. Let us imagine what then might be seen by an intelligent being on the planet Venus who had "an eye for planetary detail." Might he not see a system of faintly shown lines stretching from lake to lake and to the polar caps? Might they not show evidence of seasonal change? And might he not then conclude that they were canals made by beings of greater intelligence than his own, though in reality they were only fronds of a gigantic seaweed that had developed from the gigantic seaweeds that at present exist in the Sargasso Sea? Is it not likely that in the course of ages the fronds of such vegetables would contract until they formed straight lines from oasis to oasis, and so further the idea that their production was due to intelligence?

These ideas are obviously merely of the nature of suggestions, and I wish expressly to disclaim holding any definite opinion or belief as to the nature of the life on Mars. Prof. Lowell has measured the rate of flow of water in some of the Martian canals. Is this rate the "economical rate" for the flow of water along an open canal, or does it agree better with the economical rate, if the phrase is applicable, for the flow of water along pipes of a vegetable organism, where presumably the loss from percolation and evaporation would be trivial?

My position is that one may admit that Prof. Lowell's brilliant researches prove the existence of life on Mars, and still ask from him further evidence before we are convinced that that life is intelligent. E. H. HANKIN.

Agra, India.

## The Warm Stratum in the Atmosphere.

WHILE not presuming to offer an explanation of the isothermal or relatively warm stratum in the high atmosphere, which the recent letters in NATURE have made known to others than meteorologists, I desire to point out that it is probably a universal phenomenon, existing at some height all around the globe. This inversion of temperature was first discovered by M. Teisserenc de Bort with the *ballons-sondes* sent up from his observatory at Trappes, near Paris, in 1901, and almost simultaneously by Prof. Assmann from similar German observations. Since then almost all the balloons which have risen more than 40,000 feet above Central Europe (that is, near latitude 50°) have penetrated this stratum, without, however, determining its upper limit. Teisserenc de Bort early showed that its height above the earth, to the extent of 8000 feet, varied directly with the barometric pressure at the ground. Mr. Dines (NATURE, p. 390) gives the average height of the isothermal layer above England as 35,000 feet, with extremes of nearly 50 per cent. of the mean. Observations conducted last March by our indefatigable French colleague, Teisserenc de Bort, in Sweden, just within the Arctic circle, showed that the minimum temperature occurred at nearly the same height as at Trappes, namely, 36,000 feet, although Prof. Hergesell, who made use of *ballons-sondes* over the Arctic Ocean, near latitude 75° N., during the summer of 1906, concluded that the isothermal stratum there sank as low as 23,000 feet.

During the past three years the writer has dispatched seventy-seven *ballons-sondes* from St. Louis, U.S.A., latitude 38° N., and most of those which rose higher than 43,000 feet entered the inverted stratum of temperature. This was found to be somewhat lower in summer, but the following marked inversions were noted last autumn:—October 8, the minimum temperature of −90° F. occurred at 47,600 feet, whereas at the maximum altitude of 54,100 feet the temperature had risen to −72°; October 10, the lowest temperature of −80° was found at 39,700 feet, while −69° was recorded at 42,200 feet, showing a descent of nearly 8000 feet in the temperature-inversion within two days. The expedition sent out jointly by M. Teisserenc de Bort and the writer, on the former's steam yacht *Otaria*, to sound the atmosphere over the tropical Atlantic during the summer of 1906, launched *ballons-sondes* both north and south of the equator within the tropics, and although some of these balloons rose to nearly 50,000 feet, they gave no indication of an isothermal stratum. In fact, the paradoxical fact was established that in summer it is colder eight miles above the thermal equator than it is in winter at the same height in north temperate regions. This results from the more rapid decrease of temperature in the tropics and the absence of the numerous temporary inversions which, as Mr. Dines has pointed out, are common in our regions below 10,000 feet. If, therefore, as seems probable, the isothermal or relatively warm stratum does exist in the tropical and equatorial regions, it must lie at a height exceeding 50,000 feet, from which height, as the data quoted show, it gradually descends towards the Pole, at least in the northern hemisphere.

## The Nature of X-Rays.

PROF. BRAGG in a recent letter (NATURE, April 16) credits me with the admission that the experiments I made on the intensity of secondary (scattered) X-rays are not so contrary to the neutral pair theory as I at first supposed. Will you permit me to correct this by saying that all the evidence I have obtained has verified the ether pulse theory in a more striking way than I ever anticipated, and I cannot think of a single experimental result obtained in researches on secondary X-rays which gives any support to his theory?

Prof. Bragg refuses, on the plea of want of knowledge of the constitution of the atom, to accept as conclusive the results of experiments I recently made. It appears to me, however, that such absence of knowledge is insufficient to conceal the disproof of his theory, and that the evidence (though by itself not sufficient to establish any theory) is quite sufficient to distinguish between the ether pulse theory and that proposed by Prof. Bragg.

The supposed difficulty in accounting on the ether pulse theory for the change in the ratio of intensities, to which he refers, is not one affecting the theory at all. Sufficient experiments have not yet been made to lead to a final choice between several possible causes as producing the bulk of this effect. The result itself is in harmony with the results of other experiments.

As Prof. Bragg is apparently not convinced, I venture to recommend the consideration of the following evidence obtained in investigating secondary X-rays, for I can only think that the study of this evidence would at least lead him to confine the application of his hypothesis to the explanation of phenomena which at any rate do not furnish so striking a disproof.

The evidence may be briefly summarised as follows:—

(1) The partial polarisation of a primary beam of X-rays.

(2) The identity in penetrating power of secondary (scattered) rays from light atoms, and of the primary producing them, though the scattered constitute only a fraction of the incident rays.

(3) The equality in the proportion of rays of different penetrating power which are scattered.

(4) The fairly complete polarisation of the rays scattered in a direction perpendicular to that of propagation of the primary.

(5) The distribution of the secondary (scattered) rays.

(6) The order of magnitude of the energy of scattered radiation.

(7) The homogeneity of a second type of secondary X-radiation from many substances.

(8) The fact of this homogeneous radiation being characteristic of the element emitting it, and independent of the penetrating power of the primary radiation producing it.

(9) The fact that for large ranges in the penetrating power of the primary these homogeneous secondary rays from some substances are proportional to the ionisation produced by the complex primary in air.

These are points that occur to me while writing; there are probably others.

The first five results (though not explicitly stated) were contained in the theory as given by Prof. J. J. Thomson ("Conduction of Electricity through Gases") shortly after the publication of the second experimental result, and before the others were experimentally observed. The sixth is in harmony with the calculation given by Prof. Thomson if we accept his theory of the number of electrons in the atom. Results (7), (8), and (9), obtained in joint-work with Mr. C. A. Sadler, can be explained on the ether pulse theory.

Prof. Bragg has given an explanation (based on what seem to me doubtful assumptions as to the behaviour of a neutral pair on collision with light atoms) of the fourth result. An explanation on his theory of the other facts necessitates in some cases very improbable assumptions; in others it appears to me to lead to absolute impossibilities. In no case can I find the slightest support for the neutral pair theory.

Regarding the nature of $\gamma$ rays, or even of very penetrating X-rays, the direct evidence is much less conclusive, the corresponding phenomena being in reality more complex, for reasons which are beginning to be understood. For that reason I do not wish at present to discuss them, preferring to deal with what is to me a certainty, and waiting for the results of further experimental work to throw light on the more complex. Prof. Bragg commences at the other end with a hypothesis which gives an easy explanation of what on the pulse theory is somewhat obscure, but when an attempt is made to apply this to the simpler phenomena it is found inadequate, not only as a complete theory, but even as a supplementary one.

CHARLES G. BARKLA.

Liverpool, April 27.

### Echelon Spectroscopes and the Green Mercury Line.

It is interesting, in reference to Prof. Nagaoka's letter in Nature of April 23 (p. 581), to note that I exhibited photographs of the green mercury line, showing a nu nber of new components, at the Leicester meeting of the British Association. I did not publish the number or position of the lines in the report, not being quite satisfied that some of the fainter ones might not be produced in the instrument, and I discovered later (Nature, vol. lxxvii., pp. 198 and 222) that secondary effects, due to light reflected in the echelon, have to be taken into account. Since then Von Baeyer's measurements with a Lummer and Gehrcke spectroscope and Galitzin's echelon measurements have confirmed two of the lines that were new, and added confirmation to my values for the old ones. A doubt still remains, however, about some of the fainter lines, and as a comparison of the values given by different instruments is the most obvious way of confirming the true components and eliminating false ones, I give my results for comparison below.

It is usual in stating results of this kind to give the wave-length intervals between the components and the principal line, but this leads to mistakes in comparing results, because the principal line given by most of the observers has been divided by Von Baeyer and Nagaoka into two components, and by taking the brighter component as the principal line they shift the reference point about 15 milli-Ångström units, and the agreement, which would otherwise be evident, is quite obscured. I have given below the distances of the various components from the component of shortest wave-length, which happens to be a good reference line. The differences shown in Prof. Nagaoka's comparison are in this way much reduced.

*Comparison of Recent Echelon Spectroscope Determinations of the Components of the Green Mercury Line,* λ 5461.

| Janicki | Galitzin | Nagaoka | Stansfield | |
|---|---|---|---|---|
| 0 | 0 | 0 | 0 | 17 bright |
| | | | 23 | faint |
| | | 31 | | |
| | | | 41 | very faint |
| | | | 59 | ,, |
| | | 72 | 75 | ,, |
| | | | 93 | ,, |
| | | 105 | | |
| 133 | 137 | 137 | 135 | 12 bright |
| 166 | 168 | 163 | 165 | 12 ,, |
| | 189 | 189 | 188 | 8 medium |
| **232** | **236** | { 223<br>**247** } | **232** | { 52 bright<br>*principal line* |
| | | 280 | 277 | 5 faint |
| 320 | 321 | 315 | 319 | 16 bright |
| | | | 345 | 8 medium |
| 365 | 365 | 356 | 363 | 12 bright |
| | | 390 | 386 | 8 faint |
| | | | 409 | very faint |
| | | 448 | 448 | 14 faint |
| | | 477 | 473 | very faint |

The numbers give the distances of the components from the component of shortest wave-length in milli-Ångström units. In the fifth column the widths of the brighter lines, taken from the photographs, are given in the same units.

It will be seen that there is generally close agreement as to the position of the five bright companion lines. As to whether the principal line is single or a close double, it is interesting to note that several of my photographs showed it divided, the brighter component being on the longer wave-length side as Nagaoka and Von Baeyer give it, but owing to the secondary effects in the echelon I have not been able to make sure of the division.

Prof. Nagaoka's values agree fairly well with mine for all the faint lines on the list below the principal line, although he does not give the lines on my photographs at 345 and 409, but we do not agree about the positions of those which fill in the long gap between the first and second bright companion lines. The agreement is not sufficiently good to exclude the possibility of some of the faint lines having their origin in the echelons.

H. Stansfield.

The University, Manchester, April 25.

### Appearance of the Slug Testacella in a Flooded District.

Some time ago I wrote to you to say that the remarkable slug Testacella occasionally appeared in large numbers on the surface of the ground in my garden. This phenomenon only occurs when the district is heavily flooded. The abnormal weather of the last half of April has brought severe floods out in many parts of the Thames valley, and yesterday, through the kindness of a friend who now occupies the house and garden referred to, I was able to collect about a hundred of these animals. I shall be pleased, therefore, to send specimens alive or preserved to those correspondents who wrote to me on the subject when my previous letter appeared in Nature, whose addresses I have mislaid, unfortunately, while changing houses. I may add that it is only in this particular garden that I have seen these animals. What the conditions may be that cause the slugs to live there and not elsewhere, so far as I know, in the neighbourhood, I am quite unable to suggest. They live too far down even in wet weather to be found during ordinary gardening operations.

M. D. Hill.

Eton College, Bucks, May 3.

## *THE TOTAL SOLAR ECLIPSE OF JANUARY* 3, 1908.

SINCE the brief announcement made in this journal (vol. lxxvii., January 23, p. 273) in the first month of this year, relative to the success of the eclipse expedition organised by Mr. F. K. McClean, further information has become available.

The communications received give a complete account of the doings of the expedition from the time it left Auckland in the Union S.S. Company's *Taviuni*, which Mr. McClean had chartered specially for the expedition, to its return to that port. A detailed report, containing the scientific results of the expedition, will in due course be presented to a society, but a short sketch will no doubt be of interest to many readers of this journal who have been waiting for further information.

The members who finally formed Mr. McClean's party were as follows:—Joseph Brooks, F.R.A.S., retired surveyor in charge, Trigonometrical Survey, N.S.W.; W. E. Raymond, F.R.A.S., first assistant, Sydney Observatory; J. W. Short, astronomical photographer, Sydney Observatory, and magnetic observer; Rev. F. W. Walker, of Auckland; Henry Winkelmann, of Auckland.

The party left Auckland on the afternoon of December 12, 1907, arriving at Tahiti on December 20; Flint Island was reached on December 23, at 7 a.m. The expedition from the Lick Observatory was already located on the island, and Prof. Campbell came off to meet the ship.

The landing place is described as consisting of a small channel blasted through the reef and extremely dangerous. In spite of the rough surf, everything was safely landed. As it was raining hard all the time, the first piece of work was the erection of the tents and the temporary housing of all the instruments in them.

The camp was located amongst a number of cocoanut trees, some of which were at least 100 feet high, rendering the horizon invisible. Considerable lopping of branches was found necessary, not only to allow sufficient sky field for the efficient working of the large siderostat, but room for the tents themselves. The accompanying illustration (Fig. 1) will give the reader some idea of the tropical and dense nature of the vegetation on the island. The negative from which this illustration has been taken was made by Mr. Winkelmann.

December 24 was even wetter than the previous day, but in spite of that the remaining tents were erected, and the first layer of concrete for the large

22-inch siderostat was laid. On January 1 everything was complete and drills were commenced, and eventually the programme was arranged to be carried through, utilising the signals called by Prof. Campbell's timekeeper.

From the account given of the weather conditions, on the morning of the eclipse the party seems to have met with exactly the same peculiarities as those which were experienced by many of the observers at Palma in 1905. Fortunately, Mr. McClean was present at Palma on that occasion, so the experience was not new to him, and in his letter he writes, "It has been another Palma and four plates in my bag."

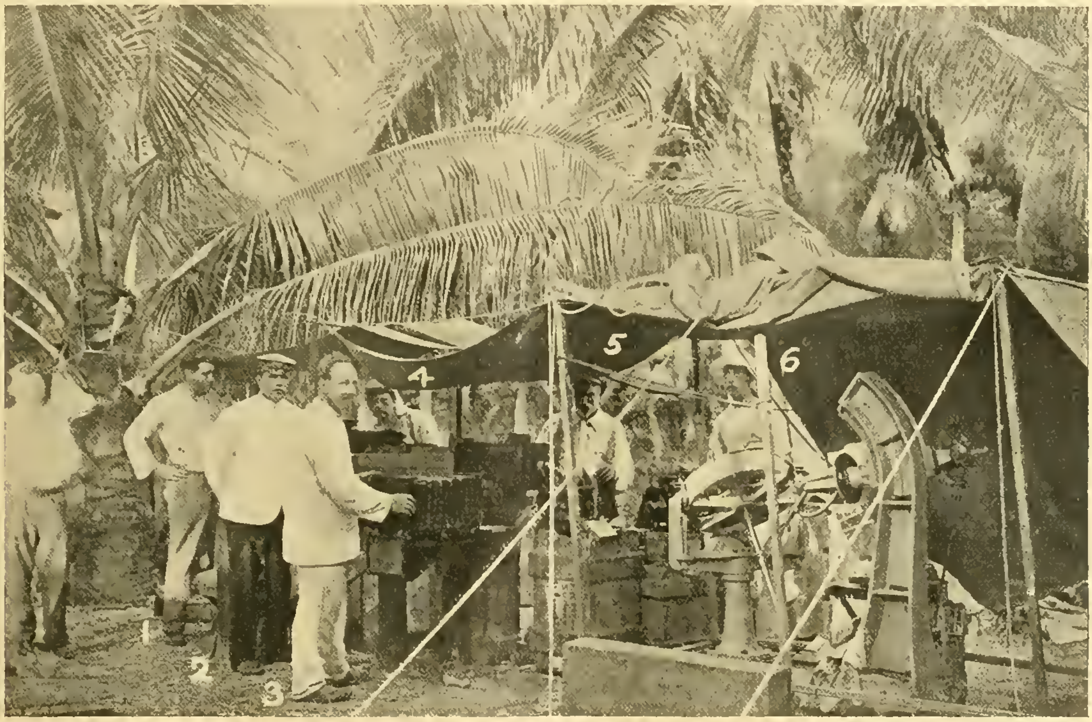
As the wind came in from between the north-east and east, special watch was kept in that quarter. First contact was observed in a perfectly clear sky, and it remained fairly clear to almost within a few minutes of totality. Everyone was prepared to carry out his allotted task when "five minutes before totality" was called out by the American timekeeper.

A heavy bank of cloud then made its appearance in the north-east, and at the signal "48 seconds to go before totality" it began suddenly to rain heavily, and it poured until one second before totality. It had been arranged to determine the instant of totality by observing the cusps, but the clouds prevented their observation. The timekeeper was to have received a signal from the "cusp" observer to commence his counting, but no such signal could be given. At what time the timekeeper started counting is not stated, but it is mentioned that just before totality, probably one or two seconds, because the thin crescent was seen to be just changing into beads, the cloud cleared, and the rain ceased.

The instruments were quickly uncovered, and the exposures made according to the prescribed programme. The clouds continued during the first minute with short intervals of clear sky, after which the eclipse was clearly visible, though light cloud was still present. At the call of 3 minutes 50 seconds, sunlight had broken out, several seconds before it was expected, and was preceded by a brilliant prominence.

Such a sudden and unexpected ending did not, however, spoil the plate which Mr. McClean was exposing at the time, for, as he writes, "then, while expecting another ten seconds, I looked up and saw a red prominence, and shut things up just in time. The others were not so lucky."

The eclipse does not seem to have been a dark one. It is stated that it never became too dark to read large figures, in spite of the instrument being surrounded by trees. Another statement is that a "newspaper could have been read without any difficulty whatever."



*Photograph by H. Winkelmann.*

FIG. 1.—Mr. McClean and party standing by the instruments they worked during the Eclipse. (1) Mr. McClean. (2) Mr. Caffyn. (3) Mr. Short. (4) Rev. Walker. (5) Mr. Brooks. (6) Mr. Winkelmann.

Captain G. H. Lacy, who observed the eclipse from the bridge of the *Taviuni*, compared the light during totality to that which would be produced from an arc lamp placed on deck.

Mercury and Venus were seen, the former to the south-west and the latter to the north-east of the sun. Very few stars were observed.

Mr. Raymond, who undertook sketching the corona, using a 4-inch Grubb refractor to project the sun's image on to a sheet of cardboard, likened the form of the corona to "an irregular star of seven points." The corona had a pearly-grey colour, and three of the streamers were shaped like pyramids. These were capable of being faintly traced down to the edge of the moon's limb.

Mr. Flynn, first officer of the *Taviuni*, also made a sketch of the corona.

With regard to the photographs, the following is a brief summary of the successful exposures secured:—

Messrs. McClean, Brooks and Walker, working with the 4⅝-inch De La Rue Coronograph, 8 feet focal length, obtained four pictures.

The same observers secured no results with the Voigtländer 4-inch objective, fitted with a Thorp replica grating.

Mr. Winkelmann, working with a telephoto lens of equivalent focal length of 5 feet 3 inches, obtained five pictures, showing various depths of corona.

Mr. Short (assisted by Mr. Caffin, purser of the *Taviuni*) worked a photoheliograph of about 7 feet focal length and a telephoto lens. Some of his results will also prove very useful.

It will thus be seen that while no spectroscopic results were secured, a very complete record of the form of the corona was obtained, and this was the chief object of the expedition.

With the exception of Raymond's refractor, all the objectives were fed from the 22-inch siderostat mirror taken out by Mr. McClean (see Fig. 1). The De La Rue and photoheliograph received the sunlight directly from the mirror, while the remainder were placed at right angles to the beam from the siderostat, and obtained their light by means of small mirrors placed in the path of the main beam.

Some of the original negatives, and glass positives of others, which have arrived from Auckland indicate at a glance what a magnificent sight the corona must have presented. No wonder the eclipse was not described as a dark one when such an extent of corona encircled the dark moon!

It has been stated, I do not know on what authority, that this eclipse resembled that of 1898. Mr. McClean's beautiful negatives do not in the least remind me of the form it took in that year. Mr. Raymond's description, as quoted above, "an irregular star of seven points," seems to define it very well, and that description could not be given to the form of the corona of 1898, which I observed in India.

In my opinion the photographs of the 1908 eclipse display a form which approaches more to that generally seen when the sun is most active, that is, a "maximum" corona, than to those of the "square" and "wind-vane" variety. Perhaps if it be classed as intermediate between a "maximum" and a "square" form, one cannot be far from wrong. In looking up the records of eclipses, I find that the drawing made by Mr. Weedon of the corona of 1860 July 18 (Memoirs, R.A.S., vol. xli., 1879, p. 543) more closely resembles that of 1908 than any I have been able to find. The year 1860 was a time of maximum sun-spot activity (and also probably a maximum of prominence activity, only no data are available to state this definitely).

Mr. McClean's photographs show several streamers more than one and a half lunar diameters in length. One striking feature of them is their great length and comparatively small breadth, giving them a very spiky appearance. Several prominences are also recorded on some of the negatives. Polar rifts are by no means clearly evident, and this is due possibly to the presence of some streamers in high latitudes.

As was to be expected, Prof. Campbell rendered considerable assistance to Mr. McClean's party, and Mr. McClean writes further in flattering terms of the cooperation of Mr. Mortimer, resident on the island, who rendered him "every assistance during the whole period we were on the island." He also expresses his deep obligations to Mr. A. B. J. Irvine, manager at Auckland of the Union S.S. Company, who did everything in his power to render the expedition a success.

Fortunately only one case of illness is reported. This was Mr. Raymond, who was confined to his bunk on board the *Taviuni* for four days owing to a severe attack of cholera. Although left very weak, he was able to rejoin the party ashore the day before the eclipse, and carry out his programme of sketching the corona as above mentioned.

In conclusion, it may be remarked that the results of the expedition are far more successful than one was led to believe from the previous information received, and the discussion of the photographs will form a valuable contribution to science.

William J. S. Lockyer.

## THE MUTATIONS OF ŒNOTHERA.[1]

THE name of an animal or plant may become famous for one of two reasons. Fame may be due either to the intrinsic interest of morphological or developmental characters of "intermediate," "primitive" or rare species, or to the fact that the form in question has been the material by means of which discoveries, which help in the revelation of the fundamental nature of living things, have been made. Examples of plants of the first class are Ginkgo, Ophioglossum, Coleochæte, and Anthoceros. Examples of animals of the first class are Peripatus, Archæopteryx, Acanthobdella, Ceratodus, Okapia, Sphenodon, Anaspides, and Tarsius. Thousands of specimens of an animal which is an example of the second class are daily hurled into the corner of the knacker's stable in the shape of *Ascaris megalocephala*. Thousands of specimens of a vegetable example of the second class could be gathered in a very short time on the sand-dunes along certain tracts of the coast of Lancashire in the shape of *Œnothera Lamarckiana*.

Yet these two classes of forms agree in one respect, that there is a certain magic about their names. Any contribution, however trivial, to a closer knowledge of such forms is regarded as worth publication. The importance of the material is held to compensate for the triviality of the contribution. We are not arguing that this should not be so, but merely pointing out that it is. A new fact, which, if it related to Periplaneta, would not be thought worth publishing will soon find its way into print if it relates to Peripatus.

Every biologist is familiar with, even if he does not take a critical interest in, the wonderful series of observations which have made *Œnothera Lamarckiana* a household word in the mouths of everyone interested in organic evolution. It is not surprising, therefore, to find this form subjected to an investigation which for minuteness and exhaustiveness is without parallel. Those who are familiar with the mutation theory might be excused for thinking that de Vries did not leave much to be done. But the memoir before us shows that, much as de Vries did, this is by no means the case; there is nothing in "Die Mutationstheorie" which for minuteness of detail compares with Dr. Shull's description of the fluctuations of Œnothera.

The memoir is illustrated by a series of beautiful heliotype plates of the various new elementary species to which Œnothera has given rise. Plate 5, which is here reproduced, shows at a glance the striking difference between two of these, *Œnothera lata* and *Œ. albida* forms with which everyone who knows de Vries's work must be familiar.

The part of this memoir which has interested us most is that which deals with the origin of mutants from strains of Œnotheras different from that which

[1] "Mutations, Variations, and Relationships of the Œnotheras." By D. T. Macdougal, A. M. Vail, and G. H. Shull. Pp. 92. (Washington: Carnegie Institution, 1907.)

de Vries found at Hilversum and observed his classical series of mutations in.

Three of these strains, from widely different sources, may be referred to.

In September, 1904, Mr. E. P. Bicknell, of Nantucket City, sent two sheets of dried material to the Botanic Garden at New York. The seeds of these specimens were sown in sterilised soil in November of the same year, and amongst the seedlings raised six corresponded exactly to the mutant *Œ. albida* raised by de Vries.

Amongst the seedlings raised from a packet of seed supplied by MM. Vilmorin et Cie., of Paris, there were one *Œ. lata*, one *nanella*, and one *albida*.

Lastly, some plants and seeds of a form provisionally called *Œnothera "biennis"* (Linnæus) were sent over from this country by Mr. H. Stuart Thompson, who had collected the actual seed he sent near Bidston Junction, not far from Liverpool. The plants raised from these seeds proved to be identical with the *Œnothera Lamarckiana* of de Vries, and the strain turned out, like that studied by de Vries, to be in a mutable state, for it gave rise to no less than four of the mutants which appeared at Amsterdam—namely, *Œ. lata, oblonga, albida*, and *rubrinervis*.

A. D. D.

A. Rosette of *Œnothera lata*, four months old, separate leaves of the same age. B. Rosette of *Œnothera albida*, four months old, and separate leaves of the same age.

## *THE INDIAN INSTITUTE OF SCIENCE.*

IN a recent article on the Jubilee of the Calcutta University it was shown that considerable efforts have been made in Bengal during the last few years to raise the level and tone of university education, and to render it more thorough and practical. Similar efforts are also being made in other parts of India by the Universities of Madras, Bombay, the Punjab and Allahabad, so that it may be hoped that a fairly high standard of university education will be maintained in future in India. Other indications also show that India is becoming alive to the necessity of modelling its educational system on the most modern European lines from the lower forms up to the very highest. The Indian Institute of Science, which is now being started at Bangalore, in Southern India, is an instance in point, and shows how the most advanced of the thinkers in India have grasped the necessity for the prosecution of the very highest forms of post-graduate work. Bangalore, which has been finally chosen for the site of the new institute, has (for India) a most excellent climate; it is situated about 3000 feet above sea-level, and the temperature there is never excessive, so that the conditions for work will be most favourable.

The institute owes its inception to the munificent generosity of the late Mr. J. N. Tata, a Parsee millionaire, who gave (during his lifetime) property which brings in an annual income of about Rs. 1,25,000 (8333*l.*) for the creation of an institute to be devoted to original research. Before the arrangements as to the endowment had been completed Mr. J. N. Tata died, but his two sons, Mr. D. J. Tata and Mr. R. J. Tata, have generously continued the arrangements made by their father.

Considerable discussion ensued as to the best method of utilising this endowment, and a committee was first formed in India to discuss it. Later Sir William Ramsay was asked by Mr. Tata to visit India and advise on the subject, and still later a committee consisting of Prof. Masson and Col. Clibborn made a report as to the best site for the institute and the best scheme of work. The final scheme, however, has been largely worked out by Dr. Morris W. Travers, F.R.S., who was appointed director of the institute about two years ago.

The actual starting of the institute has been much facilitated by two munificent gifts from H.H. the Maharajah of Mysore, who has made a grant of half a square mile of land at Bangalore (in Mysore) for the purpose of the institute, and has also given an annual endowment of half a lakh of rupees (3333*l.*). This has also been supplemented by an annual grant of Rs. 87,500 (about 5833*l.*) from the Government of India, so that the institute will have an annual income of at least Rs. 2,62,500 (nearly 18,000*l.*) for its work.

In addition, too, the Maharajah of Mysore has given five lakhs of rupees, and the Government of India two and a half lakhs, for the erection of buildings, and these sums, together with the accumulations of interest, will give about ten lakhs of rupees (66,666*l.*), and the buildings are to be proceeded with at once.

The constitution of the governing body has been decided on, and the greater part of the detailed initiative has been left to a local committee, consisting largely of the director of the institute and professors of the staff. Practically only post-graduate work and research will be carried on in the institute, and from its nature and position it will be able to attract the cream of the graduates and intellect of India. Provision is to be made for about sixty students to be at work. The subjects which will be taken up are those which are likely to have an important influence in the development of the various arts and industries of India. To begin the work of the institute, for the present five subjects have been decided on: pure and applied chemistry, organic chemistry, bacteriology and the study of fermentation processes, and electrical technology. Probably a sixth (metallurgy) will be added shortly.

India is thus bringing itself into line with the most advanced European countries in the matter of high education, and it may be hoped that every possible success will attend the new institute in its work.

## ANTARCTIC ICE.

THE following interesting account of Antarctic experience is from a letter by Prof. Edgeworth David, F.R.S., to Prof. W. J. Sollas, F.R.S. Prof. David is a member of Lieut. Shackleton's expedition:—

GREAT ICE BARRIER, EAST ANTARCTICA.
Lat. 78° 8′ S., Long. 173° 43′ W.
*British Antarctic Expedition*, 1907.
*January* 27, 1908.

S.Y. *Nimrod.*

We had some fearfully heavy gales after leaving New Zealand. Our little ship is only 200 tons, and if she had not been an excellent sea-boat and been splendidly handled she might not have survived it. At last we reached the belt of Polar Calms, and were at peace for a day or two: then sighted the heavy brigade of the Ice King, such a sight as I doubt whether any mortal man had seen before. We met, not pack-ice, but countless great tabular icebergs. It was like threading one's way through the streets of Venice with the Doge's Palace and blocks of buildings represented by the purest white alabaster inlaid with liquid sapphire and resting on a foundation of limpid emerald.

The bergs were mostly about 50 to 80 feet high, rarely over a hundred feet; many only about 30 or 40 feet high. Often we had to pass close between them, with a wall of ice on this side and a wall of ice on that. Frequently we seemed to be jammed into a *cul-de-sac*, but always there was some narrow channel into which our ship could be headed. We were about 20 hours steaming through them, the belt being altogether fully 100 miles wide, and probably of much greater dimensions from E. to W.

We knew after this experience that we should get no pack-ice at all between us and the Great Ice Barrier, towards which we were steering almost on the 180° meridian, and our anticipations were fully realised. We arrived at the Great Barrier on January 23. It is a sight that beggars all description. Imagine a continuous wall from Land's End to John o' Groats, 500 miles long and 100 to 200 feet high, the exquisite blue of the crevasses contrasting finely with the dazzling white of the weathered ice on either side of them. We followed it eastwards for about 80 miles, making for an intended base on the Great Barrier, Balloon Inlet. On arriving there the following day we found that Balloon Inlet, fully 10 miles long in 1901, had now completely disappeared, on a piece of ice over 12 miles in width, nothing but more or less high ice-cliffs.

Shackleton, our leader, then tried to force his way along the Great Barrier westwards, so as to get to King Edward VII. Land, but we were blocked by impenetrable pack-ice. Then we followed the pack north for about 100 miles, but it started slowly to envelop us, and we only just escaped in time. Shackleton was very disappointed at not being able to get to King Edward VII. Land, and now we are making for the only base available to us, that of the National Antarctic Expedition of 1901, MacMurdo Sound.

Shackleton is a very capable leader, and I believe that, bar serious accident, he will get to the Pole.

## INAUGURATION OF THE NEW CHANCELLOR OF CAMBRIDGE UNIVERSITY.

ACCORDING to custom the inauguration of the new Chancellor of the University of Cambridge took place in London. The Rev. E. S. Roberts, Master of Gonville and Caius College, the present vice-chancellor, accompanied by a certain number of members of the Senate, proceeded on Friday last, May 1, to 4 Carlton Gardens, where the Chancellor-elect received them in the house of his brother-in-law, Mr. Balfour. At noon the vice-chancellor took the chair, and the Senior Esquire Bedell escorted the Chancellor into the room. The train of the black and gold gown of office was carried by Lord David Cecil, the young son of Lord and Lady Salisbury.

In his address to the Chancellor, the vice-chancellor first dwelt upon the loss the University had sustained in the death of the late Duke of Devonshire. In referring to the new Chancellor, Mr. Roberts spoke as follows:—

It is of happy omen, my lord, that you yourself as a student attained to the highest possible academical honours in the oldest and most distinctive of our academical studies. This fact is not without significance for our University in the opening years of a new century. For you afford in your own person a conspicuous example, on the one hand, of reverence for a study which has in former generations made our University famous, and on the other hand of devotion to those newer outgrowths of that study in which Cambridge holds an eminent, if not a preeminent, rank. It is, therefore, with the more ready confidence that we look forward to the period of your Chancellorship as one in which the just balance between the old and the new may be stoutly maintained, and in which the studies of literature and social science may thrive and expand no less exuberantly than that of the natural sciences. One inestimable function of our University has been to quicken the intellectual life of the nation by lessons derived from the history and thought of the ancient world, and to hand on from generation to generation the humanising influence of literary culture. It would be a strange and cruel irony of fate that our generous and whole-hearted welcome of every development of modern science should in any way tend to alienate from us the sympathy and loyalty of those to whom the ancient studies have been dear. Yet it has at times appeared as if the danger of such alienation were no unreal one; as if the honest desire of Cambridge to meet national and Imperial needs were likely to entail consequences which would be deplored by the most ardent enthusiasts in modern science. In passing through such a crisis, if it is a real one, it is well and fortunate that we should have for our chief one whose public life and scientific reputation command the attention conceded only to an authority that is unquestionable.

Towards the end of his speech, the vice-chancellor announced that Lord Rayleigh had consented to occupy the chair of the Cambridge University Association which the Duke of Devonshire so ably and wisely filled.

The senior proctor then read the patent, which was handed by the vice-chancellor to the Chancellor, together with a copy of the statutes. The vice-chancellor read the "affirmation," to which the Chancellor replied "Ita do fidem." The vice-chancellor then handed the Chancellor to the chair, and the public orator read the following Latin speech:—

Dignissime Domine, Domine Cancellarie,—Kalendis Maiis, Floralium nostrorum festo et sollenni die, animo laeto agnoscimus, auspiciis quam bonis, "quo praebente domum," non iam Academi inter umbras sed urbis magnae in luce, Cancellarii novi in honorem purpura nostra vestiti, hic potissimum simus congregati. Tibi vero, vir honoratissime, quod Academiae officium summum a nobis libenter oblatum tam benigne accepisti, senatus totius nomine gratias propterea et agimus et habemus maximas. In honoribus quidem Academicis Duci Devoniae septimo, quondam Cancellario nostro, comparandus, inter nosmet ipsos illam ipsam scientiarum provinciam per quinquennium illustrasti, quae Henricum Cavendish, alumnum nostrum, inter conditores suos numerat, quae Willelmi Cavendish, Cancellarii nostri, munificentiae et officinam splendidam et experimentorum omnium supellectilem amplam iamdudum debuit. Cancellarium alterum, Cancellarii illius filium illustrem, virum de nobis praeclare meritum nuper amisimus, qui qualis in Academiam et in patriam universam quantusque vir fuerit, non est quod longius inter peritos exsequamur. Te vero, muneri illi insigni suffragiis nostris unanimis designate, virum salutamus et Regiae Maiestatis concilio privato et virorum optime meritorum ordini adscriptum, Regiae Societatis praesidem, scientiarum in republica principem, qui lucis sonitusque leges penitus indagasti, qui vis electricae modulos accuratissime determinasti, qui aëris ipsius partem inertem illam prius ignotam detexisti, qui scientiarum physicarum in provincia praemium orbi terrarum toti propositum haud ita pridem adeptus, pecuniae summam magnam non inertem reliquisti, sed Matris almae in manus totam collocasti, et Matris eiusdem filiis omnibus liberalitatis exemplar conspicuum praebuisti. Cancellarii autem ad officium hodie admissus, sine dubio iura et privilegia nostra omnia in tutelam tuam tradita, si quando opus fuerit, fortiter defendes. Tuo, ut speramus, sub patrocinio, non scientiarum modo studia florebunt, sed etiam, praemiis a Cancellario ipso iuventuti Academicae quotannis propositis, et iuris et litterarum Graecarum, Latinarum, Anglicarum, amor, sicut antea, accendetur. Dum gratias tibi hodie omnes ex animo agimus, nihil amplius restat quam ut tibi, vir honoratissime, Cancellarii in munere magno feliciter obeundo, annos prosperos quam plurimos exoptemus.

In his reply the Chancellor expressed his sense of the honour the Senate had done him in electing him to the high office, and mentioned his close connection with Cambridge, "the nursing home of Herschel, Airy, Stokes, Kelvin, and of Adams," both as student and as professor. Lord Rayleigh also recalled the fact that he had served, under the Act of 1877, on the Commission which framed the new statutes for the University and colleges; in fact, he and the Bishop of Bristol, who acted as secretary, are the sole survivors of that Commission. He spoke of the reforms which had been then effected, and referred to the view that they may still need supplementing, and he dwelt for a moment on the fact that the efficiency of the University would be promoted by the command of ample resources. The Chancellor paid a tribute to the late Duke of Devonshire, whose quiet and persistent interest in the University manifested itself in many ways. Indeed, his unremitting efforts to advance its welfare are probably only recognised by those who were brought into contact with him, both as head of the University and as president of the Cambridge Association.

In choosing Lord Rayleigh as its Chancellor, Cambridge has chosen one of the most distinguished men of science of the age, and one whom we feel sure will devote his energies to the promotion of the good of that ancient institution. In these days chancellors of universities have a good deal more to do than even the members of the Senate usually recognise. Apart from occasional appearances at ceremonies there is much and continuous work to be done; the interpretation of the statutes rests with the Chancellor, and in many ways he represents the University in the larger world. The new Chancellor of Oxford has shown what can be done even in a few months of wise activity in re-awakening interest in the older universities, and in defining and formulating a definite policy of expansion.

## PIERRE JACQUES ANTOINE BÉCHAMP.

BY the death of Béchamp, on April 15, at the ripe age of ninety-two, France lost the *doyen* of her chemists, and the world of science is the poorer by the disappearance of one more link connecting the new chemistry with the old. The nature of that link will be evident from the circumstance that Béchamp was born in the same year as Gerhardt, and that the period of his greatest scientific activity was contemporaneous with that of Laurent and Gerhardt.

Béchamp was born at Bassing, near Dieuze (Meurthe), on October 16, 1816. He lost his parents when he was eleven years of age, and was taken charge of by an uncle, who had settled in Roumania, and with whom he remained until 1834. In his seventeenth year he was apprenticed to a pharmacist at Strasburg. Pharmacy at that period constituted the main avenue to scientific chemistry, and in traversing it Béchamp simply followed in the footsteps of a dozen of his predecessors, some of whom, like Scheele, Vauquelin, Dumas, are among the most renowned of chemical investigators. At Strasburg, at that period, were Gerhardt and Wurtz, and, as in their case, Béchamp was soon attracted to the study of the rapidly extending branch of organic chemistry, and made ample use of the opportunities which his master's laboratory afforded to prosecute his inquiries. At that time, even in England, pharmacy was a profession, and the pharmacist was a practical chemist, abreast of the science of his time, whose laboratory was of more importance to him than his shop.

In 1851 Béchamp became attached to the School of Pharmacy at Strasburg, and thenceforth devoted himself to an academic career. Pasteur was then a professor of the Faculty of Science of Strasburg, and to him Béchamp presented a thesis on the newly discovered gun-cotton, which gained for him his doctorate of science in 1853. In 1856, at the age of forty, he became a doctor of medicine, and in the following year was appointed to the chair of medical chemistry in the Faculty of Medicine at Montpellier.

Béchamp was a prolific contributor to the literature of chemistry. The Royal Society's Catalogue of Scientific Papers enumerates upwards of 140 papers which proceeded from his pen down to the year 1873. As he continued his activity to the last, the total number cannot fall short of a couple of hundred. In addition he published a number of scientific treatises in book-form, mainly relating to chemical biology.

Béchamp's work ranged over nearly every department of chemistry. Inorganic chemistry appears, however, to have had little attraction for him, and his name is associated with not more than a dozen communications in that branch of inquiry.

It is mainly in connection with the early history of what is called coal-tar chemistry, and more especially in connection with the fields of investigation with which the name of Pasteur is preeminently associated, that Béchamp's services will be recalled. The method of manufacturing aniline ultimately made use of by Perkin in England, and by the brothers Renard in France, was due to Béchamp. It consisted in the action of ferrous acetate on nitrobenzene, and appears to have been first made known in 1854. He also contributed to the French Academy in 1860–61 communications on fuchsine and allied colouring matters.

But it was to the domain of biological chemistry that Béchamp's energies were principally directed, and he took an active part in the inquiries and controversies which ultimately led to the triumph of Pasteur and his immediate followers. Although much of Béchamp's work on fermentation, on the production of moulds, on the silk-worm disease, and on zymases ran parallel with Pasteur's inquiries, his interpretation of the phenomena was generally opposed to that of Pasteur, and the two investigators were frequently in acute controversy on these subjects. Béchamp's fame has probably suffered in consequence. We must, however, do him the justice to admit that his main contention, that unorganised ferments play a larger and more important part in the phenomena of metabolism than the immediate followers of Pasteur were willing to concede, is intrinsically sound. Béchamp developed his views into a general theory, which he published in 1866, whilst at Montpellier, in a work entitled "Microzymas et Microbes. Origine des ferments." This he supplemented some years later by a further work, "Les Microzymas dans leurs rapports avec l'hétérogénie, l'histogénie, la physiologie et la pathologie," Paris, 1883. Whatever may be the ultimate fate of his theoretical conceptions, his experimental work on blood, fibrin, milk, proteins, and his position in regard to the great and fruitful controversies of half a century ago out of which modern bacteriological doctrine has sprung, will ensure him an honourable place among the founders of biological chemistry.

On the creation of the Faculty of Medicine at Lille, Béchamp accepted the offer of a chair, and he remained there, as Dean, until his resignation in 1887, when he retired to Paris, and, accepting the hospitality of Friedel's laboratory in the rue Michelet, continued his biological inquiries, occupying himself to the end in searching for support for the comprehensive generalisation of organic change on which his fame will ultimately rest.

## *NOTES.*

THE Croonian lecture of the Royal Society will be delivered on Thursday next, May 14, by Prof. G. Retzius, upon the subject of "The Structure of the Central Nervous System of the Higher and Lower Animals."

THE President of the Board of Trade has appointed a committee to prepare a programme for the consideration of the delegates to the International Conference on Electrical Units and Standards to be held in London in the ensuing autumn, and to make arrangements for the reception and assembly of the delegates attending the conference. The members of the committee are Mr. G. R. Askwith, K.C., Sir John Gavey, C.B., Dr. R. T. Glazebrook, F.R.S., Major P. A. MacMahon, F.R.S., Major W. A. J. O'Meara, R.E., C.M.G., and Mr. A. P. Trotter. Mr. M. J. Collins, of the Board of Trade, will act as secretary to the committee.

M. BIGOURDAN read a paper at the meeting of the Paris Academy of Sciences on April 27 on the use of wireless telegraphy for weather forecasting. He pointed out that our weather is associated with the passage of atmospheric depressions arriving from the west, and generally from parts of the Atlantic situated north of 35° N. latitude, and it is estimated that about one-half of these depressions come from North America, whilst the others form in the open Atlantic. To forecast the arrival of depressions it is necessary to have observations from the open ocean. Floating observatories have been suggested, coupled with the continents on either side of the Atlantic. M. Bigourdan suggests that steamships should communicate, to the responsible authorities, their position and meteorological observations by wireless telegraphy, and by this means modify and improve our conditions for weather forecasting to the benefit of the general community. For some time past our English Meteorological Office has published in its Daily Weather Report wireless telegrams from ships of His Majesty's Navy.

THE sixteenth Congress of German Electrotechnical Engineers will be held at Erfurt on June 11–14.

THE Entomological Society will hold a conversazione on Friday, May 15, in the rooms of the Civil Service Commission, Burlington Gardens.

THE Rumford medal of the American Academy of Arts and Sciences has been awarded to Dr. E. G. Acheson, of Niagara Falls, for his work with the electric furnace.

THE Chemical Society of Rome, the Chemical Society of Milan, and the Association of Industrial Chemists of Turin will, from January 1, 1909, be united under the name of the Italian Chemical Society.

PROF. W. H. WALKER, professor of technical chemistry at the Massachusetts Institute of Technology, has been awarded the Nichols medal by the New York Section of the American Chemical Society.

MESSAGES from Catania report that dense clouds of vapour issued from the central crater of Mount Etna on April 29. The crater of 1852 in the Valle del Bove was also in eruption. On May 2 the volcano was again in active eruption, and a stream of lava was slowly advancing.

A CONVERSAZIONE will be given by the Medical Society of London on Monday, May 18, in the rooms of the society, Chandos Street, Cavendish Square. After the reception by the president, the Fothergillian medal will be presented to Sir Almroth Wright, F.R.S. An oration will be given by Mr. T. Clinton Dent on the subject of the after results of injuries.

ON Tuesday next, May 12, Prof. F. T. Trouton will begin a course of two lectures at the Royal Institution on (1) "Why Light is believed to be a Vibration"; (2) "What it is which Vibrates." The Friday evening discourse on May 15 will be delivered by Dr. H. T. Bulstrode on "The Past and Future of Tuberculosis," and on May 22 by Prof. J. C. Kapteyn on "Recent Researches in the Structure of the Universe."

AT the Institution of Electrical Engineers on April 30 Prof. Silvanus P. Thompson, F.R.S., gave the first Kelvin memorial lecture, his subject being "The Life and Work of Lord Kelvin." Before the lecture was delivered Mr. H. F. Parshall presented the institution with a bust of Benjamin Franklin on behalf of the American Institute of Electrical Engineers as a souvenir of their visit to England about a year and a half ago. The gift was acknowledged by Lieut.-Colonel R. E. Crompton, the president of the institution.

THE sixteenth International Congress of Americanists will be held under the presidency of Baron Weckbecker at the University of Vienna on September 9–14. The object of the congress is to promote scientific inquiries into the history of both Americas and of their inhabitants. Communications may be oral or written, and may be in one of several languages, English included. For further information application should be made to Herr Franz Heger, Vienna (Austria), I. Burgring 7. A programme will be issued early in the summer.

PROF. ANGELO MOSSO, of Turin, writes to remind us of the fact, to which attention was directed in an article by the late Sir Michael Foster in NATURE of March 9, 1905 (vol. lxxi., p. 445), that the Royal Society has the right to nominate two investigators to occupy tables in the Monte Rosa and Col D'Olen international laboratories. The tables are available for the study of botany, bacteriology, zoology, physiology, terrestrial physics, and meteorology. The two tables at the disposal of the Royal Society are, it will be remembered, due to the generosity of Dr. Ludwig Mond, F.R.S.

AT the annual general meeting of the Institution of Civil Engineers on April 28, Mr. J. C. Inglis was elected president of the institution. The council has made the following awards for papers read and discussed during the past session:—a Telford gold medal to Mr. W. Barclay Parsons (New York); a Watt gold medal to Sir Whately Eliot; George Stephenson gold medals to Sir John Ottley, K.C.I.E., Dr. A. W. Brightmore, and Messrs. J. S. Wilson and W. Gore; Telford premiums to Messrs. F. W. Davis (Darlington), C. R. S. Kirkpatrick (Newcastle-on-Tyne), Hugh T. Ker (Glasgow), G. H. Scott, R. R. Gales (India), and S. H. Ellis.

The exceptionally cold weather which had prevailed throughout April was temporarily interrupted with the opening days of May, and on the first and second of the present month some remarkably high temperatures were reported from different parts of England. At Greenwich the shade temperature on Saturday, May 2, registered 75°, which is a record reading for that day during the last half century. The thermometer on the previous day registered 73°. The report of the weather issued by the Meteorological Office for the week ending last Saturday states that at Jersey and Bettws-y-Coed the thermometer rose to 78° on May 2, and to 76° at places in the south-east of England and the Midland counties, and to 75° in the east and south-west of England. There was an abrupt change to cool weather again on Sunday, May 3, when in London the highest temperature was 52°.

The death is announced of M. C. E. Chamberland, the sub-director of the Pasteur Institute, Paris, at the early age of fifty-seven. M. Chamberland is probably best known in connection with the porcelain filter which bears his name together with that of his great master, Pasteur. He did much work on surgical asepsis, showing that the germs in the air may be disregarded provided the skin, the instruments, and the dressings be rendered sterile. He also contributed much to the prevention of animal diseases by the method of vaccination with attenuated viruses.

We regret to have to announce the death of M. Alfred Riche, one of the last of Dumas's pupils at the Sorbonne. Riche was born at La Roche-sur-Yannon on February 5, 1829. He was originally intended for the law, but becoming attached to science, after a course of study at the École Centrale, he accepted the position of *aide préparateur* under Dumas (1849). He subsequently became *préparateur* at the Institut Agronomique at Versailles, and then at the Sorbonne under Balard and Dumas. In 1874 he succeeded Bussy in the chair of mineral chemistry, which he occupied until 1899, and where he had as assistants Jaques and Pierre Curie, and as a pupil Moissan, who eventually succeeded and predeceased him. In 1862 Riche became an assayer at the Monnaie, and ultimately, in 1887, director of assays, a post which he continued to fill until last year, and he had charge of the revenue laboratories under the Minister of Commerce. He published a considerable number of papers on organic and mineral chemistry, chiefly on the organo-metallic derivatives of tin and arsenic, on copper-tin alloys, on the electrolytic estimations of metals, on sugar-analysis, &c. For many years he was the principal editor of the *Journal de Pharmacie et de Chimie*, and was the author of a number of text-books and manuals.

Mr. F. Howard Collins has sent us a copy of a paper by him, reprinted from the *Nautical Magazine*, in which he describes a method of representing by diagrams the characters of the lights of lighthouses, and of fog signals, so that they may be identified at a glance. He suggests that the system should be applied to Admiralty Charts and to the Admiralty List of Lights. A leading authority upon the subject has favoured us with the following remarks upon the proposed method and application:—"The writer proceeds on the assumption that each lighthouse completes its cycle in a minute. This is not the case, and this system of diagrams could not apply to lights the periods of which are (*a*) more than a minute; (*b*) not an integral fraction of a minute. That is to say that only lights with periods of 1, 2, 3, 4, 5, 6, 10, 12, 15, 20, 30, or 60 seconds can be represented. This would exclude the Nab, Hanois, Royal Sovereign, Dover Pier, South Foreland, Sunk, Galloper, Orfordness, Flamborough, and many other of our most important lights. Apart from this, it is considered that the diagrams are no improvement on the clearly composed description of each light as given at present in the light lists (such as Flash, 5 seconds, Eclipse, 10 seconds); indeed, it is very doubtful if they would convey any meaning at all to the less educated members of the seafaring community. This applies with additional emphasis to the diagrams representing fog signals. The extra expense of diagrams (and their periodical corrections) would be objectionable. The application of this system to the Admiralty Charts is altogether impracticable."

Sealing in 1907, according to a note by Mr. T. Southwell in the April *Zoologist*, was, owing to bad weather and the heavy ice-pack, nearly as bad as in 1905, which was the worst since 1898. Two of the fleet of twenty-four vessels were wrecked, and the number of skins secured by the others fell short of last year's total by close on 100,000, with a decrease of rather more than 30,000*l.* in money value. The total number of seals killed was just over 245,000, the market price being 4·20 dollars per cwt. for those of young animals and 3 dollars for those of adults.

According to *Museum News* for April, an exhibition of South American birds' nests has been installed in the children's museum, which has proved highly attractive alike to children and to adults. Excellent examples of protective resemblance are shown among the nests of certain flycatchers, in some of which the lichen-covered walls blend insensibly into the supporting branch or simulate a knot or other natural excrescence. Other exhibits are nests of the slate-headed tody swinging at the end of long, slender branches, and looking like bunches of drift-grass left in their present positions by receding waters. Nests of two species of spiny-tails (a group of woodhewers) are also shown, which by their dissimilarity in structure and material would not suggest relationship in their builders. The nests of five species of spiny-tails agree, however, in having a lining of grey lichens.

A collection of valuable and scarce books appertaining to botany and zoology, including a series of zoological works by J. Gould and D. G. Elliot, is offered for sale in the antiquarian catalogue recently issued by Mr. B. Quaritch.

A catalogue of new or noteworthy flowering plants from Mexico, Central America, and the West Indies, determined by Dr. J. M. Greenman, comprises a number of new species of Senecio and various composites, also additions to the Verbenaceæ, Euphorbiaceæ, and other orders. It is issued as Publication No. 126 of the Field Museum of Natural History.

The account of the desert basins of the river Colorado in the delta region where it flows into the Gulf of California provides a remarkable record. Attention was directed to the locality by the rise of water in the Salton Lake at the head of the delta from November, 1904, to March, 1907, since which time the waters have receded. The recession affords an opportunity for noting the spread of the vegetation, that is chiefly halophytic and partially xerophytic. With this purpose, surveys have been made by workers from the desert laboratory of the Carnegie Institution, beginning at the time when the flood was at its height. The preliminary account, by Dr. D. T. Macdougal, is published as a Bulletin of the American Geographic Society (December, 1907). Reference is made to a hot spring near Lake Maquata, where the water gave a temperature of 120° F. Two species of the algal genus Phormidium, and a new species of rain-water fish, *Lucania brownii*, were taken there.

The Geological Survey of Western Australia has issued an important report (Bulletin No. 29) upon the geology of the Cue and Day Dawn districts, Murchison goldfield, by Mr. H. P. Woodward. Owing to the voluminous character of the report, it has been issued in two parts, the first of which is confined to the Cue and Cuddingwarra centres, and the second to the Day Dawn centre. Much of the latter is occupied by an elaborate report upon the Great Fingall mine, the subject being dealt with, not only from the standpoint of the geologist, but also from that of the mining engineer. This mine, which produced 95·38 per cent. of the total production of 778,606 ounces from the district up to the end of 1906, is a low-grade property, which, owing to excellent management, is being worked at a profit. The reports are illustrated by five large geological maps, twenty-three mine plans, and nineteen admirable photographs. Particularly striking is the view, here reproduced, of the waste heap to which the sands from the cyanide process are delivered by belt-carriers. This heap, being more than 100 feet in height, forms a conspicuous landmark.

Tailings Dump of the Great Fingall Mine.

A vigorous article on the crisis in the French vineyard appeared in the *Times* (April 25), in which the author, Prof. L. Daniel, traces the sequence of events that have led to the present disastrous conditions. Primarily the fault is ascribed to the indiscriminate confidence placed in grafting as a panacea for combating phylloxera. The grafted vines also gave a large yield that suggested increased profits, so that growers were ready to overlook any possible disadvantages, such as deterioration in quality. As a result, there has been a large production of inferior wines, that are also unsuitable for storing. Prof. Daniel attributes the inferiority to the difference in root-growth, the American vine being a surface feeder, while the roots of the French vines penetrate deeper. It is noted how, in the course of time, grafted plants have deteriorated, and evidence has accumulated to show that phylloxera is amenable to treatment; in these circumstances growers are being officially advised to return to old methods, and aim principally at quality.

Three bulletins have reached us from the University of Wisconsin, all dealing with matters of considerable practical importance. One describes the conditions necessary for growing lucerne, a crop which is common enough in the United States as a rule, but is not as yet much grown in parts of Wisconsin. Since the development of the plant depends on the presence of the proper bacteria in the soil, farmers are recommended in doubtful cases to inoculate the land by scattering on each acre about two tons of soil from old lucerne land. If no such soil is available, the University Experiment Station is willing to supply hundred-pound lots so that a start may be made on a few rods of land, from which, of course, a considerable area can afterwards be inoculated. Another bulletin deals with the necessity for properly housing pigs, and the third urges the importance of systematically examining herds for tuberculosis, and slaughtering all animals that give the tuberculin reaction.

A report on the delimitation of the Turco-Egyptian boundary (June–September, 1906), by Messrs. E. B. H. Wade, B. F. E. Keeling, and J. T. Craig, which has just been published by the Survey Department of the Egyptian Ministry of Finance, furnishes an excellent example of the application of modern methods of surveying so as to yield a maximum of accuracy in result with a minimum expenditure of time. The survey operations consisted in running a traverse 210 kilometres in length, from a point on the beach at Taba, on the Gulf of Akaba, to Rafa, on the Mediterranean coast, fourteen points being determined on the route. The method employed was that of latitudes and azimuths, an assumed longitude being first taken for Taba, where the work began, and a final longitude obtained for Rafa, where it ended, by exchange of telegraphic signals with the Helwan Observatory, near Cairo. Notwithstanding the difficult nature of the country, both as regards topography and the troubles from dust-haze and mirage incident to work on a heated desert plateau, the traverse was completed in thirty-one days, including the computations and plotting of the boundary. The demarcation by permanent signals occupied fifteen days, and it is further interesting to note that the total cost of the survey operations amounted to £E460. The report includes detailed examples of the observations and reductions, and is valuable as a specimen of this class of work.

A convenient and handy form of refractometer, especially adapted for the rapid determination of the refractive indices of faceted gem-stones, but also applicable for liquids, has been designed by Dr. G. F. Herbert Smith, and two patterns of the instrument have been constructed and placed on the market by Mr. J. H. Steward. With the later (1907) pattern it is possible to determine a faceted stone in whatever form of mounting it may be set, and a scale visible in the field of the instrument enables the refractive index to be read directly to the second place of decimals. The range extends from 1·300 to 1·775, which includes the refractive indices of corundum (ruby and sapphire), the only gem-stones falling beyond this being almandine, demantoid, zircon, sphene, and diamond. The two patterns of instrument have been described in detail by Dr. Herbert Smith in the *Mineralogical Magazine* (1905 and 1907), and a more popular account is given by him in a pamphlet published by Mr. J. H. Steward ("The Herbert Smith Refractometer, and its Use, particularly for the Discrimination of Faceted Gem-stones," London, 1907, pp. 28). In this pamphlet a concise summary is given of the methods applicable for the discrimination of faceted gem-stones, it being pointed out that the determination of the refractive indices is often the only trustworthy test that can be applied when the stones are mounted. A carefully compiled table of the constants of thirty-four mineral species used in jewellery contains some new determinations, and will be found useful for reference.

The thirtieth yearly report of the Deutsche Seewarte, for the year 1907, shows that the work of that active and useful institution has been continued on the same lines as hitherto; the constant increase of its operations, as in the case of most other meteorological organisations, has made it necessary to add to its working staff. The number of observers in the mercantile marine was 962 at the close of the year; they are encouraged in their work by the award of medals and diplomas for excellent observations, as well as by a liberal presentation of official publications. The most important event of the year in the department of weather prediction was the acquisition of telegraphic reports from Iceland and the Færöe Islands, which have been found of great service; the early morning reports from the British Isles are also much appreciated. As in this country, special forecasts for agriculturists are issued during the summer season, but the dissemination of the information is on a much larger scale. Exploration of the upper air by means of kites and balloons is actively continued whenever practicable.

In the monthly meteorological charts of the North Atlantic and Indian Oceans for May, issued by authority of the Meteorological Committee, every available space is, as usual, occupied with data of importance to seamen. The face of the charts shows the average statistics relating to the atmosphere and the sea for the month in question, with latest intelligence on such subjects as ice, monsoons, &c. Among the interesting matters dealt with on the back of the charts we find a discussion of the observations of the Sargasso or Gulfweed from the records kept for the Meteorological Office during the seven years ended 1907, and the monthly frequency of fog in the Gulf of St. Lawrence for the period 1892–1906. There are also charts showing the cyclone tracks in the South Indian Ocean for 1848–1905, and a picture of the Southern Ocean ice during each of the months April to June, for twenty-three years ended 1907; some of these huge icy masses are said to have projected 1000 feet above the water-line, and to have been from two to forty miles in length.

Dr. Moschou, of Smyrna, has invented some improvements in the beams and bearings for physical balances. Balance beams have previously been designed which are roughly elliptical in cross-section or are of a channel section. According to the present invention, a section is adopted which is approximately elliptical, but has vertical sides, and if desired the elliptical tube may be strengthened by a rhombic frame. The bearings of the balance have also been considerably modified; for the usual knife edges, discs taking the form of two truncated cones placed base to base are substituted. For the centre bearing there are two such discs secured to the elliptical beam, and at the ends of the beam similar discs are supported by small axles. In some cases two discs are provided at each end of the beam, and the balance pans are supported upon these by hooks, hollowed at their bearing surfaces so that they always take up the same position upon the discs whenever they are removed and replaced. When two discs are thus used, the swinging of the balance pans backward and forward is largely prevented.

Part v. of the *Verhandlungen der deutschen physikalischen Gesellschaft* for the present year contains the results of Dr. P. Nordmeyer's further work on the mean specific heats of pure substances between the two temperatures −188° C. and 18° C. The method is identical with that used previously, and depends on the determination of the weight of liquid air evaporated by a body at ordinary temperature placed in it. The following are the values obtained:—sodium, 0·253; magnesium, 0·222; calcium, 0·157; iron, 0·097; molybdenum, 0·063; thallium, 0·038; gold, 0·033; aluminium, 0·182; yellow phosphorus, 0·178; potassium, 0·170; bromide of potassium, 0·103.

An eighth edition of Mr. Andrew Jamieson's "Elementary Manual of Applied Mechanics" has been published by Messrs. Charles Griffin and Co., Ltd. The book has been revised, some additions have been made to the text, and further examination papers included.

Messrs. Smith, Elder and Co. have almost ready for publication a work on "Animal Life," by Dr. F. W. Gamble. The volume comprises a series of studies in the life-history of typical members of the animal kingdom, describing their vital activities in relation to their structure, and the general scheme of development.

The current issue of the *Central*, the organ of the Central Technical College Old Students' Association, contains a portrait of Dr. G. T. Moody, and articles on the electrification of railways, by Mr. Lionel Calisch, and on the City of Victoria and Hill district waterworks, Hong Kong, by Mr. D. Jaffé.

A third edition of Dr. Alex. Findlay's translation of Ostwald's "Principles of Inorganic Chemistry" has been published by Messrs. Macmillan and Co., Ltd. The fundamental character of the book remains unaltered, and the changes in detail are not great, but here and there slight mistakes have been corrected and some additions made.

The report of the council and proceedings of the Hampstead Scientific Society for the year 1907 has been received. The membership of the society now stands at 286, and its finances are in a satisfactory state. As usual, the lectures given at the general meetings during the winter have been appreciated widely. Among the list of lecturers we notice the names of Prof. E. H. Starling, F.R.S., and of Dr. C. W. Andrews, F.R.S. The activity of the various sections of the society has been well maintained.

Mr. John Cooke, editor of Murray's "Guide to Ireland," is preparing an account of the tumuli and other pagan antiquities of the Boyne Valley for the "Handbook" of the British Association. It is to be hoped that at last their astronomical orientation will be given. Mr. Nathaniel Colgan, author of the "Flora of Co. Dublin," and one of the editors of "Cybele Hibernica," will deal with the local botany. The geology of the immediate neighbourhood of Dublin is specially interesting, ranging as it does from the Cambrian Bray Head to the Carboniferous limestone of the great central plain.

## OUR ASTRONOMICAL COLUMN.

DANIEL'S COMET, 1907*d*.—Signor Pio Emanuelli, of Rome, has favoured us with a manuscript copy of a daily ephemeris for Daniel's comet, calculated by him from the elements computed by Prof. E. Millosevich. An abstract from this ephemeris is given below:—

*Ephemeris 12h. (M.T. Paris).*

| 1908 | α (1908·0) h. m. | δ (1908·0) | r | Δ |
|---|---|---|---|---|
| May 8 | 14 7·6 | 0 51·1 | 0·590 | 0·467 |
| 16 | 14 1·4 | −0 31·0 | 0·000 | 0·487 |
| 24 | 13 56·2 | −0 18·8 | 0·010 | 0·508 |
| 31 | 13 52·6 | −0 14·5 | | |

From this it will be seen that the comet is now apparently travelling very slowly through the constellation Virgo in an easterly direction; its present magnitude is about 11·0, and it crosses the meridian about 11 p.m.

THE SOLAR ROTATION DETERMINED FROM HYDROGEN PHENOMENA.—From a discussion of the results obtained in a spectrographic determination of the solar rotation, using the hydrogen lines Hα, Hγ, and Hδ, Prof. W. S. Adams arrives at conclusions fundamentally important in any study of the solar structure; the full discussion, together with a description of the instrument and methods employed, appears in No. 3, vol. xxvii., of the *Astrophysical Journal* (April, pp. 213 *et seq.*).

The first conclusion is that the sun's rotational velocity as shown by the hydrogen lines is higher than that given by those of other elements and by the study of sun-spots and faculæ; the excess amounts to 1° in the angular motion at the equator. It is worthy of remark that Hα, which shows abnormal tendencies in its width, its intensity, and its behaviour at the sun's limb, gives slightly higher velocities than the other hydrogen lines. The second conclusion is that in the regions where the hydrogen lines are produced the equatorial acceleration of the solar atmosphere is non-existent, or too small to be measured by the present method. These conclusions point to the absorbing hydrogen being situated at a higher level than other absorbing media, *e.g.* calcium; a previous investigation (see NATURE, No. 1990, p. 158, December 19, 1907) showed that carbon and lanthanum gave lower velocities than general, and are, therefore, probably situated at a lower level.

The results of a study of the solar rotation, based on the measurements of hydrogen flocculi, are published by Prof. Hale in the same journal, and they confirm the absence of the equatorial acceleration in the absorbing hydrogen atmosphere of the sun.

THE CANALS AND OASES OF MARS.—In the *Century Magazine* for May (vol. lxxvi., No. 1, p. 127), Prof. Lowell continues his explanation and discussion of Martian features, taking the canals and oases as the special subjects of this article.

Recounting the history of the canaliform marking since their discovery by Schiaparelli in 1877, Prof. Lowell strongly emphasises the numerous points which go to prove their actual reality. The narrowest canal appears as it would were it but three miles across, but the average width is some twenty miles. They vary in length from 250 to 2500 miles, and one, the Eumenides Orcus, extends for some 3450 miles. Schiaparelli mapped 113, but 436 canals are now known to the Flagstaff observers. Of the oases, first seen by Prof. W. H. Pickering in 1892, there are now 186 marked on the Flagstaff map of Mars. The special features of all these markings, their seasonal variations, their similarities and concordant behaviour, and the weight of evidence added by the geminated canals, are all discussed by Prof. Lowell, and the results are shown to be consistent with the theory that the features are there for a set purpose, their functions having been determined by sentient beings for the sustenance of life and vegetation on a planet which has reached a stage further in the evolutionary process than has the earth.

THE COLOUR SENSIBILITY OF SELENIUM CELLS.—In a recent determination of the moon's light, Messrs. Joel Stebbins and J. C. Brown, of the Illinois University Observatory, found that the results depended upon the cell used, and suggested that the variation was due to differences between the colour-sensibility curves of the several cells (see NATURE, January 16 and 30, pp. 258 and 302). In a recent investigation Mr. Stebbins found that this explanation is correct, and in No. 3, vol. xxvii., of the *Astrophysical Journal* (April, p. 183) he gives the numerical results and a series of colour curves illustrating the variations of the four cells employed.

THE ASTRONOMICAL SOCIETY OF ANTWERP.—The third annual report (1907) shows that this society is progressive, and is fulfilling its primary purpose, the popularisation of astronomical science, exceedingly well. The instrumental equipment has been largely added to, the various meetings for practical work and for lectures are well attended, and there are now about 140 names on the list of members. An important event in the history of the society during the past year was the foundation of the *Gazette astronomique*, a most useful monthly journal for amateur observers.

## MICROGRAPHIC STUDY OF LEATHER.

UNDER the title "Étude micrographique du Cuir," M. Henri Boulanger has published in the *Bulletin de la Société d'Encouragement* for February of this year a series of interesting drawings showing the microscopic appearance of various sections of raw and tanned hide. The chief interest in these consists in the demonstration of the changes which take place in the skin during the process of tanning. About thirty years ago a very similar study was undertaken by the late Franz Kathreiner, of Worms, on the microscopic preparations of raw and tanned calf skin, in all the various stages of the tanning process, and the writer has had the privilege of seeing these very beautiful preparations; unfortunately, Kathreiner's results were never published.

The microscopic appearance of sections of raw skin is well known to those who have made a scientific study of tanning, but that of leather has not received so much attention owing to the difficulty of preparing sufficiently thin sections to be of use, and further of differentiating the constituent parts.

The author himself remarks that it is almost impossible to make a satisfactory section of the flesh side, and he has therefore confined his studies exclusively to the "grain" side of the skin. This is commonly called the epidermis, but it is difficult to apply strictly the vocabulary of the histologist; in this case the true epidermis disappears completely in the process of preparing the skins for tanning, and what the tanner calls the "grain" of the skins is the hyaline membrane covering the upper surface of the Rete Malpighi.

M. Boulanger's method of preparing the sections of raw skin has the advantage of being a rapid one; small pieces of skin are soaked for twelve hours in a solution composed of:—distilled water, 5 grams; glycerin, 5 grams; acetone, 90 grams. They are then allowed to dry, embedded in hard paraffin, and are ready for the microtome. The staining and mounting of the sections is carried out by the usual methods. The microscopic appearance of the sections was reproduced by coloured drawings made with the camera lucida, since a photograph will not show the various depths of the section. The illustrations shown are photographs of these drawings. Fig. 1 shows the appearance of a section of the grain side of a fresh cow-hide taken from the breast between the fore legs; in scientific language, the upper surface of the dermis—the fibro-elastic layer. It is stained with carmine alum, and shows clearly the flat, inert cells of the epidermis, which it is often difficult to preserve intact in microscopic sections, especially in a hide or skin which has been salted. Immediately below this are the living cells of the Malpighian layer; the nuclei of these cells are well shown in the figure. Just below this layer, which will eventually form the "grain" of the tanned leather, are seen the papillæ of the dermis; the dark spots are the nuclei of the cells of the connective tissue. A hair follicle is also shown, as well as a hair in vertical section. The magnification of the plate in the memoir is 285 diameters, and is one-half this amount in the accompanying reproductions of two figures. Compare the appearance of Fig. 1 with that of Fig. 2, which shows a section of cow-hide tanned with oak bark and curried with *dégras*.

Before describing Fig. 2, it is necessary to explain the mode of preparation of the section. A small strip of leather about 10 mm. wide is taken, and the flesh side shaved away until the piece has a thickness of about

FIG. 1.

2 mm. The shaved strip is placed in melted tallow, not too hot, for about a quarter of an hour; after cooling, the strip is embedded in hard paraffin and cut in a Ranvier microtome, the sections degreased with xylol, then washed two or three times with alcohol, and stained with Weigert's fuchsin; the staining takes about three hours; the

FIG. 2.

Weigert solution is poured off, and a few drops of absolute alcohol put on to the section; this removes excess of dye, and differentiates the various parts. It is now washed twice with alcohol, passed two or three times through xylol to eliminate the alcohol, and finally mounted in balsam.

In M. Boulanger's view, the skin, when freed from the hair and the histological epidermis (both of which are got rid of in the preparatory processes), is composed of two tissues, an upper and a lower, intimately united, although of distinctly different natures. No scientific designation has been given to these two distinct layers, but the whole has been called the dermis; in view of their special constitution, and to distinguish them, he calls the "grain" the fibro-elastic layer and the "flesh" the layer of giant connective fibres. The elastic fibres in their natural state take up Weigert's stain readily, and they retain this property after tanning; both before and after the tannage they form the essential framework of the skin or leather; without them there is no elasticity or suppleness, and tanning does not appear to alter their constitution. The connective fibres, on the contrary, are completely changed, so that we may conclude that the tannin acts differently on the two tissues.

The present writer will not here discuss this conclusion, though in his opinion there is no such distinct difference between the two portions of the skin, but that in the "grain" the connective tissue is fine and closely compacted, whereas in the "flesh" it becomes loose and coarse; thus the difference is in degree, and not in constitution. Boulanger's fibro-elastic layer must not be confounded with the elastic yellow fibres which form a comparatively small part of the volume of the skin. Comparing the two figures, there is a striking contrast in the general setting of the elastic fibres. In the raw skin they ramify in all directions, whereas in the tanned skin they only exist in a longitudinal direction, as a consequence of the dilation and preparation that the skin has undergone.

M. Boulanger has utilised his method in the study of leather for use as belts, &c., the results of which are published in his book, "Essais du Cuir dans ses Applications industrielles." There is no doubt that the method of microscopic examination of leather might be of considerable use after much practice in the manipulation and comparison of various leathers has been acquired. It would then be possible to determine whether the leather under examination had been made from a salted skin or a fresh skin, of European origin, or from a foreign dried skin, the sex of the animal, cow, ox, or bull; whether the leather had been adulterated, overloaded with tannin or weighting materials, &c., in short, the history of the pelt might be deduced from the study of the tanned leather. Let us hope that the younger generation of tanning students now being trained in the leather industries department at the University of Leeds and at Herold's Institute in Bermondsey will keep up the reputation of England in this work.

J. T. W.

## THE ATOMIC WEIGHT OF RADIUM.[1]

ALTHOUGH there has been a considerable amount of discussion, based upon spectroscopic considerations and on its supposed mode of genesis, respecting the place of radium in the system of the elements, and inferentially, therefore, concerning its atomic weight, we are indebted for the only direct experimental determinations of this value hitherto made known to the discoverer of the element, Mme. Curie. Her first observations, published in 1902, were made on about 90 milligrams of the chloride, and furnished the value 225.

In the autumn of last year Mme. Curie communicated to the French Academy the results of a second series of estimations made upon about 4 decigrams of the carefully purified chloride; these afforded the value 226·2 as the mean of three closely concordant determinations ($Ag = 107·8$, $Cl = 35·4$).

In 1906, at the instance of Sir William Huggins, then president of the Royal Society, and by the aid of the kind interest shown by H.R.H. the Prince of Wales, the Austrian Government placed about 500 kilograms of pitchblende residues from Joachimsthal at the disposal of the Royal Society. These residues were worked up by M.

[1] Bakerian Lecture for 1907. Delivered at the Royal Society by Dr. T. E. Thorpe, C.B., F.R.S.

Armet de Lisle at Nogent-sur-Marne. The funds were defrayed from a grant made by the Goldsmiths' Company to the Royal Society, in 1904, for the purpose of the investigation of radium.

The process of extraction produced about 413 grams of anhydrous barium chloride, containing radium chloride sufficient to give the salt a radio-activity 560 times that of uranium.

This salt was received by the Royal Society in the autumn of 1906, and was handed to me in January, 1907, with the request that I would extract the radium chloride from it, and undertake, if possible, a re-determination of the atomic weight of the element.

The method of extraction was substantially that adopted by Mme. Curie, namely, systematic fractional crystallisation, first from water and then from increasingly strong hydrochloric acid, until finally the acid used was the strongest that could be obtained by distillation.

Whilst still engaged in the isolation of the radium chloride from the material furnished by M. Armet de Lisle, I received a further small supply of radium from the Royal Society. It was bought in Cambridge, and purported to be radium bromide, but on removing it from the capsule, in which it had been stored since 1903, it was found to be wholly insoluble in water. On treatment with pure dilute hydrobromic acid it readily passed into solution. The salt obtained by evaporation was sent to Prof. Rutherford, who had kindly undertaken to make any measurements of radio-activity which I needed. He estimated the amount of radium present as equivalent to 33 milligrams of radium bromide. This salt was eventually converted into chloride, and was purified by repeated crystallisation from strong hydrochloric acid.

*Determination of Atomic Weight.*—This was effected by ascertaining the amount of silver chloride yielded by a weighed quantity of the anhydrous radium chloride—the principle of the method already employed by Mme. Curie.

A method was devised whereby the whole of the operations of drying and weighing the radium chloride, precipitating, washing, drying, and weighing the silver chloride, might be performed in one and the same vessel, thus obviating the necessity of transferring the silver salt and of separating it by any of the ordinary processes of filtration.

The vessel in which these operations were made consisted of a thin glass tube with a conical base furnished with a hollow, well-ground stopper. It had a capacity of about 15 c.c., and was as light as was consistent with the requisite strength, and could be suspended from the balance-arm by fine platinum wire. In all the weighings a precisely similar bottle of almost identical weight and capacity, suspended in like manner, was employed as a tare. The weighings were made on a very sensitive assay balance, with 4-inch arms, carrying a maximum load of 12 grams, and provided with light stirrup pans.

The washed silver chloride was first dried at 100°, and then heated in the air bath to 160° for about a couple of hours, and, after standing in the desiccator over phosphoric oxide for about eighteen hours, was weighed in the manner described.

In order to test the practicability of the method and to acquire experience of its working, as well as to gain some idea of its accuracy before actually making use of it in the case of the radium salt, a series of determinations of atomic weight of barium was made with purified barium chloride.

The results were as follows:—

$Ag = 107\cdot93$. $Cl = 35\cdot45$.

| Barium chloride, milligrams | Silver chloride, milligrams | Atomic weight, Ba |
|---|---|---|
| 114·7 ... ... | 157·8 ... ... | 137·5 |
| 172·1 ... ... | 236·8 ... ... | 137·5 |
| 57·1 ... ... | 78·8 ... ... | 136·9 |
| 62·6 .. ... | 86·1 ... ... | 137·6 |
| 68·1 ... ... | 93·7 ... ... | 137·5 |

The value for barium adopted by the International Committee on Atomic Weights, 1907-8, is 137·4.

It will be seen from these numbers that a close approximation to the true atomic weight of barium can be obtained by the method described, the maximum error being about half a unit, or less than 0·5 per cent. Considering that the atomic weight of radium is probably nearly double that of barium, the same fortuitous errors would affect its value to about a unit.

As the work of isolating and purifying the radium chloride proceeded, determinations of the amount of chlorine were made as described from time to time, and as soon as approximately constant values were obtained it was assumed that any barium or other impurity present was too small in amount to affect the results when regard was had to the unavoidable experimental errors. The resulting chloride was then repeatedly and carefully recrystallised from pure, strong hydrochloric acid, the "tails," which were comparatively rich in radium, being specially set apart.

The purified salt finally extracted from the material supplied by M. Armet de Lisle weighed, when anhydrous, 64 milligrams.

I regard this salt as substantially radium chloride. I am not, however, in a position to say that it was absolutely free from barium. At the same time, I have reason to believe that the amount still present was probably too small materially to influence the result, considering the limited quantity of the salt I had to work with, and the consequent relatively large experimental errors.

With the aid of Sir William Huggins, who kindly made the spectroscopic trials for me, I was able to carry out Mme. Curie's test of comparing the relative intensity of the lines of barium and radium in the spark spectrum of the separated radium chloride. Mme. Curie compared the relative strengths of lines 4554·2 of Ba and 4533·3 of Rd. Although these have the advantage of being close together, they are of dissimilar intensity. Sir William Huggins advised that a more stringent test would be to take the line 5536·2 of Ba of intensity 10, and compare it with the Rd lines 5813·8 and 5560·8, which are also of intensity 10. On actually making the trials, which were repeated several times, the green Ba line 5536·2, although visible, was seen to be relatively very feeble—less intense, indeed, than that afforded by the most dilute solution of barium chloride we were able to employ.

With this material, therefore, I attempted to make the determination of atomic weight. Accordingly, the greater portion was transferred to the vessel already described, and the amount of chlorine in the anhydrous salt determined with all possible care. The result was:—

| Radium chloride, milligrams | Silver chloride, milligrams | Atomic weight, Rd |
|---|---|---|
| 62·7 ... ... | 60·4 ... ... | 226·8 |

The radium was recovered from the solution, re-converted into chloride, added to what remained of the original quantity, and the amount of chlorine again determined in the anhydrous salt. The second result was:—

| Radium chloride, milligrams | Silver chloride, milligrams | Atomic weight, Rd |
|---|---|---|
| 63·9 ... .. | 61·8 ... ... | 225·7 |

The purified chloride obtained from the Cambridge material amounted to 24 milligrams.

It was added to the main bulk, and the whole was repeatedly crystallised from strong hydrochloric acid, about 6 milligrams being thus removed in the mother liquors. After being dried at 150° it was again analysed, with the following results:—

| Radium chloride, milligrams | Silver chloride, milligrams | Atomic weight, Rd |
|---|---|---|
| 78·4 ... ... | 75·3 ... ... | 227·7 |

The mean value is 226·7, or, to the nearest unit, 227. This, it will be observed, is in very close accord with Mme. Curie's latest number.

I think, therefore, it is reasonably well established that the atomic weight of radium is now known to within a unit which, considering the relatively high number, is, in the present circumstances, as fair a degree of exactitude as could be anticipated.

## KINEMATOGRAPHY IN NATURAL COLOURS.

AT the inauguration, on May 1, of Urbanora House, where the Charles Urban Trading Co. make kinematograph films, Mr. G. Albert Smith gave a demonstration of the first examples that he has prepared of his system of animated photography in natural colours. The results were excellent, the colours being bright and clean, and so far as one could judge from the drapery, flowers, and flesh tints, they were very good copies of the originals. The method which Mr. Smith has practically perfected allows of the use of the ordinary bioscope and projection apparatus and the ordinary film. The film itself is not coloured at all, but consists, as in other methods, of colour records, the colour being supplied by stained films behind it.

The three-colour method of projection, of which Mr. Ives was the chief pioneer from a practical point of view, has been described in this Journal, and consists, shortly, in photographing the redness, greenness, and blueness of the subject, and then, by means of colour screens placed behind these photographs and three projection lanterns, combining the coloured images on the screen. Kinematography with three lanterns would offer great, if not insuperable, difficulties, besides requiring new and very complicated apparatus. Mr. Smith therefore makes his colour records alternately on the same strip of film by fixing a disc that carries the necessary colour screens in front of the film and causing it to rotate synchronously with it. As seen on the sheet, the alternating colours combine perfectly. To simplify the matter further, Mr. Smith has done away with the blue screen altogether, and broadened the spectrum bands transmitted by the red and green screens, the latter including some blue. As the blue in three-colour work is always a dark colour, its elimination, together with the readjustment of the other two colours, is justified in the result, whether it is theoretically correct or not. The method thus simplified left the difficulty of the comparative insensitiveness to red of ordinary films. The method of rendering the film so sensitive to red that the red image may be photographed at the necessary speed Mr. Smith does not describe, but apparently he used a bathing process.

Thus it has been demonstrated that it is now possible to represent colour and movement at the same time in a thoroughly practical manner, and with comparatively simple apparatus.

C. J.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The date of the installation of the Chancellor in the Senate House is fixed for Wednesday, June 17.

Graces will be offered on Thursday, May 14, recommending the establishment of the proposed new professorship of biology, and gratefully accepting the proposal of a member of the University to contribute the sum of 300*l.* per annum for five years towards the stipend of the professor, this offer to be increased to 400*l.* per annum for any portion of the five years during which the professor may be holding a professorial fellowship.

It is proposed to continue the Caley lectureship now held by Dr. Baker and the Stokes lectureship now held by Dr. Hobson in mathematics; each lecturer is to receive a stipend of 200*l.* a year, payable by the University so far as the benefactions received for these purposes are insufficient. It is also intended to continue the appointment of the lecturers in mechanical engineering and in electrical engineering, which would lapse at Midsummer unless the University otherwise determine, and it is proposed in future to appoint three demonstrators of mechanism and applied mechanics in place of the two who now exist.

The special board of studies recommends the appointment of a university lecturer in agricultural physiology for five years from Midsummer, at an annual stipend of 150*l.*, payable out of the agricultural education fund.

The election to the professorship of political economy will take place on Saturday, May 30. Candidates are requested to communicate with the Vice-Chancellor on or before Monday, May 18.

The professor of botany records the gift of more than 4000 specimens of British plants, in excellent order, and mounted and prepared with unusual care. These have been presented by the Rev. J. D. Gray, Clare College, Vicar of Nayland, Suffolk.

The syndicate appointed to consider the steps to be taken for the erection of a building for the department of agriculture recommends that it be authorised to accept a tender for the building described in a report to the Senate, provided the cost does not exceed the architect's estimate of 13,000*l.* If this proposal should be accepted by the Senate and the building be proceeded with, it will almost exhaust the funds collected by the Cambridge Association for the agricultural school, and leave nothing for furniture and fittings or for maintenance. It is hoped that the funds of the agricultural building, in which the late Duke of Devonshire took so keen an interest, and which he did so much to collect, will be increased materially before the end of the year.

LONDON.—A course of eight lectures on the "Structure and Functions of the Central Nervous System" will be given in the physiological department of University College by Dr. W. Page May on Wednesdays at 5 p.m., beginning on Wednesday, May 13. The lectures are open to all students of the University and to qualified medical men on presentation of their cards.

PROF. H. POINCARÉ, professor of astronomy in the Paris École polytechnique, has resigned his chair, and has been given the title of honorary professor.

THE new Education (Scotland) Bill introduced in the House of Commons on March 26, and read a second time on Tuesday, May 5, is not so comprehensive a measure as the Bill of last session. It is interesting, however, to notice how much larger a part educational matters pure and simple take in the Scottish Bill compared with Education Bills affecting England. The Bill for Scotland now before Parliament proposes to give school boards additional general powers for the supply of meals subject to provisos with regard to defraying expenses, for bringing opportunities for education within easier reach of children in outlying districts, and for collecting and distributing information as to employments open to children on leaving school. It makes it the duty of the parent to provide efficient education for his children from five to fourteen years of age, and gives the school board power to summon to one of its meetings parents neglecting their duty, and if satisfactory reasons are not forthcoming to issue an attendance order, which, however, may be made the subject of appeal to the Sheriff. The school board is given power also, in issuing exemption certificates, to impose as a condition of exemption such attendance as it shall prescribe, after the age of fourteen and until such age not exceeding seventeen years as the school board shall think fit, either at a day school or continuation class, or both. The school board must provide continuation classes, and may make, vary, or revoke bye-laws regulating attendance at continuation classes. It is made a punishable offence to employ a boy or girl at any time when his attendance is by any bye-law required at a continuation class, and parents must assist the school board under liability to fine. The Bill is thus a first step to make education in Scotland compulsory up to the age of seventeen, through continuation schools.

A DISCUSSION took place in the House of Commons on April 29 on the subject of education in India, and a motion was brought forward for "an impartial and searching inquiry into the scope, character, and methods of education in India." The grounds on which this proposal was urged were that the Indian Government had pronounced in favour of free elementary education, but no progress had been made towards it. Also that only one-tenth of the boys of school-going age were actually at school, while the proportion of girls at school was very much smaller even than this. It was also pointed out that the "amount of money spent on education was deplorably inadequate, being only about $1\frac{1}{2}d.$ per head of the children of school age." It was also urged that the education given had been a "great deal too literary," and that the "whole training had not been sufficiently scientific and practical." The proposal was supported by two or three members and opposed by others who are well acquainted with India and with educational problems, and it was pointed out that "it was a bad thing too frequently to pull up a plant by its roots to see how it was growing." Mr. Hobhouse, who replied on behalf of the Under-Secretary of State for India, had no difficulty in showing that the request for a committee of inquiry was unnecessary. He assured the House that educational questions had within the past few years been thoroughly investigated and discussed in India by various conferences, commissions, and committees, that the educational system had been recently thoroughly overhauled and re-modelled, and that it is now on more practical and thorough lines than formerly, and that special attention had been paid to primary, secondary, and technical education. Also that the expenditure on education had been almost doubled within the last ten years, and that every effort would be made to increase this expenditure, due consideration being given to other pressing wants in the country. He assured the House that the Secretary of State for India was in fullest sympathy with the object which those proposing the motion had in view, but he was unable to accede to the request, "because the work of education in India had progressed and was steadily being pushed forward, and any inquiry of the sort suggested would not really expedite it." The motion was then withdrawn.

WHEN the British Association met in Bristol ten years ago, Sir Norman Lockyer referred at the closing meeting to the fine educational establishments of the city, and expressed the hope that at some future meeting the association would find Bristol at the head of some great south-western university. Since that time the movement for a University of Bristol has made substantial progress, and frequent references have been made to it in these columns. An important meeting was held at Bristol on April 25 under the auspices of the Bristol and District Workers' Educational Association, when an earnest appeal on behalf of the scheme for a university for Bristol was made by the Bishop of Hereford, the president of the University College. Dr. Percival said he was not sure that the people of Bristol at large had really grasped the extent of the advantages which would accrue to the city in connection with the establishment of a university for Bristol and the west of England. Bristol claims to be the "lantern of the west," and if she is to maintain that claim in future and to maintain her position in the forefront with all the other great cities of England, all grades of citizens must unite in the endeavour to crown their system of educational institutions by the establishment of a university. As local patriots he appealed to them to give their sympathy and their efforts in support of the movement. He put this question to himself, "Why should not I, as a citizen of Bristol, be able to claim as much as if I belonged to Liverpool, Manchester, Sheffield, Leeds, or Birmingham?" Every one of those great cities has secured its university. But the question may naturally be asked, "What are we to gain by a university?" He said he could answer that question in almost a single word. We need only look at a country like Scotland to see what is gained by the possession of popular universities. The population of Scotland is only about $4\frac{1}{2}$ millions, and Scotland has its four ancient universities. If any part of the kingdom or the Empire has profited more by education than all the rest it is Scotland, and Scotland owes its preeminence to the fact of its having enjoyed and made use of those four universities. If we turn from Scotland, Wales is close behind, and has profited immensely by her university colleges and national university. Then in Ireland we are beginning to multiply the universities, and should the citizens of Bristol be content to stand aside? He assured them from a long experience that nothing they could do in Bristol would be better for the education and the future well-being of the working classes of the city than that they should use their best efforts to secure a university.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Chemical Society**, April 2.—Sir William Ramsay, K.C.B., F.R.S., president, in the chair.—Rate of hydrolysis of chloroacetates, bromoacetates, and $\alpha$-chlorohydrin by water and by alkali, and the influence of neutral salts on the reaction velocities (preliminary note): G. **Senter**. The results of an investigation of the rate of displacement of halogen by hydroxyl for bromoacetic acid, its sodium salt, and for $\alpha$-chlorohydrin, and the effect of certain neutral sodium salts on the reaction velocities are given. These confirm the view that the effect of neutral salts is mainly due to their action on the reacting substances, and appear to be incompatible with the hypothesis advocated by Armstrong and his co-workers, that neutral salt action is due to combination between salt and solvent, with consequent concentration of the solution.—The constituents of Cyprus origanum oil. Isolation of a new terpene, "origanum": S. S. **Pickles**. The oil consists mainly of carvacrol. There are also present (1) a hydrocarbon, $C_{10}H_{16}$, apparently a new terpene, for which the name *origanene* is proposed (2·5 per cent.); (2) cymene, which, together with associated terpenes, constitutes 8·5 per cent.; (3) terpene alcohols (3·5 per cent.); and (4) high boiling residue (1·3 per cent.), besides very small quantities of a second phenol, and probably *iso*butyric acid. Origanene is probably $\Delta^{1:3}$-p-*menthadiene*.—The displacement of halogen in *l*-phenylchloroacetic acid by hydroxy- and methoxy-groups. A contribution to the chemistry of the Walden inversion: A. **McKenzie** and G. W. **Clough**.—The condensation of epichlorohydrin with phenols: D. R. **Boyd** and E. R. **Marle**. The condensation product of phenol and epichlorohydrin is glyceryl diphenyl ether, and not phenyl glycide ether, as Cohn and Plohn suggested. Similarly, the crystalline compound obtained from *p*-cresol and epichlorohydrin is glyceryl di-*p*-tolyl ether.—A new general method of preparing diazonium bromides: F. D. **Chattaway**. Primary aromatic hydrazines react quantitatively with the diazonium perbromides, producing diazonium bromides.—The absorption spectrum of triphenylmethane: A. G. G. **Leonard**. The cause of the difference between the absorption curve plotted by Hartley in 1887 and that plotted by Baker in 1907 is shown to be due to the presence of an impurity in the sample originally examined.—The nature of the impurity found in preparations of triphenylmethane: W. N. **Hartley**. The impurity referred to in the preceding paper appears to be triphenylmethyl.—The constitution of coordinated compounds: S. H. C. **Briggs**. The existence of the two compounds $(Pt6NH_3)Cl_4$ and $(PtCl_6)K_2$, in which the platinum atom is the basis of a complex cation and anion respectively, suggests the view that the platinum atom has both positive and negative affinities, and formulæ giving expression to this view are suggested and discussed.—A combined stop-cock and capillary connecting tube for gas burettes: A. E. **Hill**. The apparatus is figured and described in the original.—The hydrolysis of amygdalin by emulsin, part i.: S. J. M. **Auld**. It has been shown that Jorissen and Hairs's "emulsin" is really a mixture of two enzymes, viz. true emulsin and a maltase-like ferment, and the effect of varying the concentration of amygdalin and emulsin has been investigated, as also the action of many inhibitants.—Complex nitrites containing potassium and lead (preliminary note): A. N. **Meldrum**.—The composition and formula of Wells's potassium lead periodide: A. N. **Meldrum**.—The molecular complexity of amides in various solvents: A. N. **Meldrum** and W. E. S. **Turner**. Determinations of the molecular complexity of eleven amides in various solvents confirm the Nernst-Thomson theory that the smaller the dielectric constant of the solvent the greater is the association of the solute.—The optical activity of compounds having simple molecular structure: W. J. **Pope** and J. **Read**. Chlorosulphoacetic acid and chlorobromomethanesulphonic acid each contain an asymmetric carbon atom in the molecule, but, although their strychnine and quinidine salts crystallise well, no evidence was obtained that the acids are resolvable into enantiomorphously related components.—Acetylketen: a polymeride of keten: F. **Chick** and N. T. M. **Wilsmore**.—Saponification of ethyl formate by water in presence of acids as catalytic agents: A. **Lap-**

worth.—The triazo-group, part iii., bistriazo-derivatives of ethane and of acetic ester: M. O. **Forster**, H. E. **Fierz**, and W. P. **Joshua**.

Physical Society, April 10.—Dr. C. Chree, F.R.S., president, in the chair.—An experimental investigation of the nature of $\gamma$ rays: Prof. W. H. **Bragg** and Mr. **Madsen**. The view that the $\gamma$ rays are not ether pulses, but are material and consist of neutral pairs of one negative with one positive electron, developed in previous papers (*Phil. Mag.*, October, 1907), is held to be established by the experiments described in this paper with the secondary radiation produced by the $\gamma$ rays of radium.—Experiments on artificial fulgurites: Miss D. D. **Butcher**. The first part of the paper deals with natural fulgurites, and the second with the production of artificial fulgurites. The experiments show:—(1) The tubes are formed by fusion of the powder which surrounds the column of air in which the spark passes. The length and thickness of the tube depend on the energy of the spark, and also on the character of the spark, *i.e.* whether it is unidirectional or oscillatory. (2) There is no appreciable difference in the two ends of a tube provided that the two electrodes are alike. When one electrode is a point and the other a flat plate, any branching that may occur will be towards the plate, whichever electrode is made positive. In nature, the flat plate would be represented by the moist lower strata of the soil. Therefore we cannot say from the character of the tube whether the lightning discharge was from a positive or negative cloud. (3) The difference between thick and thin tubes is due probably to a difference in the sharpness of the flash and the resulting explosive effect. When the explosive effect is great and the quantity of material melted is small, the result will be a large-bored, thin-walled tube. Whether this remains circular or becomes pressed together and distorted depends merely on whether the fused matter has time to cool before the outward pressure of the blowing has been overcome by the inward pressure on the surrounding sand or not. In nature, the damp sand or soil probably acts as the damp string in these experiments, and consequently causes many lightning discharges to be unidirectional. In the experimental tubes the outward pressure was so great, and the quantity of fused material so small, that the walls were broken through and left as a mere network.—Short-spark phenomena: W. **Duddell**. The paper deals with two effects which the author has observed in connection with some measurements of the current in the secondary circuit of an induction-coil. The apparatus in use consisted of a 12-inch Newton induction-coil, which was supplied from the 200-volt direct-current mains. A large resistance was placed in series with the primary of the coil to limit the current, and the current was interrupted by means of a mercury-jet interrupter. The secondary circuit contained a galvanometer to measure the mean current, and a thermo-ammeter to measure the root mean squared current. When there was no spark-gap in the secondary circuit and the coil was in action, the mean current, as read by the galvanometer, was zero, and the root mean squared current about 3·8 milliamperes. If, now, a microscopic spark-gap, say between two aluminium points, was introduced into the secondary circuit, two curious effects took place. Firstly, the R.M.S. current enormously increased in value, and, secondly, a very large deflection was produced on the galvanometer in the direction corresponding to that due to making the primary circuit. The introduction of a spark-gap 1/10 mm. long caused the R.M.S. current to rise to 38·5 milliamperes, and this continued to increase with increasing length of spark-gap until it reached a maximum with a gap about 1·4 mm. The author thinks that this effect is due to very high frequency oscillations set up in the wires connected to the secondary circuit of the coil when a spark-gap is introduced. He has observed the effect with brass, iron, zinc, and aluminium electrodes, but the latter metal is the best to use.

Mathematical Society, April 30.—Prof. W. Burnside, president, in the chair.—A general convergence theorem and the theory of the representation of a function by a series of normal functions: Dr. E. W. **Hobson**. A general convergence theorem is established, which, when applied to series of Sturm-Liouville functions, suffices to show that the question whether the series converges, or not, at a particular point, depends only upon the nature of the function in an arbitrarily small neighbourhood of the point, whilst the nature of the function throughout the whole interval of representation is restricted only by the condition that it must possess a Lebesgue integral in the interval. The theorem is further employed to show that, subject to the same condition as regards the nature of the function, the question whether the series converges uniformly, or not, in an interval in which the function is continuous, depends only upon the nature of the function in an interval which encloses the interval of continuity in its interior, exceeding it in length by an arbitrarily small amount.—The ordering of the terms of polars and transvectants: L. **Isserlis**. Between any two non-adjacent terms $T_1$, $T_2$ of a polar or a transvectant a series of terms $T_{1,1}$, $T_{1,2}$, . . . $T_{1,i}$ can be placed so that any term in the series $T_1$, $T_{1,1}$, . . . $T_{1,i}$, $T_2$ shall be adjacent to the terms on either side of it. In the paper a method is developed for actually ordering all the terms in this way.—Oscillating successions of continuous functions: Dr. W. H. **Young**. The paper deals with the theory of series which neither converge nor diverge to a definite limit. In such cases the sum function is replaced by two functions, the upper and lower functions of a sequence. The theory of uniform convergence and divergence is extended to series of functions which oscillate at every point.—The relation between the convergence of series and integrals: T. J. I'A. **Bromwich**. It is proved that when $\phi(x)$ tends steadily to infinity, as $x$ increases, but more slowly than $x$, the behaviour of the integrals

$$\int^{\infty} f(x)\sin\phi(x)dx,\quad \int^{\infty} f(x)\cos\phi(x)dx,$$

determines the character of the series

$$\sum^{\infty} f(n)\sin\phi(n),\quad \sum^{\infty} f(n)\cos\phi(n).$$

—The multiplication of series: G. H. **Hardy**.—Porisms: H. **Bateman**.—The influence of viscosity on wave motion: W. J. **Harrison**.—Informal communications were made as follows:—(1) Mersenne's numbers; (2) Quartans with numerous quartan factors: Lieut.-Colonel A. **Cunningham**. In the first a factor 150287 was reported of the number $2^{163}-1$. This result reduces to 18 the number of Mersenne's numbers (of the form $2^q-1$) which have not yet been verified, and none of these 18 numbers contains any factor less than 200,000. In the second it was shown how to construct numbers of the form $x^4+y^4$ which shall have any desired number of divisors of the same form.

PARIS.

Academy of Sciences, April 27.—M. H. Becquerel in the chair.—A problem relating to the theory of left-handed curves: Gaston **Darboux**.—The application of wireless telegraphy to the improvement of meteorological warnings: G. **Bigourdan** (see p. 14).—The zoological relations of the shrimps of the order of Stenopidæ: E. L. **Bouvier**.—Entropy: M. **Auric**. An expression for entropy derived from the density of the ether, assuming its pressure to represent the absolute temperature.—The ionisation of air by ultra-violet light: Eugène **Bloch**. On repeating the original experiments of Lenard, it was found that the greater part of the Lenard effect could be traced to the presence of particles in the gas. When the gas is completely freed from dust, the Lenard effect, if it exists, represents only a small fraction of the effect due to the dust.—The velocity of transport of the ions H, Cl, and OH in the electrolysis of solutions of hydrochloric acid: E. **Doumer**. From the experiments described the author concludes that the ionisation of water takes an active part in the electrolysis of solutions of hydrochloric acid, and the velocity of transport of the Cl and H ions is sensibly the same.—The detection of helium in minerals containing uranium: F. **Bordas**. The method described in a previous paper (selective absorption with charcoal at low temperatures) has been applied to numerous minerals containing uranium. Its delicacy is sufficient to detect helium in 1 milligram to 2 milligrams of brœggerite, liebigite, or æschynite. Minerals containing definite crystallised uranium compounds, such as torbernite, autunite, and Californian carnotite, give no helium. A list of minerals containing uranium in which helium has been detected is given.—The direct use of copals in the manufacture of varnish without a preliminary heating: Ach. **Livache.** The necessity for preliminary heating of the copal, with its accompanying loss, can be avoided by using amyl alcohol containing some tenths per cent. of acid as the solvent.—The levers in the organism: Aug. **Michel.**

CALCUTTA.

**Asiatic Society of Bengal**, April 1.—Skull of a gigantic ray of the genus Ceratoptera: Captain R. E. **Lloyd.** The specimen was cast ashore at Puri, on the Orissa coast, and forms the type of a new species. The genus does not appear to have been recorded hitherto from Indian seas.—Fresh-water sponges from the Bombay Presidency and Burma: Dr. N. **Annandale.** The two collections were made in November, 1907, in the Western Ghats, and in March, 1908, at Rangoon and the Amherst district of Tenasserim. The Bombay collection includes several species originally described by Carter from that Presidency, as well as others new to science, not hitherto known from India, or only recorded from Bengal.

## DIARY OF SOCIETIES.

*THURSDAY*, MAY 7.

ROYAL SOCIETY, at 4.—Election of Fellows.—At 4 30.—Helium and Radioactivity in Rare and Common Minerals: Hon. R. J. Strutt, F.R.S.—The Action of Resin and Allied Bodies on a Photographic Plate in the Dark: Dr. W. J. Russell, F.R.S.—Seleno-aluminium Bridges: Prof. G. M. Minchin, F.R.S.—A Tantalum Wave-detector, and its Application in Wireless Telegraphy and Telephony: L. H. Walter.

ROYAL INSTITUTION, at 3.—Mendelian Heredity: William Bateson, F.R.S.

CHEMICAL SOCIETY, at 8.30.—The Interaction of Diazonium Salts with Mono- and Di-hydric Phenols and with Naphthols: K. J. P. Orton and R. W. Everatt.—The Condensation of Benzoin with Methyl Alcohol: J. C. Irvine and D. McNicoll.—The Mutual Solubility of α-Methylpiperidin and Water: O. Flaschner and B. MacEwen.—The Melting Points of the Anilides, *p*-Toluidides, and α-Naphthylamides of the Normal Fatty Acids: P. W. Robertson.—The Refraction and Dispersion of Triazo-compounds: J. C. Philip.—The Dissociation Constants of Triazoacetic and α-Triazopropionic Acids: J. C. Philip.—The Absorption Spectrum of Camphor: W. N. Hartley.—The Viscosity of Solutions: C. E. Fawsitt.—The Action of Fused Potassium Hydroxide and of Hydrogen Peroxide on Cholesterol, Preliminary Note: R. H. Pickard and J. Yates.—The Fermentation of Mannose and Fructose by Yeast Juice, Preliminary Communication: A. Harden and W. J. Young.—The Volumetric Estimation of Silver: W. R. Lang and J. O. Woodhouse.—The Constituents of Olive Leaves: F. B. Power and F. Tutin.—The Constituents of Olive Bark: F. B. Power and F. Tutin.

LINNEAN SOCIETY, at 8.—Colony-formation as a Factor in Organic Evolution: H. M. Bernard.—Antipatharia from the Voyage of H.M.S. *Sealark*: C. Forster-Cooper.—A List of the Fresh-water Fishes, Batrachians, and Reptiles obtained by Mr. J. Stanley Gardiner's Expedition to the Indian Ocean: G. A. Boulenger, F.R.S.—A Cinematographic Representation of the Movements of Peripatus and other Invertebrate Animals: F. Martin Duncan.

CIVIL AND MECHANICAL ENGINEERS' SOCIETY, at 8.—Abbreviated Formulæ for Structural Engineers: E. Fiander Etchells.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Manufacture of Electrical Condensers: G. F. Mansbridge.

*FRIDAY*, MAY 8.

ROYAL INSTITUTION, at 9.—Ice and Its Natural History: J. Y. Buchanan, F.R.S.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Theory of the Motion of the Moon; containing a New Calculation of the Expressions for the Coordinates of the Moon in Terms of the Time: Prof. E. W. Brown.—The Proper Motion of Small Stars: S. W. Burnham.—Second Index Catalogue of Nebulæ and Clusters of Stars found in the Years 1895 to 1907: J. L. E. Dreyer.—Results of Micrometer Observations of Double Stars made with the 28-inch Refractor in the Year 1907: Royal Observatory, Greenwich.—*Probable Papers*: An Empirical Law of Astronomical Refraction: Prof. H. H. Turner.—On the Practical Testing of Concave Parabolic Mirrors: Rev. C. D. P. Davies.

PHYSICAL SOCIETY, at 8.—A Modified Theory of Gravitation: Dr. C. V. Burton.—An Examination of the Formulæ for the Grading of Cables: C. S. Whitehead.—Illustrations of Geometrical Optics: R. M. Archer.

*SATURDAY*, MAY 9.

ROYAL INSTITUTION, at 3.—Chile and the Chilians: G. F. Scott Elliot.

*MONDAY*, MAY 11.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Geographical Conditions and Railway Construction in the Balkan Peninsula: Noel Buxton.

*TUESDAY*, MAY 12.

ROYAL INSTITUTION, at 3.—Why Light is believed to be a Vibration: Prof. F. T. Trouton, F.R.S.

ZOOLOGICAL SOCIETY, at 8.30.

FARADAY SOCIETY, at 8.—The Industrial Uses of Ozone in Connection with Water Purification: F. Mollwo Perkin.—Determination of Boiling Points of very small Quantities of Liquids: L. O'Dowd and F. Mollwo Perkin.—An Apparatus for Measuring Dielectric Constants of Non-conducting Liquids: Dr. Veley, F.R.S.

*WEDNESDAY*, MAY 13.

ROYAL SOCIETY OF ARTS, at 8.—The Underground Water Supplies of the Thames Basis: Clayton Beadle.

*THURSDAY*, MAY 14.

ROYAL SOCIETY, at 4.30.—Croonian Lecture: The Structure of the Central Nervous System of the Higher and Lower Animals: Prof. Gustaf Retzius, For.Mem.R.S.

ROYAL INSTITUTION, at 3.—Mendelian Heredity: W. Bateson, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—On the Invariants of the General Linear Homographic Transformation in Two Variables: Major P. A. MacMahon.—On the Order of the Group of Isomorphisms of an Abelian Group: H. Hilton.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Switch Gear Control Apparatus and Relays for Alternating-current Circuits: Dr. C. C. Garrard.

IRON AND STEEL INSTITUTE, at 10.30 a.m.—On Improvements in Plate Rolling Mills: A. Lamberton.—On the Physical Qualities of Steel in Relation to its Mechanical Treatment: J. E. York.—On a New Fatigue Test for Iron and Steel: Dr. T. E. Stanton.—On an Experimental Electric Furnace for the Smelting of Iron: Prof. B. Igewsky.

*FRIDAY*, MAY 15.

ROYAL INSTITUTION, at 9.—The Past and Future of Tuberculosis: H. T. Bulstrode.

IRON AND STEEL INSTITUTE, at 10.30 a.m.—On Cast Iron in the Construction of Chemical Plant: F. J. R. Carulla.—On the Application of Colour Photography to Metallography: E. F. Law.—On the Utilisation of Blast-Furnace Slag for Portland Cement: C. von Schwarz.—On the Department of Metallurgical Chemistry in the National Physical Laboratory: W. Rosenhain.—On the Pyrometric Installation of the Ordnance Factories, Woolwich: J. Wesley Lambert.

ROYAL SOCIETY OF ARTS, at 8.—The Dangers of Coal Dust and their Prevention: W. E. Garforth.

## CONTENTS.

THURSDAY, MAY 14, 1908.

## A CONTRIBUTION TO THE HISTORY OF MEDICINE.

*The History of the Study of Medicine in the British Isles.* By Dr. Norman Moore. The Fitz-Patrick Lectures for 1905–6, delivered before the Royal College of Physicians of London. Pp. viii+202. (Oxford: Clarendon Press, 1908.) Price 10s. 6*d.* net.

THERE are two ways in which a scientific subject may be taught—the logical method, which describes the facts, and follows the course of reasoned demonstration; and the historical method, which follows the progress of knowledge by which facts are accumulated long before their logical sequence has been ascertained. The geometry of Euclid follows the former course, as do most of the exact sciences. The history of navigation follows the historical method, and so does the history of medicine.

Complete histories of medicine are few and far between, and, with the exception of the unfinished treatise of Dr. Freind, have not dealt with more than fragments of the subject. Medical biographies, like Dr. Payne's "Life of Sydenham," or the excellent biographical articles dealing with physicians in the "Dictionary of National Biography," begun by Leslie Stephen, and happily completed by Sidney Lee, furnish an example to all professions, but to write the history of a science demands a knowledge of the successive labours by which each in turn contributed his stone to the great edifice.

Dr. Caius, president of the College of Physicians of London in 1555, Sir Hans Sloane, president in 1719, beside Dr. Hamey in 1640, and Dr. Freind in 1725, had each of them attempted a history of medicine.

After mentioning the names of some, chiefly Royal physicians of our Norman kings, Dr. Moore gives a comparatively full account of John Mirfeld, the author of a treatise on medicine which he called the "Breviarium Bartholomei"; he lived in the Convent of St. Bartholomew, in Smithfield, a separate foundation from that of St. Bartholomew, though both were founded by Rahere.

Among other "cases," Mirfeld records that of hydrocephalus in a girl, who was tapped by a cautery on two occasions, and with final success.

Another patient of Mirfeld was a Canon, who was thrown from his horse and taken up without sense or motion; the patient's head was shaved, rubbed with oil of roses in warm vinegar, bound up with bandages, and covered over all with a lamb's skin. Strict abstinence from food was enforced until the fourth day, when for the first time he spoke, and was able to swallow; on the sixth day he was given some chicken broth, followed by laxative pills. Mirfeld afterwards recommended the patient to eat brains of kids and fowls, with the object of supplying the injuries of the patient's brain.

Beside the "Breviarium," which is based on the famous "Regimen Sanitatis Salerni," Mirfeld compiled a "Florarium Bartholomei," which was discovered among the MSS. of the British Museum. Mr. Gilson, the discoverer of this MS., lent it to Dr. Norman Moore, who has given us four columns of the text, which can be deciphered with comparative ease by the help of a magnifying glass. Yet another fragmentary MS. by Mirfeld was discovered in the library of Lambeth Palace, which is inscribed with the name of Archbishop Sancroft. Among the more modern medical works which Mirfeld mentions were translations of "Rhazes' Serapion" and of "Avicenna." He knew something of Horace, Ovid and Virgil, of Boethius, of the Vulgate, and of the commentaries of Augustin, Anselm, and Thomas Aquinas.

Dr. Moore, in his second lecture, deals with the education of London physicians in the century of Harvey and Sydenham. Thomas Linacre, the first president of the college, was a learned man who had studied Greek under Demetrius Chalcondylas, a refugee from the Turkish invasion. He will always be revered as the founder of the Royal College of Physicians. Like Mirfeld and the earlier physicians, he was a scholar first and a physician afterwards, and like Mirfeld he took holy orders. He wrote a Latin grammar, and belonged to that little group of learned men who adorned the golden time of Henry VIII.'s youth. Erasmus was a welcome addition to the English scholars, Sir Thomas More and Dean Colet, the founder of St. Paul's School. The young king was himself a scholar and a musician in that happy *Decennium Neronis.*

All these scholars were accomplished Grecians. Edward Wotton, who was president of the college in 1541, was a learned man, and also a natural historian. He describes three kinds of thrushes, the missel-thrush, *Turdus viscivorus,* the song-thrush, *Turdus musicus,* and the red-wing, *Turdus iliacus.*

Another learned physician, Caius, who took up the study of natural history, wrote a book on the breeds of dogs in England, and a most valuable monograph on the sweating sickness. He also founded at Cambridge the college called after his name, which has always been connected with the study of medicine. A greater genius than any except Harvey himself was Wm. Gilbert (1540–1603), the author of the first treatise on the magnet, published in 1600, the year in which he was elected president of the College of Physicians; it has lately been re-published in a fine edition by Prof. Silvanus Thompson in 1902.

Dr. Moore wisely passes the two greatest names in medicine with a bow, for the life and works of Harvey and Sydenham have been repeatedly and adequately dealt with. Dr. Payne's admirable volume on Sydenham, and several recent Harveian orations, render full justice to each. Another early fellow of the college was a French physician, Theodore de Mayerne (1573–1655), an accomplished chemist, to whom we owe "Lotio Nigra."

Glisson is chiefly known by his work on the "Anatomy of the Liver," but to him is due the first recognition of what he called irritability as a property of living tissues of which muscular contractility is only one manifestation. We must not forget the connection of the College of Physicians with what is now called "The Pharmacopœia," and thereby with the growing study of chemistry.

The eminence of Sir Thomas Brown was literary rather than scientific, but his "Religio Medici" confers undying lustre on perhaps the greatest prose writer of the seventeenth century. His son, Dr. Edward Brown, was educated at Trinity College, Cambridge, and in 1644 he petitioned for his degree, and was duly admitted by a Grace when Dr. Francis Glisson was regius professor of physiology.

On one of his visits to London, Edward Brown studied the anatomy of a hare and a skeleton of a monkey, and a few weeks later dissected a hedgehog and a badger; on this occasion he saw in the King's zoological collection several outlandish (*i.e.*, foreign) deer, a sheep from Guinea, a white raven, and a stork which had broken his leg and used a wooden substitute with dexterity.

Edward Brown remained with his father at Norwich, studying anatomy, botany, and chemistry; in 1664 he left Norwich for London and Dover, and thence to Paris, where he lived in a room in the Rue Zacharie for seven francs a month; here he attended lectures on surgery, hernia and fevers, and studied in the "Hotel Dieu" and "La Charité," as so many English physicians have done since, and still do if they are wise. On leaving Paris he went to Montpellier, then famous as a school of medicine.

He next visited Rome, thence travelled to Venice and Padua; and returned to Montpellier and Paris where he caught small-pox. After his recovery he returned home, but in 1668 he visited Holland devoting himself to its libraries, museums, and universities: Thence he travelled to Vienna and Greece, and returned by Styria and Hungary to England; his last journey was to Cologne. He was president of the College of Physicians in 1704, and died in 1708.

Sydenham was comparatively uninfluenced by the progress of anatomy and science, and this, as Dr. Payne has shown, was probably due to his brothers and possibly himself having enlisted in the Commonwealth Army.

It is remarkable how very few "cases" of disease are described by Sydenham or his predecessors; the explanations of the symptoms, which were mostly mistaken, leave little room for observation of facts. We must admit that in the latter part of the seventeenth century, as in the first half of the nineteenth century, the most fruitful progress in clinical medicine was in Paris, not in London.

Dr. Moore was the first to direct attention to the accurate clinical account of the symptoms during life, and to read between the lines by the light of our present knowledge, that in all likelihood the death of Henry Prince of Wales, which changed the course of English, and perhaps of European, history, was due to enteric fever, as shown by the symptoms during life and by the examination after death.

The medical memoir on his father, James I., was accurate and interesting, but it is difficult to make out more than that he suffered from gout, while that on Ann of Denmark is illustrated by a letter from herself to Mayerne.

Thomas Willis, the author of "The Anatomy of the Brain," published in 1664, accomplished his great anatomical work at Oxford, where he filled the chair of natural philosophy.

Richard Morton published in 1689 his treatise on consumption under the title "Phthisiologia." It has the great merit of being no mere speculation, but *variis historiis illustratum*. He discusses causes of phthisis, which he regards as sometimes a nervous disease. Other cases he ascribes to hæmorrhage, others to excessive lactation or to dysentery.

Another section treats of wasting due to diabetes with polyuria. He gives the names and addresses of many of his patients, but uses the decent obscurity of a learned language. Other cases of diabetes he ascribes to salivation, others to dropsy.

The eighteenth century was, on the whole, inferior to the seventeenth in England. The leading physicians were Radcliffe, the founder of the museum which bears his name at Oxford; and Arbuthnot, the first of the many physicians who earned perpetual fame by their services to great men of letters. They were followed by Mead, who was also repaid by the gratitude of Pope; Freind, who began the "History of Medicine" too early to be of much value, but who gave occasion for extorting from Walpole the prescription which cured his gout, and also secured Freind's pardon. Sir Samuel Garth was more literary than medical. Mead and Freind were good writers, but did not attain to the level of Arbuthnot.

In the latter half of the eighteenth century, Heberden was the leading physician in London after he had lectured on medicine in Cambridge, where notes of his lectures were taken by Dr. Erasmus Darwin in 1752. He died in 1801, having lived nearly ninety years, and his admirable commentaries were only published after his death by his second son. This was the most original and valuable treatise an English physician had then made; as Dr. Moore remarks, the method of examining a patient in the time of Heberden scarcely differed from that of Galen in the reign of Marcus Aurelius, the chief exception being counting the pulse. Percussion and auscultation, the ophthalmoscope, the laryngoscope, and electrical reactions were all invented in the nineteenth century.

In the eighteenth century, Sir Hans Sloane, the eminent botanist as well as physician and traveller, was president of the College of Physicians, 1719 to 1735. An Irishman by birth, he studied medicine at Paris and Montpellier, and took his degree in the University of Orange; on his return to England he lived for a time with Sydenham, and practised as a physician in London, but in 1687 he accompanied the Duke of Albemarle to Jamaica, where he studied the natural history of that island.

His first volume appeared in 1707. He was deservedly elected president of the College of Physicians and of the Royal Society.

Dr. Moore's book is a most interesting and scholarly contribution to the history of medicine.

## THE CALIFORNIA EARTHQUAKE.

*The California Earthquake of* 1906. Edited by David Starr Jordan. Pp. xv+371; illustrated. (San Francisco: A. M. Robertson, 1907.)

THIS is a collection of nine well-written essays, which, as might be expected, more or less overlap in their subject-matter. The first of these, by the editor, deals almost entirely with the Great Fault or Rift, the sudden yielding along which caused the earthquake. The strongest motion was felt where the fault enters the sea, near to which hotels and houses were thrown into the water. A fact that there was some disturbance in the sea suggests that a portion of the origin was beneath the same. At one place a train was overturned. We read that persons in an undisturbed district looking towards one that was shaken may have seen rows of trees and rows of bushes filing past them. The earthquake, we learn, was not connected with eruptions in the Aleutian Islands. The author gives us lists of Californian earthquakes, the more destructive of which apparently have had a period of thirty to forty years. He is inclined to ridicule electrical theories as a cause of earthquakes, and in referring to the destruction which took place in town and country, he quotes from the book of Isaiah, which declares that "men shall be plagued by their own inventions."

The second essay is by Prof. Branner. It deals with the geology of the earthquake. He chiefly describes the Great Fault, which split both trees and houses. Prof. Derleth confines his remarks to the effect of the earthquake upon structures. Destructivity is marked along a belt 300 miles in length and fifty miles in breadth. Apparently there was an attempt to tell outsiders that San Francisco had only been visited by a fire, but Prof. Derleth thinks it will do San Francisco and California more good if it is admitted that there really was an earthquake. Santa Rosa, like San Francisco, had fire simultaneously with the earthquake. Varieties of buildings in San Francisco are described in a variety of terms. Some were honest, some dishonest; some were fire-traps, others fire-proof without but not fire-proof within. Destruction varied according to the nature of the ground on which buildings were placed. The failure of water-pipes and sewers is described in great detail. In short, this essay is a treatise on building, for which thirty-nine rules are given. With most of these we quite agree, but not with all. Rule 4 refers to brick chimneys, which, we are told, should be built of weak lime mortar. Built in this way, when the earthquake comes they will crumble and fall as individual bricks, but if built with rich cement they will fall *en bloc*, and crush through the roof. We admire what Prof. Derleth has done off his own bat, which, taken altogether, is certainly good, but we cannot help suggesting that he might with advantage have consulted the results which have been arrived at with regard to construction in countries other than his own.

Mr. G. K. Gilbert, of the U.S. Geological Survey, also describes the Great Fault, seventy-five miles from which the shock was observed by nearly all persons awake, but at 200 miles it was perceived by only a few. Mr. S. Taber, of the Stanford University, estimates the area of greatest damage as being a little more than 200 miles in length and forty miles in width. The intensity of the shock was greatest along the line of faulting, and the initial movement was parallel to the same.

Dr. F. Ōmori, of the Imperial University of Japan, gives us interesting notes with regard to several points not touched upon by other writers. He tells us that in San Francisco the greatest number of monuments were overturned towards the east; the ascertained number of persons killed in San Francisco was 300, while the total number of persons killed in the earthquake area was probably not more than 1000; the double amplitude of motion in San Francisco was about 4 inches, and the period was about 1 second. For twenty or thirty years, Central California may seismically be regarded as a very safe place.

The last article is a personal narration by Mary Austin. It is not intended to be scientific, but it contains sufficient epigram, pathos, and humour to make it well worth reading. The first words are, "there are some fortunes harder to bear once they are done with, than while they are doing." Later we read, "It is perfectly safe to believe anything anyone tells you of personal adventure; the inventive faculty does not exist which can outdo actuality." Speaking of intelligence that reads God behind seismic disturbance, the writer says that the actual damage done by God to San Francisco was small beside the damage that resides in man's contrivances. Man made things carry the elements of their own destruction.

J. MILNE.

## ELECTRIC RAILWAYS.

*Electric Railways Theoretically and Practically Treated.* Vol. ii., Engineering Preliminaries and Direct-current Substations. By Sydney W. Ashe. Pp. vi+282. (New York: D. Van Nostrand Co.; London: A. Constable and Co., Ltd., 1907.) Price 10*s*. 6*d*. net.

THIS is essentially a book for experts, and especially American experts. The English engineer may find here and there in the book some information that will be useful, but he must be an expert to understand it. On the title-page we read that this is "Volume Two," and that it deals with "Engineering Preliminaries and Direct-current Substations." By preliminaries the author means statistics as to the relations between the number of inhabitants in a town and their requirements in the way of travelling facilities.

The amount of statistical material brought together in the first few pages is very large, but as it refers exclusively to American towns it is almost useless to the European expert. The condition of the public roads, the scarcity of cabs, the hustling tendency of the business man, and the general tendency to ride rather than walk, all make for a greater development of travel facilities by tramway than on this side of the Atlantic, so that the figures given by the author would have to be used with great caution in estimating tramway requirements in Europe. Fortunately there is no need to use American figures at all, since sufficient data are available from European experience. A curve on p. 14 is interesting as showing that with the expansion of towns the mileage of electric lines per 1000 inhabitants goes down, and the yearly number of journeys made by each inhabitant goes up. The figures are not directly applicable to European towns, but the tendency shown by these curves is the same in Europe. Towns of about 40,000 inhabitants show the greatest mileage, namely 0·76 per 1000 inhabitants, but only 110 journeys per inhabitant yearly, whilst towns of one million inhabitants and above have on the average only half a mile of line per 1000, but each inhabitant uses the cars on an average 230 times a year.

It is not clear from the author's figures whether they refer to what we should term tramways or whether they include railways also; the latter is probable, for tables giving mileage, equipment, cost, and earning of electrified main lines are mixed up with the other statistics. The next three chapters are devoted to what the author calls "Electrical Features," and deal with motor capacity and running diagrams. Various methods for getting out these curves are given, namely, Armstrong's, Storer's, and Hutchinson's methods, the latter at some length. The treatment is by no means lucid, formulæ and coefficients being introduced without explanation. Unless the reader is a thorough expert in this subject (when he needs no further instruction from the author) he will make nothing of these chapters.

Altogether the author's mathematics is not characterised by exactitude. Thus, on a later page, when he treats of converters, following (with due acknowledgment) Mr. Hay's method for the determination of the output, we find him calling a line like the following

$$\tfrac{1}{4}I_d^2+\tfrac{1}{2}I_a^2-\tfrac{1}{2}I_a\int_0^\pi \cos 2\left(\alpha-\frac{\pi}{n}\right)\pm I_dI_a\int_0^\pi \sin\left(\alpha-\frac{\pi}{n}\right)$$

an equation, without saying what it is equal to, and omitting the differential $d\alpha$. It will also be noticed that the third term should contain either the product of two currents or the square of a current, so that the expression is also wrong in the matter of dimension. A reader having Mr. Hay's book at hand will perhaps be able to find his way through the author's mathematics, but without such aid he had better skip the part on p. 195.

The author seems to pin his faith to the system, almost universal in America, of transmitting by three-phase current and converting into continuous current by means of rotary converters in substations. Motor generators, direct working, or the use of boosting batteries are not even mentioned. The important matter of heating of transformers and means of cooling is dealt with in less than two pages of general remarks, but to make up for this we get plenty of catalogue pictures of plant installed by the two leading American companies. Chapter ix., treating of insulating oils, is instructive. On p. 234 a curve is given showing the enormous influence on the insulating property of the oil of even slight traces of moisture, and the specification given on p. 239 should prove useful.

GISBERT KAPP.

## OUR BOOK SHELF.

(1) *Algebraic Equations.* By G. B. Mathews, F.R.S. Pp. viii+64. (2) *The Theory of Optical Instruments.* By E. T. Whittaker. Pp. viii+72. Cambridge Mathematical Tracts, Nos. 6 and 7. (Cambridge: The University Press, 1907.) Price 2s. 6d. each net.

(1) THE solution of a given equation is a problem which has attracted the attention of many of the greatest mathematicians. In this tract we have a short summary of the results arrived at. The solution depends on the properties of a certain permutation-group called the Galoisian group; if this group is soluble, the equation is solvable by radicals. Interesting types of soluble groups are cyclical, Abelian, and metacyclic groups. To each of the corresponding equations is devoted a chapter in which are explained the application of cyclical groups to cyclotomy, the dependence of Abelian on cyclical equations, and Kronecker's solution of the metacyclic equation. Prof. Mathews's masterly epitome of the subject is not very easy reading, and he assumes some knowledge of Tschirnhausen's transformation, the theory of permutation-groups, &c. The student will probably have to prepare himself for the study of this tract by reading some more elementary treatise on the same subject (*e.g.* Dickson's "Algebraic Equations"), and some book on groups, such as Burnside's.

(2) Dr. Whittaker does not follow Prof. Mathews in writing for the advanced mathematician, but appeals in the first place to those students of physics to whom mathematics is interesting chiefly for its applications. The professed object is to give "a simple theoretical account of those defects of performance of optical instruments to which the names of coma, curvature of field, astigmatism, distortion, secondary spectrum, want of resolving power, &c., are given." Limitations of space necessitate in places proofs which, though clear, are rather too concise; but except for this the beginner will find the tract fairly straightforward reading. The author has succeeded in producing a book which will prove remarkably interesting, not only to the user of optical instruments, but also to any student of mathematics. The leading principles and results are very attractively presented, and can be readily grasped without plodding through every detail of the somewhat laborious approximations which the subject at times requires.

H. H.

*Detection of the Common Food Adulterants.* By E. M. Bruce. Pp. vii+84. (London: A. Constable and Co., Ltd., 1907.) Price 5s. net.

THE United States used popularly to be looked upon as *par excellence* the land of wooden nutmegs and similar examples of perverted manufacturing ingenuity. Perhaps, therefore, it is fitting that what our author calls "the great pure food reform" should find especial favour there. Be that as it may, there has undoubtedly arisen in the States a quickening of interest in the matter of food adulteration; wherefore Mr. Bruce speaks of health officers, food inspectors, chemistry teachers, and even students being constantly called upon to test the purity of various foods—at whose instance is not quite clear. He proposes to help them and others in this task, which he says "usually involves nothing more than making simple qualitative tests for adulterants," by bringing together in one small book the best and simplest qualitative methods of detecting all the common sophistications of foodstuffs.

As a collection of recipes the work is good; in other respects it commands but qualified admiration. For the glorified cookery-book in chemical literature we have no great liking, and this compendium of "tests" is little more. The numerous pitfalls which beset the unwary are rarely indicated in the directions given; and the reasons for the various operations are left for the operator to discover for himself. Now this is well enough if the person using the book is already a master of his craft, knowing the pitfalls and how to avoid them, cognisant of the why and wherefore of his procedure, and only employing the work as a convenient collection of notes wherewith to refresh his memory when applying the various processes. But in the hands of the unpractised person, whether student or "inspector," it is quite another matter. Differences of conditions, apparently slight, may lead him wholly astray. It would be well enough for the enthusiastic student or teacher to test his breakfast bacon for borax, or his morning milk for added water, provided he does it merely for his private information; only in that case it would not benefit the pure-food movement much. But if he is going to lodge a serious complaint on the strength of his discoveries, it would be well, also, first to have those discoveries confirmed by a practised analyst. Otherwise there may arise unpleasant references to the law of libel.

The experiments are well selected and tersely described. As a compendium of some of the best qualitative tests for ordinary food-adulterants the book will be useful, especially to the man who already knows how to apply the processes. C. S.

*Altitude Tables.* Computed for Intervals of Four Minutes between the Parallels of Latitude 0° and 30°, and Parallels of Declination 0° and 24°. Designed for the Determination of the Position Line at all Hour Angles without Logarithmic Computation. By Frederick Ball. Pp. xxxiii+245. (London: J. D. Potter, 1907.) Price 15*s*. net.

SINCE the notice of the first part of this work appeared in NATURE of February 20, the companion volume for latitudes 0° to 30° has been published, making these tables complete between the parallels of 60° N. and 60° S. By their means the navigator can with facility and rapidity determine his position by the observation of any heavenly body the declination of which does not exceed 24°, and, as the latitude and declination are interchangeable in the tables, they are consequently available for all stars up to 60° in declination between 24° N. and 24° S.

This valuable contribution to scientific navigation will be appreciated by all navigators who employ the "New Navigation"—Captain Marcq St. Hilaire's method—as a practical and direct help in saving the tedious computation of the altitude required in the problem. The tables will undoubtedly tend to popularise that excellent method, which has hitherto been neglected by so many navigators, mainly on account of the lengthy calculations entailed, and more especially when it is realised that their practical utility equals their mathematical exactness.

The introduction to each volume fully explains the various uses of the tables, so that no difficulty need be experienced when employing them. The book is of a handy size and well bound, with clear type well arranged and spaced, so that the navigator with but little light and limited time will find a pleasure in using it. MIREMONT.

*Logarithmic and Other Tables for Schools.* By Frank Castle. Pp. 36. (London: Macmillan and Co., Ltd., 1908.) Price 6*d*.

THE introduction of more practical methods in the teaching of mathematics in schools has led to an increasing demand for inexpensive tables of logarithms, values of trigonometric functions, and other data which pupils are now encouraged to use at quite an early stage of their mathematical work. Mr. Castle has compiled a series of four-figure tables which will meet every need of mathematical classes in schools, and be of great service in school laboratories. The tables include logarithms and antilogarithms, natural and logarithmic sines, cosines and tangents, degrees to radians and radians to circular functions, hyperbolic logarithms, powers, roots and reciprocals, and exponential and hyperbolic functions. The type is clear and the style attractive, and these qualities, combined with the wide scope and low price, should ensure a wide popularity for the tables.

*Praise of a Simple Life.* Edited by E. A. Baker. Pp. x+258. (London: George Routledge and Sons, Ltd., n.d.) Price 2*s*. 6*d*. net.

MR. BAKER has compiled a collection of extracts on the theme of a life according to nature from classical writers to the end of the eighteenth century. These utterances are arranged in four sections, which the editor calls respectively the antique world, the dawn of a new age, the age of expansion, and the age of reason. More than four-score authors are drawn upon, so that the reader is provided with a diversity of points of view. The volume is dainty, will go into the pocket, and should be a favourite with readers of poetic temperament.

## LETTERS TO THE EDITOR.

*[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.]*

### On the Radio-activity of Potassium and other Alkali Metals.

IN the course of some experiments made by them on the radio-activity of a series of salts which had hitherto been considered inactive, Messrs. Campbell and Wood (Proc. Camb. Phil. Soc., vol. xiv., part i., p. 15, 1907) found that potassium salts exhibited a radio-activity greater than that of any other substance previously examined which did not contain any of the so-called radio-active elements.

In seeking for the source of this activity, these experimenters found it impossible to separate out any active impurity from the salts examined, and they were led by the results of their investigation, which included measurements on the activities of a limited number of the compounds of potassium, to conclude that the activity originated with the potassium itself, and was an atomic property of that metal.

In a later paper (Proc. Camb. Phil. Soc., vol. xiv., part ii., 1907) Campbell described some additional experiments dealing with the character of the radiation emitted by the potassium salts, and in concluding expressed the opinion that the radiation consisted of $\beta$ rays possessing an average velocity less than that of the $\beta$ rays of uranium.

During the last few months the writer, in collaboration with Mr. W. T. Kennedy, has made, in the Physical Laboratory at Toronto, a close examination of the radioactivity of a large number of potassium and other salts, and while the results of this examination confirm the discovery of Campbell and Wood that potassium salts generally possess an exceptionally high activity and emit a radiation possessing considerable penetrating power, they do not support the conclusion that the activity of these salts is a *normal* atomic property of potassium, and that it is always directly proportional to the amount of that metal present in the salt.

In measuring and comparing the activities of the different salts, these were spread in turn in thin regular layers on a shallow tray, which was placed on the bottom of an ionising chamber 40 cm. long, 26 cm. wide, and 28 cm. deep. The saturation currents through the air in this chamber were measured with a sensitive quadrant electrometer, and were taken as measures of the activities of the different salts. Experiment showed that the saturation current increased with the thickness of the salt layer up to between 2 mm. and 3 mm., and for greater thicknesses remained constant.

The investigation included the examination of some thirty specimens of potassium salts, and thirteen samples of the salts of the other alkali metals. As a result of this examination it was found :—

(1) That samples of a selected potassium salt obtained from different sources exhibited widely differing degrees of activity. Two chlorides of potassium, for example, were found to differ by more than 40 per cent. in their activities, and two of hydroxides by an almost equal amount. In the case of cyanide of potassium, the variation in activity was especially marked, as two samples of this salt exhibited activities which were approximately only 5 per cent. and 20 per cent. respectively of that shown by a number of other samples of the same composition. A sample of potassium sulphite, too, was found to possess an extremely small activity.

With the majority of the salts, however, the variations were not so marked, but the differences observed, even when due allowance was made for the varying densities and states of division of the salts, were so extensive and of such magnitude as practically to preclude the view that the activity of potassium and its salts was connected with a *normal* atomic property of the metal.

(2) That while metallic sodium and several sodium salts did not exhibit the slightest trace of activity, some samples of sodium chloride, obtained in the form of rock salt, showed an activity comparable with that exhibited by a number of the potassium salts. This result, taken in conjunction with the low value obtained by Elster and Geitel in their measurements on the conductivity of air in a salt mine, would indicate that very probably some active impurity was present in the samples of rock salt examined.

(3) That with the exception of ammonium chloride, which exhibited a feeble activity, none of the lithium and ammonium salts examined showed the slightest trace of radio-activity; that a sample of rubidium alum was found on examination to exhibit an extremely small activity, and that a sample of cæsium chloride exhibited one which was only just measurable.

## Chemical Analyses of Water from Dew Ponds.

I have been interested in the reviews of books and articles which have appeared in Nature from time to time on the subject of dew ponds; and it occurred to me that the chemical analysis of the water of these ponds would help to settle the question of the origin of the water. This is a method used to some extent by sanitary authorities. I have had the opportunity of obtaining some specimens of water from different districts, and the specimens have been analysed by Mr. Claude Saville Grace, one of the students at this institute.

The first specimen (*a*) came from a dew pond on the southward down to the north of Ramsbury, Wiltshire. The pond is on the flat upland near the 693-feet mark on the 1-inch Ordnance map south of Aldbourne. The formation is chalk, so that analysis would immediately settle the point as to whether the water had come through the chalk or had been condensed from the air. The other two specimens, (*b*), (*c*), come from St. Boniface Down, north of Ventnor, Isle of Wight. The pond (*b*) is near the 787-feet mark, almost at the highest point of the down; the second pond (*c*) is on the neck between St. Boniface and Shanklin Downs. The downs are chalk masses lying on Greensand rock. I have added the analysis of the St. Boniface spring water, a spring on the south side of the down facing Ventnor, about 450 feet above sea-level. It is locally known as a wishing well, and its chemical peculiarity is that it contains sulphuretted hydrogen in small quantity. It undoubtedly comes out of the chalk, and the sulphuretted hydrogen is due to the decomposition of pyrites which occurs in masses in the chalk.

| | $CaCO_3$ parts per 100,000 | Cl parts per 100,000 | |
|---|---|---|---|
| (*a*) Ramsbury pond ... ... | 3·6 ... | 0·75 ... | inland |
| (*b*) St. Boniface pond ... ... | 4·3 ... | 3·5 ... | near sea |
| (*c*) Shanklin pond ... ... ... | 7·7 ... | 3·4 ... | .. |
| (*d*) St. Boniface Wishing Well. | 23·9 ... | 7·3 ... | traces $H_2S$ |

The quantities of $CaCO_3$ indicate to me that the waters are, in the cases (*a*), (*b*), (*c*), condensed waters which have been lying in the pond sufficiently long to take up a little $CaCO_3$. The ponds near the sea show increased chlorine, probably from salt spray blown up from the sea. The sulphuretted hydrogen shows the origin of the wishing-well water in the deep chalk.

To me there is very little doubt that all three ponds are simply water butts in which rain water is stored. Inspection of the ponds shows that they have much larger catchment areas than simply the water area, and the area is generally more than nine times that of the pond. We have to remember that for circular ponds and catchment areas of radii 1 and 3 respectively a rainfall of 20 inches would mean a depth of 180 inches (15 feet) when collected into the pond area, so we can easily understand the presence of water all the year round under these conditions.

It is interesting to note that a fresh-water pond is easily distinguished from the hard-water pond by the waterweed growing in the former. I have noticed the same carex in all the fresh-water ponds.

## The Reflection of Distant Lights on the Clouds.

I do not know whether observations have ever been made to determine how far the reflection of distant lights on the clouds may be seen. It may possibly, however, be of some interest to know that the lights of London may at times be seen in this way at a distance of at least fifty miles. At 11 p.m. on April 30 the reflections of the lights of several neighbouring towns were unusually bright as seen from here. The altitude of the Portsmouth glare was about 10°; the distance of the centre of Portsmouth is about 12·5 miles; the cloud height was therefore about 2·2 miles. Over Hindhead and Blackdown a bright band of light was visible. Circumstances prevented me from measuring its altitude, but I estimated it as one or two degrees. Now London lies exactly in this direction, and fifty miles would bring one to the well-lighted area of south London. If the cloud height were uniform, the altitude of the reflection at this distance should have been a little more than 2°. The only other large town in the same direction is Guildford; the altitude of its glare should have been 5°. I do not think I could have made so large an error in estimating the altitude, but apart from this the Guildford glare would not stretch along the horizon for more than 2°, while the observed band of light stretched for at least 10°, and possibly more, for trees bounded the view to the west and the downs to the east.

## Jupiter's Eighth Satellite.

The discovery at Greenwich Observatory of Jupiter's eighth satellite, its great distance from the planet, and its retrograde motion, have excited the interest of the astronomical world.

Until more extended observations have led to a more certain knowledge of the orbit, speculation is premature. But it is impossible to resist the conjecture that there is a bare possibility that the object is really the long lost Lexell's comet, which in 1770 was describing an elliptic orbit with an eccentricity of 0·7858, with a periodic time of $5\frac{1}{2}$ years, in a plane inclined 1° 34′ to the ecliptic; the next return of which it was impossible to observe from the earth's position; which about 1779, August 23, approached Jupiter within 0·01 of the earth's mean distance from the sun; and which has not been again observed.

At that distance Jupiter's attraction exceeds that of the sun in the proportion of at least 200 to 1, and the distance from one of the satellites may have been very small. In this way it is not altogether impossible that the comet may have been diverted into an elliptic orbit round Jupiter, and a retrograde motion round the planet would be as likely as a direct motion to ensue. The intervention of a satellite is essential, and this, combined with the observed large angular distance from Jupiter in one part of its orbit, implies a large eccentricity. Should further observations reveal a moderate eccentricity, the impossibility of identity between this satellite and Lexell's comet will be proved.

The Athenæum, May 6. GEORGE FORBES.

### The Corrosion of Iron and Steel.

IN a letter to NATURE of April 16, Dr. Frank Clowes states his belief that pure lead will dissolve to a slight extent in perfectly pure water "as iron did in the experiments made by Whitney and repeated by the American investigators, when they brought iron into contact with water under conditions similar to those which I had secured."

The American investigators here referred to are W. H. Walker, Cederholm, and Bent, who have recently studied the process of the rusting of iron (Journ. Amer. Chem. Soc., 1907, xxix., p. 1251), and agree with Whitney in regarding the whole subject as an electrochemical one.

With reference to the behaviour of lead in contact with water, I have nothing to say, for although the study of the corrosion of metals has been pursued by me for several months, my observations have not as yet been extended to lead. I wish to point out, however, that if this metal does dissolve to an appreciable extent in water as Dr. Clowes suggests, then the analogy adopted by this gentleman is open to criticism. I have made a very careful study of the process of the rusting of iron, and my results point conclusively to the fact that it is primarily the result of acid attack. These results will, I hope, shortly appear in print; it is unnecessary, therefore, to enter into any detail here. Nevertheless, one or two general remarks may prove of interest.

Walker and his co-workers found that if water in which iron has been boiled is concentrated to a few drops, the presence of iron can be detected by chemical means. It is clear that if the concentration of the iron in solution can be increased by the evaporation of the water, as these authors say, the same result should be obtained by protracted boiling of the water and iron, keeping the volume of the former constant by using a reflux condenser.

My experiments show, however, that such is not the case. The presence of traces of iron discovered by Walker, Cederholm, and Bent is not, therefore, to be ascribed to the action of pure water alone, but to that of traces of dissolved carbon dioxide.

In a very interesting series of investigations, Leduc (*Comptes rendus*, 1906, cxlii., p. 149) has recently shown that all the dissolved air cannot be expelled from water by the mere process of boiling. He further calculates that at least 1 c.c. of gas remains in a litre of water even after thorough boiling. Since carbon dioxide is not only much more soluble than oxygen and nitrogen, but also combines with the water to form carbonic acid, it is not unreasonable to suppose that a considerable percentage of this residual gas is carbon dioxide. This will effect the solution of a trace of iron. Although this quantity may be too minute to detect at once by chemical means, its concentration can be greatly increased by evaporating to small bulk, when the characteristic reactions for iron may be obtained. On the other hand, protracted boiling with reflux condenser cannot increase the concentration of the iron, since the amount of carbon dioxide remains the same. The extreme difficulty of removing all traces of this gas from water is not generally realised by chemists, and the precautions adopted by Walker and his co-workers were not sufficiently refined—hence their results. A single molecule of carbonic acid is sufficient, theoretically, to cause the corrosion of iron (see my remarks, NATURE, September 27, 1906), and I have shown that in practice a very few molecules are operative.

There can be no reasonable doubt, therefore, that the electrolytic theory is wholly inadequate.

In a letter to NATURE of October 11, 1906, Mr. Richardson asks if the rusting of iron is not caused by bacterial agency. As no reply has been given, it may not be out of place to deal with the question here. The suggestion is not new. Schorler, Beythien, Adler, Raumer, and others have directed attention to a bacterium, *Gallionella ferruginea*, which obtains its life energy by oxidising ferrous carbonate or organic ferrous salts with the precipitation of rust. But no organism has been found capable of feeding on metallic iron. Indeed, if one such were found, it would have to effect the solution of the iron by some presumably acid secretion, and this brings us back to the acid theory of rusting.

J. NEWTON FRIEND.

### Fault Lines in the Atlantic.

IN Prof. J. Milne's discourse at the Royal Institution which appeared in NATURE of April 23 is given an interesting map on p. 593 showing the folds and probable direction of fault lines in the Atlantic. In that map is shown the mid-Atlantic "rise" extending to about 40° S. The map, however, would have been more interesting had Prof. Milne included in it the recent bathymetrical researches of the *Scotia*, which were described in a preliminary paper in the *Scottish Geographical Magazine* in August, 1905. Here it is shown that the Scottish expedition sounded out this "rise" for a thousand miles further south than Prof. Milne has marked it, and also that that "rise" has probable connection with another running in a more or less E.N.E. and W.S.W. direction from the south of South America through South Georgia and the Sandwich Group, and also from Graham Land, Antarctica, through the South Orkneys and the Sandwich Group, thence passing eastward through Bouvet Island to Madagascar and the east coast of Africa. The extension of the mid-Atlantic "rise" continues the reflection of the South American continent, and again the transverse "rise" reflects the hypothetical and known portions of the coast-line of Antarctica. WM. S. BRUCE.

### The Pollination of the Olive.

As Knuth's great work on flower pollination, compiled from all available sources, says nothing whatever about the olive, I recently asked Prof. J. E. Coit, of Arizona, to look out for insects upon the flowers. He carefully examined many olive trees in flower at Tucson, and did not find a single insect at the flowers, with the exception of a thrips (apparently *Euthrips occidentalis*, Pergande), which occurred in great numbers. He kindly sent me some twigs with the Euthrips upon them, and I was able to observe that these insects were profusely dusted with pollen. No bees were seen at all. Prof. Coit adds:—"Olive pollen is formed and shed in such enormous quantities that I think the wind among the branches is the chief agent in pollination. If you jar a large branch of olive while it is in full bloom, a perfect cloud of *green* pollen will be seen to float away on the breeze."

Arizona, however, is not the original home of the olive, and the purpose of this note is to suggest that those who have an opportunity to see the plant in bloom in Mediterranean and other countries should make some observations.

University of Colorado, May 2.

### The Coloration of Birds' Eggs.

I SHOULD be very grateful if anyone could tell me whether there is anything known with regard to the egg-colour of birds. Is there here, by any chance, a field for investigation which may throw light upon the so-called Mendelian phenomena? Or is there yet any explanation of how the egg becomes coloured, or why?

66 Hallam Street, W. R. L. LESLIE.

## THE CRUISES OF THE "VALHALLA."[1]

IN taking with him as collector on the *Valhalla* a young naturalist and presenting the specimens obtained to the British Museum, Lord Crawford has set an excellent example to all yacht-owners who, from considerations of health (as in his Lordship's own case) or pleasure, enjoy the opportunity of cruising leisurely among islands of which the natural history is still imperfectly known. Not only does the systematic collecting of natural history specimens add largely, if undertaken in an appreciative spirit, to the interest and pleasure of such a cruise, but it may, as in the present instance, add very appreciably to zoological knowledge. For during two of the *Valhalla's* cruises, described in the present volume, no fewer than eleven birds were obtained, which in the opinion of the British Museum experts are entitled to rank as new species.

In obtaining the services of Mr. Nicoll as naturalist, the owner of the *Valhalla* may be considered to have been specially fortunate, as the book before us is evidently the work of an acute observer, who knows what to look for, and how to describe in readable language what he has seen. The selection appears indeed to have been fortunate in more ways than one, for the training and experience acquired during the three cruises doubtless aided Mr. Nicoll in obtaining his present post at the Giza Zoological Gardens, where he has every prospect of a successful career.

The first and longest voyage, during which no fewer than 38,000 miles were covered, consisted of the circumnavigation of the African continent, to which, however, a wide berth was given on the west side, where the vessel touched the Brazilian coast at Bahia. The second cruise was to the West Indies and back, during which the ornithology of the Caiman Islands was worked as fully as circumstances permitted; while the third and last was a voyage round the world, in the course of which the yacht touched at quite a number of interesting islands, including the Comoros, Seychelles, Aldabra, and Tristan da Cunha. It was this voyage that afforded by far the great majority of the new birds; while it is also the one which has acquired a historical celebrity on account of the sight of the "sea-serpent" off the Brazilian coast. Since reference has been made to this incident on a previous occasion in NATURE, it will be unnecessary to make special comment in this place, except to mention that Mr. Nicoll now expresses, apparently for the first time, his belief that the creature was a mammal.

At Punta Arenas the author was asked 50*l.* for a small fragment of the skin of the now well-known ground-sloth of the cavern of Ultima Esperanza—an offer which gives him the opportunity of stating that the creature is almost certainly extinct, as otherwise specimens would have been killed and offered for sale by the natives. If we have to abandon all hope of seeing a live ground-sloth, it is satisfactory to learn that the giant tortoises of Aldabra are still to the fore. On Aldabra itself there are only a few remaining, which the party was unable to visit, but in the Seychelles a number are now kept in a walled enclosure at Government House. While some were of huge size, others were but recently hatched; and it seems that these reptiles breed freely in captivity, and that all the islands of the group have tortoise-farms.

Another noteworthy event of the third voyage was a visit to Marie Louise Bay, in Praslin Island, Seychelles, for the purpose of inspecting the famous "coco-de-mer" trees, which grow in a small valley above the bay, and are found in a wild state nowhere else in the world. The author was informed that the huge nuts take many years to mature; while practical experience convinced him that even when they reach that stage their contents are insipid, and far inferior to the ordinary cocoanut.

"Coco de Mer" Trees, Praslin Island, Seychelles. From "Three Voyages of a Naturalist."

Did space permit, reference might be made to many other interesting passages in Mr. Nicoll's volume, which, although containing little that is absolutely new, may be commended as a well-written narrative of the experiences of an eager naturalist in remote islands.

## ALBERT DE LAPPARENT.

GEOLOGISTS throughout the world will be grieved to hear that one of the best known and most illustrious of their number, M. de Lapparent, has passed away after a brief illness. It seems but yesterday since, with so notable a company of his fellow-countrymen, he attended the centenary celebrations of the Geological Society here, apparently in the fulness of health, and with still many years of vigorous life before him. Lately, however, he had not been well, and for a time his condition had even given cause for some anxiety. But the danger seemed to have passed off, and his friends hoped soon to welcome him back to his place at the Academy of Sciences in Paris. But a rapid change for the worse supervened, and he died in the early part of last week at the age of sixty-seven years.

The loss sustained not only by geology, but by science at large, through the death of so accomplished a writer cannot at once be fully appreciated. It was not so much by the extent of his contributions to original research as by the philosophical discussion of all contemporary investigation regarding the history of the earth that he gained the commanding position which he held for so many years. His well-known essay on the Pays de Bray, published in 1879, proved what he could have achieved had he devoted himself to field-work. His "Traité de Géologie," which first appeared in 1881, showed the full bent of his genius by its luminous presentation of every department of the science, its admirably logical arrangement, and its characteristic elegance and clearness of style. The first edition formed a single volume, but in the course of a quarter of a century it was continually augmented and enriched, until, when the fifth edition was issued two years ago, it formed three volumes, with an aggregate of more than 2000 pages. This noble treatise will remain as its author's best monument. It has taken its place as an indispensable book of reference and suggestive guidance to every student of modern geology, and it will in future years be consulted as an ample exposition of the condition of the science at the beginning of the twentieth century.

The later editions of the "Traité," among many improvements and additions which the author's wide range of reading enabled him to make, have especially been marked by the numerous maps introduced into the text in illustration of the geographical features of different regions in successive geological periods. Following up the brilliant outlines of Neumayr and the generalisations of Suess, M. de Lapparent embodied in definite charts what he conceived to have been the distribution of land and sea throughout the ages of the earth's history. No one can peruse these restorations without a sense of the enormous amount of research which they involved in the published geological literature of every part of the globe. Although they could only be tentative, for the data obtainable are often meagre and not always trustworthy, yet as sketches of what may have been the geography of the earth's surface in the remote past they are replete with interest and suggestiveness. The author's other minor text-books on geology, mineralogy and physical geography, distinguished, as they are, by the same lucidity of arrangement and elegance of expression, have been of the greatest service in furthering the progress of these branches of science in the general advance of education.

There was something eminently attractive in de Lapparent. His gentle and kindly manner drew men of all nationalities to him. His charm as a speaker led to his being continually called upon to address an assembled company. The well-modulated voice, the felicitous choice of words, and the flashes of humour made his speeches delightful to listen to. Under a playfulness of conversation he would from time to time reveal the depths of his serious nature. He was an eminently religious man, and sacrificed not a little in life for the sake of his convictions. No temptation could induce him to abandon the Institut Catholique, where from its foundation he continued to be one of its pillars of strength. So widely recognised were his personal qualities as well as his scientific distinction and his literary accomplishments, that on the death of Berthelot last year the Académie des Sciences could find no more fitting successor as secrétaire perpétuel than Albert de Lapparent. By his death the cause of science has been deprived of one of its most strenuous and successful advocates, and those who were privileged with his friendship have to mourn one whose memory they will never cease to cherish.

A. G.

## M. ALBERT LANCASTER.

M. LANCASTER, whose death was announced recently, was connected with the Royal Observatory of Belgium for so many years that it is impossible, as it would be undesirable, to disconnect his career from that of the institution he served so well. He saw the observatory grow in extent and reputation under several directors, from Quetelet to Lecointe, and gave loyal and devoted service to each. The site shifted from Brussels to Uccle, where a new and modern observatory replaced the modest building that long did duty, but M. Lancaster remained true to its fortunes. With the change of building and with the enlargement of its usefulness, M. Lancaster had to adapt himself to new conditions, but throughout the continual onward development, his energy and industry contributed not a little to the maintenance of the prestige of the observatory with which he was so long connected.

In three distinct ways M. Lancaster deserved well of science and his countrymen. In his capacity of librarian to the observatory, he appreciated the rapid extension of astronomical literature, and early recognised the desirability of making known to all what had been accomplished by individual effort, and of placing at the disposition of those who were engaged in a particular inquiry the results achieved by others similarly engaged. He took steps to give practical effect to this view, and not only did he publish several useful time-saving compilations, but he was led to the collection and arrangement of a vast mass of information, which in collaboration with the late director, M. Houzeau, was issued as an astronomical bibliography. Later and more complete compilations have necessarily superseded these early efforts, but Houzeau and Lancaster were the first to make any serious attempt to bridge the interval that separated the work of Lalande in 1802 from that of modern times.

Again, by the encouragement and assistance he gave to amateurs, M. Lancaster did much to create an interest in meteorology and astronomy throughout Belgium. He founded and edited the popular review, *Ciel et Terre*, which made the study of physics and astronomy attractive to the many, and fostered the true spirit of scientific inquiry. He gave to this periodical, which first appeared in 1880, the closest attention, wrote many articles for its pages, and by his enthusiasm made it not only a vehicle for the diffusion of information, but the means of encouraging a vast amount of amateur work in very varied directions.

Lastly, since 1898, he became director of the Meteorological Department of the Royal Observatory, and the successive volumes that have appeared bearing upon the climatology of Belgium testify to his skill and energy. He was well qualified for this position because meteorology had for him many attractions. As early as 1876 he tried to give greater uniformity to the method of meteorological observing by publishing a code of instructions for observers, and throughout an active life he exhibited a keen interest in this branch of physics. His rain-chart of Belgium is a specimen of what he could accomplish by ingenuity and painstaking industry.

If M. Lancaster's services were not brilliant, they were persistent and practical. He admirably filled the position in which he was placed, and by his comparatively early death at the age of fifty-nine years the observatory has lost a capable and devoted servant. In his lifetime his scientific ardour was adequately acknowledged. He was a member of many learned societies at home and abroad, and in addition to being Chevalier de l'Ordre de Léopold, he was decorated with the Ordre de la Couronne du Congo, La Croix civique de 1re Classe, and la Croix commémorative du Règne de S. M. Léopold II.

## *NOTES.*

THREE years ago the late Sir Michael Foster described in these columns (vol. lxxi., p. 443) the foundation by Prof. A. Mosso of the Col d'Olen Laboratory, at an altitude of 3000 metres on the southern slopes of Monte Rosa. On that occasion it was pointed out that the financial condition of the laboratory left much to be desired, and the hope was expressed that Prof. Mosso would secure ere long the necessary additional funds required. We are glad to learn, from a pamphlet descriptive of recent work at the laboratory, that the income of the institution has improved greatly, the subscriptions now reaching 117,504 francs, being very near the 120,000 francs originally considered necessary. It has been decided that the affairs of the laboratory shall be administered by a committee consisting of the professors of physiology, botany, and hygiene in the University of Turin, with the president and treasurer of the Italian Alpine Club. Prof. A. Mosso is the president, and Prof. O. Mattirolo the secretary. As was mentioned last week, two places in the laboratory are reserved to England, on the nomination of the Royal Society. Applications for a place should be made in the first instance to the Royal Society.

WE regret to see the announcement of the death, in his eighty-fourth year, of Prof. K. Möbius, professor of zoology in the University of Berlin.

ON Thursday next, May 21, Dr. Alexander Scott will deliver the first of a course of three lectures at the Royal Institution on "The Chemistry of Photography."

PROF. A. LAWRENCE ROTCH, the founder and director of Blue Hill Meteorological Observatory, Massachusetts, U.S.A., has been elected an honorary member of the Royal Meteorological Society.

A REUTER message from Athens announces that the German Emperor has presented Prof. Dörnfeld, head of the German Archæological Institute there, with a sum of 5000 marks (250*l.*) for the purpose of starting excavations on the site of the ancient Pylos.

AT the meeting of the National Academy of Science held in Washington on April 23, the following foreign associates were elected:—Prof. Svante A. Arrhenius, Stockholm; Prof. J. Larmor, Sec.R.S., Cambridge; Dr. Ivan P. Pavlov, St. Petersburg; Prof. Hugo R. van Seeliger, Munich; and Prof. T. Barrois, Lille.

THE death is announced of Dr. Hermann Wedding, professor of metallurgy at the Berlin School of Mines. He was an honorary member of the Iron and Steel Institute, and in 1896 received the Bessemer gold medal of that society. He translated Dr. Percy's works on metallurgy into German, and was the author of a large number of important metallurgical treatises.

THE Paris correspondent of the *Times* states that, within a year, in virtue of a contract with a French firm, Spain is to be provided with wireless telegraphy stations. The Canaries and the Balearics are to receive, respectively, seven and two stations, which will keep them constantly in touch with the fifteen stations of the Peninsular coast. It is anticipated that radio-telegraphic communications will shortly be arranged between Pernambuco and Tenerife. In that case the Spanish stations will form a link between Europe and South America.

IN the Journal of the Franklin Institute (vol. clxv., No. 4) Dr. Persifor Frazer traces the history of the Franklin Institute from its foundation in 1824 to the present time, giving portraits of the eminent men who have helped in the development of the society. A subscription of 50,000 dollars, given to the building fund by Mrs. Anna W. Walker in memory of her father, has assured the institute a new lease of life under greatly improved conditions.

THE death is announced of Mr. Caleb Barlow, chief preparator of fossils in the British Museum (Natural History). Mr. Barlow entered the British Museum as a mason in 1874, and gradually acquired remarkable skill in the preparation and restoration of fossil skeletons. He was especially successful in mounting imperfect specimens and modelling missing parts to complete them. Much of his unofficial time was devoted to other institutions, and examples of his skilful work are to be found in many museums.

THE *Comptes rendus* of the Paris Academy of Sciences for May 4 contains a communication, by M. Alfred Angot, with respect to the application of wireless telegraphy to the forecasting of the weather. The communication is practically amplifying the note by M. Bigourdan, to which reference was made in NATURE of May 7, and gives a *résumé* of the present situation. It is mentioned that for the last year the Meteorological Office has received each day wireless messages from several ships, the information being regularly published in the Daily Weather Report. M. Angot states that this information adds somewhat to our knowledge of the state of the atmosphere over the Atlantic. He directs attention to the report of Dr. Shaw on this subject to the International Meteorological Committee at Paris in September, 1907. It is pointed out that the obstacle to the extension of the use of wireless messages for weather forecasting is one purely of finance, and the necessary expense precludes the English and French weather offices from taking full advantage of the opportunity afforded.

"THE Daylight Saving Bill," which passed its second reading in the House of Commons on March 26, and is now before a committee of the House, proposes that early on the morning of each of the first four Sundays in April all the public clocks shall be set forward twenty minutes and be set back twenty minutes on each of the first four Sunday mornings in September. Cape Town has been cited as an example to show how easily the origin of public time can be changed. But Sir David Gill shows, in a letter in Tuesday's *Times*, that even to change the origin of time once for all requires careful preparation, and that to make changes in the manner proposed by the Bill must lead to confusion. Instead of adopting this method of making use of daylight hours, Sir David Gill suggests a change in our national habits and customs, such as was advocated in an article in NATURE of February 20 (vol. lxvii., p. 372). He points out that if, for example, the Bank of England could be persuaded to open business at 9 a.m. instead of 10 a.m. from April 1 to the end of September, no doubt all other banks and offices would follow suit, and if employers of labour would open their works an hour earlier in the spring and summer months the objects of the Bill would be in great part gained without difficulty or confusion.

THE news of the death on May 10 of the Rev. Father Eugene Lafont, S.J., C.I.E., has been recently notified from India, and will be received by his numerous friends with great regret. He died in Darjiling, the hill station of Bengal, to which place he went some little time ago. His age was seventy-one years, and he lived almost continuously in Bengal, with perhaps one visit to Europe, for about forty-three years. Father Lafont will long be remembered in Bengal for his distinguished scientific attainments and for the enthusiastic zeal with which he fostered the study of practical science by every means in his power among Indian and Eurasian students. He was, however, an educationist rather than an original thinker or original worker, but he did yeoman service for science in Bengal. For many years he was professor of physical science at St. Xavier's College, in Calcutta, and afterwards he became rector of the same institution. This college is one which makes provision for the education of the domiciled European and Eurasian population of Calcutta and Lower Bengal, and in this way Father Lafont secured great influence among these classes. The college is also popular with native Indian gentlemen, and by his influence with Rajahs and other men of note Lafont was able to obtain several endowments for the purchase of scientific apparatus. This college possesses an excellent supply of most costly lecture apparatus, especially of the kind necessary for popular lecture demonstration, in which way that college is better equipped than any other in India. Indeed, in addition to his sterling qualities as an educationist, Father Lafont was a born popular scientific lecturer, and had a peculiar facility for putting dry facts in a popular way and an equal facility for making his lectures interesting by excellent experimental illustrations. For more than thirty years he was a prominent fellow of the Calcutta University, both under its former and its present constitution, and he held a number of prominent honorary posts under it, while his influence is to be found in many of the science courses of study as at present arranged. He was always held in the greatest respect and esteem by all his fellow-workers, and was most popular with all Indian gentlemen. It was to a considerable extent owing to his cooperation and influence that the late Dr. Mahendra Lal Sarkar, C.I.E., was able to start, some thirty years ago, a society called the "Indian Association for the Cultivation of Science" in Calcutta, an association which is still doing very useful work in diffusing scientific knowledge among various classes of Indian gentlemen. Father Lafont was for many years an active supporter of this society, and was one of its honorary lecturers, and later on became its vice-president. His name will thus be long kept in mind as that of one of the pioneers of scientific education in Bengal, and his death is hence a great loss, especially at this time, when strenuous efforts are being made to put education in Bengal on a satisfactory basis.

WE have to acknowledge the receipt of the ninth fasciculus of the "Fauna of New England," now in course of publication in Occasional Papers of the Boston Society of Natural History. It is devoted to a list of the spiders (Araneida), which has been drawn up by Elizabeth B. Bryant, and comprises 309 definitely recognised species, together with about a dozen others which are at present unrecognised.

WE are indebted to the author, Dr. E. Balducci, for a copy of a paper entitled "Morfologia dello Sterno degli Uccelli," published by C. and G. Spighi, of Prato, at the price of five lira. It is illustrated by a large number of figures of the sternum in a numerous series of nocturnal and diurnal birds of prey. After discussing the bearing of the characters of this part of the skeleton on the relationship of the Striges to the Accipitres, the author points out that not only can the different species of these two groups be recognised by means of the sternum, but that there are also recognisable sexual features in the sterna of individual species.

IN the February issue of the Proceedings of the Philadelphia Academy, Mr. F. W. True discusses the fossil cetacean beak from Charles County on which Cope founded the genus and species *Rhabdosteus latiradix*, together with certain other fragmentary beaks and teeth which have been assigned to the same form. In Mr. True's opinion, it is probable that while the teeth belong to the widely spread genus Schizodelphis, the type beak is generically distinct. Of the other two beaks, one apparently indicates a dolphin allied to the Amazonian Inia, while the third may be provisionally assigned to the extinct genus Priscodelphinus.

PROTECTIVE colouring in South African birds forms the subject of an article by Mr. A. Haagner in the April issue of the Journal of the South African Ornithologists' Union. One of the most remarkable instances of such protective resemblances is furnished by the rufous-cheeked nightjar. Noticing what appeared to be a strange protuberance on a bough, the author on one occasion ascended a tree to ascertain its real nature, when he was astonished to see a nightjar fly off. "The bird had been sitting lengthways on the bough, flattened up against it, and the assimilative nature of its plumage was most marked, the mottled grey-brown and rufous colouring harmonising with the bark of the tree on which the nightjar sat."

To the first number for the current year of the *Bulletin de la Classe des Sciences* of the Académie Royale de Belgique, Comte Goblet d'Alviella contributes a memoir on the excavations at Court-Saint-Etienne, in the valley of the Orne, one of the richest prehistoric cemeteries in Belgium. The remains discovered consist of articles in bronze and iron, with numerous examples of pottery. Of bronze, the most remarkable article is either a portion of a sword-belt or of a horse bridle. In some of the mortuary jars the bones of children have been discovered, pointing either to the burial of infants with their dead mothers or to a sacrifice intended to ensure the fertility of the crops. The cemetery appears to be of the well-known Hallstadt period, and the researches of Comte d'Alviella are of much interest in relation to the extension of the bronze and iron culture from the south into northern Europe.

IN the fourth part of vol. xvii. of the Proceedings of the Royal Physical Society, Edinburgh, Prof. D. C. M'Intosh discusses variation in the lobster, both in respect of the relative sizes of males and females, the relative numerical proportions of the two sexes, and in regard to the number and arrangement of the genital apertures in the male. In respect to the first point, measurements show that the female is shorter than her partner, while she also seems to be more slenderly built. The relative numbers of the two sexes cannot yet be definitely determined; it is true that more males than females are captured, but this may be due to their larger dimensions, which prevent them from escaping through the meshes of the nets, and may also lead to a smaller number being rejected as unsaleable on account of inferior size. Finally, it is demonstrated that the occurrence of additional genital apertures is by no means uncommon.

The March number of *Biometrika* contains two papers dealing with the inheritance, in two separate instances, of split hand and foot deformities in man, the so-called "lobster-claw," in which Messrs. Lewis and Embleton show that the deformity is inherited and varies in degree, although not in kind. The nature of the deformity is illustrated in a series of radiographic plates. The authors discuss the application of Mendelism to their results, and conclude that, despite the apparent segregation, the transmission is not governed by Mendelian laws. In an addendum Dr. Lewis cites cases in which hypophalangia or brachydactylia has been transmitted through normal individuals, so that the basis for the Mendelian application fails. "It may be," he urges, "and very probably is the case, that Mendelism applies to certain hereditary human deformities; but the conclusions which are being drawn, or implied, conclusions having a serious sociological aspect, are at present ahead of the facts at our disposal." In the family discussed by Mr. Pearson, there was no instance of transmission through a normal individual, but the Mendelian ratios do not fit. This case is illustrated by plates bringing out the variability of the deformity.

Among several articles of more than usual interest in the February number of the *American Naturalist*, attention may be directed to one on the law of geminate species, by Dr. D. S. Jordan, of Stanford University. Starting with the axiom that in any region the nearest representative of a given species is to be found, not in the same region or in a remote region, but in a neighbouring district separated from the first by a barrier of some kind or other, the author points out that this law rests on the fact that the minor differences separating species and races of animals are due to some form of segregation or isolation. On account of the presence of some obstacle or barrier, the members of one group are prevented from breeding with those of another minor group or with the bulk of the species, and as a result local peculiarities arise, which eventually develop into distinct races or species. On the other hand, where a number of individuals of a species are simultaneously modified in the same way by similar conditions of food or climate, they show no permanence in heredity, and should have no permanent place in taxonomy. This is exemplified by Mr. Beebe's researches into the effects of moist air in inducing dusky colours in birds, which demonstrate the impermanence of the groups or subspecies characterised by dark shades of colour developed in regions of heavy rainfall. These words, it may be added, should be well weighed by those taxonomists who name local forms characterised by the development of either unusually pale (in desert districts) or unusually dark (in moist forest regions) colouring. The fishes on the two sides of the Isthmus of Panama, which have been separated since the late Miocene or early Pliocene, afford excellent examples of geminate (twin, or representative) species, or perhaps, as we might in many cases better say, races.

In a letter to Nature of October 3, 1907, Mr. Ainley Walker asked for definite evidence bearing upon the widespread belief in many countries that the stings of bees act both protectively and as a cure for rheumatism. Dr. J. Newton Friend, North Terrace, Mildenhall, Suffolk, sends us an account of a case which has just come under his personal knowledge. Two or three years ago a country schoolmaster in Norfolk, who suffered very severely from rheumatism in the back, deliberately exposed his arms to the stings of bees, and was stung all over the arms. By the time, however, that his arms were well again, his rheumatism had completely disappeared. The gentleman who took these heroic measures is now close on fifty years of age. Dr. Friend suggests the addition of the following two questions to those given by Mr. Walker:—(1) What is the approximate age of the person supposed to have been cured? (2) In what part of the body was the rheumatism manifested, where was the person stung, and for how long was the cure effective?

Mr. T. E. D. Innes has compiled a list of Indian jungle products used as food by the natives during periods of famine, that has been issued as an appendix to the February number of the *Indian Forester*. Some of the fruits, although lacking flavour, are eaten raw, others are parched, or, as in the case of *Ficus glomerata*, *Shorea robusta*, &c., the fruits are ground into flour and baked into cakes. Several climbers yield roots that are parched or boiled, and vegetables are provided by the leaves of *Vicia hirsuta*, *Chenopodium album*, *Chlorophytum tuberosum*, and others.

The sixth number of the botanical section of the *Philippine Journal of Science*, concluding the section for the year 1907, is devoted to short notes and to the third portion of the index to Philippine botanical literature compiled by Mr. E. D. Merrill. Mr. Merrill also contributes a first addendum to his identifications of the species described in Blanco's "Flora de Filipinas," and a few additions to the species recorded for the islands. Species of Pteridanthus and Petraeovitex are new to science, and provide first records for the genus in the Philippines. Dr. E. B. Copeland is responsible for a revision of the fern genus Tectaria; many of the species are transferred from the subgroup Sagenia of the genus Nephrodium.

A note on the flora of Prince Charles Foreland, Spitsbergen, by Mr. R. N. R. Brown, published in the Transactions of the Botanical Society of Edinburgh (vol. xxiii.), refers to collections made by Dr. W. S. Bruce. The number of species totals fifty-five, or rather more than a quarter of the number recorded for the whole archipelago. The character of the flora is evident from the observation that *Saxifraga oppositifolia* is probably the commonest plant on the island and covers large areas; other species of Saxifraga are *Hirculus*, *aizoides*, *caespitosa* and *nivalis*; the species of Ranunculus and Draba are also interesting. The flora is European, and shows an entire absence of an American element.

Mr. G. H. Shull records some additions to the list of plants that conform to Mendelian principles in the February issue of the *Botanical Gazette*. The first instance cited is that of a branched specimen of the so-called "Russian" sunflower; experiments made in crossing branched and unbranched plants indicated that branching is a dominant character. Other examples were provided by plants of *Lychnis dioica* and *Verbascum Blattaria*. In the former case purple and white flowers provided reciprocal characters when according to expectation white proved to be recessive. For Verbascum, yellow colour in the flowers was found to be dominant over white, this being contrary to the experience with Polemonium and Matthiola; it is noted that in Verbascum the yellow is a sap-colour, whereas in the other two plants it is a plastid-colour.

THE new identifications, "Decades Kewenses, XVII.," that are published in the *Kew Bulletin* (No. 3) are almost entirely Malayan plants named by Sir George King, F.R.S., and Mr. J. Gamble; species are added to the genera Clerodendron, Premna, Vitex, and Petræovitex of the order Verbenaceæ. Colonel Prain forms a new genus allied to Cymaria (order Labiatæ) on the Malayan plant, *Acrymia ajugiflora*. To the same number Mr. T. W. Brown communicates an article on banana cultivation in Egypt, where the Chinese or Canary banana provides the commercially important variety. A synopsis of the New Zealand species of Rhodophyllis, by Mr. A. D. Cotton, is concerned with corrections of diagnoses by Harvey and J. Agardh; a new species is proposed, and the recently formed *Rhodophyllis chathamensis* is withdrawn. The seventh list of additions to the wild fauna and flora of the gardens includes Coleoptera, ants, scale insects, and a few plants. Mr. R. A. Rolfe contributes an article to show that there is considerable doubt as to the localities of some of Cuming's Philippine plants.

AT the meeting of the Vienna Academy of Sciences of April 2, Prof. J. Hann presented a paper entitled "The Daily Variation of Wind-force on the Mountain Peaks of South India in their Relation to the Daily Oscillation of Air-pressure." The author calculated the daily range of wind-force on the Dodabetta peak (lat. 11° 32′ N.), and at the Kodaikanal Solar Observatory (lat. 10° 40′ N.), for separate months, and found that from October to May, during the period of the north-east monsoon, the maximum wind-force occurred between 9h. and 10h. a.m., but that in June, with the advent of the south-west monsoon, it suddenly jumped backwards to 4h.–1h. a.m., while at the recurrence of the north-east monsoon in October it again jumped forward to 9h.–10h. a.m. After much laborious investigation Prof. Hann traced the cause of the shift of epoch to the double daily oscillation of the barometer, which affects the east and west wind in a different manner, as the author fully explains in the paper.

THE *Scottish Geographical Magazine* for April contains a very interesting article on the climate of the British Isles by Mr. A. Watt, secretary to the Scottish Meteorological Society. The average distribution of temperature in mid-winter and in midsummer is shown with great clearness by two maps drawn by Dr. Buchan, and reproduced from Bartholomew's "Atlas of Meteorology"; the trend of the isotherms plainly exhibits the ameliorating influence of the sea on the climate. The least difference between winter and summer is in the south-west of Ireland, where the isotherms shift by only 14°, and the greatest in the east central district of England and near London, where the isotherms shift by 25°. The author points out that the prevalence of warm south-westerly winds is the controlling factor of our climate; the Gulf Stream, to which the mildness of our winters is commonly attributed, has but little direct influence, though it may have an indirect effect by probably producing the low-pressure area off Iceland, which, together with the area of high pressure near the Azores, is the cause of our south-westerly winds. The average rainfall is exhibited by a map specially drawn by Dr. Mill from his unique collection of records. The author mentions several interesting facts tending to show that there is no evidence that our climate has changed, although it has been subject to considerable oscillations.

THE paper on electric supply prospects and changes as affected by metallic filament lamps and electric heating, by Messrs. Handcock and Dykes, read before the Institution of Electrical Engineers recently, gave rise to a very important discussion, which occupied two meetings. The metallic filament lamp has been welcomed on all sides as a solution of the problem of cheap electric lighting to compete with incandescent gas among small consumers, and there is no doubt that it has done, and will do, a great deal towards bringing the cost of lighting by electricity within the means of the smaller consumer. At the same time, central station engineers are faced with the problem that, owing to the small consumption of the metallic filament lamp, the output of the central station is very greatly reduced, thus entailing a very large increase in consumers to make up the loss incurred. Granted that this increase can be obtained, owing to the facilities that the metallic filament lamp offers, a two-fold difficulty still remains to be surmounted—(*a*) the cost of installing the wiring in small houses, and (*b*) the cost of the house-service connection. The first falls on the consumer, whether he installs it at his own cost or on the "free wiring system," the latter on the supply company. The present systems of wiring employed in this country have been made as good, as solid, and as safe as is possible, and consequently the expense is great. On the Continent the course followed is the reverse. Perhaps the system employed is not quite so secure from possible danger as is desirable, but surely some happy mean may be found. Surface wiring with a high-grade flexible would be infinitely cheaper than our present methods, and if central station engineers would agree to this or some cheaper method than that now employed, the wiring contractors would be pleased to avail themselves of the permission. At present the contractor is handicapped by the cost of the installation being too great for the prospective consumer, and consequently the central station loses also.

IN connection with the letter from Dr. J. W. Evans on the amount of helium in the earth's atmosphere which appeared in NATURE of April 9 (vol. lxxvii., p. 535), Prof. J. Hann has sent us the following table given by him in the *Meteorologische Zeitschrift* for March, 1903:—

*Percentage composition by volume of the atmosphere at different altitudes and probable temperatures.*

| Altitude ... ... | 0 km. | 10 | 20 | 50 | 100 km. |
|---|---|---|---|---|---|
| Temperature .. | 10 C. | −18°·5 | −38°·5 | −60° | −80 C. |
| Nitrogen ... ... | 78·03 | 81·20 | 84·34 | 79·17 | 0·099 |
| Oxygen ... ... | 20·99 | 18·10 | 15·19 | 7·03 | 0·0 |
| Argon ... ... ... | 0·94 | 0·56 | 0·31 | 0·03 | 0·0 |
| Carbonic acid ... | 0·03 | 0·015 | 0·006 | 0·0 | 0·0 |
| Hydrogen ... ... | 0·01 | 0·035 | 0·147 | 13·64 | 99·45 |
| Neon ... ... ... | 0·0015 | 0·002 | 0·004 | 0·0 | 0·0 |
| Helium ... ... | 0·00015 | 0·0 | 0·002 | 0·126 | 0·453 |
| Krypton ... ... | 0·00010 | 0·0 | 0·0 | 0·0 | 0·0 |
| Total pressure... | 760 mm. | 199·2 | 42·2 | 0·32 | 0·0223 |

DR. LULL'S memoir on the evolution of the elephant, referred to in NATURE of March 26 (vol. lxxvii., p. 494), appeared, not in the March number of the *American Naturalist* as stated, but in the March number of the *American Journal of Science*.

LIEUT.-COLONEL SEDGWICK writes to say that in the notice of his book, "Man and his Future," which appeared in last week's issue of NATURE (p. 5), the date of his paper on the "Form of the Atom" should have been given as 1892, and not 1902, as stated at the end of the review.

A SECOND edition of Mr. Richard Semon's "Die Mneme als erhaltendes Prinzip im Wechsel des organischen Geschehens" has been published in Leipzig by Mr.

Wilhelm Engelmann, and copies may be obtained in this country from Messrs. Williams and Norgate. The first edition was reviewed at some length in NATURE of February 8, 1906 (vol. lxxiii., p. 338), and reference may be made to that notice for a description of the characteristics of the work.

MESSRS. CHAPMAN AND HALL, LTD., have published a second edition of Dr. F. H. Getman's "Laboratory Exercises in Physical Chemistry." The first edition was reviewed in the issue of NATURE for July 28, 1904 (vol. lxx., p. 296). A chapter on thermostats has been inserted in the new edition, and the chapters treating of electromotive force, solubility, and chemical dynamics have been extended. The measurement of radio-activity has been dealt with briefly, and some other modifications made.

THE *Physical Review* for February contains an article by Mr. F. L. Bishop on the heats of dilution of certain aqueous solutions he has measured recently at the Massachusetts Institute of Technology. He finds that if concentration be represented by the ordinate, and the heat absorbed when a solution containing one gram-molecule of a dissolved salt is diluted down to the concentration in question be represented by the abscissa of a curve, the curve is a straight line for the nitrates of potassium, sodium, and barium, and approximates to two straight lines intersecting at a concentration of about 1·2 gram-molecules per litre in the case of potassium chloride. The break in this curve the author puts down to some chemical change taking place in the solution.

WE have received from the Charles Urban Trading Company, Ltd., 89–91 Wardour Street, London, W., a copy of their latest catalogue, entitled "Urbanora, the World's Educator." The list, which runs to 252 pages, deals with scientific and educational subjects treated in such a way as to be suitable for exhibition by the bioscope and microkinematograph. Films are available which depict various forms of animal life, bacteriological and other microscopic forms, and typical natural phenomena. The catalogue provides detailed information as to the subjects of science which can now be illustrated in such a way as to bring vividly before students essential facts. The actual steps in the life-histories of lowly organisms, the sequence of events in the study of the habits of plants and animals in their natural surroundings, and the reproduction of the details in typical operations to assist the teaching of operative surgery may be mentioned as examples of the way in which the kinematograph is now being utilised for educational purposes.

## OUR ASTRONOMICAL COLUMN.

THE $D_3$ (HELIUM) ABSORPTION LINE IN THE NORMAL SOLAR SPECTRUM.—An important statement by Mr. J. Evershed, concerning the presence of the dark helium, $D_3$, line in the solar spectra photographed by Mr. Nagaraja, appears in No. 396 (p. 212, May) of the *Observatory*. Readers of these columns will remember that various observers have criticised copies of Mr. Nagaraja's photographs, and have arrived at the conclusion that the dark line shown thereon is probably not the absorption line ($D_3$) of helium. But Mr. Evershed has carefully measured this dark line shown on a number of plates, and the results of his measures lead him to the belief that the line is really the helium absorption line. Micrometer measures on the actual photograph from which the copies were taken (May 4, 1907) give 5876·15 and 5876·17 as the wave-lengths of the bright line at the limb and of the dark line respectively, whilst from six determinations of each of a series of photographs obtained during 1907 Mr. Evershed obtains the mean values 5875·96 and 5875·97 respectively. The coincidence is indeed very close, and the mean value is in good accordance with the values obtained by Prof. Rowland and Prof. Hale. Mr. Evershed suggests that the prolongation of the dark line across the umbral areas, a phenomenon which proved a difficulty with the visual observers who criticised the results, may be due to the unsteadiness of the image on the spectrograph slit during a long exposure.

THE LIGHT-CURVE OF δ CEPHEI.—Between June, 1906, and September, 1907, Mr. Joel Stebbins, of the Illinois University Observatory, made a large number of observations of δ Cephei with a polarising photometer attached to the 12-inch refractor. Seventy-four observations, each consisting of ninety-six settings, were made, giving a total of 7104 settings, and every precaution was taken to make each observation perfectly independent and free from systematic errors; a sixth magnitude companion at a distance of 41″ was the only comparison star employed, but there is no evidence to show that all the variation exhibited is not due to the well-known variable. The light-curve obtained from the observations shows secondary fluctuations with maxima at 4·6 and 0·4 days. A maximum occurred on 1906, July 3·29 (=J.D. 2417395·29) and a minimum on July 1·87 (=J.D. 2417393·87), G.M.T.; the range of magnitude is shown to be 0·76 (*Astrophysical Journal*, vol. xxvii., No. 3, p. 188, April).

THE MASSES OF α CARINÆ AND α PAVONIS.—In a recent note in these columns (No. 2005, p. 520, April 2) we directed attention to a communication from Mr. Gore to the *Observatory* in which the writer, basing his conclusions on spectroscopic observations made at the Lick Observatory, showed that the binaries α Carinæ and α Pavonis should have very small masses. From a letter now published in the same journal (No. 396, p. 215, May), from Mr. H. C. Plummer, it appears that Mr. Gore's deductions were based on a slight misapprehension as to the data given in the Lick publication, and his results are therefore erroneous. Mr. Plummer's correction shows that it is quite impossible to justify the inference that the systems of these two stars are necessarily of very small mass.

THE NEW TOWER TELESCOPE OF THE MOUNT WILSON SOLAR OBSERVATORY.—No. 3, vol. xxvii., of the *Astrophysical Journal* (p. 204, April) contains an interesting description, by Prof. Hale, of the tower telescope recently erected at the Mount Wilson Observatory. We gave a brief description of the instrument proposed in our issue of February 28, 1907 (p. 424, No. 1948), and for fuller details must refer our readers to Prof. Hale's illustrated description of the actual instrument. The advantages expected to be obtained by this form of telescope mounting have been fully realised, and only one or two minor modifications, *e.g.* the reduction of the thickness (12 inches) of the mirrors employed, will have to be made. Among the illustrations reproduced in Prof. Hale's paper there is an excellent photograph of a sun-spot spectrum, on the scale of Rowland's map, which shows with remarkable clearness the "widened lines" in the *b* region.

FURTHER OBSERVATIONS OF JUPITER'S EIGHTH SATELLITE.—In No. 4246 of the *Astronomische Nachrichten* (p. 367, May 1) Sir W. H. M. Christie gives the positions of the newly discovered eighth satellite of Jupiter. The plates from which these positions were deduced were obtained on March 31 and April 3 with the 30-inch reflector, and the position of the satellite referred to three or four faint comparison stars. The positions of the latter were then determined, with reference to some thirty A.G. Catalogue stars, on a plate taken with the 13-inch astrographic refractor.

OBSERVATIONS OF PERSEIDS IN 1907.—The results of the observations of the Perseids, made by three sets of observers connected with the Kasan Observatory during the nights of August 11, 12, and 13, 1907, are given by Herr W. Milowanov in No. 4246 of the *Astronomische Nachrichten* (p. 353, May 1). The paths of 201 Perseids were recorded, and the general radiant was found to be $\alpha = 43°{\cdot}8$, $\delta = +54°{\cdot}0$ (1905·0). The real paths of some forty meteors were computed, the mean heights at the beginning and end of their visible traces being 127 km. and 86 km. respectively.

## THE EXTINCTION OF MALTA FEVER.[1]

THE subject of this evening's discourse is the extinction of Malta fever, and I propose to bring before you in this paper the various steps in the investigation of this disease which led up to the discovery of its mode of spread, and so to its prevention and extinction.

### HISTORICAL.

This fever has been studied in various ways for the last quarter of a century, but it was not until 1904 that the Government, alarmed by the great wastage in man caused by it, took the matter up seriously, and asked the Royal Society to undertake a thorough investigation of the disease. This the Royal Society agreed to do, and early in the summer of the same year sent out to Malta a small Commission for this purpose; and it is principally the result of the work of the Commission which I have the honour of bringing before you this evening.

It seems a pity that this research was not undertaken twenty years earlier, as during this time some 14,000 or 15,000 sailors and soldiers have suffered from the disease. It is to be hoped that the result of this work will bring home to the Government the great good to be gained by introducing scientific methods of research into the study of disease in the Army. This, strange as it may seem, has not yet come home to Government departments. If an application was made to the Treasury to-morrow for, say, 100*l.* for such scientific purposes, the answer would be that it was not the function of the Royal Army Medical Corps to engage in scientific research, but that their duty was to attend to the sick soldiers. This waiting until a man is sick is fatal. It ought to be our chief duty to anticipate and prevent sickness.

Before I leave the subject of the Commission, I may remark that its work went on for three years before the successful result was attained.

But now to return to Malta fever.

### DESCRIPTION OF MALTA FEVER.

At the outset it will be necessary to give a short description of this fever, in order that you may know what we are dealing with.

Malta fever is no trivial complaint, but is a severe and dangerous disease, which lasts a long time, and is accompanied by a good deal of pain. To give you an idea of the long duration of this fever, I may tell you that our soldiers remain under treatment in hospital with it on an average for 120 days, and it is by no means uncommon for a patient to suffer almost continually from it for two or even more years.

During the whole course of his illness the patient is apt to suffer from severe rheumatic pains in the joints, and neuralgia in various nerves, and this, combined with the long-continued fever, brings about a condition of extreme emaciation and weakness, from which recovery is slow.

In order to show you to what a degree of emaciation a few weeks of this fever may bring a man, I will take the liberty of throwing on the screen a photograph of a soldier who has been suffering from it for a few weeks. (Here a picture of a man extremely thin and evidently very ill was thrown on the screen.)

On admission to hospital this man was a robust and muscular soldier, and now see what a few weeks have brought him to.

### INCIDENCE OF MALTA FEVER IN THE GARRISON.

Next I would direct your attention to the number of cases of this fever which occur among our sailors and soldiers in Malta, in order to impress upon you the importance of this disease to the State. Among our soldiers, who number about 7000, there have been on an average 312 admissions to hospital every year from Malta fever alone, and among the sailors about the same number. This means that 624 soldiers and sailors have been treated in hospital 120 days each, which makes about 75,000 days of illness per annum.

To illustrate this I throw on the screen a diagram (Fig. 1).

Now I have said enough to show you that we are dealing with a severe and important form of disease.

### STUDY OF MALTA FEVER FROM THE EPIDEMIOLOGICAL POINT OF VIEW.

Before we begin the experimental investigation of this fever, it is well that we should know as much as possible about it from a general point of view. For example, in what parts of the world is it found; under what conditions of climate; whether any connection can be made out between it and the temperature or rainfall; whether age or sex render a person more liable; whether occupation or social position has any bearing on it; whether a difference in sanitary conditions has any effect, as, for example, do people living in small villages without any proper system of water supply suffer more than those living in towns supplied with pure water and a modern drainage system?

Now it is clearly impossible for me to go into all these points with the time at my disposal, but I would like to

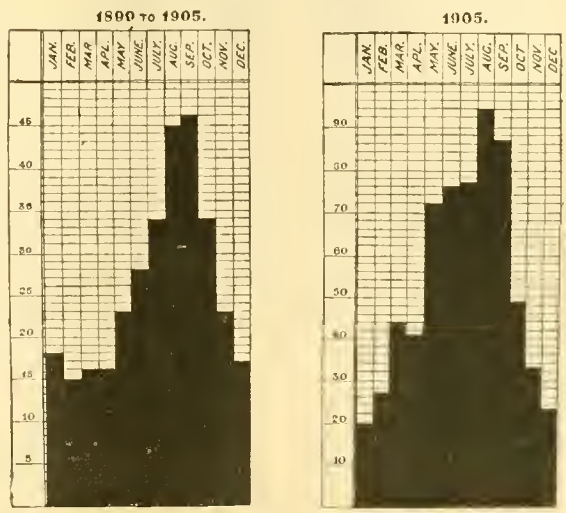

FIG. 1.—Charts of incidence in 1899–1905, and 1905.

bring before you a few facts which bear on the problem we have before us.

*Geographical Distribution.*—For example, it is interesting to know that Malta fever is not confined to Malta, but occurs in most parts of the world.

*Climatic Conditions.*—Then again in regard to the effect of climate. Malta is extremely hot and dusty in the summer, and correspondingly cold and wet in winter. But, although the number of cases of Malta fever do show an increase in summer, yet it is a disease which is prevalent all the year round, one-third as many cases occurring in the coldest and rainiest months as in the hottest and dustiest.

Another fact of importance is that if we study the occurrence of Malta fever in individual years we are struck by its irregularity, a number of cases appearing in December or February or other of the cold and rainy months.

*Social Position.*—Another curious fact in regard to this disease is that the better the social position of a person the more risk is there of catching this fever. Officers and their wives and children, living in large, airy, and clean houses, suffer more frequently than the men in their more crowded barrack-rooms. In fact, the chance of a naval or military officer taking this fever was more than three times as great as in the case of the men.

[1] Discourse delivered at the Royal Institution on Friday, January 24, by Colonel David Bruce, C.B., F.R.S.

This is shown on this diagram (Fig. 2).

*Distribution of Malta Fever among the Civil Population.*—Another important fact is the distribution of Malta fever among the civil population. Until recently it was supposed by many of us that it was restricted to the

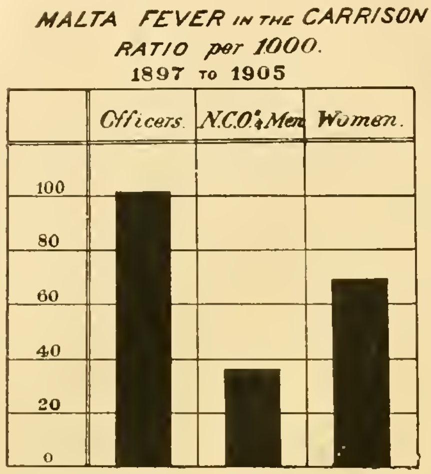

FIG. 2.—Incidence in officers, men, and women for 1897–1905.

inhabitants of the cities surrounding the Grand Harbour. This was in the days when the theory was held that the poison which causes this fever was found in the air. As the Grand Harbour at that time was in a very dirty condition, the drainage of Valletta and the three cities falling into it, there was some excuse for this belief.

Malta fever is now known to occur in every part of the island, and, in fact, the general distribution of this disease is very striking. It is not the cities round the Harbour which are struck most heavily, some of the inland towns and villages showing a much higher fever-rate.

This is illustrated by the following diagram (Fig. 3).

### SUMMARY OF EPIDEMIOLOGICAL EVIDENCE.

What, then, have we learned from the study of this fever from the general point of view?

We have found that Malta fever depends on no local conditions, as it occurs in many parts of the world. It cannot have any great dependence on climatic conditions, as it occurs in the cool and rainy months almost as frequently as in the hot, dusty, and rainless.

Poverty and insanitary surroundings do not predispose; in fact, the well-to-do classes have been shown to be more liable to take the fever than the poor. It has no connection with water supply or systems of drainage, as it breaks out as frequently in the smallest country villages as in the large cities.

What, then, is the cause of this fever?

### STUDY OF MALTA FEVER BY THE EXPERIMENTAL METHOD.

*Discovery of the Parasite.*—Let us approach this problem from the experimental side. The first step to be taken is to discover if any parasite or micro-organism is associated with this fever. To do this we examine the blood and the tissues of the various organs, both microscopically and by means of cultivation, on suitable media, to find out if anything can be seen or grown. In this way, as long ago as 1887, it was discovered by an army medical officer that a minute organism, to which the name of *Micrococcus melitensis* was given, is the cause of this disease.

*Description of the* Micrococcus melitensis.—There is not much to be said about this micro-organism, except that it is very minute, only becoming visible under a magnification of 1000 diameters. It is round or oval in shape, and non-motile. It is found in every case of Malta fever, and if injected under the skin of monkeys gives rise in them to a fever similar to that in man.

### CHARACTERISTICS OF THE *Micrococcus melitensis.*

*Behaviour outside the Body.*—Now, having found the micro-organism, it is necessary to study its characteristics.

It is found to survive outside the body for some time. For example, it can retain its vitality and virulence in a dry condition in dust or on clothing for at least two or three months. It can also live in a moist condition; in water—tap-water or sea-water—for a somewhat shorter period.

The important thing to be noted is that it does not increase outside the body; it merely survives for some time and then dies off, and, if exposed to direct sunlight, it disappears in a few hours.

Many attempts were made to discover it outside the body under natural conditions. As the generally accepted theory was that it was conveyed in air, naturally the air of fever wards or of places where cases had occurred was examined with great care. It was also looked for in the dust of suspected places and in the water of the Harbour, but with no success. It is evidently what is known as a facultative parasite, or one which depends on a host for its existence.

Thus, then, the first important step in our discovery of a means of preventing Malta fever has been taken. We now know the cause of the disease, and can look with some chance of success for the source whence man obtains it.

The next steps are to find out how this micrococcus leaves and how it gains entrance to the body.

Map of Malta and Gozo, showing the Distribution of Malta Fever in the various Towns and Villages of the two Islands

FIG. 3.—Incidence in civil population.

### HOW DOES THE *Micrococcus melitensis* LEAVE THE BODY?

In regard to the first of these, it is conceivable that it might leave the body by way of the expired air, in the saliva, in mucus from the lungs, as in consumption, in the secretion of the skin, as in scarlet fever, in the renal secretion, or by way of the intestinal tract. Or it might leave the body by way of the blood, by the agency of mosquitoes or other biting flies.

Many experiments were made along all these lines, and finally it was decided that this micro-organism leaves the body principally in the renal secretion, and in the blood taken out of the body by blood-sucking insects.

The result, therefore, of this experimental work was to give rise to the belief that the disease was either conveyed from the sick to the healthy by contact, by inhalation of infected dust, or, lastly, by the agency of mosquitoes.

### HOW DOES THE *Micrococcus melitensis* GAIN ENTRANCE TO THE BODY?

The investigation of these various modes of infection was therefore undertaken.

*By Contact.*—Let me first consider infection by contact. Experiments were made by placing monkeys, one affected by Malta fever, the other healthy, in more or less intimate contact, and it was found that if the monkeys lived together in the same cage infection did take place. If, on the other hand, the monkeys were kept in the same cage, but separated by a wire screen, so that, although they could touch each other, contamination of the healthy monkey's food by the sick monkey could not take place, then infection did not take place.

In regard to this question of conveyance by contact, there is one argument against it which has always seemed to me unanswerable, and that is that thousands of cases of Malta fever have been invalided home to England, and treated in our naval and military hospitals, without, as far as I am aware, a single case of the fever arising among the patients, orderlies, or nursing sisters.

It was therefore concluded that contact with Malta fever patients, or the handling of infected clothing or discharges, is not the mode of infection.

Then the question of infection by contaminated dust was taken up.

*By Dust contaminated by the* Micrococcus melitensis. For some time it was considered probable that this would prove to be the common method of infection. The fact that the micrococcus withstands drying for a long time, the dusty nature of Malta, and the probability that gross contamination of the surface of the soil takes place by infective discharges, rendered this view likely.

Experiments were made to put the theory to the test. Dust was artificially contaminated with micrococci and blown about a room in which monkeys were confined, or blown into their nostrils or throat. Several of these experiments were successful. It was therefore proved that dust *artificially* contamined with *Micrococcus melitensis* could give rise to the disease.

This, however, was no proof that this mode of infection occurs in Nature. The artificially-contaminated dust contained myriads of micrococci. Under natural conditions they could seldom be numerous, and the powerful Maltese sunlight would tend to kill them off rapidly. The dust blown about by the wind must also dilute the micrococci to an enormous extent, so that it is only possible to conceive of a micrococcus here and there in a vast quantity of dust. Experiments were therefore made with dust naturally contaminated, in order more closely to resemble natural conditions. Dust contaminated in this way, and also that collected from suspicious places, and blown about the cages, sprinkled on food, or injected under the skin, always gave negative results.

The conclusion was therefore again come to that conveyance of the infective germ by means of contaminated dust could only rarely, if ever, give rise to the disease.

*By Mosquitoes or other Biting Insects.*—As already mentioned, the theory had been strongly advanced that Malta fever, like yellow fever or plague, might be conveyed by blood-sucking insects. The fact that the micrococci are frequently found in the peripheral blood gave some colour to the belief. This point was therefore fully investigated, and numerous experiments made with the different species of mosquitoes found in Malta, and also with other blood-sucking insects.

The results, again, were all negative, and it was therefore decided that Malta fever is not conveyed by contact, by contaminated dust, or by mosquitoes.

What, then, could be the mode of spread?

*By Way of the Alimentary Canal.*—It had long been known that the smallest quantity of the micrococci introduced under the skin or applied to a scratch would give rise to the disease in man or monkeys, but some work by previous observers had led us to believe that infection did not take place by way of the mouth in food or drink. They had fed monkeys on milk contaminated by the micrococci, and stated that in no case had infection taken place. This observation kept the Commission at first from making feeding experiments. As infection, however, did not appear to take place by contact, by the inhalation of infected dust, or by mosquitoes, it was clearly necessary to repeat these feeding experiments.

FEEDING EXPERIMENTS.

Here is a table showing the result of some of these feeding experiments, and you see it is abundantly proved that Malta fever can be conveyed to healthy animals by way of the alimentary canal. Even a single drink of a fluid containing few micrococci almost certainly gives rise to the disease (Fig. 4).

*Malta Fever*

| Species of animal | | Mode of infection. M = M. melitensis | Probable time which elapsed before infection took place in days | Result. + Infection − No infection |

FIG. 4. Feeding experiments.

From the results, then, of all these experiments it seemed most probable that the micrococcus gained an entrance to the body by way of the alimentary canal, and therefore by some infected food or drink.

FIG. 5.—Milking goat

This led to an examination of food-stuffs, and among these the milk of the goat is one of the most important.

### INFECTION BY MEANS OF GOATS' MILK.

The goat is very much in evidence in Malta, and supplies practically all the milk used. There is, I believe, one goat to every ten of the population, so that, as there are 200,000 inhabitants, there must be 20,000 goats. Flocks of them wander about the streets from morning until night, and are milked as required at the customers' doors (Fig. 5).

It must be confessed there seemed little hope that an examination of these animals would yield any result. The goats appeared perfectly healthy, and they have the reputation of being little susceptible to disease of any kind.

To put the matter to the test several goats were inoculated with the micrococcus, and the result watched. There was no rise of temperature, no sign of ill-health in any way, but in a week or two the blood was found to be capable of agglutinating the specific micro-organism.

This raised our suspicions, and a small herd of apparently healthy goats was then procured and their blood examined to see if they were all healthy. Several of them were found to react naturally to the agglutination test, and this led to the examination and the discovery of the *Micrococcus melitensis* in their blood, urine, and milk.

### Micrococci in Goats' Milk.

Some thousands of goats in Malta were then examined, and the astounding discovery was made that 50 per cent. of the goats responded to the agglutination test, and that actually 10 per cent. of them were secreting and excreting the micrococci in their milk.

Monkeys fed on milk from an affected goat, even for one day, almost invariably took the disease.

### s.s. *Joshua Nicholson*.

At this time, curiously enough, an important experiment on the drinking of goats' milk by man took place accidentally. Shortly, the story is as follows:—In 1905 the s.s. *Joshua Nicholson* shipped sixty-five goats at Malta for export to America. The milk was drunk in large quantities by the captain and the crew, with the result that practically everyone who drank the milk was struck down by Malta fever.

Sixty of the goats (five having died) on arrival in America were examined, and thirty-two found to give the agglutination reaction, while the *Micrococcus melitensis* was isolated from the milk of several of them. This epidemic of Malta fever on board the s.s. *Joshua Nicholson* therefore clinched the fact that the goats of Malta act as a reservoir of the virus of Malta fever, and that man is infected by drinking the milk of these animals.

### Epidemiological Features.

Here, then, at last was discovered a mode of infection which explains the curious features of Malta fever—the irregular seasonal prevalence, the number of cases which occur during the winter months, when there are no mosquitoes and little dust. It is true there are more cases in summer than in winter, but this may be explained by the fact that more milk is used at that time of the year for fruit, in ice-creams, &c. It also explains the fact that officers are more liable than the men, as the former consume more milk than the latter. It also explains the liability of hospital patients, milk entering so largely into a hospital dietary.

### Result of Measures Directed against the Use of Goats' Milk.

As soon as goats' milk was discovered to be the source of infection, preventive measures were begun. The result is very striking, as is shown in the charts thrown on the screen, which give the number of cases of Malta fever among the soldiers in the garrison before and after the preventive measures came into action.

Here is a chart of the incidence of Malta fever among the soldiers each month before the preventive measures were put into force (Fig. 6).

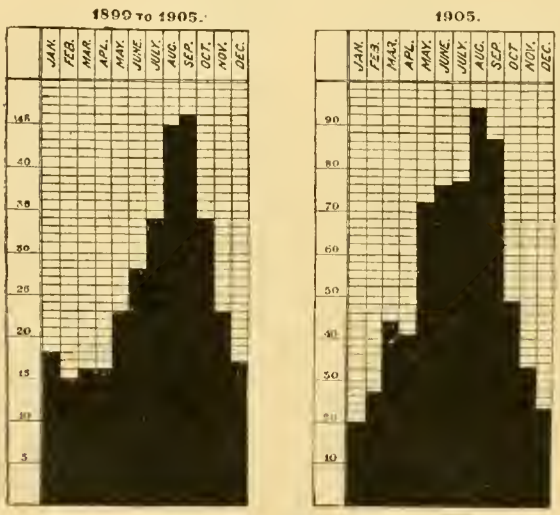

Fig. 6.—Charts of incidence among the soldiers in 1899–1905, and 1905.

And here is another showing the incidence of this fever among the soldiers and sailors in Malta since goats' milk has been banished from their dietary (Fig. 7).

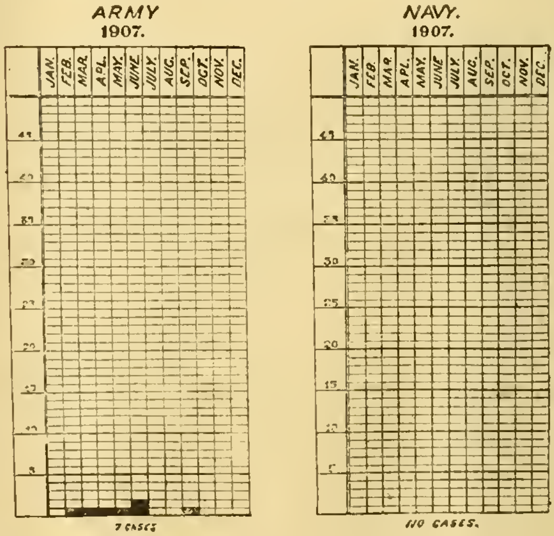

Fig. 7.—Charts of incidence among the soldiers and sailors, 1907.

With this chart, which shows the practical extinction of Malta fever, my discourse comes to a close.

---

## RUSSIAN TRANSLITERATION.

THE system of transliteration from Russian generally adopted in British libraries and scientific bibliographies is that first published in Nature on February 27, 1890. It was the result of consultation by a committee of which the secretaries were Prof. Miers and the writer. This system was intended to satisfy the need for some uniform practice, and it was based on the principle that no system of transliteration from Russian would be suitable for bibliographic work unless every word may be re-transliterated into the original Russian spelling, so that it may be found in a dictionary. It was accordingly necessary that each Russian character should have one constant equivalent, and that the equivalents should be so arranged that the same combination of letters should not result from different Russian characters. It was also considered advisable to use accents as little as possible. Phonetic considerations and elegance in appearance were regarded as unimportant in comparison with the main requirements of certainty in re-transliteration.

The Imperial Academy of Sciences of St. Petersburg has recently adopted a system from the transcription of proper names into Russian. The symbols adopted by the Imperial Academy of Sciences are as follows:—

| | | | | | | | | | | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| а | б | в | г | д | е[2]) | ё[5]) | ж | з | и[3]) | і | й | к | л | м | н | |
| a | b | v | g | d | e, je | ë | z | z | i, ji | i | j | k | l | m | n | |
| о | п | р | с | т | у | ф | х | ц | ч | ш | щ | ъ | ы | ь[4]) | ѣ[2]) | |
| o | p | r | s | t | u | f | ch | c | | š | šč | — | y | ĭ | e, jě | |
| э | ю[1]) | я[1]) | ѳ | ѵ | | | | | | | | | | | | |
| e | ju, ĭu, | ja, ĭa | f | i | | | | | | | | | | | | |

The table of Russian and Latin characters is accompanied by the following notes:—

(1) The liquid vowels я and ю beginning a syllable or preceded by ъ or ь (which, in the last case, are omitted from the transcription) are transcribed by "ja" and "ju"; if preceded by a consonant these vowels are transcribed by "ia" and "iu," if they form a syllable with the preceding consonant.

(2) The liquid vowel "e" and the vowel ѣ preceded by ь or ъ (which in this case are omitted in the transcription) are transcribed by "je" and "jě"; if preceded by a consonant these vowels are transcribed by "e" and "ě." But the liquid vowel "e" beginning a prope name is transcribed by a simple "e." Thus Egorov (pronounced Yegorov) begins with the liquid "e."

(3) The letter и preceeded by ь is transcribed by "ji" (the liquid "i").

(4) The letter ь at the end of a word or before a consonant is transcribed by "ĭ."

(5) The letter "e," when it is pronounced "jo," is represented, as in Russian, by "ë," but only when the author writes his name in that way.

(6) The names of foreign authors who have written in Russian are re-transcribed according to this system when the original orthography of these names is unknown; when it is known, the transcription of the Russian form of the name can be given in a note.

The British system also proposed to use the original form of any Russianised proper name in preference to re-transliterating them.

The Russian Academy's system does not attempt to secure the precision in re-transliteration which was the main object of the British system; for the letter "f" stands for either ѳ or ф; "u" stands for "y" or occurs in combination with "j" (which is itself the transliteration of й) for ю; "i" may be the transliteration of any one of four letters, и, i, ь, or ѵ, as well as in combination with "u" and "a" from ю or я. The English "e" is the equivalent of either "e," ѣ, or э. Five Russian letters have alternative transliterations. Phonetically, the Russian system has some advantage over the British, although in this respect it is in some ways less satisfactory. The Russian system, however, is proposed only for proper names, for which a less rigid system is perhaps necessary than for general scientific and bibliographic work.

J. W. Gregory.

## DYEING QUALITIES OF NATURAL AND SYNTHETIC INDIGO.

The annual report, written by Mr. Cyril Bergtheil, of the Indigo Research Station of the Bihar Planters' Association for the year 1907–8 has just been issued; it contains an interesting statement with regard to the value of "synthetic" indigo as a dye-stuff compared with natural indigo. From last year's experiments (see Nature, vol. lxxv., p. 614) it was concluded that "synthetic" indigo gives poorer results under practical conditions than those obtained with the natural dye, the latter imparting a richness of shade or "bloom" which was unobtainable with the synthetic material. It has since been ascertained that the synthetic indigo supplied for the tests was "brand E" of the Badische Anilin- und Soda-Fabrik, which contains some 25 per cent. of lime; the presence of this high proportion of alkali would of itself account for the bad results obtained in the hydrosulphite vat. Experiments will now be made using the material which the Badische company itself recommends for the hydrosulphite vat.

The rest of the report deals with the results obtained in experiments made to ascertain the best conditions to be observed during the growth of the indigo plant, and in the extraction of the dye subsequently. Good results have been obtained by the use of sulphuric acid as a means of facilitating the germination of the seed of the Java plant, as recommended in a previous report (Nature, vol. lxxv., p. 497), but care must be observed in ensuring that the acid used is of correct strength. A number of interesting experiments made to ascertain the effect of manuring on the production of indican in the plant are also reported. It would appear that the proportion of indican in the plant is independent of, or is actually decreased by, manurial treatment; in fact, the production of indican appears to be a starvation phenomenon, the proportion of the dye being increased by the absence of moisture and by adverse climatic conditions. On the other hand, the fertility of the land must not be allowed to drop too much, otherwise the growth of the plant as a whole is interfered with, and the return of the dye per acre is affected. New fungoid diseases, and an insect pest producing ravages on indigo plants, are also dealt with in the report.

## MAY METEORS

May, like June, cannot be said to be prolific of meteoric showers or to offer special inducements to observers. There are, of course, the May Aquarids, due during the first week of the month in the morning hours. There is also a pretty rich shower of Coronids between about May 11 and 18, but they are not often seen in marked prominence; and I believe there is a special shower at the close of May from the N.W. region of Pegasus, at about $334° + 28°$, which deserves more attention. I found the position of this radiant on reducing a number of meteors recorded by the Italian Meteoric Association in 1870, and very satisfactorily confirmed the showers in 1886 May 29 to June 4, the exact positions being $330° + 28°$ and $333° + 27°$ respectively.

There is a well-marked radiant of slow meteors from this point in July and August, but it has been seldom noticed at the close of May and early days of June. This year moonlight will not interfere with observation, and it would be interesting to watch the eastern sky in the mornings of May 29 to June 4 for the purpose of further investigating these $\eta$ Pegasids. They are of the Perseid type, being swift and streaking meteors, and I think the stream may prove of some importance among the spring showers, though very little is known of it.

Any observations conducted for the purpose of re-detecting the system may also be found useful in giving us a fuller insight into the other meteoric displays of the same period.

W. F. Denning.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Twenty students matriculated this term, bringing the total number for the year up to 1162. This is an advance of seventy-nine on the numbers for last year, and of ninety-seven on the numbers for 1906 to the present date. The increase in the number of advanced students over that of last year is *ten*.

It is proposed to confer the degree of Master of Arts, *honoris causa*, upon Mr. A. Henry, reader in forestry.

Mr. F. Darwin, F.R.S., has been nominated the representative of the University at a meeting convened by the Linnean Society of London to be held in July in celebration of the fiftieth anniversary of the reading of the joint essay by Charles Darwin and Alfred Russel Wallace "On the Tendency of Species to form Varieties; and on the Perpetuation of Varieties and Species by Natural Means of Selection."

The general board has reported on the proposed readership in metallurgy which the University will be enabled to establish by the munificence of the Goldsmiths' Company, which has presented 10,000*l.* for the purpose of founding and endowing a readership in metallurgy. The board is of opinion that the generous offer of the Goldsmiths' Company should be accepted, that a readership in metallurgy should be established, that the readership should be associated with the name of the company, and that among the principal duties of the reader should be that of research and other work in the precious metals and of instruction in the theory and practice of assaying. The board is of opinion, further, that the stipend attached to the readership should be 300*l.* a year, or such larger or smaller sum as the capital may produce. The board has consulted the professor of chemistry, and finds he is of opinion that there is suitable and sufficient accommodation in the present chemical laboratory to enable the reader to carry out the special duties of his office, but if the metallurgy of the commoner metals is to be studied accommodation will have to be provided on another site more suitable for the purpose.

LONDON.—Sir Arthur Rücker, principal of the University, was unfortunately absent through illness on Presentation Day, May 6, and was therefore unable to deliver his valedictory address. The principal's report, read by the secretary to the Senate, showed continued progress. Matriculation candidates were 7356 in 1907–8, compared with 7112 in 1906–7 and 7036 in 1905–6; of the 7356, however, only 3277 were admitted to the University. Eighty-five graduates of other universities and others similarly qualified have taken advantage of Statutes 113 and 129, and are now studying in London as internal students with the view of taking a higher degree of the University of London. Gifts amounting to 24,667*l.* had been received by the University during the past year. In concluding his report, the principal said:—"For three-quarters of a century all efforts for the establishment of university education in London were spasmodic, disconnected, and sometimes even avowedly antagonistic. Eight years of an attempt to substitute for this condition of chaos a common policy and such common government as may be compatible with the free play of individual effort have justified those who supported and carried the great reform which took effect in the autumn of 1900." The presentees included eleven Doctors of Science (eight in science, one in engineering, and two in economics), thirty-three Doctors of Medicine and eight Masters of Surgery, one Doctor of Literature, and one Doctor of Divinity.

The University exhibit at the Franco-British Exhibition promises to be very interesting and comprehensive. It will consist mainly of photographs, publications, and charts. An exhibit representing medical education in London, and another illustrating the social and athletic life of the students, have been specially organised. One of the most valuable exhibits is a collection of publications by teachers of the University and their students in the year 1907; a special catalogue of this collection is to be published. The University will publish a special handbook containing a catalogue of the University exhibit. The medical schools have prepared a large and fully illustrated handbook on medical education in London, and the students' representative council has published a students' handbook dealing especially with the social and athletic life of the student. Copies of all these publications will be available for visitors to the exhibition.

Admission is free to the following lectures addressed to advanced students of the University and others interested in the subject of the lectures:—Eight Mercers' Company lectures on "Recent Advances in Physiology," Prof. E. H. Starling, F.R.S.; four lectures (under the Chadwick benefaction) on "The Engineering Aspect of Recent Advances in connection with Sewering," W. D. Scott-Moncrieff; eight lectures on "Cholesterol and Lecithin: from the Chemical and Physiological Standpoints," J. A. Gardner; three lectures on "The Early Development of Mammalia," Prof. J. P. Hill; eight lectures on "Fossil Ferns and Allied Seed Plants," Dr. D. H. Scott, F.R.S.; three lectures on "The Thames and its Tributaries," Prof. H. G. Seeley, F.R.S.; and four lectures on "Recent Advances in the Determination of Minerals by Optical Methods," Dr. J. W. Evans. Particulars as to the lectures can be obtained from the academic registrar of the University.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting Prof. W. James for the degree of D.Sc., *honoris causa*, on May 12:—

Adest Willelmus James, in Academia Harvardensi Professor emeritus, novi rerum ordinis in Psychologia inventor. Qui vir, quo magis eam scientiam promoveret quæ mentis humanæ agitationes, cogitationis memoriæque rationem, sentiendi, percipiendi modos complectitur, nulla fere disciplina non institutus est. Neque enim solum acuto, ut philosophus, ingenio, sed usu et scientia, ut medicus, peritia etiam experimentis parta, ut physiologus, præstabat. Accessit, quod caput est, mira quædam divinandi facultas. Quæ renuntiat suis oculis assecutus est, vir non legendo sed intuendo doctus: idem admirabili dicendi genere inventa explicat. Mox a psychologia ad philosophiam conversus fecit ut hæc studia in omni orbis terrarum parte revivescerent. His quidem diebus apud nos de philosophia luculenter contionatus magno iuniorum seniorumque conventu Academiam nostram maxime delectavit.

THE Court of Glasgow University has decided to establish a lectureship in geography at the University.

THE King has consented to visit Leeds in July, accompanied by the Queen, for the purpose of opening the new university buildings.

VISCOUNT MORLEY OF BLACKBURN has been elected Chancellor of the University of Manchester in succession to the late Duke of Devonshire.

ARMSTRONG COLLEGE, Newcastle, has accepted with thanks an offer from Lord Barnard to place the sum of 1000*l.* in trust for the benefit of the agriculture department of the college.

THE public bequests announced under the will of the late Mr. T. Webb include:—University College, London, 5000*l.*, to be used and applied, so far as is practicable, for the purposes of physical research; University College of South Wales and Monmouthshire, 5000*l.*, also to be applied, so far as is practicable, for the purposes of physical research.

AT a meeting of the Bristol City Council, held on May 5, a resolution was passed in favour of the proposal "to establish a university for Bristol and the west of England, and agreeing to give financial assistance to such university in the event of a charter for its establishment being obtained, provided arrangements as to the constitution of the university satisfactory to the council have been made."

IN the House of Lords on Tuesday, Lord Stanley of Alderley moved the second reading of a Bill the main object of which was to make thirteen the minimum age at which a child can be exempted from the obligation to attend school. The second reading was rejected, not because any argument against the Bill could be put forward from the point of the physical and mental welfare of the nation, but because, to use the words of Lord Tweedmouth, "a sudden change in the law would cause a very considerable amount of inconvenience, especially to the agricultural interest, to the cotton interest, and to some extent to the woollen interest." So the healthy development of the body and mind of the child has to be sacrificed to these various interests. Meanwhile, the Education Bill for Scotland, read a second time in the House of Commons on May 5, makes fourteen the normal age of leaving the primary school. Evidently, we have to look to the north for advance in educational standards.

PROF. AINSWORTH DAVIS has been appointed principal of the Royal Agricultural College, Cirencester. The college was founded in 1845, and has hitherto been conducted without the least aid from Government or local authorities. It has been decided, however, to re-constitute the college, making it a public institution with a representative governing body, in association with the county councils of Gloucestershire and the adjoining counties. In addition to providing courses for pupils proposing to become farmers or manage estates, it is proposed to hold vacation courses for village schoolmasters desiring to become qualified to teach rural subjects. Forty acres of land are attached to the college, and, in addition, the students have access to a farm, arable and pasture, of more than 450 acres. Great attention is directed to forestry, and the professor and students have the advantage of a forest nursery located in Earl Bathurst's park, a portion of which he placed at the disposal of the college for this purpose.

THE Board of Education has published (Cd. 4037) the Regulations for English Secondary Schools for the year beginning August 1 next. The regulations are in main substance the same as those of last year. Owing to difficulties which have arisen during the past year in the interpretation of the regulations referring to the provision of free places in secondary schools, these rules have been further defined. It is made clear that boys and girls applying for such free places may be required to pass an entrance test of attainments and proficiency, having due regard to the age of the applicants, the subjects in which they have been receiving instruction, and the standard of attainments and proficiency required for the admission of fee-paying pupils. Pupils who enter the school as bursars or pupil teachers must not be counted in estimating the number of free places provided. In examinations held for the selection of boys and girls to occupy free places, importance is to be attached to the report of the candidate's own teachers, and the masters or mistresses of the secondary school are to be associated with teachers familiar with elementary-school conditions in conducting the examination. The regulations make provision, too, for greater elasticity in the way of adapting the instruction to the requirements of the pupil, though precautions are taken to see that this privilege is used with proper moderation. To meet the difficulty of providing secondary education in rural areas and less populous urban or semi-urban districts, the Board is prepared next year to recognise secondary schools with fifteen instead of sixteen as the normal leaving age, but this concession is only made where a consideration of local circumstances shows that it will be of distinct educational advantage to the district, and that a longer school-life is not under actual conditions possible.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Royal Society,** June 27, 1907.—"On the Polymorphic Changes of Ammonium Nitrate." By U. **Behn.** Communicated by Prof. A. Schuster, F.R.S.

The main results of the research may be summarised as follows:—

(*a*) From the dilatometric and crystallographic work no definite information is forthcoming which affords any precise proof as to a difference in properties of the two tetragonal modifications of ammonium nitrate.

(*b*) The argument derived from the investigation of the thermal properties tells, so far as it goes, against the identity of the two tetragonal modifications, but it cannot be considered as decisive.

January 30, 1908.—"The Refractive Index and Dispersion of Light in Argon and Helium." By W. **Burton.** Communicated by Prof. J. J. Thomson, F.R.S.

The initial object of this research was to find the dispersion of light in the monatomic gases argon and helium, but as it was necessary to know the absolute value of the refractive index with considerable accuracy, determinations of the refractive index were made.

The results for argon and helium are tabulated below, and, for comparison, Mascart's values for hydrogen are also given.

Refractive index, reduced to 0° C. and 760 mm. pressure for $D_1$ line.

| | |
|---|---|
| Argon ... ... ... ... | 1·0002837 |
| Helium ... ... ... ... | 1·00003500 |
| Hydrogen (Mascart) ... ... | 1·0001387 |

Dispersion:—In equation

$$n-1=a\left(1+\frac{b}{\lambda^2}\right),\ \text{or}\ n=A+\frac{B}{\lambda^2},$$

| | $b$ | $a$ | A | B |
|---|---|---|---|---|
| Argon ... | $5{\cdot}6\times10^{-11}$ | 0·0002792 | 1·0002792 | $1{\cdot}6\times10^{-15}$ |
| Helium... | $2{\cdot}2\times10^{-11}$ | 0·00003478 | 1·00003478 | $7{\cdot}5\times10^{-16}$ |
| Hydrogen (Mascart) | $4{\cdot}3\times10^{-11}$ | 0·0001376 | 1·0001376 | $5{\cdot}9\times10^{-15}$ |

It may be noted that the values of $a$ $b$ for these substances are approximately in the ratio 3 : 1 : 2.

February 13.—"The Effect of Hydrogen on the Discharge of Negative Electricity from Hot Platinum." By Prof. H. A. **Wilson,** F.R.S.

The view taken in this paper is that the effect of the hydrogen on the leak is due to its presence in the surface layer of the platinum. To explain this it is supposed that the hydrogen atoms in the layer are positively charged, so that they diminish the charge per unit area in the electrical double layer covering the surface of the platinum. The hydrogen appears to dissolve in the platinum at first, but at high pressures in time forms a stable combination with the platinum, having a very small dissociation pressure. Before this compound has been formed, the leak is proportional to a power of the pressure of the hydrogen.

February 20.—"On the Dispersion of Gaseous Mercury, Sulphur, Phosphorus, and Helium." By C. **Cuthbertson** and E. Parr **Metcalfe.** Communicated by Prof. F. T. Trouton, F.R.S.

In continuation of previous work on the refractive indices of certain elements in the gaseous state, the authors have measured the dispersion of the elements named above within the limits of the visible spectrum.

The results obtained may be summarised as follows:—

$$\text{Mercury} \quad \ldots \quad \ldots \quad \mu-1=0{\cdot}001755\left(1+\frac{2{\cdot}265}{\lambda^2 10^{10}}\right).$$

$$\text{Sulphur} \quad \ldots \quad \ldots \quad \mu-1=0{\cdot}001046\left(1+\frac{2{\cdot}125}{\lambda^2 10^{10}}\right).$$

$$\text{Phosphorus} \ldots \quad \ldots \quad \mu-1=0{\cdot}001162\left(1+\frac{1{\cdot}53}{\lambda^2 10^{10}}\right).$$

$$\text{Helium} \quad \ldots \quad \ldots \quad \mu-1=0{\cdot}0000347\left(1+\frac{2{\cdot}4}{\lambda^2 10^{11}}\right).$$

The dispersion of mercury is about four times that of air.

The index of sulphur for infinite waves is, within 2 per cent., four times that of oxygen. Its dispersion is, not so exactly, four times that of oxygen.

The index of phosphorus, for infinite waves, is exactly four times that of nitrogen. Its dispersion is almost exactly twice that of nitrogen.

The index of helium is, within 1·6 per cent., one-eighth of the best existing value for the index of argon. Its dispersion is about three-sevenths that of air.

March 5.—"On the Electrical Resistance of Moving Matter." By Prof. F. T. **Trouton,** F.R.S., and A. O. **Rankine.**

The question of relative motion between the earth and the neighbouring ether has been under discussion for many years. It has, from time to time, been the subject of important investigations, but these have all resulted negatively. The experiment described in the present paper is not different from them in this respect, yielding, as it does, no definite information on the main point. Indirectly, the aim was to measure the direction and magnitude of ether-drift, the actual method having been to attempt to demonstrate the existence of the Fitzgerald-Lorentz shrinkage, which has been supposed to mask the effect in the direct experiments of Michelson and Morley, and of Trouton and Noble.

The results lead the authors to conclude:—

(1) The total electrical resistance of a wire is not altered by an amount exceeding $5\times10^{-10}$ of the whole amount by any change of its position relative to its motion through space.

(2) On the assumption that the Fitzgerald-Lorentz shrinkage is a real effect, the specific resistance of a material is dependent upon the direction of flow of the current, being greater to a current flowing parallel to the velocity of the material through space than to a current in a perpendicular direction. The magnitude of this change of specific resistance is shown by the experiments to be certainly within 2 per cent. of being sufficient to compensate the change of length.

March 12.—"Bacteria as Agents in the Oxidation of Amorphous Carbon." By Prof. M. C. **Potter.** Communicated by Prof. J. B. Farmer, F.R.S.

Under conditions of exposure to the air, a slow oxidation of amorphous carbon takes place through the agency of bacteria. This has been conclusively established by experiments upon such carbonaceous substances as charcoal, lamp-black, coal, and peat.

When these substances are subjected to bacterial action carbonic acid is given off, as estimated volumetrically by absorption in baryta solution and titration with standard oxalic and hydrochloric acids.

The amount of $CO_2$ given off increases in proportion to the rise of temperature, and ceases to be evolved at a supra-vital temperature. There is no evolution of $CO_2$ under perfectly dry conditions such as preclude the possibility of bacterial life.

A distinct rise of temperature occurs through the action of bacteria. The heat generated was determined by measurement, with a galvanometer, of the electromotive force produced by the difference of temperature between two thermo-elements, one placed in a sterile and the other in an inoculated flask.

The evolution of $CO_2$ and the accompanying rise of temperature does not take place when carbonaceous substances are preserved from the intrusion of micro-organisms.

The heat generated by microbial activity is an influence to be taken into account in connection with the oxidation and spontaneous combustion of coal; it may be a dangerous motive force acting upon explosive gases.

The oxidising action of bacteria must be largely responsible for the disintegration of coal and the high percentage of depreciation which it undergoes in store.

Coal and peat, like other organic matter, are liable to decomposition as soon as conditions are presented suitable for the life of aërobic organisms. The carbon is then once more liberated in the form of $CO_2$ to play its *rôle* in the life-cycle. It is thus conceivable that the vast supplies of carbon locked up in the world's coalfields may become available for plant nutrition without the intervention of direct combustion.

"The Origin and Destiny of Cholesterol in the Animal Organism," parts i. and ii. By C. **Dorée** and J. A. **Gardner.** Communicated by Dr. A. D. Waller, F.R.S.

These two papers throw some further light on the interesting question of the part played by cholesterol in the economy. The authors made, first, a very thorough and careful examination of the excretion of cholesterol by the dog. The animal was fed for periods varying between fourteen and thirty days on diets the cholesterol content of which varied greatly. The output of cholesterol in the fæces was in every case found to be a function of the food taken. Thus in seventeen days on horseflesh one gram of cholesterol was recovered, in thirty-one days on oatmeal and water 0·1 gram only. On a diet of raw brain, which is rich in cholesterol, a very interesting result was observed. In fourteen days the output amounted to 17 grams, and it consisted entirely of coprosterol, the dihydrocholesterol normally present in human fæces. In every experiment the cholesterol actually found was very much less than the quantity that should have been poured into the intestine with the bile.

In the excrement of grass-fed animals the main cholesterol product is the so-called hippocoprosterol, which is shown to be an alcohol, $C_{27}H_{54}O$, melting at 79° C. But far from being, as previously supposed, reduced from cholesterol in the intestine of the animal, it is merely a constituent of the grass taken as food. This was finally and clearly proved by feeding a rabbit on grass from which the chortosterol (as the authors propose to re-name it) had been removed by extraction with ether. The body could no longer be obtained from the fæces. No trace of cholesterol was found in the excrement of the herbivora examined, and it thus appears probable that the cholesterol of their bile is actually absorbed in the intestine—a point at present under investigation.

April 2.—"The Antagonistic Action of Calcium upon the Inhibitory Effect of Magnesium." By S. J. **Meltzer** and J. **Auer.** Communicated by Prof. E. H. Starling, F.R.S.

In a series of recent studies which the authors have carried out upon the relations of the effects of calcium to magnesium, many facts came to light which demonstrate unmistakably that calcium is the most available agent to neutralise inhibitory effects of magnesium. The following experiment is an instance:—

By subcutaneous injections of a magnesium salt (for instance, Epsom salt—about 7 c.c. of a 25 per cent. solution per kilogram), rabbits are brought to a profound state of anæsthesia and paralysis. The slow and shallow respirations indicate the approaching danger. Now 6 c.c. or 8 c.c. of an M/6 or an M/8 solution of a calcium salt are given through the ear vein. Within a few seconds the respiration becomes quicker and deeper, and within one minute the animal turns over, sits up, and appears normal.

Here calcium not only did not add an inhibitory effect, but completely neutralised the profound inhibitory effect of magnesium. The companionship of calcium and magnesium within the body means, at least in many instances, not a concerted action of similar effects, but rather a resultant effect of antagonistic actions.

**Royal Microscopical Society,** April 15.—Mr. Conrad Beck, vice-president, in the chair.—Dendritic growths of oxide of copper on paper: J. **Strachan.** The results verified previous investigations, showing that these dendrites originated in minute particles of copper, their branching being due to the direction of the fibres in the paper.—Nature's protection of insect life: F. **Enock.** The slides were taken by the Sanger-Shepherd three-colour process, and Mr. Enock described the method he employed in their production.

**Geological Society,** April 15.—Dr. J. J. Harris Teall, F.R.S., vice-president, in the chair.—The geological structure of the St. David's area (Pembrokeshire): J. F. N. **Green.** The Cambrian rocks were first traced and found to be faulted greatly. The faults have been followed into the volcanic tuffs (Pebidian), and the succession determined and pieced together. In this way the Pebidian has been subdivided into fourteen horizons, with a total visible thickness of more than 3000 feet. The subdivisions are classified into four series, the lower two of which are composed of trachytic pebbles in a chloritic matrix, and separated by a schistose quartz-felspar-porphyry sill. The third series is composed of rhyolite and hälleflinta fragments in a silicified matrix, and the topmost of highly sheared schistose beds. The tuffs appear to be mainly detrital. An unconformity between the Pebidian and the Cambrian is demonstrated. The schistose sill has been traced into the porphyritic margin of the St. David's granophyre (Dimetian), and it is inferred that the granophyre is a laccolitic intrusion in the Pebidian. The boundaries between the granophyre and the Cambrian are prolongations of faults proved in the latter, except at one point in the well-known Porthclais district. A trench opened here exposed basal Cambrian rocks resting upon a denuded surface of the granophyre, which is therefore of pre-Cambrian, but of post-Pebidian age. The relationships of the basic igneous rocks west of St. David's are discussed, and they are all described as post-Cambrian intrusions.—Notes on the geology of Burma: L. V. **Dalton.** The results are given of geological expeditions in the Irawadi Valley, carried out between 1904 and 1906, and present knowledge of the geology of Burma in general and of the Tertiary system in particular is summarised.

**Zoological Society,** April 28.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—A revision of the sharks of the family Orectolobidæ: C. Tate **Regan.** Twenty-one species were described, and were referred to eight genera. Attention was directed to the great differences in form, coloration, &c., among the members of the family, corresponding to differences in habits and environment.—Identification of an oligochæte worm obtained in considerable numbers from a well near Cambridge, England: F. E. **Beddard.** The author described the worm as a new species of the genus Phreatothrix, the only other species of which had been described thirty years ago from the underground waters of Prague.—The amphipod genus Trischizostoma: Mrs. E. W. **Sexton.** The memoir was based on a rich material obtained by the steamer of the Marine Biological Association in the Bay of Biscay, and by the steamer of the Irish Department of Agriculture off the west coast of Ireland.—Certain errors respecting George the Fourth's giraffe: H. **Scherren.** The author adduced evidence to show that the time the animal lived at Windsor had been much understated, and added details as to its life in confinement, the presentation of the skin and skeleton to the museum of the society, and the notes made by R. B. Davis while painting a picture of the animal at Windsor.—Observations on the breeding-habits of a cichlid fish (*Tilapia nilotica*) made in the course of a visit last year to Lake Qurun in the Fayûm province of Egypt: C. L. **Boulenger.**—A revision of the Oriental pelobatid batrachians (genus Megalophrys): G. A. **Boulenger.**

**Challenger Society**, April 29.—Sir John Murray in the chair.—A series of hydrographical sections, illustrating the work of Dr. R. N. Wolfenden's yacht *Silver Belle* in 1905 off south-west Ireland and down to Gibraltar: Dr. H. N. **Dickson.** The observations allowed the extension into the Atlantic of the Gibraltar under-current of high temperature and salinity to be carefully re-studied; its effects were observed to reach to 700 or 800 fathoms, where it spreads out as a flat sheet, the high salinity of which gives it a specific gravity equal to that of the colder, fresher Atlantic water. The northward range of this water varies from year to year, and must be taken into account by the International Commission for the Study of the North Sea as a third factor in tracing the sources of Channel and North Sea water.—Practical methods for the collection and investigation of water samples and temperatures: D. J. **Matthews.**

### Dublin.

**Royal Dublin Society**, March 24.—Prof. Sydney Young, F.R.S., in the chair.—Reports upon the Irish peat industries (part ii.): Prof. Hugh **Ryan.** The author begins with a description of the methods employed in Ireland for the preparation of peat fuel, and then reviews the attempts which have been made at various times to convert peat into a fuel of greater density than that ordinarily obtained by the Irish farmer. A recommendation is made for the establishing of suitable industries, such as that of glass-manufacture, at carefully selected points of the peat districts having machine-formed turf and peat-moss litter factories in connection with them. The economic importance of "generator gas" and of "mixed power gas" from peat is also considered in the paper, which concludes with a description of the "Woltereck process," employed at Carnlough, co. Antrim, for the preparation of ammonia from peat.

April 14.—Prof. Sydney Young in the chair.—The eruption of Vesuvius, 1906: Dr. H. J. **Johnston Lavis.** The author describes, from information collated and from personal observations a few days after the great outburst, the succession of events at Vesuvius in April, 1906. He points out that these events, and the manifestations since 1872, may be referred to the usual local alteration of "Strombolian" and paroxysmic "Vesuvian" stages of activity. He attributes the great outbursts of volcanic dust, accompanying the crater-forming stage, to the falling in of loose material from the crumbling cone when the lava-column has been drained down to a low level, and to its second ejection by the upbursting steam. In the cone-building stage, on the other hand, the lava-cake on the top of the magma-column, now high up in the vent, is exploded in the form of "essential" scoriæ. The courses of the lava-flows of 1906 are traced out, and their petrography and mineralogy are described. The paper was illustrated by a number of original photographs, including panoramic views showing the ash-deposits and the truncation of the cone.—The radium contents of the rocks of the St. Gothard Tunnel (preliminary note): Prof. J. **Joly.** Estimates of the radium in some typical rocks through which the tunnel was carried show a distribution of radium in accordance with the elevation of temperature which Stapff observed at the northern end of the tunnel and the lesser gradients met with at the south end. So far as the investigation has gone, the average radium content of the rocks of the central and southern sections of the tunnel is considerably below that observed by the author in the case of the Simplon rocks.

**Royal Irish Academy**, April 13.—Dr. F. A. Tarleton, president, in the chair.—Malignant tumours in birds, with observations on certain changes in the blood: Prof. A. E. **Mettam.** The tumours were round cell sarcomata, seen in the domestic fowl (three cases), and a true carcinoma found replacing the left lung in a thrush (*T. musicus*). Interesting changes were observed in the red blood corpuscles of the thrush. Numerous corpuscles showed profound nuclear degeneration; the nuclei were swollen, approaching the circular in outline, the chromatin network being more distinct. The protoplasm of the corpuscles showed polychromatophilia, and eventually entered into solution. The nuclear substance, now having lost its structure, remains as an irregular lump, staining especially with the acid dyes.—Spirochætes in infective sarcomata of dogs: Prof. A. E. **Mettam.** The author describes certain spirochætes, fusiform and bacillary bodies in smears obtained from the infective sarcomata developed on and in the genital organs of dogs. The number of undulations in the spirochæte is generally five, the length of the organism about 17 $\mu$. The bacillary bodies are long or short, stiff, or, when long and attenuated, slightly undulating. They show metachromatic granules, and may have some relation to the spirochæte which they invariably accompany.—The mouth-parts of some Blattidæ, including a detailed account of the mandibles and maxillæ of *Periplaneta australasiae*, compared with those of other species of the family: J. **Mangan.** The author shows the presence of a distinct lacinia mobilis in the mandible, and gives a full description of the musculature, both of mandibles and maxillæ. He discusses the various views that have been proposed as to the homologies of the parts of a maxilla, and controverts Verhoeff's recent suggestion that the hexapodan maxillæ are primitively posterior to the labium.

April 27.—Dr. F. A. Tarleton, president, in the chair.—A new Devonian isopod from Kiltorcan, co. Kilkenny: Prof. G. H. **Carpenter** and I. **Swain.** The fossil, named *Oxyuropoda ligioides*, bears a general resemblance to an oniscoid. The first thoracic segment is closely united with the head, and appears to carry chelate limbs; the uropods are lateral, elongate, acuminate, and unjointed. This forms an interesting addition to the few Palæozoic isopods hitherto known.

### Paris.

**Academy of Sciences**, May 4.—M. H. Becquerel in the chair.—Formulæ relating to the minima of classes of binary, positive quadratic forms: G. **Humbert.**—The discovery of the law of falling bodies: Pierre **Duhem.** The fact that the velocity of a freely falling body increased in velocity proportionally to the time of fall was well known to Leonardo da Vinci, but it is not stated in his manuscripts whether this was his own discovery, or whether he had derived it from earlier sources. A clear definition of uniformly varying motion was given by Albert de Saxe in 1351, but his view as to the law of a falling body appears to have been erroneous, and it would seem probable that the real law was discovered by da Vinci.—Canonical hyperelliptic functions of the second species: Z. **Krygowski.**—The application of the laws of similitude to the propagation of deflagrations: M. **Jouguet.**—The comparison of continuous current series and shunt dynamos from the point of view of rapidity of starting: Paul **Girault.** Series winding gives the more rapid starting.—A new radiographic method capable of deciding whether a supposed still-born child has really lived or not: Charles **Vaillant.** With infants which have not lived no organ is visible on the radiograph. With infants which have taken a few breaths the stomach alone is visible. When the stomach is more transparent and the intestine becomes visible, the child has lived from one to fourteen hours. In the case of infants who have lived some days without food, the abdominal organs, the lungs, and the liver show on the radiograph. With infants fed during several days all the organs are clearer, and the mass of gas in the intestine allows of a much clearer image of the intestinal mass.—The ultra-violet spark spectrum of dysprosium, and on some remarkable magnetic properties of this element: G. **Urbain.** A catalogue of the spectrum lines of this element for wave-lengths between 2872 and 4221 is given. The coefficient of magnetisation of dysprosium oxide was determined by means of the Curie and Chéneveau magnetic balance; the oxide was found to be about 12·8 times more magnetic than the oxide of iron, $Fe_2O_3$.—The removal of certain soluble substances from solution by precipitates: Paul **Frion**. It has been shown by Jean Perrin that contact electrification plays an important part in certain physicochemical phenomena, and he has applied this to the case of colloidal solutions. The author shows that similar considerations are capable of explaining the removal of soluble salts from solutions by precipitates.—The variation of the electromotive force of liquid chains by the polarisation of interposed diaphragms: Pierre **Girard**. The modifications in the voltage of liquid couples caused by diaphragms or membranes do not appear to be due to the variation of the mobility of the ions in the interposed medium. They appear rather to be due to phenomena of contact electrification.—The synthesis of ammonia and hydrocyanic acid: Herman C. **Woltereck**. By the passage of air through a Dowson generator charged with wood carbon, considerable quantities of ammonia and hydrocyanic acid appear to be produced. If a mixture of air and ammonia is passed over the heated carbon (at a temperature of about 1100° C.) the yield of hydrocyanic acid is increased, and the amount of ammonia found exceeds that introduced with the air.—The estimation of the halogens in organic chloro-bromo-compounds: H. **Baubigny**. The method of combustion with sulphuric and chromic acids has been modified for the analysis of organic compounds containing both chlorine and bromine. Test analyses are given showing the exactness of the method.—A new method for the preparation of homologues of naphthalene: G. **Darzens** and H. **Rost**. An acyl derivative of naphthalene is prepared by Friedel and Crafts's method, and this reduced by hydrogen in presence of reduced nickel. The yields are quantitative, and the addition of hydrogen to the ring has not been observed.—The action of phenylmagnesium bromide upon the second methyl ester of paradimethylamido-orthobenzoylbenzoic acid: J. **Pérard**.—The formation of the cyanohydrin of benzoylacrylic acid: J. **Bougault**. The addition appears to be made at the ethylene linking, the acid formed being $C_6H_5.CO.CH_2.CH(CN).CO_2H$.—The anatomy and development of the embryo in palms, the Musaceæ, and Cannaceæ: C. L. **Gatin**.—The ecological characters of the southern region of Kabylie du Djurdjura: G. **Lapie**.—Simple schizogony in *Amoeba blattae*: L. **Mercier**.—The geology of the north and east of Corsica: E. **Maury**.—The migration towards the north of the watershed in the Lepontine Alps: Gabriel **Eisenmenger**.—The application of wireless telegraphy to weather forecasts: Alfred **Angot** (see p. 34).

## DIARY OF SOCIETIES.

*THURSDAY*, May 14.

Royal Society, at 4.30.—Croonian Lecture: The Structure of the Central Nervous System of the Higher and Lower Animals: Prof. Gustaf Retzius, For.Mem.R.S.

Royal Institution, at 3.—Mendelian Heredity: W. Bateson, F.R.S.

Mathematical Society, at 5.30.—On the Invariants of the General Linear Homographic Transformation in Two Variables: Major P. A. MacMahon.—On the Order of the Group of Isomorphisms of an Abelian Group: H. Hilton.

Institution of Electrical Engineers, at 8.—Switch Gear Control Apparatus and Relays for Alternating-current Circuits: Dr. C. C. Garrard.

Iron and Steel Institute, at 10.30 a.m.—On Improvements in Plate Rolling Mills: A. Lamberton.—On the Physical Qualities of Steel in Relation to its Mechanical Treatment: J. E. York.—On a New Fatigue Test for Iron and Steel: Dr. T. E. Stanton.—On an Experimental Electric Furnace for the Smelting of Iron: Prof. B. Igewsky.

*FRIDAY*, May 15.

## HISTORICAL GEOGRAPHY OF AUSTRALASIA.

*Historical Geography of the British Colonies.* Vol. vi. Australasia. By J. D. Rogers. Pp. xii+440. (Oxford: Clarendon Press, 1907.) Price 7s. 6d.

ALTHOUGH the geocentric idea of the structure and movements of the universe was abandoned ages ago, mother earth must always remain as much the focus of interest to the dwellers on the globe as if it were still regarded as the point from which the heavens radiate and round which everything revolves. It is not surprising, therefore, that geography is assuming the position of the mother science, and tends to include, not only the physical features of the earth, but all the events which have taken place upon it.

Sir Charles Lucas appropriately names the series in which he describes the Britains beyond the sea a "Historical Geography of the British Colonies." Viewed in the modern manner, geography becomes invested with a human interest, and each country is dealt with as an organic entity. Dry bones are thus made to live. The study of the science is, as it were, transferred from the anatomical museum to the biological laboratory. Disconnected gazetteer paragraphs no longer suffice even for text-books, and for a volume with any pretensions some degree of style is now demanded; nevertheless, it is not often that we open the pages of a geography compiled with such artistic skill and clothed in such literary garb as "Australasia," vol. vi. of the series. Here we have an enormous mass of closely-packed information which would defy assimilation were it not traversed and lightened by veins of fancy in the form of apt similes and ingenious images which at once arrest the attention and fix the memory.

The volume deals with the most significant of modern developments, the transformation of the mystery of the old Pacific into the modern problem which confronts the civilised world. The story opens with a graphic account of the quest of the great South land of which the ancients dreamed. Eager was the search; Spain, Portugal, Holland and England panted in the chase. The privateering enterprise of England's sea dogs vied with expeditions equipped with all the resources of the mighty State of Spain. Every human motive was enlisted in the pursuit. The great unknown was adventured for the glory of God, for lust of conquest, for greed of gold, and for prospects of trade. The adventurers sought as saints, as soldiers, as misers, as bag-men. Human lives were as dust in the balance compared with the laying up of treasure here or hereafter. Quiros, a Spaniard, landing on one of the New Hebrides, imagined he had gained the goal, and called the island Australia del Espiritu Santo; this is the first mention of the term afterwards applied to the great island continent which emerged out of the turmoil of hope and disappointment.

The actual discovery of Australia was made from the Dutch East Indies, hence the name New Holland. The best part of Australia, the east coast, guarded towards the north by the Barrier Reef, remained a sealed book until the detailed investigation narrowed down into a rivalry between France and England. But though the ships of these two great colonising nations haunted and pursued one another as shadow and substance, the sincerity and high-mindedness of the commanders led to mutual aid and admiration, and not to conflict. As La Perouse remarked, all Europeans are compatriots so far from the home land. The history of the Pacific had hitherto been regarded as an inseparable whole; henceforth this homogeneity becomes particulate. In accordance with the laws of evolution, the New Pacific advanced towards organisation by a separation into parts.

The political history of Australia falls within three epochs. The first epoch was undiluted socialism. In the beginning was the State which fed, clothed, and employed every man; but as wealth increased private enterprise grew. The State, which at that time meant England, gradually became a total abstainer from production and industry; then, as under increasing autonomy, the State became identical with the Colony, private enterprise was fostered by grants in aid; important works, such as railways and waterworks, being undertaken by governments, which extended their activity in many other directions, so that since 1890 State socialism has been reintroduced in a way which vividly recalls that of the first epoch.

This aspect of State action alternating with individual action is both interesting and instructive as bearing on the much-vexed question of socialism. Evolution advances at one time by the impulse that makes for difference, and at another by that which induces agreement; the first shows itself in the diversified activities of the individual, the second in the corporate action of the municipality or State. Thus difference in agreement becomes harmony. Both tendencies are essential, and the individuals who denounce socialism as altogether evil are no more enlightened than those socialists who seek to minimise the importance of individual initiative.

Mr. Rogers deals with the pioneer laws of Australia and New Zealand in the matter of industrial arbitration. The wages boards, which, originating in Victoria, have done so much to stamp out sweating, are of special interest at the present moment, when it seems likely that the mother country will, in this as in so many other cases, follow the lead of the daughter States. In an appendix to the first portion of the volume a graphic account is given of the constitution of the Australian Commonwealth.

The second portion of the volume is devoted to geography pure and simple, and here the method of the first, or historical, portion is reversed, for whereas the history began with continents and ends with islets, the geography, in accordance with modern custom, proceeds from the local to the general; "the wayside flower will be examined before the garden and the garden before the forest." The book is a living entity which cannot be dealt with after the methods of the dissecting room; it must be read as a whole to be appreciated. Its perusal will be found to give both pleasure and a real acquisition in knowledge. Mr. Rogers is to be congratulated on the production of a volume in every way worthy of its place in a series designed by one so conversant with our colonial empire as Sir Charles Lucas.

John A. Cockburn.

## BRITISH ASCIDIANS.

*The British Tunicata.* An unfinished Monograph by the late Joshua Alder and the late Albany Hancock. Edited by John Hopkinson. Vol. ii., with Lives of the Authors by Canon A. M. Norman, F.R.S., and the late Dr. Dennis Embleton. (London: Ray Society, 1907.) Price 25*s*. net.

THE first volume of this work was published in 1905, and was noticed in Nature in the following year (vol. lxxiii., p. 508). So far as the so-called "simple" and "social" Ascidians are concerned, the work is now complete. No statement is made as to whether we are to expect a third volume on the "compound" Ascidians. We understand, however, that such a volume is in preparation, and that it will include a bibliography of the Tunicata by the editor. We may repeat our congratulations to the Ray Society for publishing this long-lost work, and to Mr. Hopkinson for his careful editorship under many difficulties. The numerous coloured and photographic plates included in this volume maintain the same high standard as in its predecessor, and the lives of the authors, by their friends Canon Norman and the late Dr. Embleton, which are prefixed to this volume, are full of interest for all who can appreciate the simplicity of nature and patient genius of two of the most distinguished pioneers in the field of British marine zoology.

Mr. Hopkinson has, with one exception, limited his notes to the addition of bibliographic and distributional records published before 1871. The monograph consequently possesses as nearly as possible the character which it would have assumed if it had been published in the latter year, two years before Hancock's death.

The present volume deals with Ciona and Corella among the Ascidiadæ, and with the families Molgulidæ, Cynthiadæ, and Clavelinidæ, in the broadest sense of these various terms. Between fifty and sixty "species" are described, of which no less than eleven are put forward as new. Three of the latter are referred to the genera Molgula, Cynthia and Clavelina respectively, two to Styelopsis, and six to Styela. In most of these cases it is more than doubtful whether the characters relied upon by the authors possess sufficient stability to serve as a criterion of specific differences. Some of these "new species" are undoubtedly mere variants from common types, together with other forms which are described in the monograph under names previously conferred upon them by the authors and other naturalists. The "new" species *Clavelina corrugata* is described as differing from the common *C. lepadiformis* merely in the wrinkling of the test and in the pinkish colour of the pharyngeal stripes, which are white or yellowish in the common type. A single tide-pool on the Devonshire coast will occasionally show half a dozen equally well-marked variants from the same type.

It would be tedious, as well as unprofitable, in this notice to enter upon a detailed comparison of the authors' nomenclature of recognised species with the systems in current use. But it is to be hoped that the publication of this monograph will not have the result of introducing further confusion into a subject already sufficiently tangled, in which the more critical revision work of the last twenty years has not yet produced complete concordance of results. The revival of Müller's *conchilega* for a species of Molgula is particularly unfortunate, for there is good reason to regard Müller's type as a common species of Ascidia, while Alder and Hancock's *Molgula conchilega* is plainly identical with Kupffer's *Molgula occulta*. It is doubtful, by the way, if Mr. Hopkinson is justified in assigning to this species the various records of *Ascidia conchilega* which have been based upon Müller's original description. The substance of a remark which I made in my previous notice may be fitly repeated, that the monograph, after all these years, must be cautiously used as a repository of descriptions and figures, but not as a guide to the classification or nomenclature of the group.

In one respect Mr. Hopkinson has departed advantageously from his rule not to add any observation of later date than 1870, since he has incorporated a definition of the genus Styelopsis, which was founded in 1882 by Traustedt for the common *Styela grossularia*, a species which Alder and Hancock themselves recognised as markedly distinct from the other species of Styela. In these circumstances the editor might well have pointed out that the form described by Victor Carus as *Thylacium sylvani*, which is included in this monograph under that name, is in all probability nothing but *Styelopsis grossularia*, of which the young individuals, fixed on the tests of the parents, had been erroneously regarded as evidence of gemmation. I can confirm all that Michaelsen has recently said on this point ("Revision der compositen Styeliden oder Polyzoinen," Hamburg, 1904), with some additions, since in 1891, with the permission of the Linacre professor, I dissected a portion of Carus's type in the Oxford Museum, and found it to be identical in structure with *S. grossularia*, while the so-called buds were true metamorphosed larvæ, possessing characteristic protostigmata (Proc. Royal Soc., li., pp. 505–13). In the following year also I searched the original locality, and many others, in the Scilly Islands, and found the same species covering the rocks in immense numbers, as described by Carus in the case of *Thylacium sylvani*. It is interesting to notice that in this monograph Alder and Hancock record the fact that they also had "seen" the original specimen in the Oxford Museum, and record their doubts as to the existence of gemmation, as well as their impression of the "very close resemblance between the *Thylacium sylvani* and some of the smaller gregarious Cynthiæ already described." The only discrepancy in this interpretation is the fact that Carus recorded *Cynthia rustica* (=*S. grossularia*) as well as *T. sylvani* from the Scilly Islands. Presumably the former term was restricted to the less crowded clusters in which the larvæ had not fixed themselves to the bodies of their parents.

WALTER GARSTANG.

## PRINCIPLES OF BREEDING.

*Principles of Breeding. A Treatise on Thremmatology.* By E. Davenport, with appendix by H. L. Rietz. Pp. xiii+727. Country Life Education Series. (Boston, New York, Chicago, London: Ginn and Company, n.d.) Price 12s. 6d.

THIS is the first serious attempt to present a modern scientific text-book on the principles of breeding (or, as the author prefers to call it, thremmatology) to English-speaking agricultural students, in which recognition is accorded to much of the recent work done on genetics and some other branches of the physiology of the generative system, and in which effort is made to show the essential value of that work to breeders. The book is most welcome, and our thanks are due for it to the professor of thremmatology in the University of Illinois.

The author's idea of what is needful for the education of an agricultural student is very far in advance of what is usually considered sufficient for that purpose; his book is adapted not only to convey a much wider knowledge of scientific work than has been hitherto thought necessary, but to demonstrate the direct effect such work must have on the fortunes, the ultimate success, of the modern practical breeder.

In spite of the fact that Prof. Davenport declares the breeder of the future will be a book-keeper and statistician, his book shows he has a somewhat wider appreciation of the breeder's qualifications than these words indicate. At the same time, it does seem possible that his enthusiasm for the pure science of genetics has led him to load his book somewhat too heavily with figures, and to neglect to inculcate with sufficient force the necessity for a breeder's close attention to and intimate knowledge of the capacities and peculiarities of individual members of a flock or herd. This is, in our opinion, a serious defect in a text-book for agricultural students; the power of close observation is an essential qualification for a breeder.

Similarly, the author's endeavour to induce the student to take "short cuts" to success is to be deprecated. He urges "A man must realise the fruit of his own labours." "The breeder must therefore work faster than nature." The "evolutionary principle" must be accelerated; and so forth. In so far as it is possible to gain these ends his attempts to further them are good, but he omits to point out that at the best these ends can be only partially gained, and that the evolutionary principle cannot be accelerated sufficiently to *satisfy* individual aims. He notes that "experience shows that the purposes, standards, and methods of a successful breeder are seldom handed down from one man to another," but he does not attempt to point out the means whereby this can be obviated, and yet it is the most severe handicap to progress which breeders suffer from.

There is one great opportunity which all professors of a big agricultural college have to their hand, that of organising a system of records of the practical results subsequently gained by all the students which pass through their schools. Such records, compiled by men trained by modern scientific methods and made available for use at their college, would be of incalculable value, both to the professors and the breeders of future generations; in order to carry out such a scheme, however, the student must be taught to understand that there are no short cuts to knowledge, and that the only way they can hope to accelerate the acquisition of knowledge of evolutionary principles is by pooling their experiences, their failures as well as their successes.

Part i., on variation—the author makes variation rather than heredity the initial leading thought of his scheme, putting the cart before the horse and thereby somewhat confusing the issue—is a brief *résumé* of some of the leading features of that branch of the subject, instances being given of a kind specially suitable to stimulate the interest of American students, for whom the book is written.

Part ii., on the causes of variation and the relative stability of living matter, and part iii., on transmission, constitute the bulk of the book. The author's clear and forcible writing, the thoroughness of his treatment, the arrangement of his facts, and the wealth of illustration he gives are worthy of great praise. These sections are not only a valuable summary of what is known, but contain much original thought, and deserve the attention of all students of the subject.

Part iv. is on practical problems. Those dealt with under the headings selection, systems of breeding, plant breeding, and animal breeding are full of good common sense and sound advice; any breeder would do well to consult them.

Thus if it has failings the book has great merit, and it is to be hoped the example set by Prof. Davenport will be followed in this country, where the education of agricultural students in the science of breeding is sadly behindhand.

## THERMOCHEMISTRY.

*Thermochemistry.* By Julius Thomsen; translated from the Danish by Katharine A. Burke. Pp. xv+495. (London: Longmans, Green and Co., 1908.) Price 9s.

OWING to the rapid strides which have recently been made in physical chemistry, the subject of thermochemistry, which is itself of a physical nature, has been rather left in the background. At one time it was hoped that thermochemistry would be of very great help in elucidating the hidden laws governing chemical reactions, but unfortunately it has hardly realised expectations.

Although a very large amount of work has been done upon this subject, we can hardly say that it has been found possible to rely upon thermochemical methods to give us more than a general idea as to the course of reactions. At the same time, it is by no means a subject which can be dismissed as being useless, because a very great deal of help may at times be obtained by the study of thermochemical data. For example, in manufacturing operations, it is of the first importance to know heats of combustion, because the number of calories required to decompose a substance is of course a guide to the manufacturer in connection with the energy required in a given process.

Quite recently Prof. J. W. Richards contributed a very useful and interesting series of papers in an American technical journal upon the thermochemistry of metallurgical processes. Furthermore, the subject is of great importance to the electrochemist, who is able to determine the voltage necessary to be employed in an electrolytic process if he knows the heats of combination of the compound. Or we might take another example. In aluminothermics it is owing to the very high heat of formation of aluminium oxide that such an enormous amount of heat is given out when aluminium reacts with certain metallic oxides, and consequently one can tell beforehand whether a given oxide will be readily reduced by means of aluminium or not.

Of all the workers in the field of thermochemistry none has done such thorough, careful, and pioneering experimental work as Julius Thomsen, and it was a happy idea of Sir William Ramsay to include a translation of Thomsen's Dutch work in the well-known text-books on physical chemistry which are now finding such an important place in the chemical literature of the country; and we may say at once that Miss Burke has done her part of the work extremely well. As she states in the preface, it has been necessary at times, owing to the advance in other branches of physical chemistry, slightly to alter the reading of certain sentences; for example, taking her own illustration, where Thomsen has used the expression "Neutralisation is regarded as a union of acid and base, with formation of water," Miss Burke has changed this to "Neutralisation is regarded as a union of acid hydrogen and basic hydroxyl to form water." Undoubtedly some chemists will take exception to such an alteration, and will say it is pedantic and unnecessary, particularly those who are not attached to the ionic theory, and, after all, there are a goodly number who consider there are many difficulties which require to be cleared up before the ionic hypothesis can be considered fundamental.

The first portion, the introduction, introduces the subject with an explanation of experimental calorimetric methods, the apparatus being described and illustrated, and the methods of using it fully gone into. Chapter i. deals with the absorption of gases and the heat produced when they, liquids or solids are dissolved in water, and a number of tables are given, with the thermochemical data. The next chapter deals with the rather complicated question of heat of hydration; the methods of calculation for obtaining the heat formation of different compounds, provided the heat formation of certain substances is known, are carefully set out throughout the pages. The book not only deals with inorganic compounds, but also with a very large number of organic substances, the tables in chapter xii. being exceedingly full. An interesting part of this chapter is that in which the heat formation of isomeric compounds is given. Thus the difference of heat formation of propyl and isopropyl alcohol is 5·3 cal., that between isobutyl alcohol and trimethyl carbinol being 17·15 cal.

In fact, the book deals with Thomsen's work, and will undoubtedly be found extremely useful to any investigator who wishes to study this branch of the subject, and as a book of reference to be kept in all chemical libraries, though hardly, we think, for general reading, as it is rather too full for this purpose.

F. M. P.

## MATHEMATICAL TEXT-BOOKS.

(1) *The Elements of the Geometry of the Conic.* By Prof. G. H. Bryan, F.R.S., and R. H. Pinkerton. Pp. xi+270. (London: J. M. Dent and Co., 1907.) Price 3*s.* 6*d.*

(2) *Geometry, Theoretical and Practical.* By W. P. Workman and A. G. Cracknell. Part ii. Pp. ix+(330–535). (London: W. B. Clive, 1908.) Price 2*s.*

(3) *Practical Integration for the Use of Engineers, &c.* By A. S. Percival. Pp. vi+86. (London: Macmillan and Co., Ltd., 1907.) Price 2*s.* 6*d.* net.

(4) *Integration by Trigonometric and Imaginary Substitution.* By C. O. Gunther. Pp. vi+79. (London: A. Constable and Co., Ltd., 1907.) Price 5*s.* net.

(5) *A Course in Mathematics for Students of Engineering and Applied Science.* By F. S. Woods and F. H. Bailey. Vol. i., Algebraic Equations, Functions of one Variable, Analytic Geometry, Differential Calculus. Pp. xii+385. (Boston, New York, Chicago, London: Ginn and Co., n.d.) Price 10*s.* 6*d.*

(1) THIS is an attractive little book on geometrical conics. The argument is very clear, and presents the subject to a beginner in the simplest possible manner. The difficulty in writing a text-book of this sort lies in the fact that many properties of conics are far more easily treated by analytical than geometrical methods. The authors have met this difficulty by putting first those results which lend themselves more readily to geometrical proofs; other theorems are left until later on, and then the methods, if not the nomenclature, are analytical. A reasonably large number of examples is given, which are nearly all of a graphical or numerical nature. This is a pleasing innovation, and theoretical examples can be supplied by the teacher, if required, from almost any other text-book. A property of the parabola is discussed at the same time as the corresponding property of a central conic; much might be said both for and against this course. Many of the proofs are ingenious; the construction of the hyperbola by means of string and pins alone is worth noticing. A chapter is given in which are discussed those properties of the cycloid, catenary, &c., which can be proved without the aid of the calculus.

(2) This book covers the ground of Euclid ii., iii. 35 to 37, iv., and vi., together with the properties of harmonic (but not of anharmonic) ranges, the nine-point circle, the radical axis, poles and polars, inverse figures, &c. The text is on the whole more theoretical than practical; the examples are divided into theoretical riders, practical constructions, and calculations, a good and sufficient collection of each being given. The book contains rather more than the average student will require; the authors asterisk some of the less necessary sections, and probably the teacher will advise the omission of others also. The properties of rectangles are developed from the geometrical standpoint; algebraic methods are, however, also given. In the theory of proportion only commensurable quantities are dealt with at first, the extension to incommensurables being given in the last chapter. The book is sound and sensible throughout, and deserves to hold its own easily in the severe competition which text-books on elementary geometry have to face at present.

(3) The author starts by defining integration as the inverse of differentiation, and then shows how to find the indefinite integrals of all the usual standard types. This part of the book may be quite useful, but the latter portion is not so satisfactory. The author has attempted too much for the space at his disposal, and sacrifices in places not only soundness but intelligibility also. Definite integrals are introduced without any adequate explanation, and the connection between definite and indefinite integrals is obscure. It is almost impossible to make applications of the calculus to geometry clear without a single diagram or without proving that a definite integral may be considered as the limit of a sum; this is, however, what the author attempts. In fact, the argument is too condensed to be followed by the type of student for whom the book is written; for instance, such a step as " $-d\theta/dt=a\theta$, $\therefore d\theta/\theta=-adt$ " is sure to give trouble if unexplained.

Minor errors are the statement of the "test-ratio" rule on p. 36, and misprints at the bottom of pp. 42, 43. A book which aims at being "practical" should not calculate the temperature of a cup of tea to four places of decimals.

(4) This book is very short; for the margins and print are large, while twenty-six of its seventy-nine pages are occupied by a somewhat superfluous introduction, and fifteen by solutions of examples. The remainder is devoted to the indefinite integral of $\cos^m x \sin^n x$ ($m$ and $n$ integral) without the aid of reduction formulæ, and to the integral of expressions involving $\sqrt{a^2-x^2}$, $\sqrt{a^2+x^2}$, &c. This latter part is done better in other books; for surely in integrating $\sqrt{a^2+x^2}$ the substitution $x=a \sinh\theta$ is preferable to $x=2a \sin\theta$.

(5) This book is intended to cover the mathematics learnt in the first year of a two years' course at an engineering school. The authors disregard the traditional division of mathematics into distinct subjects, and introduce the principles of each subject as needed. By thus developing algebra, analysis, and calculus side by side the student has his interest stimulated, realises the interdependence of different parts of mathematics, and learns the art of choosing the best method of attacking any given problem. Against this must be set the fact that the conventional division of mathematical study has the great advantage of helping the student to systematise his knowledge. If once we admit the principle of no division, we could hardly wish for a better book. The subjects are very skilfully coordinated; the treatment throughout is sound and mathematical without ceasing to be interesting or "practical." The examples are useful and very numerous, and answers are given. In this first year's course is covered a good deal of the more elementary parts of the theory of equations, determinants, graphs, analytical geometry as far as the general equation of the second degree, and differential calculus, including curvature and critical values of functions, but not asymptotes. Conics, especially geometrical conics, are treated less fully than usual; their place is partly taken by other interesting curves. Excellent and interesting though the book is, it makes heavy demands on the reader's attention; and would probably require considerable ability on his part if it is to be mastered in one year.

## OUR BOOK SHELF.

*Nephilim.* By William J. H. Bohannan. Pp. 236. (New York: Reeve A. Silk, 1908.) Price 1.50 dollars.

"THIS book is written," so we are told, "to show the error of 'science,' and to point out the truth of statement of the Bible concerning physical phenomena."

It certainly does show the error of "science," as understood or misunderstood by the author of the book. The following extracts are given merely as examples of the style in which the book is written:—

"The more the thermic dominates in structural composition of a body, the more penetrable it is to the magnetic entities of the field of another and the less to the thermic of that field."

"The earth's thermic entities of field, emitted from her equatorial region, her southward geographical pole being toward the sun, were taken outward from him, under the action of the entities of his field, her inseparable thermic entities of field enveloping the separable of her northern regions."

As a further example, we are informed by way of correction that "Nephilim," p. 154, fourth sentence, should read: "The planet Jupiter, on the other hand, had three tails, two visible to human eye, passing outward from the poles of the planet and from the sun; the other one magnetic and invisible, but vastly greater than the visible, passing from the equator of the planet toward the sun."

Some of the chapters suggest a kind of vortex theory, while others profess to deal with the theory of the tides. The author of "Nephilim" would have stood a better chance of recognition if he had made a careful study of the whole existing literature on one or other of these two subjects. The mere quotation of extracts from articles in popular encyclopædias, the contributors of which were probably limited to 1000 or 2000 words, is a very small step in that direction. Such short articles were never intended to give a complete explanation of all the difficulties which have been studied in connection with these theories;

*e.g.* the difficulties which the author raises in connection with the energy of wave motion. No good can come of ignoring the vast number of papers that have been published dealing with such difficulties.

There are hundreds of books already written in the same polemic spirit as "Nephilim." The author of each of these books believes himself to be right and everyone else to be wrong, and nearly every possible permutation of the words "force," "energy," "atom," "ether," "gravitation," and such like is represented in the different meanings (if any) the different writers attach to these terms. It would be well if future would-be writers of such books would try their hand at evolving some kind of order out of this tangled mass of mutually contradictory tirades before adding to the collection.

*Le Principe de la Conservation de l'Assise et ses Applications.* By George Matisse. Pp. 65. (Paris: Libraire scientifique, A. Hermann, 1907.) Price 2.50 francs.

This small pamphlet describes clearly and simply certain applications of Carnot's principle to physical problems. The unique feature of the book is indicated in the title. The word "assise" groups together certain variables which refer to distinct physical quantities, but which enter into the equations of energy in the same manner. The only equivalent English word we can suggest is the word "fundamental." The solution of many types of problem may then be said to depend on the two principles of the conservation of the fundamental and the conservation of energy. The differential of energy depends in general on a product of the form $xdy$, the precise meaning of $x$ and $dy$ depending on the kind of problem under contemplation, electrical, thermal, elastic, mechanical, or chemical, as the case may be. In these several cases the "assise," symbolised above by $dy$, is respectively electric quantity, entropy, volume, length, and mass. Such quantities all obey the conservation law, which the author concisely defines in these words:—Under the action of physical and chemical phenomena there can be no creation of electricity, of space (linear or cubical), of entropy, or of matter. Four applications are given in which the principle of the Carnot cycle is ingeniously utilised. The novel use of the word "assise" seems to be the main feature of the pamphlet; otherwise there is not much which calls for special remark.

*The Case for the Goat.* With the practical experience of twenty-four experts. By "Home Counties." Pp. x+162. (London: George Routledge and Sons, Ltd., 1908.) Price 3*s.* 6*d.*

It is hoped this little book may help to remove ignorant prejudice against the goat, and induce small holders, labourers, and many rural residents to keep this valuable animal. The advantages to be derived from the "poor man's cow" are very imperfectly known in England, and the author sets himself to show what they really are. Goat's milk, he points out, is often as rich again as cow's milk; it may practically be guaranteed to be free from the bacillus of tuberculosis, and is a very valuable food for children, especially for those who cannot digest cow's milk. Moreover, the amount of milk goats yield, and the ease with which food is to be found for them—they will pick up a living in the hedgerows—ensures a very cheap supply of food for rural owners; while they thrive as hand-fed occupants of back yards in the suburbs, and require no more space than a big dog.

The author complains that the Board of Agriculture does not see its way to include the goat in its agricultural census, treating it as a negligible quantity, while a further bitter grievance against the Board is due to its refusal to permit the importation of new blood under guaranteed restrictions, when the goat stock of the kingdom is suffering from in-breeding to a deplorable extent. Less than a score of stock goats are urgently required for this purpose, and the Board's action is not inaptly described as "an oppressive absurdity."

The different breeds of goats suitable for this country, their management, breeding, and the substantial profit to be made out of them is clearly set forth. It is an interesting little book, and the author surely proves his case.

*Confessio Medici.* By the writer of "The Young People." Pp. xi+158. (London: Macmillan and Co., Ltd., 1908.) Price 3*s.* 6*d.* net.

"Confessio Medici," a title which naturally recalls that of another book by a great physician, need not fear comparison even with Sir Thomas Browne's immortal work, and surely no higher praise can be accorded it. In a series of essays on such subjects as "vocation," "hospital life," "practice," "retirement," "the very end," &c., the author presents to the reader a survey of the responsibilities, the foibles, the hopes, the failures of medical practice. We wish that every student of medicine during his student days would read, mark, learn, and inwardly digest their practical wisdom and happy maxims, and many a practitioner whose finer feelings have perhaps become blunted by too close contact with a stringent life would rise up the better from their perusal.

## LETTERS TO THE EDITOR.

*[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.]*

### Who Built the Aberdeen Stone Circles?

In an article in Nature of April 9 dealing with the orientation of the Aberdeen stone circles, Sir Norman Lockyer says:—"Another of the associated inquiries will be to see if the area of the recumbent stone has also special ethnological or craniological characteristics." It may be of interest, in this connection, to point out that the short cist skeletons in the anatomical museum of Aberdeen University have been derived from an area coinciding very closely with that of the Aberdeen stone circles. These skeletons have been recently measured by Dr. Low (see Proceedings of the Anatomical and Anthropological Society, University of Aberdeen, 1902–6), and the measurements, as I showed in a paper read before the British Association at York, reveal the existence, in the early Bronze age, in this district, of a race significantly different from all the prehistoric racial types previously determined in Britain. This race is hyperbrachycephalic, having an average cephalic index of 85, and it is of short stature, 5 feet 3 inches. It differs from the Neolithic race, which was markedly dolichocephalic, and it also differs from the Bronze age race of the round tumuli, whose index was 78 and stature 5 feet 9 inches.

The origin of this prehistoric Aberdeenshire race, with a cephalic index so much higher than that of all known races in neighbouring countries, is at present one of the unsolved problems of British ethnology. Its close association with a special form of stone circles may help to throw some light on the origin of these interesting monuments, as well as on its own.

J. Gray.

London, S.W., May 11.

### Radio-activity of Potassium and other Alkali Metals.

PROF. McLENNAN's letter in NATURE of May 14 (p. 29) makes it desirable that I should record that my experiments continue to be in contradiction to those he describes. Whether the activity of potassium is due to an extraneous impurity or to the element itself, it is to be expected that some separation of the activity should be possible. For the last year and a half I have been trying to effect such a separation without result. All samples of the same pure salt which I have procured or prepared are identical in activity. In one experiment a sample of the sulphate was crystallised twenty-two times, in another a sample of the nitrate was crystallised eighteen times without introducing any difference between the final products; in a third a sample of potassium sulphate was prepared direct from wood ashes, and found to agree with a commercial sample prepared from the Stassfurt deposits. I propose now to prepare a third sample direct from felspar.

The only difference which I can detect between Prof. McLennan's experiments and my own lies in the fact that he places the active material inside the ionisation vessel, while I place it outside an aluminium window. If he were measuring the effect of very soft rays, the difference between our results might be explained.

NORMAN R. CAMPBELL.

Trinity College, Cambridge, May 14.

### On Dispersion and Spectrum Series.

IN reply to Mr. Campbell's letter of April 30, it must suffice to point out that my letter of March 5 was limited to infinite spectrum series and to luminous gases. This seemed to me at the time of writing obvious from the context, as well as from the express reference to the finiteness of the refractive index of *luminous* hydrogen. Apparently I was mistaken; anyhow, Mr. Campbell's suggestion that I confused the emission lines of luminous with the absorption bands of dark hydrogen rests on a misconception of my meaning.

To avoid further misunderstanding, I will add that by "electrical theory of absorption and dispersion, of magnetic rotation and Zeeman effect," I mean, of course, the theory of Drude, together with its extension by Voigt to *all* magneto-optic phenomena; I do not mean theories such as those of Lorentz and Ritz, which deal with the Zeeman effect alone. I know no reason for confining that theory to one member only of a series, *e.g.* the D lines of sodium, and contend that it leads to contradictions when applied to all the members of an infinite series of similar lines.

The remaining points raised by Mr. Campbell seem to me foreign to my argument. I cannot discuss them in the space at my disposal here, but hope to do so elsewhere.

Bonn, May 8. G. A. SCHOTT.

### Secondary Waves of Light.

IT has hitherto been held that, so long as the diffraction apertures used (cut in perfectly opaque or perfectly reflecting screens) are large compared with the wave-length of light, Fresnel's expression for the amplitude of the disturbance due to a surface-element gives us a close approximation to the observed diffraction effects, and that the exact value for the obliquity factor is of little importance (*e.g.* see Schuster's "Optics," sec. 48). That this is true only in the special case in which the apertures are held normal to the waves of light, and not in other cases, is shown by some new diffraction phenomena that I have made the subject of study.

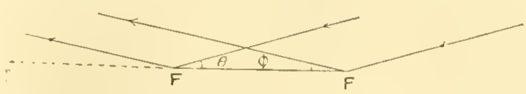
The only experiment so far known which might seem to show effects due to the obliquity factor is the well-known one with the circular disc, but it is really inconclusive. The observed fact, that the illumination along the axis of the disc decreases as the disc is approached, is more or less entirely due to minute irregularities in the rim of the disc, and not, as is sometimes stated, to the increasing obliquity of the secondary waves producing the illumination.

The theoretical grounds on which my experiments were based were these:—if diffraction bands are produced and observed in a direction in which the amplitude of the disturbance in the secondary waves varies rapidly from point to point, we might expect effects due to varying obliquity. Such effects would obviously not occur if the diffraction aperture or mirror is, as is usual, held normal to the waves of light incident on it, but might if it be held obliquely.

In the *Philosophical Magazine* for November, 1906, I showed that the diffraction bands due to a rectangular aperture held very obliquely are not equidistant, that the band-width increases progressively from one side of the pattern to the other, and that the number of bands on one side of the pattern is limited. They are most easily seen on the spectrometer if the image of the slit of the instrument formed by light reflected very obliquely from the face of a prism is observed. The positions of the minima of illumination, actually observed, are closely in agreement with those calculated from the usual formula ($\cos\theta - \cos\phi = \pm n\lambda/a$), $\theta$, $\phi$ being the complements of the angles of incidence and diffraction. Further observations have elicited the following:—from the expression for the intensity of the illumination in the pattern deduced by the ordinary method

$$I = a^2 \sin^2 \frac{\pi a}{\lambda}(\cos\theta - \cos\phi) \div \frac{\pi^2 a^2}{\lambda^2}(\cos\theta - \cos\phi)^2,$$

it would appear that the maxima of illumination in corresponding bands on either side of the middle one should be of equal brightness. This is flatly contradicted by observation, both visual and photographic. It is found that the bands on one side are considerably fainter than those on the other, and this difference becomes very large as the light approaches grazing incidence. The illumination in the diffraction pattern (with a given angle of incidence) decreases and dies away as we approach the limiting plane of the fringes, which is the plane of the reflecting surface (FF in the diagram).



This effect is inexplicable if the question of the variation of the amplitude in different directions of the secondary waves, supposed to be sent out by the elements of the reflecting surface FF, is not taken into account. It must be remembered that we are not dealing with apertures small compared with the wave-length; both the aperture and its projection are large compared with $\lambda$, and there are no polarisation effects observed. The question may be attacked analytically, and it can be shown that an element of the surface of a reflecting body is equivalent in its effect to a double source of appropriate intensity which, it is known, produces zero effect in its equatorial plane and a maximum along its axis. The effect of an element of the surface FF is therefore zero along the line FF, and in other directions increases as we move away from the line FF. Remembering that the elements are not in the same phase, and integrating their separate effects, we get an explanation of the phenomenon observed.

A fuller discussion and a mathematical investigation will be published in due course. I found that similar effects are observed when the transmitting aperture is used. Some experiments with coarsely ruled gratings are in progress which seem to point in the same direction.

C. V. RAMAN.

Science Association Laboratory, Calcutta, April 2.

### The Corrosion of Iron and Steel.

IN NATURE of May 14, Dr. J. Newton Friend alludes to *Gallionella ferruginea* as obtaining its life's energy by oxidising ferrous carbonate and organic ferrous salts, causing the precipitation of rust, or ferric hydroxide. May I point out that *Gallionella ferruginea* can live and grow well without any iron at all, and so cannot be a vital factor in the metabolism of the bacterium, using the term "bacterium" in its widest sense? The oxidation which takes place can be simply explained by the fact that ferrous carbonate in solution is very unstable, becoming very rapidly oxidised.

W. F. MACFADYEN.

54 Dunard Street, Glasgow, May 16.

## INVESTIGATION OF THE UPPER ATMOSPHERE.

THE work carried out in England in connection with the investigation of the upper atmosphere forms part of a wide and well-organised scheme. On certain days appointed by an international committee, balloons and kites are sent up from some thirty stations scattered all over the world. The kites are used for the study of the lower layers, and free balloons for greater altitudes. In a discussion bearing on the isothermal layer we have therefore only to deal with the latter.

Abroad, instruments of many types have been designed and improved by Hergesell, Assmann, Teisserenc de Bort, and de Quervain. The fact that nearly twenty different modifications exist is sufficient excuse for not undertaking here an analysis of their respective merits. These instruments cost from 10*l.* to 12*l.*, and their weight, which exceeds a pound, involves the use of relatively large and expensive balloons.

In Continental countries but few instruments are permanently lost, and as very substantial Government grants are in most cases available, the question of working expenses is not of vital importance. In England we are financially and geographically less favourably situated, and there is little doubt that but for the energy and inventive genius of one man, little work would have been attempted.

The Dines balloon meteorograph costs one-tenth and weighs one-eighth of the corresponding Continental instruments. The record, though microscopic, is nearly *indestructible*, for it is engraved by two sharp styles on a sheet of copper. This constitutes an important improvement, for the ordinary smoked record is not infrequently obliterated by the time the instrument is returned.

The record consists of fine lines, which remain parallel as long as the temperature remains constant. The bimetallic thermograph is carried on a support which is moved by the barograph. In ordinary circumstances a curve is obtained for any point of which the abscissa measures the deflection of the barograph, and the ordinate minus a constant the deflection of the thermograph.

The calibration of the thermograph is a simple matter, the deflection being practically a linear function of the temperature. The calibration of the barograph, on the other hand, offers considerable difficulties.

Variation of Atmospheric Temperature with height on April 2, 3 and 4, 1908.

In order to increase the sensitiveness of the instrument without adding to its weight, it is necessary to leave a certain amount of air in the aneroid box. This, as also the change of elasticity of the metal, causes the calibration of the instrument to vary considerably with temperature, and adds materially to the labour involved in reducing the results.

After trying and abandoning various methods of approximation, Mr. W. A. Harwood, who is in charge of this branch of the work at Manchester, now draws out for each instrument a number of independent calibration curves, each one referring to one definite temperature. These form a series of nearly parallel curves, which cover the range of temperature and pressure over which the instrument is used. The calibration made before the ascent is verified after the return of the meteorograph.

The accuracy obtainable of course decreases with the density of the air; over the first few kilometres a difference of level of less than a hundred metres is easily measured, but when the height attained is such that the prevailing pressure is only one-tenth of an atmosphere, the possible error becomes considerable.

The diagram here given, which refers to the last date on which balloons were sent up on three consecutive days, is a typical example of the results obtained. The Manchester record for January 2 lies between the Pyrton Hill curves for January 3 and 4 up to about 9 km., above which height the temperature remains constant for some distance. Two traces were inscribed by the instrument sent up from Manchester on January 4. Probably in this case, as occasionally occurs, the balloon did not burst and fall at once on attaining the maximum height, but drifted down slowly as the gas diffused out. In such cases the time to which the second trace applied cannot be determined, and the rise of temperature might well be due to the next day's solar radiation. Trustworthy or otherwise, this trace has its place on the present diagram, the primary object of which is to give a complete collection of the results obtained from one set of ascents. The Pyrton Hill balloons were sent up at 3 p.m., and the Manchester ones at 6 p.m.

It is noticeable that during the three days the average temperature gradients between 2 and 8 kilometres (*i.e.* above the disturbing influence of the ground, but below the level of the isothermal layer) remained practically constant, whereas a considerable difference existed between the temperature of the isothermal layer as measured on January 2 and 3.

Generally speaking, many improvements of the methods and instruments are doubtless still required, but it must be remembered that the work in England was commenced less than a year ago, and perfection can hardly be expected within so short a time.

J. E. PETAVEL.

## HOME AND FOREIGN BIRD-LIFE.[1]

THE authors of these three excellent little works are evidently enthusiastic bird-lovers and accomplished and patient observers. In the case of the first two, at any rate, their highest enjoyment appears, indeed, to consist in sitting for hours watching the movements and ways of their feathered favourites. Moreover, either they or their friends are well accomplished in the use of the camera, and they have thereby been enabled to make permanent records of many of the fascinating sights that have come under their observation for the benefit of those who have neither their patience nor their opportunities.

Mr. Gordon's favourite species appear to be the golden eagle and the ptarmigan, the photographs of both of which are claimed to be nearly, if not indeed completely, unique. To obtain the picture of the golden eagle's eyrie the author underwent considerable difficulty not unmingled with danger, while peril of another type was experienced when a fog suddenly descended as he was wandering among snow-clad precipices in search of ptarmigan. The photographs have therefore more than their apparent face-value, which is of itself considerable. Where all are interesting it is difficult to make a selection, although personally we have been much interested in the series of photographs of a young golden eagle at various stages of growth, one of which is here reproduced.

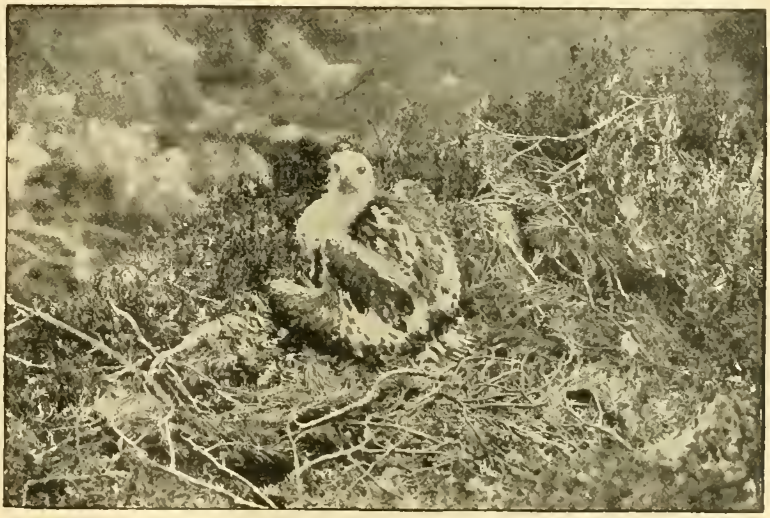


FIG. 1.—Golden Eagle six weeks old. The bird fell from the original eyrie and is here shown in one made by parent birds at the foot of the cliff. From "Birds of the Loch and Mountain."

Mr. Charles Barrett, in "From Range to Sea," covers comparatively new ground, and has attempted to accomplish for some of the birds of Australia what has already been done for those of our own islands. It must be confessed, however, that the illustrations in his booklet (whether from the fault of the photographs themselves, of the reproductions, or of the printer we cannot say) are by no means up to the level of those in some books of English bird-life. In the tiny and exquisitely built nests of such species as the rufous and the white-shafted fantail, with the parent-bird in attendance, the author has subjects quite different from any met with in this country, and in portraying these novelties he appears to have availed himself to the full of his opportunities. The nest of the lyre-bird forms, perhaps, a still more striking subject, which was the scene of an altogether unexpected incident. "On inserting my hand in the nest," writes the author, "a piercing cry, like the whistle of a steam-engine, rang down the gully. It was difficult to realise that the half-fledged lyre-bird which I could feel inside the nest was the cause of this unearthly clamour."

The present booklet is an excellent beginning in Australian bird-photography, and we shall look in the future for more work in the same style from the author and his artist, Mr. Mattingley.

The book standing third on our list is of a somewhat different type from either of the two already noticed, presenting in some degree an approximation to a popular history of South African birds generally. It may serve, in fact, as a kind of popular representative of the volumes on birds in the "Fauna of South Africa," and should be of the greatest value to a large number of persons who for one reason or another are unable to refer to the latter. Indeed, by means of the numerous excellent photographs with which it is illustrated, this volume will enable the sportsman and amateur naturalist in South Africa to determine without any great difficulty a very considerable proportion of the birds with which he may be brought in contact. The illustrations (of which a sample is reproduced) are for the most part excellent, while the text contains a sufficient amount of anecdote and local colouring to redeem it from the charge of dulness.

Personally we have found special interest in the author's account of the eggs and parasitic habits of the honey-guides and cuckoos. Honey-guides, it appears, actually storm the breeding-holes of the species upon which they are parasitic, as was witnessed by the author in the case of a pair of barbets, which offered a fierce resistance to the intruder. As regards cuckoos, it is absolutely certain that in South Africa these birds must generally lay their eggs on the ground and transport them in their beaks to the foreign nests, which they are too large to enter. All the African cuckoos normally lay coloured eggs, but when they lay in nests of species with white eggs, their own eggs are also often white. In the case of the golden cuckoo the author states that "a pure white egg was taken from the oviduct of a female

[1] "Birds of the Loch and Mountain." By Seton P. Gordon. Pp. xvi + 181; illustrated. (London: Cassell and Co., Ltd., 1907.) Price 7s. 6d. net.

"From Range to Sea; a Bird-lover's Ways." By C. Barrett. Pp. 62; illustrated. (Melbourne: T. C. Lothian, 1907.) Price 1s.

"Sketches of South African Bird-life." By A. Haagner and R. H. Ivy. Pp. xxiv+181; illustrated. (London: R. H. Porter, 1908.) Price 20s. net.

shot at the Crocodile River; a white egg was also found in the nest of a Cape wagtail, which was allowed to hatch to make identity certain; further, we took a white egg from the nest of the little red-vented tit-babbler. . . . The usual host is the Cape sparrow, both of us having taken the cuckoo's eggs—coloured like those of the sparrow—from the nests of this bird." Unfortunately, there is no information as to whether there are "white-egged" and "coloured-egged" strains of cuckoos in Africa, or whether the same bird may lay white or coloured eggs according to circumstances.

FIG. 2.—Black-shouldered Kite. From "Sketches of South African Bird-life."

The book is a welcome addition to South African ornithological literature.

## *THE ROYAL SOCIETY'S CONVERSAZIONE.*

THE first of the two conversaziones given annually by the Royal Society was held at Burlington House on Wednesday of last week, May 13. The guests were received by Lord Rayleigh, president of the society, and included leading representatives of many branches of intellectual activity. There were a large number of exhibits, illustrating methods and results of recent scientific work, and in the course of the evening demonstrations were given in the meeting room by Mr. C. V. Boys, F.R.S., on the dynamics of the game of diabolo, Mr. Francis Fox, on the operations involved in the saving of Winchester Cathedral and other ancient buildings, and Mr. C. Gordon Hewitt, on the natural history of the house-fly. Following our usual practice, we give a summary, with a few additions, of the descriptive catalogue of exhibits, and so far as possible have grouped together the exhibits referring to related subjects.

*The British Contribution to the International Investigation of the Upper Air*, 1907–8: The investigation of the upper air under the auspices of the "Commission internationale d'Aérostation scientifique" is now fully organised. This country has taken part in the work unofficially since 1902, and officially since 1904. The investigation as carried on in this country is three-fold. The first part consists in measurements of temperature, humidity, and wind velocity at different levels up to about 10,000 feet, by meteorographs raised by kites. For the second part, automatic traces of the relation between pressure (height) and temperature are obtained by means of meteorographs borne by unmanned balloons (*ballons-sondes*). The balloons are arranged to reach heights up to 22 kilometres in about two hours, and then to burst and descend. The finder is invited to return the instruments and claim a reward. For the third part, the bearing and elevation of small pilot balloons are observed at measured intervals of time by one or two theodolites, and the motion of air currents at different levels is computed from the observations. The exhibits were by Dr. W. N. Shaw, F.R.S., Mr. J. E. Petavel, F.R.S., and Mr. W. A. Harwood, Mr. C. J. P. Cave, Captain C. H. Ley, Mr. Eric S. Bruce, and the Director-General of the Survey Department, Egypt; they illustrated the methods referred to and the results obtained by British investigators.

*The Astronomer Royal:* (1) Photograph on which the new eighth satellite of Jupiter was discovered by Mr. P. Melotte, showing also the sixth and seventh satellites, and photograph of the ninth satellite of Saturn (Phœbe); (2) diagrams of positions of Jupiter's and Saturn's distant satellites, from photographs taken at the Royal Observatory, Greenwich, with the 30-inch reflector; (3) drawings of the solar corona at the eclipses of 1898, 1900, 1901, and 1905, made by Mr. W. H. Wesley from the original negatives; (4) eclipse of 1901, May 18, from photographs taken in Mauritius, and eclipse of 1905, August 30, from photographs taken at Sfax, Tunisia.—*Solar Physics Observatory, South Kensington:* (1) Enlarged photographs of stellar spectra; (2) spectrum of a sun-spot; (3) spectroheliograph disc photographs, taken in "K" light; (4) photographs of prominences, taken in "K" light; (5) photograph of Aberdeenshire stone circle with Cornish circle for comparison.—*Mr. J. Franklin-Adams:* (1) Machine for counting stars upon the 15 inch by 15 inch plates of the Franklin-Adams chart. As the number of stars upon this chart is estimated at 23,000,000, only special areas—selected by Prof. Kapteyn, of Gröningen—will in the first instance be counted. This machine, by Troughton and Simms, is designed to work with such accuracy that regions adjacent to the selected areas may afterwards be added without omissions or overlappings. (2) Machine for drawing precession lines upon the plates of the Franklin-Adams chart. This machine has been designed to draw to a hundredth of a millimetre, if necessary, precession lines giving star places at epochs 1855, 1875, 1900, and 1925, both in Right Ascension and Declination.

*Mr. J. S. Wilson and Mr. W. Gore:* India-rubber models and apparatus used for the investigation of the distribution of stress in dams (Fig. 1). The model, which rests on the top of the trestle, consists of a slab of india-rubber cut to represent the section of a masonry dam, together with its foundation and substratum. The water pressure against the dam is reproduced by plates pulled against the upstream face of the model by cords passing over pulleys and attached to weights. The correct ratio between the density of the fluid represented by that pressure and the density of the masonry (1 : 2·25) is maintained by suspending a large number of weights from pins passing through the model at uniformly distributed points. To obtain strains large enough to measure, both densities are magnified forty times. Photographs are taken of the model and the system of lines ruled on it, one when unstrained and the other when strained by the various forces. The strains are determined by measuring corresponding lengths and angles on the two photographic negatives by means of the optical projection micrometers which are exhibited. The stresses are calculated from the measured strains by the equations relating them, which have been experimentally verified.

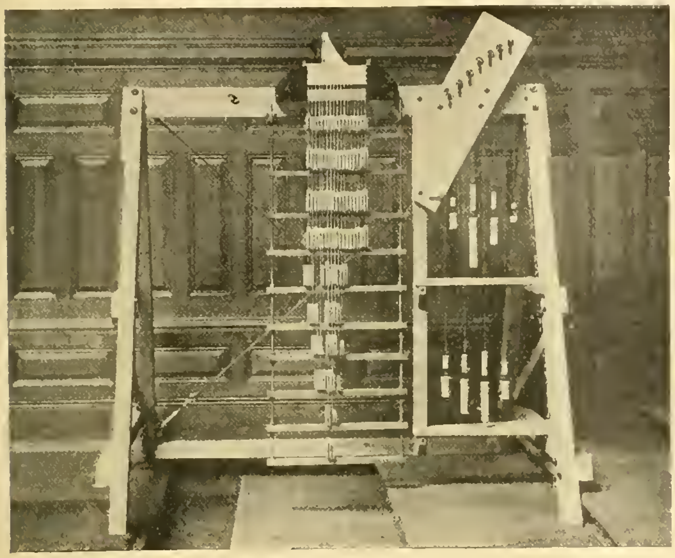

FIG. 1.—India-rubber model and apparatus used for investigations of distribution of stress in dams.

*Sir John Thornycroft, F.R.S.:* An instrument to indicate the relative rate of turning of two bodies. A sphere supported on two equal revolving cylinders rotates on axes in the same plane as the axes of the cylinders; the angular position of the axis of the sphere depends on the relative velocities of the two cylinders, and is indicated by a hand controlled by a roller touching the sphere.—*Mr. C. V. Boys, F.R.S.:* (1) A modification of the well-known hypocycloidal straight line motion of very simple construction, and requiring guides only $2\sqrt{2}$ (0·6 nearly) inch long for a 4-inch stroke. (2) An artificial horizon in which the mercury is spread out into a very thin film on a surface which it does not wet, its edge being held by deeper mercury in a peripheral trough. The film is adjusted in thickness by means of a floating plunger actuated by a screw. Ripples set up by vibration die out almost instantaneously, and altitudes of stars may be taken in towns where with deeper mercury that would be impossible. The mercury is not contaminated by its dry supporting surface. —*Mr. H. G. King and Mr. R. Kerr:* "Master gauges" or "standards" for extremely accurate measurements, the invention of Mr. C. E. Johansson, of Sweden. By using these gauges separately or combined together, more than 80,000 different sizes can be obtained, any of which sizes are accurate to within 0·00004 inch at 66° F. The steel is so treated as to reduce to a minimum any chance of change after being hardened.—*Prof. H. L. Callendar, F.R.S., and Prof. W. E. Dalby:* Apparatus for measuring temperatures in the cylinder of a gas engine.—*Mr. Joseph Goold:* A uniformly symmetrical twin-elliptic pendulum. As the deflector consists of a pair of cross-bars, its mass can be virtually elongated by fixing the bars at any other than a right angle. By this means any rate of change of phase is easily secured. The resulting figures are made available for stereoscopic effects by taking two similar figures and inverting one of them, so that each half figure becomes associated (in the stereoscope) with the complementary half of the other figure.—*Mr. Charles E. Benham:* Stereoscopic effect of twin-elliptic figures.

*Cambridge Scientific Instrument Co.:* The Cambridge patent extensometer. No mirrors or microscopes are used for magnifying the movement, but the extension of the test-piece is measured by a micrometer screw and a modified form of contact measurement. The instrument is made in two separate pieces; the lower piece carries the micrometer screw shown in Fig. 2, and the upper piece carries a spring tongue. These are fixed to the test-piece by pressing the conical points of hard steel rods into centre punch marks in the side of the test-piece, these points being mounted in strictly geometric slides. Both the upper and lower pieces are held in the definite positions shown in the illustration. If the test-piece stretches, the upper piece rotates about the conical points in the depressions in the test-piece, and the end of the tongue approaches the point on the micrometer screw head, the upper piece forming a lever. The arms of the lever are such that the part of the tongue opposite the point on the micrometer head moves five times the amount of the extension of the test-piece. By means of an adjustment the ratio of the arms of the lever can be adjusted so that this multiplication of the extension can be made exact. One arm of the lever is the flexible steel tongue which carries a hardened steel knife-edge near its outer end. If the tongue is bent sideways the knife-edge is moved across the hard steel point, which is carried from the centre of the divided head. To adjust the instrument the screw is turned and the point advanced until contact is made. Relative movement of the lower piece carrying the micrometer screw and the tongue is thus measured, and is proportional to the extension of the test-piece. It can, however, be adjusted more accurately by causing the spring to vibrate and noting the sound caused by it touching the point each time it passes over it. If the point is advanced by 1/1000 mm. nearer the screw the sound produced by contact as the spring vibrates is louder, and the final adjustment of the micrometer screw can be made quickly and accurately. The micrometer screw has a pitch of $\frac{1}{2}$ mm., and the head is divided into 100 parts; each division on the head corresponds to an extension of 1/1000 mm., and as the tenths of divisions can be estimated by eye, readings can be taken to 1/10,000 mm., although it is not claimed that the results are trustworthy to this degree of accuracy.

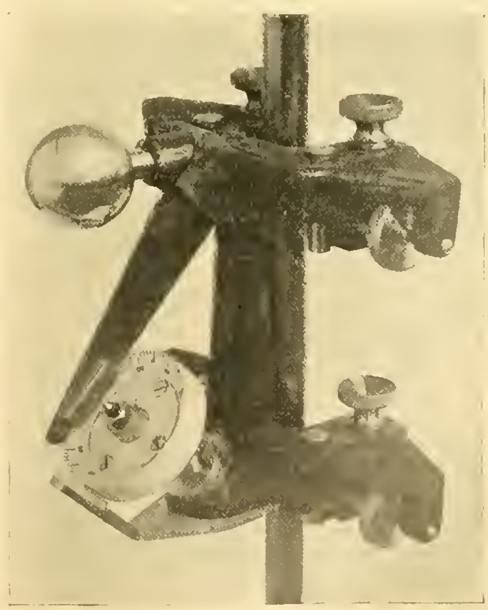

FIG. 2.—Cambridge patent extensometer.

*Mr. J. W. Gordon and Mr. H. Fletcher Moulton:* A new object-glass for high-power magnification. The objective exhibited, used with an ordinary eye-piece, constitutes a high-power ocular capable, in combination with an ordinary high-power objective glass, of yielding a perfect image up to magnifications of eight or ten thousand diameters. Being self-contained, that is to say, independent of external influences, it can be used in any position, and is therefore as well adapted to use with the telescope as with the microscope.

*Mr. J. E. Barnard:* Mercury vapour lamps for microscopic illumination. Mercury vapour lamps have considerable advantages as illuminants for microscopic work, as their visible spectrum consists chiefly of three bright lines, one each in the orange, green, and blue-violet. It is therefore possible, by using suitable absorbent colour screens, to transmit only one bright line of the required colour, the remaining ones being absorbed. The source of light then becomes truly monochromatic, and is practically of one wave-length.—*Mr. Conrad Beck:* (1) Diffraction patterns (antipoints) of point source of light viewed under the microscope with apertures of different shapes illustrating the influence of the aperture shape on microscopic resolution; (2) living bacteria, shown on a dark ground with 1/12 oil immersion lens visible by their own reflected light.

*Prof. T. Turner:* Transparent films of silver and other metals. Gold leaf supported on a glass plate and heated to about 550° C. loses its green colour and transmits white light. Silver leaf heated in air or oxygen to 400° C. becomes remarkably transparent, transmitting white light. The action begins at about 250° C. Copper leaf remains opaque if heated in a reducing atmosphere to 500° C. When heated in air for about an hour to 250°, or for a much shorter time to higher temperatures, the copper becomes transparent and transmits a brilliant green light. This colour continuously darkens with further heating. Aluminium leaf does not become transparent either in an oxidising or reducing atmosphere. Dutch metal skeletonises, but remains opaque.—*Mr. S. D. Chalmers:* Models illustrating refraction at plane and spherical surfaces. These models illustrate the influence of reduced velocity in glass on the form or direction of waves. The curvatures of the incident and refracted waves are indicated by flexible rods; the paths from a point on the incident to the corresponding point on the refracted wave are indicated by cords of constant length.

*Dr. W. J. Russell, F.R.S.:* Pictures showing the action of various coals on photographic plates in the dark. These pictures of different coals were obtained by cutting vertical sections of the coal and laying them on a photographic plate in the dark, at a temperature of about 50° C., for seven to twenty-four hours. The photographic plate was then developed, and the picture printed in the ordinary way.—*Prof. J. Symington, F.R.S., and Dr. J. C. Rankin:* A series of skiagrams illustrating the development of teeth in man. The skiagrams were taken from one lateral half of a series of skulls aged from birth up to puberty.

*Mr. S. Cowper-Coles:* (1) Specimens of bimetallic parabolic mirrors made by electro-deposition. The parabolic mirrors are composed of bands of yellow and white metal, and are made by a combined process of electro-deposition and spinning. (2) Specimens of pure electrolytic iron. Pure electrolytic iron sheets made direct in one operation by a process of electro-deposition from pig iron or ore without any rolling, with a tensile strength of about thirty tons to the inch; the iron is free from crystalline structure.—*Mr. F. W. Aston:* New dark space in helium. The tube exhibited contained helium at a pressure of about 3 mm. It was provided with aluminium electrodes, the kathode being a large flat plate. A continuous current of low density was passed through. Under these conditions the "Crookes dark space" is ill-defined and filled with a greenish glow, while next to the kathode is seen a narrow region of intense darkness sharply defined. The fall of potential across this "new dark space" appears to be invariably about 30 volts.—*Dr. J. A. Fleming, F.R.S.:* (1) Apparatus for exhibiting photo-electric effects with potassium-sodium alloy. The alloy was enclosed with an insulated platinum plate in an exhausted tube. When the plate and alloy were connected to a galvanometer and the surface of the alloy illuminated by an arc lamp, an E.M.F. of about 0·8 volt was created, and a current produced in the circuit by the light. (2) Oscillation valves or glow-lamp electric-wave detectors used for receivers in long-distance wireless telegraphy. It was shown by the exhibitor in 1904 that a carbon filament glow-lamp, having in its bulb a metal cylinder surrounding the filament carried on an insulated terminal, could be used in combination with a galvanometer or telephone as a wave detector in wireless telegraphy, owing to the emission of negative electricity from the incandescent carbon. Such a device was named by him oscillation valve, and is a very sensitive long-distance receiver. Glow-lamp detectors of the type exhibited have been used as receivers in Transatlantic wireless telegraphy, and are also of use as receivers for wireless or radiotelephony. (3) A recent form of cymometer or instrument for measuring the length of the waves radiated by, and the damping of the oscillations in radio-telegraphic antennæ.—*Mr. L. H. Walter:* (1) Tantalum wave-detector for wireless telephony or telegraphy. A tantalum wire point dipping into mercury is spontaneously restoring. At 450 miles, using less than 2 kilowatts, the results equal those of the electrolytic detector. The sound is louder than with the electrolytic when the signals are not too weak. (2) New electrolytic signalling key. A water-cooled signalling key for higher powers (2 kilowatts upwards). A local key circuit actuates two valve electrodes, normally separated, and having the whole primary voltage across them, so that the cell is short-circuited beneath the electrolyte. (3) Model of an experimental form of the exhibitor's magnetic detector of 1906.

*The National Physical Laboratory. Mr. A. Campbell:* (1) Moving-coil vibration galvanometer. This instrument belongs to the class of tuned galvanometers first introduced by Prof. M. Wien. Its novelty consists in the use of the moving-coil system. (2) Variable mutual inductance standard. Designed for the measurement of small inductances and capacities. (3) Standard of mutual inductance calculable from the dimensions. A small model of the large mutual inductance (10 millihenries) recently completed at the National Physical Laboratory. (4) Secondary standard of mutual inductance (subdivided). *Mr. W. Rosenhain:* (5) Quenching apparatus for metallographic specimens, for quenching small specimens of metal *in vacuo* without removing them from the furnace. *Mr. W. Rosenhain, Mr. F. C. A. H. Lantsberry, and Mr. P. A. Tucker:* (6) Composite photomicrographs representing relatively large areas of steel. *Mr. W. Rosenhain:* (7) Tensile fracture of steel under the Zeiss stereoscopic microscope.—*Rev. F. J. Jervis-Smith, F.R.S.:* Apparatus for generating a luminous glow in an exhausted vessel, moving in an electrostatic field, and exhibiting the action of a magnetic field on the glow so produced (see p. 70).—*Mr. J. T. Irwin:* Hot wire oscillograph.—*Mr. S. G. Brown:* Experiments with a high-frequency alternator.

*Mr. R. Threlfall, F.R.S.:* Laboratory apparatus for experiments under very high measured pressures and at very high temperatures—pressures up to 100 tons per square inch, temperatures up to 2000° C. Advantage is taken of the practically perfect fluidity of crystalline graphite at high pressures, and of the solidity of compressed magnesia, zirconia, &c., to construct an apparatus on the laboratory scale for such experiments as the possible transformations of carbon under high temperatures and pressures.—*Prof. T. B. Wood:* The factors which influence the baking value of wheat flour. The "strength" or baking value of wheat is determined by two main factors:—(1) high diastatic capacity, which continuously produces sugar in the dough, and thereby enables the yeast to keep up a continuous evolution of carbon dioxide; (2) suitable concentration of acid and salts in the flour, which affects the physical properties of the gluten, and hence the shape of the loaf. —*Dr. T. E. Thorpe, F.R.S.:* (1) Apparatus and specimens used in connection with the determination of the atomic weight of radium; (2) glass and quartz vessels coloured under the influence of radium.—*Sir William Crookes, F.R.S.:* Scandium, its salts, and its position in the scheme of the chemical elements. Scandium is an exceedingly rare terrestrial element, occurring in very few minerals and in very small amount—usually not more than 0·01 per cent. The one exception is the rare mineral wiikite, which contains scandium in considerable quantity. Astronomical research has demonstrated the presence of scandium in comparative abundance in the sun and some of the brighter stars. To enable its spectrum lines to be identified with certainty, especially in some of the fainter celestial bodies, a thorough examination of its spectrum has been undertaken.—*Messrs. Johnson, Matthey and Co., Ltd.*: (1) Apparatus in transparent fused silica; (2) various vessels of pure iridium.

*Miss Amy Barrington and Prof. Karl Pearson, F.R.S.*: Specimens of the hair of chestnut horses. Samples of hair from the ribs, mane, and tail of chestnut horses to show:—(1) the wide range of chestnut coats; (2) that "chestnut" is not a simple unit character; and (3) that the mane and tail of chestnuts can be sensibly black.—*Marine Biological Association of the United Kingdom*: (1) Living representatives of the Plymouth marine fauna; (2) photographs illustrating methods of dredging and trawling (North Sea investigations).—*The Grouse Disease Commissioners*: Specimens illustrating certain aspects of the work of the Grouse Disease Committee, 1905–8. A committee of inquiry into the causes of disease in the red grouse (*Lagopus scoticus*) was constituted in 1904 at the suggestion and under the chairmanship of Lord Lovat; the work and results, of which the exhibit represented a part, will be published by the Zoological Society of London.—*Mr. C. Gordon Hewitt*: The large larch saw-fly (*Nematus erichsonii*, Hartig). The larch saw-fly has increased during the last few years to so great an extent in many of the large larch plantations in Cumberland as to become a serious pest. Many hundreds of acres of larches were completely defoliated in 1907. Except in the young plantations, it will be necessary to rely on natural means of control, of which birds and voles are at present the most important.—*Mr. F. Enock*: Living specimens of Mymaridæ-ovivorous parasites (new to Great Britain).

*Prof. R. T. Hewlett and Mr. J. E. Barnard*: A method of disintegrating bacterial and other cells. The machine consists of a phosphor-bronze vessel, revolving at a high speed, containing hardened steel balls, which are kept in position at the periphery of the vessel by a central steel cone. By retarding the revolution of the central cone, a drag is put on the balls, so that a grinding action takes place between them and the internal surface of the vessel. Rise of temperature is prevented by the use of liquid carbonic acid or other means.—*Dr. Ernest F. Bashford, for the Executive Committee, Imperial Cancer Research Fund*: Cancer as a manifestation of cell-life throughout the vertebrates, and the biological properties of cells which have become cancerous.—*Prof. W. B. Bottomley*: Bacterial treatment of non-leguminous plants. (1) Specimens showing effect of nitrogen-fixing organisms upon growth of oats, barley, turnips, radishes, tomatoes, &c.; (2) cultures and microscopical preparations of nitrogen-fixing bacteria (*Pseudomonas radicicola, Azotobacter beyerinckii*, &c.).

*Prof. J. Milne, F.R.S.*: Seismograms recorded by a Milne seismograph in the Isle of Wight. (1) These seismograms illustrate the difference in character of records obtained from the same instrument. The Mexican earthquake of March 26, 1908, was obtained on *quickly* running paper. The earthquakes of August 9, 1901, were obtained on *slowly* moving paper. In the former halation effects do not eclipse the first preliminary tremors, and an open diagram is obtained. (2) The three earthquakes which occurred on August 9, 1901, indicate the value of seismograms in correcting cablegrams. The interval of time between the preliminary tremors and the maximum motion shows that the origins of the first and third disturbances were 6000 miles distant, while the second was nearly 7000 miles distant. The first and last came from Japan, while the second came from the East Indies. In American and European newspapers it seems to have been universally stated that the origins were in Alaska.—*Dr. C. W. Andrews, F.R.S.*: Restored model of the skull and mandible of *Prozeuglodon atrox*. *Prozeuglodon atrox* is a primitive whale (Zeuglodont), and is one of the forms which unite the true Zeuglodonts with the early land-carnivores known as Creodonts.—*Mr. J. Y. Buchanan, F.R.S.*: Features of land-ice illustrated by photographs and stereoscopic slides in the taxiphote. These slides, taken last winter in the grotto of the Morteratsch glacier, illustrate the internal structure of the ice in winter.—*Mr. A. Hutchinson*: Protractors for constructing stereographic and gnomonic projections of the sphere. The protractors exhibited are intended for the use of students of crystallography, and are designed to facilitate the construction of great and small circles in the stereographic projection.

*Mr. Henry Balfour*: Stone implements of very early date from the Zambezi River and some of its tributaries. A large proportion of the implements of chalcedony, quartzite, &c., are of forms exactly similar to types characteristic of the river-drift period of western Europe and Great Britain. These were found associated with, and evidently forming part of, ancient terrace gravels deposited as drifts by the Zambezi at a remote period. Several implements were found by excavation in undisturbed gravel deposits at depths varying from 6 inches to 2 feet.—*Prof. W. M. Flinders Petrie, F.R.S.*: Drawings of ancient zodiacs.—*Prof. W. Gowland, F.R.S.*: Megalithic monuments in Japan (see NATURE, February 14, 1907, vol. lxxv., p. 382).—*Mr. Francis Fox*: The saving of Winchester Cathedral and other ancient buildings. (1) Specimens of the beechwood logs on which the cathedral stands; (2) block of the peat found beneath the walls, in some cases 8 feet in thickness; (3) sample of the gravel bed down to which the underpinning is carried by a diver; (4) old box-wood rule found during the operations.—*Mr. J. Gray*: An instrument for measuring the colour of the hair, eyes, and skin (NATURE, February 27, vol. lxxvii., p. 406).

*Prof. Silvanus P. Thompson, F.R.S.*: Drawings of early compass cards and windroses. The compass card was developed from windroses drawn on the Portulani, or sailing charts, at the points of intersection of the loxodromic lines. The drawings shown were from old Portulani or other early works dating from 1375 to 1584.—*Messrs. T. and R. Annan and Sons*: Photographs of Lord Kelvin.—*Mr. J. Stewart, Largs*: Photographs of Lord Kelvin, and relating to him.

*Prof. A. H. Church, F.R.S.*: Documents and specimens of historical interest referring to the Royal Society, including an unpublished letter of Captain James Cook, F.R.S., the circumnavigator, dated Rio de Janeiro, September 30, 1768, and seventeen portrait medals, struck at the Paris mint, of foreigners who were members of the Royal Society.

*Messrs. B. J. Hall and Co., Ltd.*: Ordoverax copying process. This process is one for rapidly and accurately producing facsimile copies of line drawings and tracings on any materials. The original is first copied on ferro-prussiate paper; the copy is placed before development, face downwards, on a plate of ordoverax composition previously prepared. The portions of the ferro-prussiate paper not affected by light act upon the ordoverax composition, causing it to take up printers' ink from a roller, whereas the parts of the plate not so acted upon do not take up any ink.—*Mr. Donald Cameron-Swan*: A new method of reproducing pencil and other drawings. This method (which is being employed for the Memoirs of the National Antarctic Expedition) differs from most photo-mechanical processes of reproduction in that the drawings are reproduced in exact facsimile, without any background of tone where none exists in the originals.

## NOTES.

THE British associates and correspondants of the Institute of France will attend at St. James's Palace on Wednesday next, May 27, at 11 a.m., to present an address to the President of the French Republic on the occasion of his visit to this country.

THE Royal Society of London invites applications for two Mackinnon research studentships, each of the annual value of 150*l*. These studentships, which are restricted to British subjects, are offered for the purpose of researches in physical and biological sciences, one being awarded for research in the group of the physical sciences, including astronomy, chemistry, geology, mineralogy, and physics, the other for research in the group of the biological sciences, including anatomy, botany, palæontology, pathology, physiology, and zoology. Applications must be sent in to the Royal Society not later than June 10 on forms which can be obtained from the assistant secretary of the Royal Society, Burlington House, W.

ON July 1 the president and council of the Linnean Society will entertain the Darwin-Wallace medallists and foreign guests to dinner at Prince's Restaurant.

PROF. OTTO BÜTSCHLI, of Heidelberg, and Prof. A. G. Nathorst, of the Naturhistoriska Riksmuseum, Stockholm, have been elected foreign members of the Linnean Society.

THE annual visitation of the Royal Observatory, Greenwich, by the Board of Visitors will be held on Wednesday, June 3. The observatory will be open for inspection by guests at 3 p.m.

THIS year's meeting of the French Association for the Advancement of Science will be held at the beginning of August at Clermont-Ferrand. Sir William Ramsay, K.C.B., F.R.S., has accepted an invitation to lecture during the meeting on his researches. Full particulars of the proceedings at Clermont-Ferrand can be obtained from the offices of the French Association, 28 rue Serpente, Paris.

ON Tuesday next, May 26, Prof. W. Stirling will begin a course of two lectures at the Royal Institution on "Animal Heat and Allied Phenomena." The Friday evening discourse on May 29 will be delivered by Sir Ralph Payne-Gallwey on "Ancient and Mediæval Projectile Weapons other than Firearms," and on June 5 by Sir James Dewar on "The Nadir of Temperature and Allied Phenomena."

THE first International Congress of the Cold Storage Industries is to be held in Paris, at the Grand-Palais, at the end of September next. One of the sections, of which M. d'Arsonval is the president, will concern itself with questions relating to low temperatures and their general effects. We understand that Sir James Dewar, Sir William Ramsay, and MM. Van der Waals, Kamerlingh Onnes, Linde, Georges Claude, and Jean Becquerel will be among the contributors to this section.

THE Berlin correspondent of the *Times* states that a scientific expedition to the South Seas left Hamburg on May 16 on board the steamship *Peiho*, a vessel of 900 tons, which has been specially chartered for the cruise from the Hamburg-American Line. The expedition has been organised by the trustees of the scientific foundations of the city of Hamburg, and its mission is to complete the exploration more particularly of the German islands in the South Seas and to collect materials for the study of the natives and natural resources of those regions. Dr. F. G. H. H. Fülleborn, assistant at the Hamburg Institute for Tropical Diseases, is in charge of the expedition, and he is accompanied by a competent staff of assistants.

THE Home Secretary has appointed a committee on the use of lead in the manufacture of earthenware and china. The committee includes, with others, Mr. E. F. G. Hatch (chairman), Mr. A. Vernon Harcourt, F.R.S., Dr. George Reid, Mr. William Burton, and Mr. Bernard Moore. The committee is to consider the dangers attendant on the use of lead in pottery, and to report how far these can be obviated or lessened by improved appliances and methods in lead processes, by the limitation of the use of lead, by the substitution of harmless lead compounds for raw lead, by the substitution of other materials for lead, and by other means. The danger or injury to health arising from dust or other causes in the manufacture of pottery, and the special rules regulating the decoration of earthenware and china, are also to be considered.

A CORRESPONDENT writes:—"The Atlantic Ocean is in certain parts about four miles deep. Would a rock, if thrown into the ocean at its greatest depth, sink to the bottom?" The inquiry is a little indefinite, but Dr. C. Chree, F.R.S., has been good enough to send us a reply to it, in the course of which he points out that any solid of larger than microscopic dimensions will fall in a liquid with continuously increasing velocity so long as its density exceeds that of the liquid. Even at a depth of four miles the pressure of the water is only about four tons to the square inch, and such increase is quite insufficient to raise the density of water to that of ordinary rock. In the case of some exceptional form of rock, the density of which approaches closely to that of water when both are uncompressed, the result would depend on the relative compressibility of water and the material, combined with any slight effects due to change of temperature.

AT the instance of the late Secretary of State for the Colonies, and with the cooperation of the Government of the Sudan and the Royal Society, the Government has decided to establish in London a bureau for the collection and general distribution of information with regard to sleeping sickness. The Royal Society will find accommodation for the bureau at Burlington House, and one-fourth of the cost of upkeep will be borne by the Sudan Government. The bureau will be under the general control and direction of an honorary committee of management, appointed by and responsible to the Secretary of State for the Colonies. The committee will include the Right Hon. Sir J. West-Ridgeway, G.C.B. (chairman), Sir Patrick Manson, K.C.M.G., F.R.S., Sir Rubert Boyce, F.R.S., Dr. Rose Bradford, F.R.S., and Colonel D. Bruce, C.B., F.R.S. The main function of the bureau, which will be administered by a paid director, will be to collect from all sources information regarding sleeping sickness, to collate, condense, and, where necessary, translate this information, and to distribute it as widely and quickly as possible among those who are engaged in combating the disease. The publications of the bureau will be divided into two categories, viz. scientific publications intended for those who are engaged in research work or in carrying out medical administration in the infected districts, and publications of a less technical character for the use of Government officials, missionaries, and others, whose duties involve residence in those districts. One important piece of work will be the preparation of a map of the whole of tropical Africa, showing the distribution of the disease and of the different species of blood-sucking insects which are suspected of conveying it. The duties of the director of the bureau will for the present be undertaken by Dr. A. G. Bagshawe, of the Uganda Medical Staff, who has been seconded from the Protectorate service for the purpose.

A MEDUSA from Java, referable to the remarkable genus Chiropsalmus, previously known by one species from Brazil and Carolina and a second from the Rangoon coast, is described by Dr. R. Horst as new in Leyden Museum Notes (vol. xxix., No. 2) under the name of *Ch. buitendijki*. Unfortunately, the only known example of the Rangoon *Ch. quadrigatus* is in very bad condition, so that the distinctness of the Java form does not appear absolutely beyond doubt.

IN addition to a paper on fossil cetaceans by Mr. True, and one on the meteor-crater of Canyon Diablo by Mr. Merrill, which have been already mentioned in NATURE, the fourth part of vol. iv. of the quarterly issue of Smithsonian Miscellaneous Collections contains an illustrated account, by Mr. R. Arnold, of the shells from the Tertiary oil-bearing strata of Santa Barbara, California.

Students of Coleoptera should be interested in a revision, by Mr. T. L. Casey, of the tenebrionid beetles of the subfamily Coniontinæ, published in the Proceedings of the Washington Academy of Sciences (vol. x., pp. 51–166), where several new generic groups are suggested and named, and also in descriptions, by Mr. W. D. Price, of new weevil-like species of the group Anthonomini, forming No. 1604 of the Proceedings of the U.S. National Museum.

A large portion of part iii. of vol. lxxxix. of the *Zeitschrift fur wissenschaftliche Zoologie* is occupied by a contribution from Mr. Valentin Dogiel, of St. Petersburg University, entitled "Catenata, eine neue Mesozoengruppe." The new group is established for the parasites of the genus Haplozoon, one of which was discovered by the author (as narrated in the *Zoologischer Anzeiger* for 1906) in the intestine of the polychæte worm *Travisia forbesi*, and the other in that of *Clymene lumbricalis*, a second member of the same group. The paper is illustrated by three plates (one partly in colour) showing the structure and development of these remarkable organisms.

In the course of a paper on the nest of the ringed plover, published in the May number of *British Birds*, Mr. W. P. Pycraft argues that the commonly accepted theory as to the nesting of the earliest birds does not accord with the structure of Archæopteryx. Such birds, according to this theory, are believed to have nested in holes in trees, where they laid white eggs. But, urges the author, such a habit would be unsuited to a bird with a long body tail, which, in his opinion, is more likely to have made its nest in some such site as the crown of a tree-fern or a cycad. Is, however, it may be asked, the tail of Archæopteryx likely to have been much more in the way in a nesting-hole than are the tail-feathers of a hornbill?

Now that Lamarck has received the recognition due to a pioneer of the evolution-doctrine, it is interesting to learn of the existence in Harvard University of a holograph manuscript from his pen. This MS., as we gather from a notice contributed by Prof. Bashford Dean to the *American Naturalist* for March, was written some time previous to 1820, and forms a series of essays and drafts of later work, comprising about ninety folios, of which fifty have writing on both sides. It was presented to Harvard by Prof. A. Agassiz, who appears to have obtained it in Paris in 1906. Prof. Dean gives a summary of its chief contents, together with reproductions of pen-and-ink sketches of micro-organisms and of a holothurian by Lamarck himself.

The urgency of legislation for the protection of whales and turtles forms the subject of a forcible article by Dr. G. R. Wieland in the May issue of the *Popular Science Monthly*. The destruction, and in some cases practical extermination, which have resulted from the pursuit of the more valuable species of whales are familiar to all, but it is less well known how serious is the diminution in the number of turtles—edible and otherwise. It is, urges the author in conclusion, "neither Utopian nor impractical to attempt and speedily carry out the measures required for the preservation, not only of land animals, but of all our great animals of the sea. The only element of doubt is whether the volume of sentiment can soon enough make itself felt—in short, whether the race has reached the required culture stage in time."

In the *Philippine Journal of Science* (iii., No. 1), Mr. Y. K. Ohno gives formulæ which express the laws governing agglutination phenomena as regards bacteria and agglutinating sera. The union of agglutinin and agglutinable substance he regards as a chemical reaction, and not as an absorption phenomenon.

In the Scientific Memoirs of the Government of India (No. 31), Capt. Patton, I.M.S., details further observations on the tropical disease, kala azar, and its parasite, the Leishman-Donovan body, which, he finds, undergoes a cycle of development in a bed-bug (*rotundatus*), by the bite of which the disease is presumably communicated.

Opinion has of late been divided as to whether spirochætes belong to the bacteria or to the protozoa. In a paper on the *Spirochaeta pallida* of syphilis, Krzysztalowicz and Siedlecki definitely class these organisms as protozoa belonging to the Mastigophora, and propose to include them in a new family, the Spirilloflagellata (*Bull. Internat. de l'Acad. des Sciences de Cracovie*, No. 3, 1908).

To meet the requirements of students and others with small incomes, Mr. C. Baker, of High Holborn, maintains a department for second-hand scientific instruments. The quarterly list recently issued contains as many as ten different sections. All kinds of microscopes and microscopic requisites, surveying and drawing instruments, also various pieces of optical and physical apparatus can be inspected and purchased under guarantee as to adjustment.

The account of floral development and embryogeny in the wheat plant communicated by Mr. A. H. Dudley to the Liverpool Microscopical Society, and published in its thirty-ninth annual report, presents one or two special points of interest. The author obtains similar results to those recorded by Cannon for the megasporangium of Avena in so far that no parietal cell is cut off from the archesporium, and that numerous antipodal cells are produced in the embryo-sac; the limitation of the suspensor to the primary basal cell and the first divisions in the embryo appear to be similar.

Two circulars referring to the International Botanical Congress that will be held in Brussels two years hence have been received. The first announces that, in place of the late Prof. Errera, Baron de Moreau, formerly Minister of Agriculture, has consented to become a president of the organising committee, sharing that position with Mr. Th. Durand, and that Dr. E. Wildeman will act as general secretary. The constitution of various local subcommittees is also indicated. The second circular gives the names of the two committees appointed for dealing with cryptogamic and palæobotanical nomenclature, and invites expressions of opinion with regard to rules additional to those formulated for phanerogamic plants and generic names that should be maintained in spite of priority rules.

An editorial in the *Indian Forester* (March) referring to education and research in India cites the opinions expressed in Nature of January 2 as to the wisdom of appointing professors and teachers who have shown their ability for prosecuting original research; in this connection, it is urged that the training of Indian foresters should be entrusted to men who have made a special study of forest problems in India. An instructive article on the private and communal forests in Japan is contributed by Sir Frederick Nicholson to contrast conditions with those found in the presidency of Madras. It is estimated that private forests cover 14 million acres, and the communal forests exceed 4 million acres, providing about an acre and a half of woodland for every acre of arable land. Within recent years the necessity for re-planting has been recognised; *Cryptomeria japonica* and other conifers are generally selected, but camphor and chestnut trees are also largely planted; around the fields, mulberry, lacquer, and vegetable-wax trees are grown.

MR. C. F. STRAWSON has issued his ninth annual report on the destruction of charlock in corn crops during 1907 by spraying with a copper sulphate solution. Experiments extending over ten years have shown that young charlock can be destroyed in growing corn crops without injury to the latter by spraying with fifty gallons of 3 per cent. solution of copper sulphate (15 lb. to fifty gallons) per statute acre, and older charlock with a stronger solution. The corn crops are much improved, and give a better yield, where the charlock is destroyed, and young grass seeds and clover in the corn remain uninjured. The object of Mr. Strawson's annual reports is chiefly to induce those who cultivate charlock-seeded soils to adopt this new and easy method of restoring the land to its full crop-producing value.

IN a paper read before the Physiological Society on March 21, Dr. A. D. Waller, F.R.S., demonstrated that the contractility of animal and vegetal nerves observed by Prof. Bose (see NATURE, March 5, supplement, p. iii) may be obtained on fiddle-strings, or any other kind of strings, and is due to heating of the structures by the "fairly strong tetanisation" currents used by Prof. Bose. Dr. Waller calculates that the heat developed by the currents used, in the absence of evaporation, is sufficient to raise the temperature of a nerve 1°·35 per sec. Engelmann in 1895 showed that fiddle-strings in water contracted when heated. With weak tetanisation there is obtained elongation, with strong, shortening. The weight and the electrical conductivity of a fully contracted string are greatly diminished by loss of water.

ONE of the most important agricultural questions in Cape Colony, the deterioration of the veld, is discussed in the March number of the *Agricultural Journal of the Cape of Good Hope*. It seems to be established that the veld will no longer nourish cattle as well as formerly, and five causes are stated to have brought this about:—(1) overstocking and the kraaling of stock; (2) formation of sluits or dongas; (3) spread of noxious weeds; (4) burning of the veld; (5) destruction by drift sands. Overstocking, *i.e.* putting too many cattle on to a given area, is harmful, because the grasses or plants relished by the animals are so completely eaten off that they become exterminated, and their place is taken by plants which the animals have rejected, and which are, therefore, of no agricultural value. Some are positively noxious, *e.g.* the jointed cactus (*Opuntia pusilla*), which is likely to cause considerable trouble in future, the prickly pear, and the Mexican poppy. Kraaling, or herding the animals together at night to protect them from jackals, &c., has the effect of wearing down definite pathways, and thus starting the channels for the flow of water which finally develop into the sluits and dongas so characteristic of the veld. The burning of the veld is responsible for a good deal of damage, since the organic matter is largely destroyed, and there is considerable loss of nitrogen. Nevertheless, some means of removing old dead grass is necessary, for a good deal is apt to be left over from the previous season; sheep will not eat it, and it interferes with the new growth; there seems no option but to burn it. The whole problem is of vital importance, and can only be solved after careful scientific investigation.

THE American Government, in view of the rapid occupation of all the available land in the western States, has started a vast reclamation scheme. The most important is that for the irrigation of what are known as the Great Plains, the region extending from the Missouri River to the foot of the Rocky Mountains and from the Panhandle of Texas northward to the Canadian frontier. The projects now sanctioned in various parts of the country provide for the expenditure up to the year 1911 of about fourteen millions in the reclamation of some two millions of acres. The progress of this great experiment is described in the April number of the *National Geographical Magazine* by Mr. C. J. Blanchard, statistician to the U.S. Reclamation Service, under the title of "Home-making by the Government." The illustrations of fruit and other products grown under irrigation present a vivid picture of the possibilities of this important enterprise. The most remarkable of these projects is the Salt River scheme in Arizona, which involved the construction of the "most wonderful highway ever built by man," that on Fish Creek Hill, where a road has been cut along the banks of a stupendous canyon through the living rock for a distance of forty miles.

THE chain has hitherto received scant attention from investigators in the field of elasticity and strength of materials, and a welcome addition to the two or three scattered memoirs on the theory of the stresses in chain-links is made by a memoir on the strength of chain-links by Prof. G. A. Goodenough and Prof. L. E. Moore, forming Bulletin No. 18 of the University of Illinois Engineering Experiment Station. The investigation described deals with the development of the theory of the stresses induced in chain-links with given conditions as regards loading, with experimental tests of the validity of the theory employed, and with the assumptions made as to the distribution of pressure between adjacent links, and the deduction from theoretical considerations alone of rational formulæ for the loading of chains. Experiments made on steel rings were found to confirm the theoretical analysis employed in the calculation of stresses. Experiments on various chain-links further confirm this analysis. The introduction of a stud in the link equalises the stresses throughout the link, reduces the maximum tensile stresses about 20 per cent., and reduces the excessive compressive stress at the end of the link about 50 per cent. The following formulæ are applicable to chains of the usual form:—$P=0\cdot4\ d^2S$ for open links, and $P=0\cdot5\ d^2S$ for stud links, where $P$ denotes the safe load, $d$ the diameter of the stock, and $S$ the maximum permissible tensile stress.

THE report of the Meteorological Service of Canada for the year 1905 has recently come to hand; it consists of xix+418 quarto pages, nearly all of which are taken up with monthly and annual summaries, including hourly or bi-hourly observations of air-pressure and temperature at some of the first-order stations. The careful preparation of these voluminous tables is of itself a stupendous undertaking; among the extreme shade temperatures we note 104°·5 at Spence's Bridge (British Columbia) in July, and −53°·0 at two stations in Alberta in February. The percentage of fulfilment of weather forecasts is very satisfactory, the average for all districts being 85·1; the greatest annual success is 86·9, in the Upper St. Lawrence district. In an interesting supplement Prof. W. J. Loudon discusses the effect of different winds on the "seiches" observed, and also gives the results of his researches in atmospheric electricity, at High Rock station, Georgian Bay.

IN the *Physikalische Zeitschrift* for May 1 Dr. L. Mandelstam considers the question whether the usual method of representing dispersion on the electromagnetic theory, as due to the presence in the medium of electrical resonators, is capable also of explaining the gradual extinction found to take place as due to radiation from the resonators. He comes to the conclusion that it is not, and in this respect is in opposition to Prof. Planck, to whom the theory of dispersion owes so much.

THE concluding fascicule of the *Bulletin des Séances* of the Société française de Physique for the year 1907, which has just been issued, contains a valuable *résumé* of the communications made to the society during the past year. It occupies eighty pages, and is of the greatest service to those who have not the time to read the complete papers. A glance at the titles of the abstracts is sufficient to show that the Société française de Physique maintains its position as one of the most successful of the societies which receives and publishes original work done in the field of physics.

MANY geographical works, offered at greatly reduced prices, are included in a catalogue of publishers' remainders just issued by Mr. H. J. Glaisher, Wigmore Street, London, W.

AN admirable summary of the mineral resources of Western Australia is given by the Agent-General, the Hon. C. H. Rason, in the May number of the *Empire Review*. The twenty-three years' mining history of the colony proves it to be one of the richest mineral territories in the world.

AN illustrated itinerary of pleasure cruises to the Norwegian fiords by the yachting steamer *Midnight Sun* has been received from the Albion Steamship Co., Ltd., Newcastle-upon-Tyne. Each cruise extends over fourteen days, and the minimum fare is ten guineas. The sailings commence on June 6.

A USEFUL catalogue of electrical measuring instruments for technical and laboratory purposes has just been issued by Messrs. Isenthal and Co., Mortimer Street, London, W. Particulars and illustrations are given of electromagnetic, moving-coil, hot-wire, and switchboard instruments of special types, and also of aperiodic precision instruments on the dynamometer principle, and insulation testers. The catalogue makes the selection of a suitable instrument of any of these designs a simple matter.

MESSRS. MARION AND CO., LTD., of Soho Square, London, announce a prize competition in which money prizes are offered for photographic work done on their plates, films, and printing papers during the present season. Of the four classes into which the competition is divided, one is for photographs of scientific interest. Biological, geological, astronomical, and natural history photographs, spectroscopic work, and photomicrography serve to indicate the general character of this class, though other scientific subjects are eligible. The first, second, and third prizes in this class are, respectively, 10*l*., 5*l*., and 2*l*., and Mr. Chapman Jones will be the judge.

THE recent removal of Swedenborg's body from London to Stockholm, after it had reposed in the Swedish Lutheran Church in London for one hundred and thirty-six years, is a part of a larger movement for the recognition of the genius of Swedenborg in the domain of science. The movement began outside Sweden. Dr. Max Neuberger, of Vienna, in 1901 delivered an address before the assembly of German Naturalists and Physicians entitled "Swedenborg's References to the Physiology of the Brain." Following up this interest, Dr. Neuberger addressed a communication to the Academy of Sciences of Stockholm in which he expressed his regret that Swedenborg's extensive manuscript on the brain, which is preserved in the library of the Academy of Sciences, had not yet been published. This led to the appointment of a committee to investigate the matter. Prof. Gustaf Retzius, the chairman of the committee and president of the academy, made a study of the subject of Swedenborg's physiological treatises. He became so impressed with the value of these works that he proposed to the academy to issue an edition of Swedenborg's scientific and philosophical works, and offered to bear the expense of the first three volumes himself. Several volumes of these and other of Swedenborg's works have already been published. The examination of Swedenborg's manuscripts is leading to the conclusion that theories and facts in many branches of science usually assigned to much later dates and to other men of science are becoming recognised as largely the work of Swedenborg.

## OUR ASTRONOMICAL COLUMN.

A BRILLIANT METEOR.—A meteor of extraordinary brightness was seen by several observers at 9.45 on Sunday evening, May 17. Mr. T. F. Connolly, of the Solar Physics Observatory, observed the object from Wimbledon Common. It apparently commenced its flight about half a degree east of Polaris, and, travelling slowly to the east of north, passed about half-way between $\delta$ and $\gamma$ Cassiopeiæ. The brightness of the meteor exceeded that of Venus, which was above the horizon, and the head was pear-shaped. The duration of the flight was between three and four seconds; no trail was observed, and the meteor disappeared when at some twelve degrees above the horizon. This object was independently observed by Mr. H. E. Goodson, who states that it was one of the brightest he has ever seen. Mr. P. W. Copeland also writes to say that he observed the meteor at Belper, Derby, at the same time. He says:—"The meteor was of the slow-moving type, and I estimated its apparent diameter as from two to three times that of Venus at the present time. Just before the end of its path, a smaller portion, apparently at a lower temperature, separated and dropped in a more vertical direction. This observation has been confirmed by a friend who saw the meteor at Derby, eight miles from Belper."

CORRELATION OF STELLAR CHARACTERS.—A second paper by Miss Gibson and Prof. Karl Pearson on the correlation of stellar characters appears in the Monthly Notices (R.A.S.) for May (vol. lxviii., No. 5, p. 415). The characters of which the correlations have been examined in this paper are magnitude, colour, spectral class, proper motion, parallax, and position, all of which are of fundamental importance in any study of cosmical structure. As might be expected, there is found to be a marked relationship between the colours and the spectral classes of the stars considered, whilst the relation between magnitude and spectral class is but about half so marked; the latter is sensibly increased if the temperature classification of Sir Norman Lockyer be taken as the index of spectral class. The type of spectrum is also shown to be definitely associated with proper motion and parallax. It follows that, judging from the Yale parallax stars considered, there is a sensible correlation between chemical constitution and motion in space. Among the numerous other results obtained by Prof. Pearson we may mention that he confirms Prof. Newcomb's deduction that the mean parallax of an array of stars of given proper motion is one-fifteenth of that proper motion.

VARIABLE STAR WORK AT THE LAWS OBSERVATORY, MISSOURI.—Bulletin No. 13 of the Laws Observatory, University of Missouri, contains brief descriptions of the Zöllner-Müller photometer and the Gans-Crawford telescope recently acquired by the observatory for use in the series of photometric observations being carried out there. The results of numerous observations and revised elements and light-curves are also published for the variable stars X and V Lacertæ. Bulletin No. 14, from the same source, discusses 160 observations of the peculiar variable RV Tauri (45, 1905). The light-curve of this object is of the $\beta$ Lyræ type, and the maxima and secondary minima present variations in amplitude which appear to be irregular. Between November, 1904, and July, 1905, the character of the variation seems to have altered completely, while further observations made at the Laws Observatory during 1906 and 1907 indicate that the curve has again changed its form. This object then presents an unsolved problem similar to that presented in the cases of R Sagittæ and V Vulpeculæ.

PHOTOMETRIC OBSERVATIONS OF SHORT-PERIOD VARIABLE STARS.—No. 4247 of the *Astronomische Nachrichten* (p. 369, May 8) contains a series of results of the observations of twenty-nine variable stars of short period obtained by Herr H. v. Zeipel at the Upsala Observatory during 1907. For each star two comparison stars were employed, and their positions and magnitudes are given at the head of each table.

THE RELATIVE ACCURACY OF VARIOUS DOUBLE-STAR OBSERVERS.—A short paper by Herr V. Ehrenfeucht, appearing in No. 4247 of the *Astronomische Nachrichten* (p. 381, May 8), deals with the relative accuracy of the principal double-star observers. The resulting figures were obtained by comparing the measures of these observers with the ephemerides of fifty-two well-known doubles, and the probable errors in position-angle and distance are given for eleven observers. The errors in distance range from $0''.055$, for Schiaparelli, to $0''.100$, for Mädler, the mean value for all the observers considered being $0''.698$.

ITALIAN OBSERVATIONS OF THE SUN DURING 1907.—The usual summary, by Prof. Riccò, of the observations of spots, faculæ, and prominences made at Catania during last year, appears in No. 3, vol. xxxvii., of the *Memorie della Societa degli Spettroscopisti Italiani*.

The present paper deals especially with the second semestre of 1907, but the values for the whole year are given. For the period July to December the mean daily frequencies of spots, faculæ, and prominences were 5·7, 2·1, and 4·7 respectively, whilst for the whole year the corresponding values were 5·5, 3·4, and 4·3.

THE NATAL OBSERVATORY.—Mr. Nevill's report of the work done at the Natal Observatory during 1907 is, as usual, chiefly devoted to the meteorological results obtained at the various meteorological stations of the colony. The only astronomical note of general interest is that a series of observations of comet 1907*d* was made by Mr. A. E. Hodgson, and the results are to be communicated to the Royal Astronomical Society. The magnetic declination at Durban for January 1, 1908, is given as $22^{\circ} 27'$ W., with a yearly decrease of $12'$, and the present value of the dip is $63^{\circ}.2$.

SOLAR PHENOMENA AND TERRESTRIAL TEMPERATURES.—In a paper published in the *Bulletin de la Société astronomique de France* for May, Dr. J. Loisel discusses the relationships between the activity of various solar phenomena and the amount of heat received at the earth's surface. The results are based on the observations made at Montpellier during the period 1883–1901, and are of such interest as to suggest the desirability of prosecuting this research in many more different localities. Plotting the actinometric results obtained at Montpellier, together with the frequency curves for sun-spots, faculæ, and prominences, Dr. Loisel shows that they are distinctly analogous, but the terrestrial variation is an inversion of the solar variations.

## THE OKAPI MONOGRAPH.[1]

SHORTLY after the arrival in London of the first complete skin of the okapi, the administration of the Congo Free State at Brussels sent urgent orders to its officials on the Uganda border to procure other skins, and also skeletons, of the then newly discovered animal. In due course these orders were carried out, and a representative series of specimens received at the Museum of the Free State at Tervueren, a few miles out of Brussels, some of which were mounted for public exhibition, while others were reserved for study. With commendable promptitude, the administration thereupon took steps to arrange for a monograph of the okapi, the preparation of which was entrusted in 1902 to Dr. Forsyth Major, who had already made a special study of the giraffe group.

During the same year, that gentleman visited Belgium for the purpose of studying the Tervueren specimens, upon which he published several preliminary notes in *La Belgique Coloniale*. Coloured and other plates for the monograph were also prepared under his direction. Nevertheless, after something like two years' delay, no MS. was forthcoming, and the Secretary of the Free State felt himself compelled to seek another author. Accordingly, Prof. Julien Fraipont was approached, who, after some demur, eventually consented, at the close of 1905, to undertake the work, and to use, so far as practicable, the plates prepared under Dr. Major's direction.

The result of these negotiations is the present elaborate and richly illustrated monograph, which bears on every page testimony to the author's diligence and industry. In one respect the delay has been of very considerable advantage, since it has admitted of the examination and comparison of a much larger series of specimens than was available in 1902–3. Most of these, it should be mentioned, originally belonged to the authorities of the Free State, by whom examples have been presented to the museums of Stockholm, Lisbon, Paris, Madrid, and Antwerp. Altogether, the author had at his disposal no fewer than a dozen skins, seven skeletons, and eleven skulls. With such full material, the monograph could scarcely fail to be otherwise than in a great degree exhaustive.

Following the usual rule, the monograph opens with a historical sketch of the discovery of the okapi and the subsequent acquisition of fuller knowledge of its structure and affinities. In the course of this chapter the author discusses the identification of the okapi with "Set-Typhon" of the ancient Egyptian frescoes and sculptures—an identification which he refuses to admit. The idea is, however, by no means dead, a special work on the subject having been published in Paris last year.

The next chapter is devoted to the general external form and colouring of the creature, in the course of which the author expresses his opinion that, if we except the zebra-like pattern on the limbs and the general brilliance of tone (rather a large order, by the way), the coloration is not unlike that of many antelopes. Of great interest are a number of figures of the limbs of different individuals to display individual variation in the matter of colour-pattern. The skeleton forms the subject of the following chapter, in the course of which the author devotes particular attention to the nature of the horns of the giraffe and okapi, and their correspondence with those of other ruminants. The "vellericorn," or skin-covered, type presented by the former is evidently the most primitive, and there can be equally little doubt that the cap of bare bone at the tip of the okapi's horn represents the deer's antler. A further inference from the latter identification is that the shedding of the antlers in deer is an acquired character, and it is noteworthy that some Tertiary stags seem to have permanent antlers, while in several of the less specialised living species, such as the Indian sambar, the shedding does not take place annually. Front views of a male and a female skull are given, although little is said with regard to individual variation in skull-width, of which we believe there is a good deal. In mentioning the existence of a double bicipital groove to the humerus, the author scarcely gives sufficient emphasis to the fact that this feature is absolutely distinctive of the Giraffidæ.

With regard to the habits of the okapi, Prof. Fraipont has, of course, nothing new to relate, but the photographs he gives of the equatorial forest seem to confirm the suggestion that the striping of the limbs and hind-quarters serves the purpose of breaking up the outline of the creature in the comparatively clear basal zone of the forest. Copious extracts are given from the writings of those who have obtained more or less nearly accurate information with regard to the okapi's haunts and mode of life.

A casual survey of the four coloured plates included among the illustrations will probably lead to the belief

[1] "Contribution à la Faune du Congo." Vol. i., Okapia. By Julien Fraipont. Pp. 118; 38 plates. *Annales du Musée du Congo.* Zoologie, ser. 2. (Brussels, 1907.)

that the author recognises two species of okapi, as two of the plates are lettered *Okapia liebrechtsi*. This is due, however, to the fact that Prof. Fraipont had to use the plates prepared for Dr. Major, and from the descriptions of the plates we learn that the author recognises only a single species—the typical *O. johnstoni*. In this we think he is certainly right, and that some other factor than specific distinction will have to be sought to explain the differences between individual okapis in the matter both of colour-pattern and of skull-characters. If there be two kinds, the okapi certainly forms a strange exception to the law of "geminal species."

Both the author and the administration of the Congo Free State are to be congratulated on this handsome and exhaustive monograph. R. L.

## IRON AND STEEL INSTITUTE.

THE annual meeting of the Iron and Steel Institute was held in London at the Institution of Civil Engineers on May 14 and 15, and was largely attended by members from the various iron-producing districts of this country and abroad. Sir Hugh Bell presided.

The report of the council, read by Mr. Bennett H. Brough, the secretary, showed that the institute had made considerable progress during the year 1907. The membership amounted to 2100, and the financial prosperity was a matter for congratulation. In presenting the accounts, Mr. W. H. Bleckly, hon. treasurer, announced that Mr. Andrew Carnegie, past-president, had presented to the research fund the further sum of eleven thousand dollars, bringing his total benefaction to one hundred thousand dollars. In moving the adoption of these reports, the president announced that the institute had secured larger premises in the same building as those previously occupied, and that the reading-room accommodation had been much improved.

The president then handed the Bessemer gold medal to Mr. B. Talbot, inventor of the continuous open-hearth steel process, who expressed his acknowledgments.

The first paper read described improvements in plate-rolling mills. In it Mr. A. Lamberton described a new form of plate-mill now successfully at work at the Glasgow Iron and Steel Works for rolling light plates. The paper, on the physical qualities of steel in relation to its mechanical treatment, contributed by Mr. James E. York (New York) contained suggestions for changes that might result in the production of more trustworthy rails and other similar sections than those now produced by ordinary methods. The heating of the ingots is a matter of great importance, and it is recommended that the finishing temperature should be as low as possible to get the best results, and that the initial temperature should not exceed 950° C. For solidifying ingots the author's method of transverse rolling may be applied.

Dr. T. E. Stanton, of the National Physical Laboratory, described a new fatigue test for iron and steel, in which a combination of rolling abrasion and alternate bending is used. The machine designed for the purpose was exhibited and described.

Prof. B. Igewsky (Kieff) submitted a paper describing a small electric furnace of novel design erected for experimental purposes at the Kieff Polytechnic Institute. It is a rotating cylindrical furnace, with its axis horizontal, built up of fire-brick blocks with contact pieces rubbing against the outside surface. Most of the heating is done by the passage of the current through the inner surfaces of the refractory material, which, when red hot, becomes a conductor. A continuous current of 250 volts and 50 amperes is employed. Experiments for the production of steel from cast iron by the ore process were successful.

The meeting was then adjourned until May 15, when the first paper was read by Mr. F. J. R. Carulla (Derby), who directed attention to the difficulty in finding cast iron suitable for use in the construction of chemical plant. For some purposes, as, for example, ammonia stills, cast iron seems everlasting, and even acid chemicals have sometimes little action on cast iron. Yet when hydrochloric acid is in question, cast iron succumbs like any weaker vessel.

It was announced that the council had awarded Carnegie research scholarships, each of the value of 100*l*., to T. Baker (South Wales), R. F. Böhler (New York), W. Giesen (Mexico), E. Preuss (Germany), and L. P. M. Révillon (France). The president then handed the Carnegie gold medal for research to Dr. Carl Benedicks, of Upsala University, and stated that the reports submitted by the eight holders of research scholarships were considered to be of sufficient merit to warrant their publication in the journal of the institute.

Mr. E. F. Law exhibited some striking lantern photographs illustrating the application of colour photography to metallography. With the aid of Lumière's autochrome plates it is possible to obtain a photograph in colour on a single plate and by a single exposure. In order to distinguish the constituents, the polished specimen of an alloy is heated until a film of oxide forms on the surface. Owing to the different rates at which the constituents oxidise, they assume different colours, and can be readily distinguished in the coloured photograph.

The utilisation of blast-furnace slag formed the subject of a paper read by Mr. C. de Schwarz (Liége), in which he reviewed recent processes for making slag bricks and cement. Blast-furnace works, especially those producing grey pig iron, have evidently still a large field for improvement by utilising their slag for such purposes.

Mr. Walter Rosenhain gave a detailed description of the metallurgical and chemical laboratories in the National Physical Laboratory, and Mr. Wesley Lambert gave an interesting account of the pyrometric installation in the gun section of the Royal Gun and Carriage Factories, Woolwich.

The eight reports on research work submitted by holders of Carnegie research scholarships showed that a large amount of very valuable work is resulting from the funds placed at the disposal of the institute by Mr. Carnegie. The investigation described by Mr. E. Hess (New York) was carried out at a plant at Monterrey, Mexico, its object being to ascertain the microscopical structures of steels the carbon content of which is above 0·9 per cent. at various temperatures above the critical point. The rusting of iron was dealt with by Mr. J. Newton Friend (Suffolk), whose results point to the fact that the rusting of iron is primarily the result of acid attack. The object of the research described by Mr. D. M. Levy (Birmingham) was to investigate the influence of sulphur, as it affected the relations of carbon and iron, and by a series of coordinated thermal, mechanical, chemical, and microscopic tests to determine how far this action could be traced to any combination or reaction between these three elements, or what explanation could be elicited for it.

No evidence was found to support the view that chemical union between iron, carbon, and sulphur is the cause of sulphur tending to retain carbon in the combined form in irons. The purely physical—or rather mechanical—effects of the sulphide observed in the research appear to offer a satisfactory explanation of its action, exercised even by very small proportions.

Mr. A. Hiorth (Christiania) gave the preliminary results of trials in refining iron and steel by means of vapours of metallic sodium. He finds that iron treated in this way is more fusible and will remain molten longer than other iron, and that such treatment will remove the oxygen. The research submitted by Mr. B. Saklatwalla (Charlottenburg) on the constitution of iron and phosphorus compounds was made with the view of supplementing Stead's chemical researches by a complete thermal and metallographic investigation of the subject. The function of chromium and tungsten in high-speed tool steel was investigated by Mr. C. A. Edwards (Manchester); and Mr. H. C. Boynton (New Jersey) submitted a continuation of his researches on the hardness of the constituents of iron and steel.

Lastly, Dr. Carl Benedicks (Upsala), in a memoir for which the Carnegie gold medal was awarded, gave the results of experimental researches on the cooling power of liquids, on quenching velocities, and on the constituents troostite and austenite. He finds that the essential condition for a quenching liquid to give effective cooling appears to be a high latent heat of vapour, and so low a temperature that the vapour bubbles formed at the surface of the metal may be easily condensed in the surrounding liquid. The rate of flow of the liquid has very little influence on the effectiveness of the cooling. The investigations of cooling velocities were made with an automatic quenching apparatus and temperature calibration device, with a string galvanometer, calibration of which instrument has been investigated. The cooling velocity is considerably lowered with increasing carbon content, and possibly silicon has a similar effect. Results are given confirming the theory that troostite is a solid colloid solution of cementite in iron, or, in other words, a pearlite having ultra-microscopic particles of cementite. The last section of the report is devoted to the study of austenite, for which a new etching medium, 5 per cent. alcoholic solution of metanitrobenzolsulphonic acid, was found to be of use. Austenite was observed to be more liable to rusting than martensite. The most important fact found concerning the preservation of austenite in carbon steel is that it requires a high mechanical pressure. Austenite never occurs in the outer layer of a hardened specimen, but it is entirely erroneous to ascribe this to oxidation; it has been shown to depend on the lack of the necessary pressure.

The annual dinner of the institute was held on May 14, with Sir Hugh Bell in the chair. Four hundred members and visitors were present, the principal speakers being Sir Edward Grey, Secretary of State for Foreign Affairs, Sir W. H. White, K.C.B., the Right Hon. J. L. Wharton, Sir Walter Runciman, Mr. R. A. Hadfield, Viscount Ridley, and General Baden-Powell.

## SCIENTIFIC AID TO EGYPTIAN AGRICULTURE.[1]

FEW of the changes effected during the past decade in our management of the Crown colonies, India, and Egypt will be of more lasting benefit than the establishment in them of scientific, as distinct from the ordinary administrative, departments of agriculture. Although they have only been working a short time, some of them have already rendered very useful service, and give promise of even better things in the future; indeed, in this respect these countries are usually better off than the self-governing colonies—one might almost add than ourselves; in proof it is only necessary to refer to the admirable work accomplished in Jamaica and in the Transvaal, where, on the advent of self-government, it was decided to maintain the scientific department.

The volume before us contains an account of the work done by the scientific staff of the Khedivial Agricultural Society. More than half of it is devoted to cotton, the staple Egyptian crop.

Mr. Willcocks gives some notes on the Egyptian cotton-bug or cotton-stainer (*Oxycarenus hyalinipennis*), an insect which receives its name from the fact that it stains the fibre either with its excrements or with the juices of its body, but which in addition inflicts other damage by sucking the juices from the bolls and the seeds. Once the pest has invaded a cotton field there appears to be no way of getting rid of it, but various suggestions are given for keeping it down. Mr. Willcocks has worked out the life-history, and the stages in its development are shown in a beautiful coloured plate by Miss Connie Beard.

This is followed by a long paper, or rather a collection of papers, by Mr. Lawrence Balls, dealing mainly with heredity in cotton. The cotton plant follows Mendel's laws of gametic segregation in certain of its characters, but the practical problems involved are likely to prove difficult of solution. The history of cotton in Egypt has not yet been worked out; the crop is undoubtedly of great antiquity, and some indigenous culture still exists in the Soudan. But the modern crop is not indigenous; it is closely related to Sea Island cotton, from which, indeed, it has probably sprung, since Sea Island cotton was certainly imported into Egypt in 1822. It is not, however, a pure type. Mr. Balls shows that cross-fertilisation takes place to a certain extent under field conditions, and the accumulated effect of this has been to convert the crop into a mass of hybrids. This is no doubt of prime importance in studying two of the most pressing practical problems, the deterioration of the crop in yield and quality and the multiplication of a weed cotton in the fields. Much can be done by selection to get rid of the weed cotton, but selection alone cannot solve the problem, since there will always remain the splitting forms arising from natural crosses between the wild and cultivated varieties. The only permanent solution is to breed pure types, and though Mr. Balls is aware of the special difficulties involved (notably the fact that many of the characters of importance to the manufacturer and cultivator are dominant), he is quite hopeful of the result.

Cotton is not the only hope of the scientific staff. The Nile Valley is well adapted to wheat cultivation, and was in Roman times a great wheat-producing district. To-day wheat is actually imported, but it is pointed out that the crop might very well come into the rotation with cotton, so that Egypt could once again take a place among the wheat-producing countries of the world.

Mr. Hughes contributes some notes on Egyptian and Soudan soils. Generally speaking, the Nile soils do not contain much organic matter, and the "total" phosphoric acid is not high, but a large proportion is "available," so that Dyer's method may show 0·02 per cent. to 0·08 per cent. In spite of this, however, application of superphosphate has been found beneficial. We may expect some very interesting and important results when the manurial requirements of these soils, as ascertained by field trials, are compared with their chemical composition. It would also be desirable to get out the full mechanical composition of some of the typical soils of known history. Mr. Burns gives an interesting series of analyses of the solids dissolved in the Nile water, samples having been taken for this purpose every month during 1906. The results will be of great value to students of the Nile flood.

Altogether, the work is very satisfactory, and is full of promise for the welfare of Egypt.

E. J. R.

## THE PIGMENTATION SURVEY OF SCOTLAND.

THE last half-yearly number of the Journal of the Royal Anthropological Institute contains an important memoir, prepared by two enthusiastic Scotch anthropologists, Messrs. Gray and Tocher, on the pigmentation of hair and eyes among the school children of Scotland. In one respect the methods employed fail to secure that precision which is necessary to an investigation of this kind. Attempts were made to furnish the correspondents with standard colour cards produced by the three-colour lithographic process, but English manufacturers have up to the present been unable to provide them. There seems, however, to be a prospect of overcoming this difficulty by the adaptation of Lovibond's tintometer to anthropological work. The new instrument is described by Mr. Gray in the April number of *Man*.

Even with these imperfect methods the results are valuable. In the first place, the percentage (24·9) of Scotch boys with fair hair is unexpectedly low. The obvious inference is that the pure Norse or English element in the population is by no means predominant, and that there is a dark or brunette element at least equal, and probably greater. The highest density of fair hair is to be found in the great river valleys opening on the German Ocean and in the Western Isles. In the former case this probably points to invasions of a blonde race into those regions. Similarly, the higher percentage of fair hair in the Spey valley and in the Western Isles implies inroads of the Vikings or Norsemen. It is perhaps pushing the evidence too far when the writers suggest that the high percentage of fair-haired girls in the neighbourhood of Dunfermline is due to the train of blonde damsels who are supposed to have accompanied the Saxon princess Margaret, who about the time of the Norman Conquest became Queen of Malcolm Canmore.

The survey appears to corroborate the conclusions of Dr. Shrubsall in regard to London slum districts, that the percentage of fair-haired people in industrial towns is very low. For some reason as yet obscure, whether from alien invasion or the influence of environment, in towns like Glasgow and Dundee the conditions are specially unfavourable to the survival of blonde men, while the reverse is the case with women. Another important conclusion seems fairly well established, that improvements in communication do not, as might naturally be expected, tend to homogeneity of type; on the contrary, owing to selection centres or to some obscure influence of environment, all improvements in transport apparently tend to make the race more heterogeneous.

The part of the country in which dark hair specially prevails is the extreme west. "If," write the authors of the memoir, "we assume for reasons given above that the pigmentation of girls represents more nearly the pre-Norse inhabitants, this native type has crowded into the Isle of Skye and the opposite coasts of the mainland. If the Dalriadic Scots, who invaded Argyllshire in the fifth century, were a dark race, and the invaders who settled there were men only, that would account for the darkest region in the boys' map being in Argyllshire. The Hebrides have been so much affected by the Viking and Norse invasions from Scandinavia which have passed round the coast of Scotland that they have a much smaller percentage of dark type than the islands and mainland lying further east. The Isle of Lewis has a higher percentage of dark girls than boys, indicating the presence of a pre-Norse dark native population. The south-west corner of Scotland in both the boys' and girls' map is darker than the average; and since, in historical times, the Picts inhabited this region, this evidence points to the conclusion that the Picts were a dark race."

Such wide-reaching conclusions, in the present state of our knowledge, are obviously premature, and too much stress is laid upon pigmentation as a test of race. But the results of this imperfect investigation are sufficiently instructive to justify the demand for a national anthropometrical survey, which was pressed on the late Prime Minister by an influential deputation, the proceedings being reported in the same number of the journal.

## ACOUSTIC OSCILLOGRAPHS.

AN interesting addition to the phonograph or the gramophone has been designed and made by Mr. Bowron, of 57 Edgware Road. It is well known that the action of a gramophone depends on a spiral line cut in the record disc. When this line is examined with a magnifying glass, it is seen to consist of numerous small oscillatory curves; as the disc rotates the needle that follows these curves actuates a diaphragm, and thus the sounds are reproduced. In other words, the curve cut on the disc is a graph of the various sounds produced by the instrument. Several years ago Prof. Ewing studied the analysis of vowel sounds by examining the corresponding curves cut on a phonograph record. Mr. Bowron has undertaken the task of reproducing on a large scale the curves to be found on a gramophone record: he has accomplished this by means of a small mirror, which is mounted so that it oscillates with the diaphragm of the instrument; a beam of light is reflected from this oscillating mirror and from another mirror which rotates uniformly, with the result that a luminous curve of about three feet amplitude can be thrown on a white screen, and so made visible to a large audience. The variations in this luminous curve can be watched while the corresponding sounds are heard; thus the nature of the oscillations produced in the course of a song or the peformance of an orchestra can be most instructively studied.

It would, no doubt, be possible to obtain gramophone records of the various vowel sounds, and to study the corresponding oscillations in a similar manner. In teaching the elements of harmony, it would be interesting and instructive to project on a screen curves showing the characteristics of the various harmonious and dissonant intervals, while the corresponding sounds are rendered audible; and this also could be done by the aid of Mr. Bowron's invention.

Of course, for the curves to correspond exactly to the sounds, it is imperative that the oscillating mirror shall have a very small period of vibration—a period much smaller than that of any of the oscillations which it is necessary to reproduce. Hence the mirror and the mechanism by which it is actuated must be made as light as possible. Some difficulty has been found in obtaining an oscillating mirror large enough to reflect sufficient light to produce curves visible to a large audience, and at the same time light enough to have a period as small as is required; but the progress already made indicates that complete success may ultimately be obtained.

Mr. Bowron has also adapted a Koenig's manometric flame to indicate the acoustic oscillations produced by a gramophone; were it not for the fact that the variations in the shape of the flame must be interpreted before the precise character of the oscillations can be known, this method would be the preferable one. Mr. Bowron's inventions are certain to be appreciated, not only as an educational aid, but also as affording an interesting spectacular display for public entertainments.

E. E.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ST. ANDREWS.—In order to remove misapprehensions which have apparently arisen upon the subject, announcement is made that the University Court—the patrons of the Chandos chair of physiology in the United College, St. Andrews, now vacant—has resolved that the appointment should be open, and that the person to be elected should be the person deemed to be the best candidate, whatever may have been his previous sphere of work. The Court is not pledged to any one candidate, and the election is not a foregone conclusion.

CAMBRIDGE.—The election of a professor of biology will take place on Monday, June 8. Candidates are requested to communicate with the Vice-Chancellor on or before Saturday, May 30.

Mr. C. Shearer, of Trinity College, has been nominated to use the University table at Naples for five months from May 1, 1908.

The professor of botany gives notice that the botany school will be open for practical work during the long vacation. A practical course in elementary systematic botany (flowering plants) will be given in the elementary laboratory on Tuesdays and Saturdays at 9 a.m., beginning Tuesday, July 7. Fee, *1l.* *1s.* A series of botanical excursions will be arranged.

Prof. Larmor has been appointed a member of the board of electors to the professorship of chemistry until February 20, 1910, in succession to Lord Rayleigh, who has resigned his place on the board.

The general board of studies, acting on a memorandum received from the board of geographical studies, recommends a re-construction in the staff engaged in teaching geography in the University. It is proposed that the readership of geography, which becomes vacant in the Michaelmas term of this year, be suppressed, and to establish in its place three lectureships in geography. One of these lectureships will be on historic and economic geography, and will be in connection with the special board for history and archæology. The second will be in regional and physical geography, and it is proposed to connect this with the special board for biology and geology. The third will be a lectureship of surveying and cartography in connection with the special board for mathematics. The salary of each of the first two mentioned lectureships will be *150l.* per annum, and that of the last *50l.* per annum. The last two named will be known as the Royal Geographical Society lectureships in their respective subjects. The council of the Royal Geographical Society has offered to contribute *200l.* a year for three years to the geographical education fund. This offer the board recommends should be gratefully accepted. The University will pay a like sum to the same fund.

THE second annual conference of the Association of Teachers in Technical Institutions will be held in London at Whitsuntide, on June 6, 8, 9, and 10. The delegates will meet on Saturday, June 6, and in the evening there will be a conversazione at St. Bride's Institute, E.C. On Monday, June 8, the president, Mr. C. Harran, will deliver an address, and there will be papers on :—(*a*) Group courses and continuation schools; (*b*) homework and tutorial classes; (*c*) commercialism, the schools, and the decorative arts; (*d*) modern education—the technical phase. On

June 9 there will be a discussion on trade and technical schools, and on the evening of the same day the annual dinner of the association will be held at Anderton's Hotel, Fleet Street, E.C. All interested in technical education are cordially invited to attend the meetings and discussions.

WE learn from the *Pioneer Mail* that the Government of the Maharaja of Mysore is about to award four scholarships—of which two will be for mining and metallurgy, including electrometallurgy—of the value of 200*l.* each per annum, for the year 1908, for study in some British or other recognised university or approved technical institution. These scholarships will be open to all Indians who have taken with credit a degree in arts, medicine, or engineering in an Indian or other recognised university, provided that when qualifications are otherwise equal preference shall be given to candidates who are natives of Mysore or who have taken a degree from a Mysore college. The selection of candidates will be made in August. From the same source we notice that, of 157 students selected in the past three years by the Association for the Advancement of Scientific and Industrial Education of Indians to proceed to foreign countries, 100 have availed themselves of the opportunity, while the fifteen returned students have all found suitable employment.

THE second volume of the report of the U.S. Commissioner of Education for the year ending June 30, 1906, is now available. It gives a very prominent place to statistical information, designed to show the progress which continues to be made in American secondary education. School education in the States is divided according to a well-devised scheme of studies into twelve grades, and the first eight constitute what, in this country, would be called elementary education, and the grades from nine to twelve inclusive correspond to our secondary schools. The number of American secondary-school pupils in both public and private institutions in 1890 was 367,000, or about 5900 to the million of population; in 1895 the number had increased to 539,700, or 7900 to the million; in 1900 the number was 719,200, or 9500 to the million; while for the year 1906 the number aggregated 924,400, or about 11,000 to the million of population, or more than 1 per cent. The growth of public, as compared with private, secondary schools has been remarkable. The number of public schools, which in 1890 was 2526, had in 1906 grown to 8031, and they educated 87·66 per cent. of the total number of secondary-school pupils. On the other hand, the number of private secondary schools, which increased up to 1895, has since that time steadily decreased. In 1906 the number of private schools was 1520. Of the public secondary schools of the country, there were forty for boys only and twenty-nine for girls only, all the others being co-educational. Of the private schools, 304 were for boys only, 500 for girls only, and 725 co-educational.

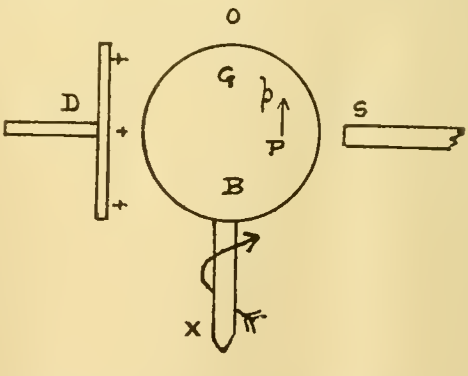
THE annual report of the superintendent of education of the public schools of Nova Scotia for the year ended July 31, 1907, contains, with much other useful information, reports on technical education by the director, Prof. F. H. Sexton, and on the Nova Scotia College of Agriculture by its principal, Mr. Melville Cumming. On April 25, 1907, an Act relating to technical education passed the Nova Scotia Legislature, and led to Prof. Sexton's appointment as director of technical education, with charge of all the schools established under the Act. The schools provided for are:—(i.) a technical college in the capital city of Halifax, to provide professional training in mining, in civil, electrical, metallurgical, and mechanical engineering, and in industrial scientific research generally; (ii.) local technical schools to be established in various industrial centres; (iii.) coal-mining and engineering schools in colliery centres. The college is to be supported by the Government solely, and by private benefactions if such become available. The expenses of the coal-mining and engineering schools are at present defrayed altogether by the provincial treasury, and the local technical schools are supported jointly by the locality and the central government. The first step in organisation was to obtain information regarding the status of existing mining and engineering schools, and the attitude of workmen, employers, and local authorities towards the proposed local technical schools. The engineering schools seem to have been conducted in such a manner that they fulfilled most of the demands on them, and up to the end of the period with which the report deals it was not considered necessary to engage instructors to devote their whole time to teaching. In respect of the local technical schools, the greatest interest was found exhibited everywhere by wage-earners, employers, and the general public. Trades unions were found to be definitely opposed to pure trade schools; the unions fear that such schools will give an imperfect knowledge of the trades, produce a surplus of "hot-house mechanics," as they designate them, who will tend to decrease the demand and wages of skilled labour. It was finally decided that the first schools to be established should be evening technical schools to educate the men already employed in the scientific principles underlying their trades. The report on the College of Agriculture shows that the number of students in 1907 reached 132, and that it is expected the total will reach 200 during the present year.

## SOCIETIES AND ACADEMIES.

### LONDON.

Royal Society, January 30.—"On the Generation of a Luminous Glow in an Exhausted Receiver moving in an Electrostatic Field, and the Action of a Magnetic Field on the Glow so Produced." By F. J. **Jervis-Smith,** F.R.S.

A glass bulb, exhausted as a Röntgen tube, was rotated in an electrostatic field and also in a magnetic field. The conditions of the experiment were varied in six ways. The static charge was either positive or negative. The direction of rotation was reversible. The pole maintaining the magnetic field was either S. or N. The relationship existing between the different conditions will be best understood by reference to the diagram, in which D is a charged disc, B the glow-bulb, S the magnet pole. The axis XO of rotation of the glow-bulb B, the axis of the electromagnet, and the stem of the inductor disc D, are situated in the same plane, when the glow-bulb B



rotates about the axis XO in a clock-hands' sense to an eye looking along XO. The metal inductor D being charged positively, it is filled with a luminous glow of a bluish-green colour, but when the S. pole is placed near the bulb the glow matter is deflected in the direction P*p*, and a bright patch of light is produced at G. The charge on D can be reversed, also the direction of rotation and the magnet pole. If while any two of these conditions are kept the same the third is reversed, the direction of deflection of the glow is reversed. The glow-bulbs were exhausted to the same degree of exhaustion as the Röntgen tube by a leading maker of such tubes. The rays emitted have a definite effect on a sensitive photographic plate, giving shadow pictures. The glow-bulb was rotated about twenty times per second; it was found that the intensity of the glow increased as the rotation increased. The distance between the charged inductor and the glow-bulb was varied from 1 cm. to 13 cm. The glow was apparent at 13 cm. In most of the experiments the inductor was charged to about 1200 volts. The diameter of the glow-bulbs varied from 1·5 cm. to 5·0 cm.

February 20.—"Effects of Self-induction in an Iron Cylinder when traversed by Alternating Currents." By Prof. E. **Wilson.** Communicated by Sir William Preece, F.R.S.

Alternating currents up to about 2000 amperes at frequencies varying from 1/45 to 1/360 were supplied to an iron cylinder 10 inches in diameter, and the change of magnetic induction at different depths was obtained from readings taken with three dead-beat galvanometers connected to coils threaded through holes in the cylinder. The total current in the cylinder was observed on an amperemeter in the circuit. The curves of E.M.F. in the exploring coils were plotted, and by integration the magnetic induction at different depths was obtained. The results show that the effect due to internal self-induction, commonly called "skin effect," is greater the greater the average permeability, and it is shown how it depends upon change of current and frequency. The phase displacement of the E.M.F. curves reckoned from zero of current diminishes with increase of current for a given frequency, and increases with increase of frequency for a given current. From the hysteresis loops of the material the total currents interior to the respective radii were found and plotted against radius as distribution curves, from which the $C^2R$ loss was calculated. The hysteresis watts were also found, and both compared with the watts which would occur if the distribution under continuous current were assumed to persist. For a given frequency, the ratio of the $C^2R$ loss with alternating to those with continuous currents is greater the higher the average permeability. For a given current, the $C^2R$ loss increases with frequency, and the hysteresis loss tends to increase with frequency, but to diminish owing to increased skin effect. The results hold for a cylinder of $n$ times the diameter if the current is varied as $n$, and the frequency inversely as $n^2$. The paper contains tables of figures and curves.

"On the Refractive Indices of Gaseous Nitric Oxide, Sulphur Dioxide, and Sulphur Trioxide." By C. **Cuthbertson** and E. Parr **Metcalfe.** Communicated by Prof. F. T. Trouton, F.R.S.

The refractive index of nitric oxide, purified by fractionation at low temperatures, was found to be 1·0002939 for sodium light. This is about 1 per cent. less than the value found by Mascart.

The index of sulphur dioxide was re-determined in view of the discrepancies between the numbers published by previous observers. The value now obtained, 1·0006609, is in agreement with the results of Ketteler and G. W. Walker, when these are corrected for the density of the gas at 0° C. and 760 mm. The index of sulphur trioxide is, approximately, 1·000737. Both this and the index of sulphur dioxide are considerably below the additive values.

**Faraday Society,** April 28.—Prof A. K. Huntington, vice-president, in the chair.—The planimetric analysis of alloys, and the structure of phosphor-copper: A. K. **Huntington** and C. H. **Deach.** The conditions under which it is possible to estimate the relative proportions of the constituent metals in an alloy by means of the planimetric measurement of the areas of the solid phases exposed in a polished and etched micro-section is discussed. Details of the method are given, and its accuracy is shown by a series of measurements of analysed alloys. The method has been most fully studied in the case of phosphor-copper, of which a number of photomicrographs are shown. In the case of alloys containing less than the eutectic proportion of phosphorus, however, the area of copper crystals is found to be considerably greater than that calculated from the composition determined by analysis. The origin of the discrepancies was traced to the segregation of the eutectic, the copper crystals which separate at first drawing to themselves a portion of the copper of the surrounding eutectic. The crystals are therefore surrounded by a belt of copper phosphide. By measuring the area of this belt, and thence calculating the amount of segregated copper, a correction may be applied to the area of the crystals, and a very satisfactory agreement with the analytical results is thus obtained.—The interaction of aluminium powder and carbon: F. E. **Weston** and H. R. **Ellis.** Very little work has been done on the combination of aluminium and carbon at temperatures lower than that of the electric furnace. The authors now show that aluminium powder and carbon can be made to react at temperatures much below that of the electric furnace. Mixtures of aluminium powder and carbon, wood charcoal, sugar carbon, and graphite have been prepared, in which reaction takes place by starting with a fuse of magnesium powder and barium peroxide, as in Goldschmidt's reaction; other mixtures have been made which only react when heated at temperatures varying from 400° C. to 1000° C. In all cases the products of reaction were found to be aluminium carbide (9·12 per cent. to 65·91 per cent.), aluminium nitride (3·67 per cent. to 42·16 per cent.), alumina (11·07 per cent. to 55·4 per cent.), aluminium, and carbon. The carbide produced is most probably that described by Moissan as aluminium carbide, $C_3Al_4$, since the gas obtained on treating the product of reaction with either water or hydrochloric acid was found to consist of $CH_4$ and H, the latter coming from (1) the action of HCl in unaltered aluminium; (2) action of $NH_3$ on aluminium, the $NH_3$ being formed by the action of water on aluminium nitride.

**Mathematical Society,** May 14.—Prof. W. Burnside, president, in the chair.—The invariants of the general linear homographic transformation in two variables: Major P. A. **MacMahon.**—The order of the group of isomorphisms of an Abelian group: H. **Hilton.**—The calculation of the normal modes and frequencies of vibrating systems (preliminary note): Prof. A. E. H. **Love.**—A question in probability: Prof. J. E. A. **Steggall.**

PARIS.

**Academy of Sciences,** May 11.—M. H. Becquerel in the chair.—The president announced the death of M. Albert de Lapparent.—A planimeter permitting of the integration of the Abelian equation $yy' = Ay^2 + By + C$: Col. **Jacob.** This form of equation occurs in the study of ballistics.—The application of the laws of similitude to the propagation of detonations: MM. **Crussard** and **Jouguet.**—Wireless telegraphy with directed waves: MM. **Bellini** and **Tosi.** The direction of the waves is obtained by the use of aërial conductors formed of closed oscillating circuits disposed in vertical planes without connection with the earth. The transmitter was installed at Dieppe, and two receiving posts were constructed, one at Havre and the other at Harfleur. The signals could be transmitted to either receiving station, and were received only by the station to which they were directed. The signals neither interfere with nor are interfered with by other systems of wireless messages.—The range of the $\alpha$ rays: William **Duane.** It has been shown by various observers that the photographic, phosphorescent, and ionising action of the $\alpha$ rays cease abruptly when the rays have traversed a few centimetres in air, and in the present paper experiments are described which were made with the object of deciding whether the other actions of these rays cease at the same distance. From the form of the curves obtained it is very difficult to decide the exact point at which the range of the $\alpha$ rays ceases, but it was found that the charge of the $\alpha$ particles and their ionisation ceases at the same point.—The electric dispersion of water: F. **Beaulard.** By extending the range of the method previously described to other wave-lengths, there would appear to be some anomalous electric dispersion for the order of magnitude of the electric field studied.—The spectrum of iron observed in the flame of the oxyhydrogen blow-pipe: G. A. **Hemsalech** and C. **de Watteville.** Using the method previously described, the gases feeding the flame were supplied with finely divided particles of the metal torn from electrodes by the electric spark. A table of the wave-lengths and intensities of the observed lines is given, and the results compared with the arc spectrum of iron.—Contribution to the study of the photographic grating: H. **Calmels** and L. P. **Clerc.**—Molecular agitation and the Brownian movement: Jean **Perrin.** An attempt to prove that molecular agitation is the cause of the Brownian motion. It results from the proof given that the number of molecules per gram of liquid is of the order $6{\cdot}7 \times 10^{23}$.—An electro-optic phenomenon in air containing dust in suspension: Eugène **Bloch.**—The commensurability of the atomic weights: M. **Hinrichs.**—

Thorium fluoride and oxyfluoride: Ed. **Chauvenet.** When hydrated thorium fluoride is heated to about 800° in a current of pure dry HF, thorium oxyfluoride, $ThOF_2$, remains. The fluoride, $ThF_4$, can be obtained by the action of anhydrous gaseous hydrofluoric acid on thorium bromide.—The combinations of silver selenide and the selenides of arsenic, antimony, and bismuth: H. **Pélabon.** The existence of compounds of these selenides is deduced from a study of the fusibility curves of their mixtures.—The origin of atmospheric ozone and the causes of the variation of carbonic acid in the air: H. **Henriet** and M. **Bonyssy.** Ozone is produced by the ultra-violet rays of the sun in the upper atmosphere, and the amount near the earth increases when air currents set in from these upper regions. The reduction in carbon dioxide found to accompany an increase in ozone is an indirect effect, due to simple dilution of the lower air with the purer air of the higher atmosphere.—The properties of starch in relation to its colloidal form: E. **Fouard.** A study of starch solutions after filtering through collodion films of different permeabilities.—The properties of the metallic thiosulphocarbamates: Marcel **Delépine.**—Contribution to the study of the amido-derivatives of *o*-dibenzoylbenzene: A. **Guyot** and P. **Pignet.**—A new method of tanning: Louis **Meunier** and Alphonse **Seyewetz.** Skin can be tanned with quinone or quinhydrone. Skins thus tanned present great affinity for both acid and basic colouring matters.—The thermal effects of high-frequency currents on the organism: A. **Zimmern** and S. **Turchini.** Experiments made in dogs and men show that a rise of the body temperature of between 0°·1 and 0°·4 is caused by high-frequency currents. As a method of thermotherapy, the authors regard this method as much preferable to the external methods in current use (hot baths, sun baths, &c.). The application to certain circulatory troubles is indicated.—Researches on the distribution of the antivirulent substance in the humours of vaccinated animals: L. **Camus.**—A new Oospora (*Oospora lingualis*) associated with *Cryptococcus linguae-pilosae* in black tongue: Fernand **Guéguen.**—The formation and disappearance of acetaldehyde under the influence of alcoholic yeasts: A. **Trillat** and M. **Sauton.** Experiments are cited showing the formation of aldehyde under the action of yeast; the reverse action also takes place, since when aldehyde is gradually added to an alcoholic liquid containing fresh yeast in suspension, the aldehyde disappears.—The nutritive value of some peptones for different microbial species: H. **Dunschmann.** Comparisons were made of the nutritive action of Dufresne, Martin, and vegetable peptone on cultures of typhoid, *Bacterium coli*, anthrax, and diphtheria.

## THE SCIENCE OF THE ELECTRON.

*Modern Electrical Theory.* By Norman R. Campbell. Pp. xii+332; diagrams. (Cambridge: University Press, 1907.) Price 7s. 6d. net.

IF Franklin had re-visited this globe a dozen years ago he would have found his view of the electric fluid in the descendent. The work of Hertz and his successors had completed the work which Faraday and Maxwell began in directing the attention of physicists to the æther as the region in which real electrical actions proceed. The conductor was made to take a secondary place only as a region in which electrical energy ceases to be electrical, being dissipated therein into heat. The supposition of one electrical fluid (or more) was scouted, and relegated to the daily Press.

If, however, his visit had been postponed to the present day it would be far otherwise. Once more recourse is had to a fluid to explain electrical phenomena. The story of modern electrical theory is the story of the re-furbishing of an old idea to form the basis of speculative thought. We have Franklin's idea once more in the ascendant; and the only wonder is that this account of modern electrical theory can be written without a single mention of Franklin's name within its pages. The explanation of the wonder is, of course, that the elaboration peculiar to the modern theory is relatively so important that the mere assumption of a fluid at all, once taken for granted, is not worth mentioning.

The main elaboration consists in assuming that electricity, like matter, is made up of discrete portions; and in speaking of "molecules of electricity," as Maxwell did (though he regarded the expression as "gross" and "provisional"), or otherwise in speaking of "electrons." The idea of "molecules of electricity," based originally on the facts of electrolysis, is needed so greatly to explain the phenomena discovered in the last decade in connection with the discharge through gases and radio-activity that no one questions that it is rightly introduced.

The present book might be called "The Science of the Electron." It is not written for the expert. "It was begun with the idea of providing a text-book from which students, well-grounded in the elementary branches of physics, might obtain some knowledge of the later developments"; and although this scheme has been departed from in some respects, the above quotation from the preface represents fairly well the general scope of the book. There is no doubt that a volume with this aim was greatly needed, and we do not hesitate to assert that Mr. Campbell has produced one of the most interesting, the most connected, and most comprehensive of all the recent books on the subject. On questions so speculative as those with which our author treats there are bound to be differences of opinion; and it will be most useful to direct attention to some of these. We will ask Mr. Campbell, therefore, to be content with the above assurance of our appreciation of his efforts, and will proceed to a few critical remarks.

The subject and the methods are so speculative that we are throughout on the fringe of knowledge, and often we pass over to the other side. There is, perhaps, scarcely a sustained argument in the volume which will not ultimately be subjected to considerable modification. It is this daring nature of the speculation which is one of the charms (though a somewhat dangerous charm) of modern physical writings. The idea of the electron has, indeed, been found so fruitful that everyone is employing it for all it is worth. We doubt if there was ever a time in the history of physical science in which so much unproved hypothesis was employed. The very success which attends its employment is the tempter which leads one beyond justifiable bounds. Take, for example, the idea that because the inertia of an electron is explicable in terms of the electromagnetic field which surrounds it, therefore all inertia is explicable in the same way. This idea takes concrete form in the supposition that all atoms are built up of electrons. The author of this idea no longer worships his creation (the present writer never bowed his knee to it); but Mr. Campbell is still attracted by it. The result is that while, according to Drude, and in recent years J. J. Thomson, the number of electrons in an atom is quite small (comparable, for example, with the atomic weight or the valency), to Mr. Campbell the number in a radio-active material, and probably in others, is at least as great as 400,000.

In making this estimate Mr. Campbell assumes that it is unlikely that the energy of each electron in an atom is greater than $4 \cdot 2 \times 10^{-11}$ ergs, this value being the energy which he calculates as necessary to liberate an electron from the atom. But we must point out that electrons are propelled from radium with nearly the velocity of light, and that therefore, after the work done against the attraction of the positive charge, each possesses energy nearly equal to $\frac{1}{2} \times 6 \cdot 1 \times 10^{-28} \times 9 \times 10^{20}$ ergs, or, roughly, $3 \times 10^{-7}$ ergs. Preserving his other datum unchanged, this gives a minimum number of (say) 60 electrons to an atom of radium. But the other datum is the energy liberated by a radium atom measured by its heating effect; this energy is supposed to be distributed amongst the electrons in the atom. Yet Rutherford has shown that something like 98 per cent. of the heating effect is due to the alpha particles. Until we know something more definite about the alpha particles no calculation on the author's lines can have any weight. Needless to say, we do not claim any greater validity for the estimate we have made above.

Our author regards the explosion theory of photo-electric action as unnecessary, and gives the alternative theory depending upon the accumulation of the effects of forced oscillations.

"The electron continues to take up energy from the light until a velocity is reached, depending only on the nature of the atom and not on the intensity of the light, when its kinetic energy is sufficient to carry it clear of the attraction of the positive atom."

We should have thought that on this explanation the velocity of the electron, when sensibly outside the metal, would have been about zero instead of nearly that of light.

We regret the choice of electrostatic units, while thoroughly approving the adoption of a single kind instead of the mixed electrostatic and electromagnetic units which are so often met with.

Many data employed are those relating to an atom or an electron. There is doubtless gain as well as loss in making use of these instead of the corresponding data for (say) unit volume or unit mass. We think, however, that there is preponderating gain in writing all formulæ so as definitely to indicate to what extent the value accepted for the number of particles in a cubic centimetre influences the numerical result. Thus in the expression for electrical conductivity,

$$\sigma = \frac{1}{4\alpha T} e^2 lu N,$$

$\alpha$ is the gas-constant referred to an electron. Now $\alpha/e$ is known with more certainty than either $\alpha$ or $e$, and there is gain in writing $eN$ as a product, so that the formula would be written—

$$\sigma = \frac{eN}{4T\alpha/e} . lu.$$

Probably the most daring speculation in this book is in connection with the problem of aberration and æther drift. Our author desires to remove the difficulties in connection with this problem by denying the existence of the æther altogether. The scientific man, in accepting the æther, "has fallen into the most glaring errors of the crudest nominalism." Our author's explanation is based upon Faraday tubes. May we suggest that these Faraday tubes seem suspiciously like an æther, but with special properties attributed to it?

In many other respects we think that the author is too dogmatic in his assertions; his exposition would gain if the overbearing tone were modified. The reader also resents the too colloquial character of some sentences, such as, "My own vote is cast, for what it is worth, for the latter." Science does not advance by the mere casting of votes, whatever they may be worth.

Although we do not find ourselves in agreement with everything in this book, it is undeniably a very invigorating study of the subject. The publishers are to be congratulated on securing it, and also on the care taken in producing it. There are exceedingly few typographical errors; as proper names are important, we mention that Spender (p. 216) should be Spencer.

## OCEANIC TIDES.

*Scientific Papers.* By Sir George Howard Darwin, K.C.B., F.R.S. Vol. i., Oceanic Tides and Lunar Disturbance of Gravity. Pp. xv+463. (Cambridge: University Press, 1907.) Price 15*s.* net.

THE syndics of the Cambridge University Press are bringing out in four volumes the collected papers of Sir George Darwin. The first volume is before us, and contains a list of about sixty papers written between 1875 and 1906, that will be distributed over the four volumes.

Sir George Darwin's papers being easily separated into well-defined groups, the collected papers will not be in chronological order, but will be classified according to subject as follows:—Vol. i., Oceanic Tides and Lunar Disturbance of Gravity; vol. ii., Tidal Friction with Astronomical Speculations; vol. iii., Figures of Equilibrium of Rotating Liquid; vol. iv., Periodic Orbits.

The height of the tide at any point at a variable time $t$ must be expressible as the sum of a number of periodic sine or cosine terms, the arguments moving uniformly with the time, and the coefficients being constant. The periods are mostly forced periods, and there is little difficulty in pointing out what they are. In addition there are the free periods. "A dynamical problem of this character," writes Sir George Darwin (p. 350), cannot be regarded as fully solved unless we are able not only to discuss the "forced" oscillations of the system, but also the "free." Hence we regard Mr. Hough's work as the most important contribution to the dynamical theory of the tides since the time of Laplace."

The coefficients of the forced oscillations are indicated by theory to some extent. We have first an equilibrium theory, and then a dynamical theory. ("The problem of the tidal oscillation of the sea is essentially dynamical," p. 349.) By laborious quadratures the effects of continents may be roughly taken into account. Finally we are driven back upon the empirical determination of coefficients from observation. This is dealt with in the sixth paper of the present volume. The work is theoretically easy, but most laborious in practice.

In the ninth paper the author concludes from tides of long period that the rigidity of the earth is about that of steel.

Tide prediction follows naturally, when the coefficients of the various superimposed tides have been obtained. An ingenious machine at the National Physical Laboratory, near Teddington, traces the combined effect of twenty-four different tides upon a chart. In two hours the curve that represents the tides of one year can be traced. It afterwards takes a computer a few days to measure the times of high and low water. The machine is used for forty different ports, and, it may be remarked, is therefore not overworked, as its services are required for eighty hours each year.

On p. 5 there is a schedule of notation of the principal tides, with the speed attached. The speeds are combinations of simple multiples, positive and negative, of the earth's rotation, and the mean motions of the sun, moon, and lunar perigee. The speeds are given numerically on pp. 20, 21, &c. On p. 139 we find tables of coefficients for Port Blair, which quickly and clearly indicate the relative importance of the various tides. On p. 116 we note that an attempt to detect the nineteen-yearly tide failed.

"The actual change of sea-level between 1870 and 1873 [at Karachi] was nearly 0·25 feet, and this is just about nine times the range of the nineteen-yearly tide. It is thus obvious that this tide must be entirely masked by changes of sea-level arising from meteorological causes."

We cannot help thinking that the methods of harmonic analysis described on pp. 157–258 are a little unnecessarily cumbrous. One simplification we should like to suggest. Given the height of the tide at intervals of one solar hour, an approximate period exactly commensurable with a solar hour might always be taken for the tide under analysis. The difference between the true period and the assumed period will then appear as a progressive change of epoch in the successive periods of analysis; meanwhile the assumed period, involving exact repetition after an integral number of hours, immensely facilitates the harmonic analysis, as the present writer has found in an allied subject.

The second part of the volume deals with the lunar disturbance of gravity, and closes with a prediction:—

"I venture to predict that at some future time practical astronomers will no longer be content to eliminate variations of level merely by taking means of results, but will regard corrections derived from a special instrument as necessary to each astronomical observation."

## GARDEN BOOKS.

(1) *Roses: Their History, Development and Cultivation.* By Rev. J. H. Pemberton. Pp. xxiv+336. (London: Longmans, Green and Co., 1908.) Price 10s. 6*d*. net.

(2) *Sir William Temple upon Gardens of Epicurus, with other Seventeenth-Century Garden Essays.* Pp. lxxii+272. (London: Chatto and Windus, 1908.) Price 1*s*. 6*d*. net.

(1) THE English literature of the rose ranks higher, and is more abundant, than that of any other florist's flower. By general consent the most popular book on the subject was the late Dean Hole's work, entitled "A Book about Roses," which is read with interest even now for the personal reminiscences it contains. "The Rose Garden," by the late William Paul, is a standard work with invaluable illustrations, and "The Book of the Rose," by the Rev. Foster Melliar, of which a new edition was published shortly before the author's death, is an eloquent expression of the views and ideas of an enthusiast in respect to the qualities of the exhibition rose, and the methods of cultivation by which the plants may be induced to produce the most perfect flowers.

There are many other published works, some newer, others older, than those mentioned, yet such is the interest in the queen of flowers that rose cultivators will gladly welcome the latest contribution by the Rev. J. H. Pemberton.

Rose-growers visit the exhibitions of the National Rose and other societies, and they are induced to emulate the efforts of the best exhibitors. But if ordinary rose-culture is simple enough to those who are willing to give their time and care to the subject, it is nevertheless true that the production of perfect blooms such as are capable of winning prizes at an important competitive exhibition is attended with all sorts of difficulties. The less experienced growers, therefore, are willing to learn from those who have already achieved success, and certainly no amateur has been more consistently successful over a long period of years than the author of the book under notice.

Mr. Pemberton tells us that his father was an ardent rose-grower, and Mr. Pemberton himself commenced to cultivate roses at the earliest opportunity, being tempted a short time afterwards to enter upon the more adventurous and exciting business of exhibiting his blooms at the competitive exhibitions.

The first portion of the book is devoted to explaining the botanical classification of roses, and to describing some of the more important of the wild species. Some of these are natives of Britain, but the larger number are exotic or foreign.

The author's request in the first chapter that readers will bear in mind that the rose is not an exotic loses much of its point when we remember that the Hybrid Perpetuals, Teas and Hybrid Teas have been obtained entirely from exotic species! These earlier chapters may be recommended to the study of hybridists, for they show clearly that very few species have yet been subjected to cross-breeding, and therefore there are good reasons for the belief that although the present variation in roses is very wide, even greater variation may be expected, and novelties that may establish types altogether distinct from those at present in cultivation.

The author has done well to exhort amateur cultivators to attempt the work of cross-breeding roses for themselves, and notwithstanding that the description given of the processes of fertilisation and fructification is not of scientific exactness, the chapter on raising seedlings will be likely to effect good.

In the second part of the volume Mr. Pemberton talks straight to the cultivator upon the details of cultivation, carefully and thoroughly explaining the systems of vegetative reproduction, such as budding, grafting, layering, and rooting of cuttings; the tilling and manuring of the soil, planting and pruning. In these pages the author's intimate and practical knowledge of his subject is plainly revealed, and the directions are given so lucidly and yet so tersely that to misunderstand them would appear impossible.

As the winner of hundreds of friendly battles Mr. Pemberton is able to afford most valuable hints and directions upon the subject of competitive exhibitions, and whilst his enthusiasm for these will be likely to beget also in his readers a desire to engage in the "Wars of the Roses," his helpful counsel will encourage them to do so with every prospect of obtaining some measure of success.

We are glad that in this book, written as it is by such an enthusiastic exhibitor, the case for the decorative value of roses in the garden is stated so fairly and sympathetically. Not all rose-growers wish to exhibit, but those who do not, equally with those who do, desire to cultivate the best varieties of roses in the best manner, and the decorative gardener will find much in this book that will specially appeal to him.

The illustrations of rose species are reproductions from authentic works on the subject, and in addition to these there are useful designs which illustrate the practical details of budding, pruning, and other operations. We heartily commend this work to the notice of all who aspire to excel in the art of rose-culture.

(2) This volume is a contribution to the "King's Classics" under the general editorship of Prof. I. Gollancz. The first portion, consisting of forty-nine pages, is devoted to an introduction by Mr. Albert Sieveking, who states that the book contains in whole or abstract the Garden Essays of Sir William Temple, Abraham Cowley, Sir Thomas Browne, Andrew Marvell, and John Evelyn, who "in their lives cover the whole of the seventeenth century, and in their writing represent not only some of the best of garden, but of English literature." The introduction is a learned *critique* of the five writers mentioned, and the views contained therein are likely to commend themselves to the reader, for they are well founded, being evidently based on a conscientious study of each. Incidentally Mr. Sieveking gives considerable information upon the history of gardening in Britain, and we commend the reader to study the introduction before reading the selected contributions from the seventeenth-century writers. Of these we regard the prose of Temple as representing a style of literature that is at once pleasing and enlightening. His essay indicates such an appreciation of the art of gardening and intimate knowledge of the best gardens of his day as are certain to appeal to the practical horticulturist.

Notwithstanding our own advanced methods, we are impressed with the insight into cultural problems Temple displays, although some of his opinions were based upon inaccurate premises. His reasons for recommending contemporary gentlemen to possess gardens for themselves are unanswerable, but the lofty air in which they were advanced invests them with a certain amount of humour.

The selection from Cowley includes a letter addressed to Evelyn, and some entertaining verses appreciative of the garden. The extracts from Browne's "Garden of Cyrus" and "Plants Mentioned in Scripture" give the reader some idea of the style of the writer, but they are unsatisfying, and it may be regretted the editor was compelled to curtail them so severely. His observations on grafting prove that numerous experiments were made in this art at that early date. Marvell's verses show an inclination to criticise gardeners for straining after the unnatural and attempting the mixing of plants by purposeful cross-breeding.

Passing to Evelyn's letters to Dr. Browne and others, these are all interesting and informative, whilst the abstracts from his famous "Diary" are not only interesting, but they go to show Evelyn's great knowledge of gardening subjects, and his unusual powers of observation.

## GERMAN SCIENCE MANUALS.

(1) *Bakterien, und ihre Bedeutung im praktischen Leben.* By Dr. H. Miehe. Pp. iv+141. (Leipzig: Quelle and Meyer, 1907.)

(2) *Lebensfragen; die Vorgänge des Stoffwechsels.* By Dr. F. B. Ahrens. Pp. vi+153. (Leipzig: Quelle and Meyer, 1907.)

(1) THIS is an excellent little book. In it Dr. Miehe expounds the story of the microorganisms so clearly that an ordinary, intelligent reader will easily and pleasantly acquire, so far as mere reading can supply it, a trustworthy knowledge of all the fundamental facts and theories of bacteriology. The author takes us from the *De re rustica* of M. Terentius Varro—who seems to have been in the matter of microbes much what Democritus was in respect to atoms—to the "denkwürdigen Brief" of van Leeuwenhoek to the Royal Society in 1683, wherein the famous observer expresses his naïve astonishment at certain frolicsome "animalcula" he had discovered in the human mouth; and our guide does not leave us until we have seen at least the outstanding features of the work of Jenner, Lister, Pasteur, Koch, Eberth, Winogradsky, and the many others whose labours have, each in its degree, helped to illuminate the dim but fascinating pathways which lead into the realms of the infinitely little. He shows us the microorganisms as helpers and as enemies, their modes of increase, and the methods of their destruction; their distribution on land and sea; and the problems of philosophy and of practical life to which the study of these "little fleas" leads.

The book strikes just the happy mean required in a work of this kind. It avoids the trivialities which often embellish expositions of "popular" science. It states the problems clearly, and discusses them soberly, yet withal is no dull and ponderous disquisition; in style it is rather Gallic than Teutonic.

There is a glossary of such terms as are unusual and not sufficiently explained in the text. Given on the part of the reader a very small modicum of scientific knowledge, no mystery of the microorganism dealt with in the book need remain a mystery for lack of simple and lucid exposition.

(2) The "Lebensfragen" contains a number of articles explaining the principles of nutrition and the origin and method of preparation of the chief foodstuffs. To persons who feel more than a passing curiosity about the production of sugar, butter, beer, vine, tea, and so forth, or about the chemical composition of these substances, the descriptions so far as they go may be recommended as trustworthy. But they do not go far enough for the technical reader, and are not intended for him. In each case a sketch of the source, manufacture, and chief chemical characters of the article is given, together with any salient facts of general or historical interest connected therewith. In the chapter on sugar, there is, for example, a description of how the beet-sugar industry was fostered in France by Napoleon. There are also chapters on enzyme action and on the production and application of artificial fertilisers.

The book is written for the general reader who wishes to know, without too much detail, something substantial about the chief things which go to nourish his kind—"the oil to make him a cheerful countenance, and bread to strengthen man's heart." To the English reader, however, there is hardly sufficient novelty, either in the substance of the essays or in their form, to make it worth his while to peruse the book, unless he wishes to give his German an airing.

C. SIMMONDS.

## OUR BOOK SHELF.

*Studies in Blood Pressure: Physiological and Clinical.* Second edition, enlarged. By Dr. George Oliver. Pp. xii+255. (London: H. K. Lewis, 1908.) Price 4s. net.

IN this second edition Dr. Oliver has carried the subject of clinical pulse gauging a distinct step forward. Not only has he greatly improved his compressed-air manometer, but he has made further clinical observations on blood pressure, and he presents the subject in a series of generalisations which cannot fail to be of practical value. The alterations he has effected in his instrument concern each of the three portions constituting it—the glass tube, the armlet, and the apparatus for regulating the air pressure in the tube. This latter is now closed at the distal end, thereby doing away with the necessity for a tap, and effectually avoiding leakage. The armlet no longer consists of a gutta-percha bag which completely encircles the limb, but of a canvas bag, constructed to encircle the limb partially, and provided with three straps; this is a great improvement on the older contrivance, admitting, as it does, of ready adjustment to the limb. Finally, instead of regulating the air pressure by a ball-pump, which causes the index to move along the tube in a series of bounds, Dr. Oliver now employs a compressor fashioned concertina-wise, the size of the chamber being controlled by means of a screw passing between the two boards constituting respectively the top and the bottom, an arrangement which enables the air pressure to be regulated with great evenness and nicety.

Dr. Russell recently directed attention to the fact that a thickened, sclerosed artery may vitiate the findings obtained with the armlet method. In this Dr. Oliver agrees. He finds that the readings he obtains with the armlet method may be higher than those yielded by his earlier spring instrument (hæmodynamometer). In the slighter degrees of arterial sclerosis the difference in the readings obtained by the two methods is small—from 10 to 20 mm. Hg.—but in advanced sclerosis this difference may be much greater, reaching to 40, 50, 70, and even 100 mm. Hg. But, as the author points out, this very difference may be of advantage, affording, as it does, a means of estimating the degree of arterial sclerosis present. He has, moreover, shown that in old people very high armlet readings may be observed in conjunction with low hæmodynamometric readings, without any evidence of cardiac strain—the actual blood-pressure, *i.e.*, being low, though a high degree of sclerosis is present. Only when the arterial wall is normal are the readings furnished by the two methods identical.

One of the most interesting parts of the book is that which deals with the causes of excessive arterial blood pressure. The condition is attributed essentially to constriction of the arterioles as the result of chemical irritation, and the sources of the chemical agents capable of bringing this about are discussed. Dr. Oliver is to be congratulated on the production of these valuable studies.

*Dairy Laboratory Guide.* By Prof. C. W. Melick. Pp. v+129; illustrated. (London: Archibald Constable and Co., Ltd., 1907.) Price 5s. net.

IN some parts of Great Britain, and in most parts of Ireland, dairying is being gradually transferred from the farm to the factory, and an increasing demand for properly trained managers has to be met. Not only must such managers be experienced in the practical operations of butter- and cheese-making, but they must also be able to manipulate the machinery providing power to the dairy, be able to carry out the chemical analysis of milk and cream, possess a knowledge of dairy bacteriology, and be business men. At three of the dairy schools in Great Britain the equipment should be sufficient for providing the course of training required, but no courses specially intended for dairy managers seem yet to be given.

In the State agricultural colleges in the dairying parts of North America, short courses of training for dairy managers are regularly given, and it is for such courses that Prof. Melick has prepared this series of exercises. The book should be useful on this side of the Atlantic by indicating the general lines on which courses can be arranged. In detail, however, the exercises are not entirely suitable for use in this country. The use of the hand churn and butter worker is nowhere referred to, but, though skill in making butter by hand is unnecessary to the creamery manager, the process provides a training which cannot be obtained by more mechanical methods. The three exercises given in hard and soft cheese-making are totally insufficient, and if the plea is offered that there is no time for more, it would surely be better to omit the making of "dried milk cocktail," "buttermilk pop," and a dozen other dietetic delicacies and nostrums which are given as exercises to the students. Again, the economics of dairying should be dealt with far more thoroughly, and the bacteriological exercises should be extended beyond the bacteriology of impurities in milk to the bacteriology of the ripening of cheese and cream.

Nor on literary grounds can the book be recommended in this country as a students' text-book. Partly owing to numerous "printer's" errors, partly to clumsy phraseology, and partly to the use of American technicalities, the meanings of which are unknown to us, portions of the book become almost unintelligible. For example, the student is directed to "make nutrose by boiling together in any alkaline solution dried casein and caustic acid," and again to "make eulactol by dissolving proteic vegetable substance and adding hydrates of carbon, salts, such as phosphate of calcium, cooking salt, or carbonate of sodium, and allow to vaporize" (pp. 107–8). On the other hand, Gray's method for the determination of moisture in butter is admirably described.

*Discoveries in Hebrew, Gaelic, Gothic, Anglo-Saxon, Latin, Basque, and other Caucasic Languages, showing Fundamental Kinship of the Aryan Tongues and of Basque with the Semitic Tongues.* By Dr. A. E. Drake. (Denver: The Herrick Book and Stationery Company; London: Kegan Paul, Trench, Trübner and Co., Ltd., 1907.) Price 25s. net.

JUST as in the sphere of the natural sciences men from time to time arise who believe that they have discovered perpetual motion, or that the circle can be squared, or that one can demonstrate that the earth is flat, so, too, in comparative philology writers are still occasionally found who, in defiance of all the rigidly scientific investigations of Brugmann, Osthoff, Henry, Sweet, Murray, and other philologists, persist, by disregarding phonetic and other ascertained linguistic principles, in connecting together utterly dissimilar tongues, such as the Indo-European languages, Hebrew, and Basque. The author of the above-named work is a writer of this type. His work bristles with philological impossibilities, and he appears to have no conception of the necessity of ascertaining, before comparison of one language with another, the laws which govern the sound changes of the languages compared and of the immediate groups to which they belong. The Hebrew word Satan he thinks is cognate with the Basque Tusuria "by transposition," and the work abounds in similar equations. The volume is unworthy of serious attention, and its only interest arises from its being one of those strange works that spring from the union of a certain kind of learned industry with misdirected ingenuity.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Fellowship of the Royal Society.

It is well known that under existing regulations the number of new fellows elected to the Royal Society every year is only fifteen. In this way the total number of fellows is kept at about 450. In the early days when this arrangement was made the limited annual number was doubtless sufficient to ensure the election of all the scientific men who really merited the honour, but since those days the scientific world has been growing larger and larger, and at the same time the general standard of work in all branches has become higher.

So long as the annual number of candidates was not more than forty or forty-five the selection of fifteen was not very difficult, and no man who had really done good work had to wait more than two or three years before election. Now, however, the annual number of candidates has increased to eighty or ninety, and this year it is said there were nearly 100 candidates.

Is it not high time, then, that the Royal Society took definite steps to make some change which would meet the requirements of the changed circumstances? Many of the older members of the society are well aware that the present state of affairs is unsatisfactory, and some have expressed their sentiments, but nothing has yet been done.

A simple plan would, of course, be to elect thirty new fellows every year instead of fifteen, but one can see objections to this plan. Has it ever been suggested that the Society should create an associateship and elect associates as well as fellows? The number of fellows might remain as it is, but if a limited body of associates was created, say fifty to begin with, and was increased by the election of twelve or fifteen every year, the pressure would be relieved, and I should think A.R.S. would be preferable to a long-deferred F.R.S. Subsequent elections of fellows could then be made from the associates, and this double election would give better assurance than now exists that none but the best men of the year were admitted to the fellowship.

Enquirer.

### Earthquakes and Earthshakes.

Some of the memoirs, professedly seismological, which have appeared during the last year or two indicate that confusion has arisen from the use of the word earthquake in two distinct and independent senses. As this confusion seems likely to increase unless a modification of our nomenclature is adopted, the introduction of a new term appears to be requisite, however much this may be deprecated on other grounds.

In the generality of cases, the phenomenon represented by the word earthquake consists of a vibratory motion of the ground, of the nature of a wave motion, propagated outwards from a more or less extensive origin or focus. In some cases this disturbance may lead to damage or destruction of buildings, or even to displacement of the surface layers of the earth; but these are secondary results of the molecular displacements involved in the propagation of the wave motion, and, apart from them, the earth, after the earthquake has passed, resumes the same position and condition as before.

Occasionally, however, the word is applied to a disturbance of a wholly different kind, resulting in the formation of fractures and displacements of the solid rock, displacements which are molar and permanent, in the sense that the masses affected by them do not return to their original position after the earthquake has passed.

As the first was the sense in which the word is invariably used in Robert Mallet's classical researches, as it is that which has been sanctioned by long-continued usage, and as the proportion of records and observations, which do not apply to this phenomenon, is probably less than one in a thousand, I suggest that the word *earthquake* should continue to be used in this sense, and that for the other sense, in which it is sometimes used, the word *earthshake* should be substituted. Using the words in this way, we may say that earthquakes, or at any rate severe earthquakes, are frequently, if not invariably, caused by rupture of the earth's crust and the formation of fractures or faults in the solid rock, but these fractures, which are the primary cause of the earthquake, are only the secondary result of the earthshake, the action of which arises at a greater depth, and the ultimate cause of which lies beyond our present ken. The distinction is an important one, and the importance may be greater than will be acknowledged immediately, for some recent studies made by me have indicated a possibility that the earthshake has sometimes a greater extent than the earthquake; in other words, that the area over which permanent displacements of the earth's surface have taken place may be greater than the seismic area, or the area over which the shock was felt.

Incidentally, it may be mentioned that the whole of Prof. See's recent publications on the cause of earthquakes, and the greater part of those by Prof. Hobbs, deal with earthshakes and not with earthquakes as here defined. This is natural, for only the permanent changes, resulting from the earthshake, are of importance to the cosmogonist or the geologist; the transient displacements produced by the earthquake concern them, directly, but little, if at all.

R. D. Oldham.

### Classification and Mathematics.

If mathematics is to be regarded as the science of classification, a view apparently taken in many recent works, it may be worth while to consider whether mathematical teaching should not begin with the use of models of classifications in general rather than with the special classifications in connection with which terms like straight line, rotation, product, power, &c., were originally introduced.

By a model of a classification is meant, for example, a set of things which can be classified by one respect as colour, and cross-classified by another as shape. Similarly, models can be made having three or four or more differentiations, in which any two differentiations have the relation of classification and cross-classification. If each differentiation is supposed to be ordered, we have then spaces of two, three, or four dimensions, of which the classified things form the points. By motion of a point in the space is meant its change in those properties which have been used in the classification. Consideration of the meaning of extension, rotation, and right angle shows the possibility of using the motion of extended bodies to construct a classification of the points of a space, even when we are unable to recognise the differentiations themselves of the space. This is the case met with in ordinary geometry.

As the foundation of geometry lies in the idea of ordered classification, so that of algebra lies in the conception of correspondence between things. A function or one-to-one correspondence is a classification and cross-classification of the things which correspond. For example, a division of a number of models having different markings into two classes by colour and a cross-classification by shape gives a correspondence of the markings in one colour class to the markings in the other. If each marking in one class corresponds to the same marking in the other, we have the correspondence one. Similarly, various circular functions may be illustrated by models, beginning with transpositions. If things which correspond are called operands, and a correspondence of operands a function, then names seem to be needed to mean a correspondence of functions, and for the still higher correspondences which occur. In the usual school course we practically begin with the correspondences of functions, namely, of the numbers one, two, three, &c. It would seem more natural to begin with the correspondence, first, of operands to operands, and then of operands to functions, and define words as power, product, sum in reference to correspondences of operands illustrated by models. For example, a set of things the correspondence of which to another set is under discussion may be called a quantity. Two quantities which correspond to the same quantity correspond to each other; and their correspondence to each other is the product of the correspondence of one to the intermediate quantity and of the intermediate quantity to the other. In the case of vectors, since a vector is a correspondence of points, this would require the term product to be given to what is generally called the sum.

The properties of permutation, association, distribution should be considered in reference to tables of operands before considering tables of functions such as multiplication and addition tables. Space will not allow of discussing the illustration of addition, rule of signs, two-to-two correspondence, &c. The study of irrational numbers and continuous spaces should be postponed to a later stage.

Oundle. C. ELLIOTT.

### An Emanation from Sodium.

DURING the course of some experiments upon the contact potential difference between the alkali metals and glass I noticed that a freshly cut piece of sodium rapidly discharged an electroscope.

Further examination showed that this action occurred only if the gold leaf was charged negatively. Little or no effect was produced if it was positively electrified. The action could be completely stopped by a membrane of celluloid sufficiently thin to give interference colours, and this fact alone points strongly to the discharging action being due to a vapour.

It was found, in fact, that a slight current of air directed so as to carry the supposed gas away from the charged plate of the electroscope enabled the leaf to retain its charge.

The effect is, however, unlike that met with in the case of phosphorus, since the vapour from that substance discharges both positive and negative electricity equally well. It does not, therefore, appear due to the air becoming ionised by a change occurring at the surface of the sodium, but more probably to the emission of an electrified gas. Experiment has shown that the rapid oxidation of the surface has little or nothing to do with the existence of the emanation, and it is very significant that all action ceases after prolonged heating (to melting point) of the metal. After some hours, however, the sodium shows signs of recovering its power to discharge a negatively electrified body.

Since all portions of the same block of sodium do not exhibit the action to the same extent, I am attempting to concentrate those parts which show it most strongly in order to determine whether some new radio-active body is present in the metal or whether there is a radio-active change occurring in the sodium itself.

A slight indication that the emanation is capable of depositing a radio-active layer of matter has been also noticed. The other alkali metals are now being examined and the whole matter fully investigated.

CHARLES E. S. PHILLIPS.

Castle House, Shooters Hill, Kent.

## WIND PRESSURE.

THE importance of a correct knowledge of the pressure exerted by the wind, as affecting the stability of modern structures, was brought prominently before the public by the disaster to the Tay Bridge on the night of December 28, 1879. At that time observatories at which wind pressure was directly measured were rare, the usual observed characteristic of the wind being its velocity as given by the Robinson cup anemometer.

At some stations both the Robinson cup anemometer and the Osler recording pressure plate were installed, and it was for this reason that in the report of the Royal Commission which was appointed in 1881 to consider the question, an attempt was made to state the relation between the probable maximum pressure which would be recorded in a gale and the maximum hourly run of the Robinson cups during that period. Also from records of pressure plates which were considered by the Commission to be not due to instrumental error depending upon momentum, but which represented real phenomena, it was decided that, for structures in exposed situations in this country, a maximum wind pressure of 56 lb. per square foot of surface should be allowed for in the design.

It was, however, felt by engineers at the time that this value, assumed uniform over the whole surface of a large structure, was very excessive, for, as the late Sir Benjamin Baker remarked at a discussion on wind pressure at the Institution of Civil Engineers soon after the report of the Commission was published, if such pressure actually obtained there ought not to be a bridge standing in the country. It was on this occasion that Sir Benjamin Baker stated his conclusions as to the nature of the motion of the wind and the pressures resulting from it, which theory was based, not on elaborate experiments, but on close observation of the behaviour of natural objects in the wind. In his words,

"If leaves and other light objects floating in an apparently steady current were watched it would be found that certain leaves would shoot forward at an increased velocity of 25 per cent. and upwards as compared with the mean velocity. Over a width of 20 feet at the centre of a wide and steady current the mean velocity might thus be constant, whilst over some particular width of 1 foot it might be momentarily fully 25 per cent. higher, and in the case of wind pressure 25 per cent. increase of velocity meant more than 50 per cent. increase of pressure. It was quite possible, therefore, that the large pressure boards might register a notably less pressure than the small boards, and might afford a clue to the reason why railway carriages were not upset when traversing lofty and exposed viaducts."

This appears to have been the first recognition of what may be called the variable structure of the wind as a factor of safety in the stability of structures, and it may be mentioned that the variation predicted by Sir Benjamin Baker was found to exist at points distant 11 feet apart in the experiments of Mr. Dines in 1894.

To test the truth of his conclusions Sir Benjamin Baker erected some wind-pressure plates on the site of the Forth Bridge, each provided with an arrangement for measuring the maximum pressures experienced. One of these gauges was 300 square feet in area, and the others $1\frac{1}{2}$ square feet. Taking the mean of the maximum daily readings for two years, the small-gauge indications were found to be 50 per cent. greater than the large-gauge indications, which was the result anticipated.

In experiments of this kind it is interesting to notice that there is one particular case in which with the assumed structure of the wind the small plate might register a pressure lower than the large one. This is the somewhat rare event when in a gale there is one gust of considerably greater intensity than those which precede or follow it. If during this gust the small plate occupied a region of low velocity, its registered maximum pressure would be lower than that of the large plate. This appears to have happened in one of the gales at the Forth Bridge during the experiments, but its rarity supports the evidence of anemometers, which show that the average gale consists of a series of gusts of nearly equal intensity, so that the probability of the maximum velocity occurring in the region of the small plate is very great. It is important to realise that the above conclusions are in no respect applicable to the pressures which may obtain at any given instant on two plates during a gale, as a little consideration will show that the probability of the small plate occupying the region of lowest velocity at any instant is the same as that of its occupying the region of highest velocity, from which the conclusion follows that the small plate will also register the lowest pressure during the gale.

In the foregoing statements the difference in resistance of large and small surfaces in the wind has been treated as depending entirely on the structure of the wind, that is, it has been assumed that if the wind were a perfectly uniform current in which the velocity over any considerable area was the same, the pressures on the two surfaces would be identical.

This, of course, is not necessarily the case, as there may exist a purely dimensional effect in the resistance of appreciable magnitude, and in the opinion of some authorities the explanation of the Forth Bridge experiments was to be found in this, and not in the structure of the wind.

For this reason, when the wind-pressure experiments were commenced at the National Physical Laboratory in 1904, the determination of the existence or non-existence of this dimensional effect was made the chief feature of the research. These experiments were made on plates and models ranging up to 100 square feet in area, erected on the top of an observation tower 50 feet above the ground, which had a fairly clear space in front of it. After some preliminary work, the method which was finally adopted consisted in the determination of the constant $k$ in what may be called the "equivalent" pressure velocity relation

$$p = kV^2,$$

that is the relation which would exist if the velocity of the wind were uniform.

The determination of this relation when a plate is moved at a known velocity in still air is fairly easy. It becomes more difficult when a plate is suspended in a uniform current of air on account of the trouble involved in forming a correct estimate of the velocity of the current, since, owing to the conditions of flow being disturbed in the region of the plate, it is necessary to place the velocity gauges at some distance from the plate. In the case of a plate exposed to the wind, there is the added complication of the varying structure of the current, and the problem at the National Physical Laboratory was to obtain the "equivalent" pressure velocity relation from observations of the resultant pressure on a plate and the corresponding pressure in a "Dines" tube, which was used as the velocity gauge, distant 10 feet from the edge of the plate. A solution was found in the observed fact that although the pressures at any instant in two tubes facing the wind, and distant 10 feet apart, might differ by as much as 50 per cent., yet if one hundred of these sets of readings were taken at successive intervals of time, the *mean* pressures for each tube were practically identical. From this it was assumed that if a large number of observations of the resultant pressure on the plate and the (simultaneously observed) pressure in the "Dines" tube were made, the means of these experiments would give the equivalent pressure-velocity relation sought. For this purpose 200 observations of this kind were made on each plate tested, two observers operating two sensitive water gauges at the foot of the tower. One of these water gauges was connected by two lead pipes attached to the legs of the tower to the "Dines" tubes, and the other by two similar pipes to an air cylinder in which the pressure varied with the fluctuations of resultant pressure on the plate. The arrangement of the 100-square-feet plate and the "Dines" tube is shown in the photograph (Fig. 1).

The results of experiments on three plates of areas of 25, 50 and 100 square feet gave identical values of the constant $k$ in the "equivalent" pressure-velocity

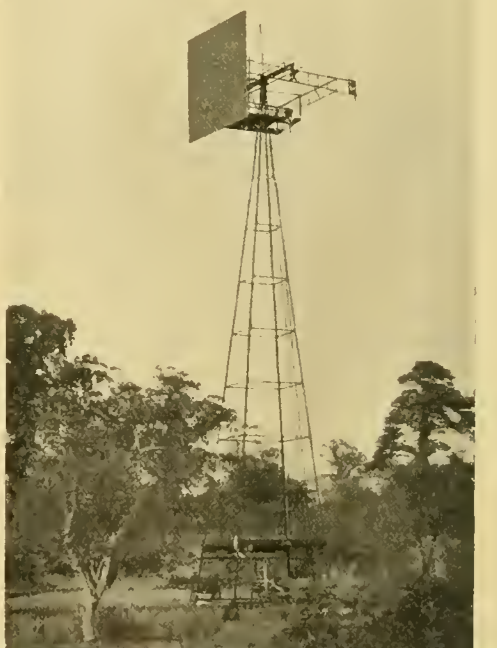

FIG. 1.—Wind Observation Tower with 100-square-feet plate in position.

relation, which in units of pounds per square foot and miles per hour was found to be 0·0032, indicating that for this range in dimensions the purely dimensional effect in the resistance was negligible. There were strong reasons, however, to suppose that it was not negligible for all ranges in dimensions, since the value of $k$ determined at the National Physical Laboratory in 1903 for plates of 2 and 3 square inches in area in a uniform current was 0·0027, and that determined by Mr. Dines in 1890 for a plate of 1 square foot in a whirling machine was 0·0029. This view has been fully confirmed by the publication during the present year of the results of M. Eiffel's experiments on plates let fall from the second stage of the Eiffel Tower. Using square plates varying in area from 10 square feet to five-eighths of a square foot, M. Eiffel found a continuous change in the value of the constant, ranging from 0·0032 for his largest plate to 0·00285 for his smallest plate. The plotted results of M. Eiffel's observations on square plates and those

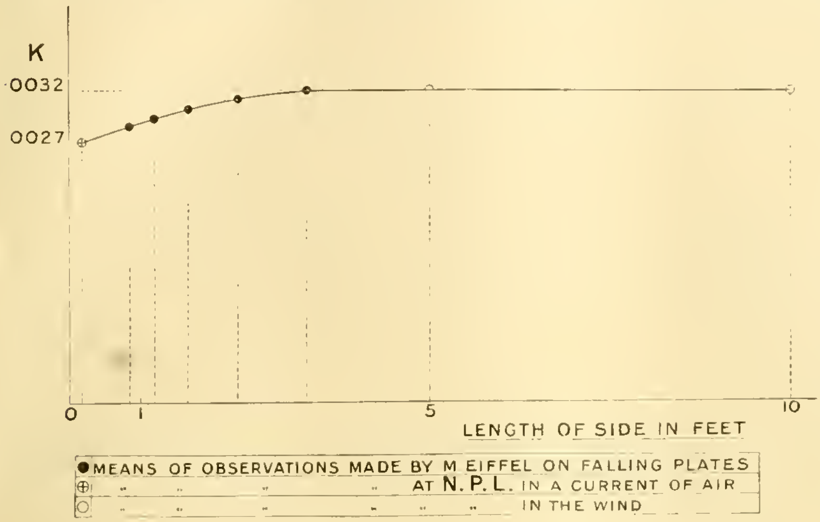

FIG. 2.—Curve showing the dimensional variation in the air-resistance of square plates.

made at the National Physical Laboratory are shown in Fig. 2. There appears, therefore, to be a purely dimensional factor in the resistance of plates, which for the case of square plates has the effect of increasing this resistance up to an area of approximately 10 square feet, when it becomes practically constant.

In the small-scale experiments made in a uniform current of air at the National Physical Laboratory, it was found that although the resistance per unit area of combinations of plates, such as lattice-work, differed considerably from that of square or circular plates, the resistances of similar combinations of plates were approximately the same. To test the possibility of predicting the resistance of a complex structure in the wind from observations on a small-scale model in a current, a model lattice girder was constructed of wood, with a span of 30 feet, and a depth of 3 feet 6 inches. This was placed on the tower (Fig. 3), and a set of observations made on it. A small-scale model of this was made in brass, the linear dimensions being reduced in the ratio of 1 to 42. The resistance of this was determined in the current. On comparing these resistances they were found to have precisely the same ratio as that of the resistances of the large square plates in the wind and the small square plates in the current, that is, the resistance of the large girder was 18 per cent. greater than that of the small one. The conclusion was that the resistance of any structure, however complicated, can be predicted with considerable accuracy from observations on a small model of it, as in the similar problem of the resistance of ships.

The important case of the resultant wind pressure on roofs is more difficult to treat experimentally, owing to the oblique impingement of the wind, which renders the position of the centre of pressure uncertain.

Until recent years it has been customary to treat the forces on a roof due to wind pressure as pressures affecting the windward side only, but from experiments on small models in a current of air, Mr. Irminger, of Copenhagen, has shown that there is a considerable suction effect on the leeward side of the roof, due to the eddies from the ridge. It does not necessarily follow from this that the resultant effect on the leeward side of a roof must be a suction, as this will depend on the pressure inside the building also.

In the National Physical Laboratory experiments a roof model was erected on the tower, having sides each of 56 square feet in area. The results of the observations of resultant pressure on the leeward side showed widely different values, according as the conditions were those of a roof supported on columns through which the wind could pass freely or on walls. In the former case it was found that the reduction of pressure inside the roof due to the eddy from the eaves of the windward side was approximately of the same magnitude as the reduction of pressure outside due to the eddy from the ridge, so that the resultant pressure on the leeward side was practically zero. When the conditions were those of a roof supported on walls, the maximum wind forces were found to exist (*a*) when the doors and windows on the windward side of the building were open and those on the leeward side closed, and (*b*) *vice versâ*. In case (*a*) the maximum wind force was on the leeward side of the roof outwards, and in case (*b*) it was on the windward side inwards. It follows, therefore, that in such a building the roof should be designed so as to be equally strong in each direction.

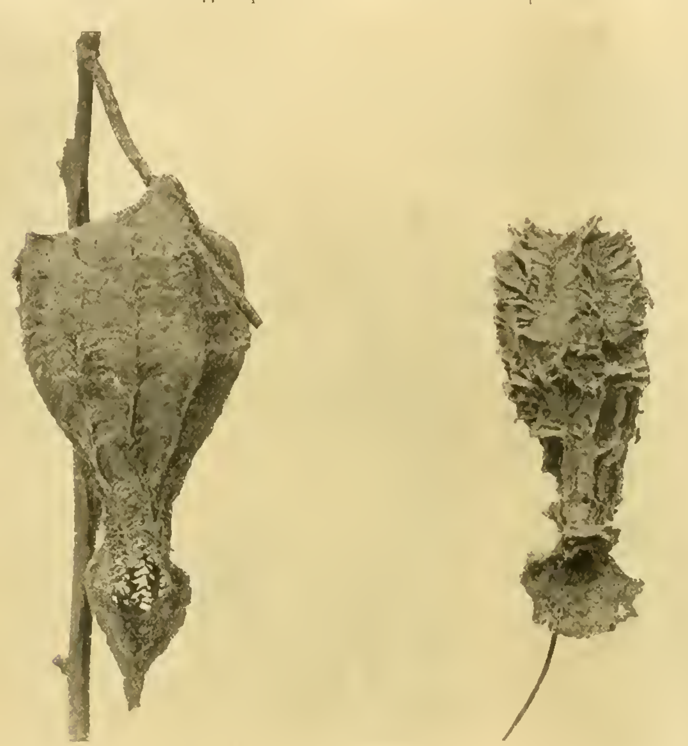
FIG. 3.—Wind Observation Tower with model girder 30 feet by 3·5 feet in position.

It will be seen from this brief sketch that although the difficult engineering problem of the distribution of the pressure of the wind on large structures is not solved, yet when the investigation on the lateral extent of gusts which is now in progress is completed, the only further information which the designer will need is that of the maximum wind velocity which is likely to obtain on the site of the proposed structure.

T. E. STANTON.

## BRITISH MUSEUM GUIDE TO INSECTS.[1]

THE publication of this work furnishes a delightful companion to the charming and highly instructive series of insects exhibited in the gallery of the Museum of Natural History. To the naturalist as well as to the layman this exhibition of the bionomics of the Insecta is a living expression of the incessant activity of those who are responsible for its display, and although Mr. Charles O. Waterhouse informs us that "considerable time must necessarily elapse before the exhibited series of insects can be completed," and that the guide must be looked upon as a provisional one, yet in its present form it gives groups of properly organised facts which cannot fail to instruct and diffuse knowledge by making the study of these animals clearly interesting and accessible to the public.



Nests of species of Ischnogaster, nat. size. Photographed from specimens in the British Museum (Natural History).

A legible plan of the gallery is given, and bold reference numbers in the text will enable the visitor to find with facility any group of insects in which he may be specially interested. Where necessary models are given to illustrate the metamorphoses of various insects, and where possible species likely to be of interest from agricultural or horticultural points of view have been chosen.

The guide is embellished with a number of full-page illustrations, in addition to the numerous figures in the text. With one or two exceptions these have been specially prepared from specimens in the museum, and they help us to an understanding of the text which renders them practically indispensable. In the classification of the Insecta, nine orders are represented in the following sequence:—Aptera, Orthoptera, Neuroptera, Trichoptera, Lepidoptera, Hymenoptera, Diptera, Coleoptera, and Rhynchota. A diagram is given showing the relationship which is believed to exist between these groups, and representatives of a great number of suborders and families are described. Attention is directed to the fact that the guide refers only to the small representative series of insects exhibited in the public gallery; the main collection, which is reserved for the purpose of study in the basement of the institution, contains 1,150,000 specimens, and comprises about 155,000 named species, occupying 13,000 drawers and 602 store boxes. This enormous collection is always available for study, and students at all times receive every attention and assistance at the hands of those who are in charge of the various departments.

In revising this guide we would suggest that reference letters be given to Figs. 14 and 19; that the word *tibia* be added to the diagram in Fig. 18; and that the magnification of Figs. 40, 57, 58, 61, and 62 be indicated.

[1] "A Guide to the Exhibited Series of Insects in the Zoological Department (Insect Section), British Museum (Natural History). London." Pp. 59; with 62 illustrations. (Printed by Order of the Trustees, 1908.) Price 1s.

## PROF. K. A. MÖBIUS.

PROF. KARL AUGUST MÖBIUS, for many years director of the Zoological Museum in Berlin, died on April 26 at the age of eighty-three. He was a notable naturalist, with a broad and cheerful outlook, greatly interested in the habits of creatures, and enthusiastic over their beauty. There are few zoologists who do not know "The Fauna of the Bay of Kiel" by Möbius and Meyer, the two volumes of which form a rich storehouse of observations on the bionomics of a shallow sea. Möbius was probably the first to establish a salt-water aquarium in Germany, and he helped to start the famous zoological garden at Hamburg. He had, indeed, a strong practical sense, and made many useful suggestions in connection with fisheries, oyster-culture, and the harvest of the sea in general.

Möbius was born in 1825 at Eilenburg, in the Prussian province of Saxony; he was trained as a school teacher, but his enthusiasm and ambition were roused by reading the works of Alexander von Humboldt, and he went to Berlin, with a light purse, to study natural history. By giving lessons to others he was able to afford a university training, and he sat at the feet of men like Ehrenberg and Johannes Müller. He became assistant to Lichtenstein, who helped him in 1853 to a congenial teaching post in

Hamburg, where he had time for faunistic studies. In 1868 he went to Kiel as professor of zoology, and it was there that he did what was probably his best work, which is embodied in great part in the book already referred to. He had his share of travel too, and made collections and observations of importance in Mauritius, the Seychelles, and elsewhere. In 1880 he had the pleasure of seeing the completion of the Zoological Museum and Institute at Kiel, to the organisation of which he had devoted himself wholeheartedly. In 1887 he was called to Berlin as director of the new Zoological Museum, a position which he held until the end of 1905. His first zoological paper was on "The Nests of Social Wasps." Of the many others, we may mention "Die Fauna der Kieler Bucht" (along with H. A. Meyer), "Beiträge zur Meeresfauna der Insel Mauritius und der Seychellen," "Die Fische der Ostsee," "Die Bildung, Geltung und Bezeichnung der Artbegriffe." He was particularly interested in marine creatures, in molluscs especially, but he ranged over a wide field, from alcyonarians to fishes. It is but a few months since his "Aesthetik der Tierwelt" was published, expressing with unabated enthusiasm his delight in the sea's endless progeny.

The Festschrift to Möbius with which his students honoured him on his eightieth birthday was an eloquent testimony to his efficiency as a teacher; the list of his papers—faunistic, bionomical, practical, and theoretical—suggests a strenuous life; and his position as president of the fifth International Congress of Zoologists in Berlin in 1901 was an indication of the esteem in which he was so widely held.

## *THE BRITISH MEMBERS OF THE INSTITUTE OF FRANCE.*

THE subjoined address was presented to Monsieur Fallières, the President of the French Republic, at St. James's Palace, on Wednesday, May 27, at 11 a.m.

In the absence of Sir Joseph Hooker, the *doyen* of the British members of the Institute, who was elected in 1866, the address was presented by Sir Norman Lockyer (elected in 1873), with the following words:—

"En l'absence du doyen des membres de l'Institut de France dans ce pays, j'ai l'honneur de vous présenter cette adresse avec le plus profond respect.

"Les sentiments de fraternité ont été maintenus depuis plusieurs siècles entre les littérateurs, les savants et les artistes de la France et de l'Angleterre.

"Nous nous réjouissons qu'à présent tout le monde va suivre notre exemple."

The President made a sympathetic reply, fully acknowledging the importance of science and culture in bringing nations together and cementing their friendship.

The members of the various academies were then presented to the President, who cordially addressed a few words to each.

*To the President of the French Republic.*

Sir,—On the auspicious occasion of your visit to England we, the undersigned Associates and Correspondents of the Institute of France, desire to be permitted to offer to you an expression of our sincere respect. The intellectual pursuits to which that illustrious Institute is consecrated form some of the most potent and enduring bonds that link the nations together in peace and goodwill. As representatives of these pursuits in this country we are proud of our connection with the Institute of France, which has for so long been one of the great centres of culture in the world. We rejoice that the feelings of sympathy and brotherhood which have for centuries been maintained between the cultivators of Literature, Science, and Art in France and Great Britain are now daily spreading more widely and deeply among the peoples of the two countries, and we are sure that your visit cannot but give a powerful stimulus to the progress of this peaceful and beneficent alliance. We desire to express the fervent hope that your tenure of the high office which you hold with such lustre and distinction may long continue to be prosperous.

We trust that you may be pleased to receive the assurance that the people of this country are heartily united in their sentiment of admiration and friendship for the people of France.

We have the honour to subscribe ourselves, with the deepest respect,

Your obedient servants,

1866. Sir Joseph Hooker, G.C.S.I., O.M., C.B. F.R.S. 1900, A.
1873. Sir Norman Lockyer, K.C.B., F.R.S.
1874. Sir William Huggins, K.C.B., O.M., F.R.S.
1878. Whitley Stokes, C.S.I., C.I.E., F.B.A. 1891, A.
1881. Sir Lawrence Alma-Tadema, O.M., R.A. 1891, A.
1883. The Rev. R. Flint, D.D., LL.D.
1887. Sir John Evans, K.C.B., F.R.S.
1890. The Right Hon. Lord Rayleigh, P.C., O.M., Nobel Laureate, P.R.S.
1890. Sir Hubert von Herkomer, C.V.O., R.A. 1896, A.
1890. Sir E. Maunde Thompson, K.C.B., I.S.O. P.B.A.
1891. Sir Archibald Geikie, K.C.B., F.R.S.
1891. The Right Hon. James Bryce, P.C., F.R.S., F.B.A. 1904, A.
1893. A The Right Hon. Lord Lister, P.C., O.M., F.R.S.
1903. Sir Frederick Pollock, Bart., F.B.A.
1903. Sir Henry Roscoe, F.R.S.
1894. R. W. Macbeth, R.A.
1895. Sir William Ramsay, K.C.B., Nobel Laureate, F.R.S.
1896. Sir William M. Christie, K.C.B., F.R.S.
1896. Sir David Gill, K.C.B., F.R.S.
1898. Sir Edward Poynter, Bart., P.R.A.
1899. Sir Edwin Ray Lankester, K.C.B., F.R.S.
1901. A Sir William Q. Orchardson, R.A.
1901. J. S. Sargent, R.A. 1905, A.
1902. J. E. C. Bodley.
1902. The Right Hon. Lord Reay, P.C., G.C.S.I., G.C.I.E., F.B.A. 1906, A.
1903. John H. Lorimer, R.S.A.
1903. W. G. John, A.R.A.
1903. Edward Caird, LL.D., D.C.L.
1904. Stanhope A. Forbes, A.R.A.
1905. Arthur J. Evans, F.R.S., F.B.A.
1905. Sir Francis Seymour Haden, P.R.S.P.E.
1905. Barclay Vincent Head, D.Litt., D.C.L., Ph.D.
1905. Richard Phené Spiers, F.R.I.B.A., F.S.A.
1906. Sir William Crookes, F.R.S.
1907. Sir George Darwin, K.C.B., F.R.S.
1907. The Right Hon. Lord Brassey, G.C.B.
1908. The Right Hon. A. J. Balfour, M.P., F.R.S.
1908. E. A. Abbey, R.A.

The following is a French translation of the Address:—

*A son Excellence, Monsieur Fallières, Président de la République Française.*

Monsieur le Président,—Nous saisissons avec empressement l'occasion de votre visite officielle à Londres pour vous prier, en notre qualité de Membres associés et correspondants de l'Institut de France, de vouloir bien accepter l'expression de nos plus respectueux hommages.

Les Arts et les Sciences au progrès desquels se dévoue l'illustre Institut de France constituent des liens à la fois parmi les plus puissants et les plus durables qui unissent les nations dans le maintien de la paix et de la cordialité. Comme représentants de ces différentes branches de culture intellectuelle en Angleterre, nous sommes heureux et fiers d'être en rapports intimes avec l'Institut de France, depuis si longtemps l'un des grands foyers de lumière du monde entier.

Nous nous réjouissons à la pensée que les sentiments de sympathie et de fraternité qui se sont maintenus depuis plusieurs siècles entre les littérateurs, les savants et les artistes de la France et de la Grande Bretagne s'étendent et se fortifient journellement entre nos deux nations, et nous sommes persuadés que votre visite ne peut manquer de stimuler puissamment le progrès de cette alliance pacifique et bienfaisante.

Nous vous prions, Monsieur le Président, de vouloir bien nous permettre d'ajouter l'expression de notre ferme espoir que votre occupation du poste élevé dont vous remplissez les fonctions avec tant de lustre et de distinction continuera longtemps à être heureuse et prospère; et nous esperons qu'il vous sera agréable de recevoir l'assurance que la nation Britannique est unanime dans ses sentiments d'admiration et d'amitié pour la nation Française.

Nous avons l'honneur d'être avec le plus profond respect,

Monsieur le Président,

Vos très obéissants serviteurs.

The Address, which was beautifully illuminated, had been approved by the President and officers of the Royal Society and the President of the Royal Academy. The organisation of the deputation and the correspondence connected with it were undertaken by the British Science Guild.

## NOTES.

The local secretaries for the Dublin meeting of the British Association desire to direct the attention of officers of the association and members who intend to be present to the urgent necessity of filling up and returning forthwith the post-card sent out with the invitation circular. Many have already done so, but the work of the hospitality subcommittee, which has to be completed months beforehand, and, as everyone knows, is of a delicate and difficult nature, is now at a standstill owing to the fact that information has not been received from a large number of the chief members of the association as to whether they will be accompanied by lady members of their families or not. This information is asked for on the card referred to, which is the only source at the command of the local committee.

A statue of Liebig is to be erected in Darmstadt, where he was born in 1803. The corporation of Darmstadt has contributed 150*l*. towards the expenses.

The death is announced of Dr. R. Chalmers, of the Canadian Geological Survey, at the age of seventy-four years. Dr. Chalmers, says *Science*, joined the survey about twenty-three years ago, and conducted work in Pleistocene geology, especially in his native province of New Brunswick.

At the anniversary meeting of the Linnean Society on Monday the King of Sweden was elected an honorary member of the society. Dr. Dukinfield H. Scott, F.R.S., was elected president in succession to Prof. W. A. Herdman, F.R.S., and Dr. Otto Stapf, F.R.S., was chosen to fill the office of botanical secretary thus vacated by Dr. Scott. The gold medal of the society was presented to the Rev. T. R. R. Stebbing, F.R.S.

A Reuter message states that an International Association for Cancer Research was inaugurated in Berlin on May 23 to promote the investigation of cancer and the care of cancer patients, the collection and publication of international cancer statistics, and the establishment of an international centre of information on all matters concerning cancer research. The association proposes to publish an international technical organ, and to organise international cancer conferences. So far, thirteen States, including all the great Powers except Great Britain, have joined the association, the seat of which will be at Berlin.

The inauguration of the International Institute of Agriculture took place in Rome on May 23 in the presence of the King of Italy, who formally opened the new building for the use of the permanent delegates. The *Times* correspondent reports that the Italian Government was represented by seven ministers and the chief State officers. Thirty foreign delegates, including Sir Thomas Eliot, representing Great Britain, attended, and were entertained at dinner by the King. The new building is the gift of the King of Italy, who also has endowed the institute with an income of 12,000*l*. a year, bringing the total annual income up to 40,000*l*. The international character of the institute is assured by the fact that it is receiving the support of every nation, and nearly all have appointed delegates. It was only in June, 1905, that the conference assembled in Rome at the invitation of the King of Italy to consider the project, and the excellent progress which has been made already augurs well for the permanent success of the institute.

The Royal medals and other awards given annually by the Royal Geographical Society for the encouragement of geographical science and discovery were distributed at the anniversary meeting of the society on Monday. The founder's medal was presented to Lieut. Boyd Alexander, for his African explorations and careful trigonometrical survey of the region between the Benue and Lake Chad. Lieut. Boyd Alexander devoted a considerable time to the exploration of Lake Chad, and added materially to our knowledge of that constantly shifting lake. A careful study was made of the hydrography of the various river systems, the Niger, the Congo, and the Nile, through which the expedition passed. Detailed maps were made of the more unknown parts of the region, such as the Bamingi, Kibali, and the Yei rivers. Much information was gathered concerning the physical features of the region passed through; careful studies were made of several of the types of natives, and important additions were made to our knowledge of the natural history of the extensive region. The patron's medal was awarded to H.S.H. the Prince of Monaco, for his work in oceanography. Among the notable additions to scientific knowledge made on board the *Princess Alice* are:—(1) the results of using the deep-sea traps invented by the Prince, which threw a new light on the life on the floor of the deepest parts of the ocean; (2) successive seasons' exploration on the coast of Spitsbergen and in the adjacent seas; and (3) studies of the conditions of the upper air by means of meteorological kites in mid-Atlantic. Other awards were as follows:—Murchison award to Colonel Delmé-Radcliffe, for his work when as resident in the Nile province of Uganda he mapped the whole province, and for the work which he did afterwards when in charge of the English section of the Anglo-German Boundary Commission, between Victoria Nyanza and Mount Ruwenzori. The Gill memorial to Dr. T. G. Longstaff, for his exploring work in the western Himalayas and Tibet, and especially on his last expedition in the Garhwal Himalayas, when he ascended the summit of Trisul. The Back bequest to Lieut. George Mulock, for his long-continued work, mostly during his own time, in preparing the six sheets of the Antarctic charts, showing the results of the *Discovery* expedition. The Cuthbert Peek grant to Rai Sahib Ram Singh, a native Indian surveyor, who has done excellent surveying work on the expeditions of Captain Deasy, Dr. Stein, Captain Rawling, and Major Ryder.

At the conclusion of a description in part iv. of vol. lxxxix. of the *Zeitschrift für wissenschaftliche Zoologie* of the remarkable land-planarians of the genus Rhynchodemus, Dr. W. E. Bendl, of the University of Gratz, points out that certain curious variations in the secondary genital structures of the members of this and the allied genera appear to be correlated with geographical distribution. In one group the male copulatory organs are found to be of much simpler structure than in a second assemblage, and it appears that while the former type is in the main characteristic of the Oriental and Australasian species, the latter is dominant in the eastern Holarctic and Ethiopian forms.

We have received a copy of an excellent little biographical pamphlet, by Prof. W. May, of Karlsruhe, entitled "Auf Darwin-Spuren," and forming part xiv. of "Gemeinverständliche Darwinistische Vorträge und Abhandlungen," published at Brackwede-i-W. by Dr. W. Breitenbach, the editor. The part before us is illustrated with portraits of Darwin's father and grandfather, and with reproductions of photographs of the Darwin statue at South Kensington, and of the house at Shrewsbury where the great evolutionist was born. Whether by intent or by accident, the fasciculus appears very opportunely in relation to the impending "jubilee" of the reading of the "origin-of-species papers" by Darwin and Wallace at the Linnean Society.

We have been favoured with a copy of a pamphlet (without printer's or publisher's name) describing the laboratory established in 1901 at Sutton Broad, Norfolk, by Messrs. Eustace and Robert Gurney for the study of fresh-water biology, in which it is announced that the gentleman last named will be pleased to arrange for the accommodation of naturalists desirous of working on this branch of research, no charge being made for the use of the laboratory. A considerable amount of work has already been accomplished in connection with the tidal system of the district, and its past and present effects on the fauna of the Broad. The crustaceans, beetles, and dragon-flies, and to a certain extent the rotifers and hydrachnids of the district, have formed the subjects of investigation, but much remains to be done in connection with the molluscs, turbellarians, and protozoans.

From the Entomological Bureau of the U.S. Department of Agriculture we have received Circular No. 99, dealing with nut-weevils, and from the West Virginia University Agricultural Experiment Station Bulletin No. 110, devoted to the grape-vine root-borer. Two species of weevil do considerable damage to chestnuts, of which large quantities are now grown in the States, and various methods of checking the multiplication of these pests are suggested. Hazel-nuts are attacked by an allied, but shorter-bodied and shorter-beaked, weevil. The grape-vine root-borer is one of the clear-winged moths, and a species indigenous to North America, where it doubtless originally infested wild vines. The caterpillars burrow long tunnels in the roots of vines, to which they do very serious damage, for the most part quite unknown to the cultivators. The cultivation of races of vine immune to the attack of root-borers is recommended.

In a recent number of Records of the Indian Museum (vol. i., part iv., No. 23, December, 1907), Captain R. E. Lloyd describes and figures, under the name *Nudiclava monocanthi*, a remarkable new genus and species of hydroids, which has been found parasitic on a fish, *Monocanthus tomentosus*. The hydroid consists of a basal cœnosarcal plate attached to the skin of the fish, and from the basal plates arise the hydranths and the gonophores. The hydranths are entirely devoid of tentacles, and have a peculiar histological structure; thus Nudiclava resembles greatly *Hydrichthys mirus*, described by Fewkes, but differs in the gonophores being sporosacs, while Hydrichthys produces free medusæ. In the Memoirs of the Indian Museum (vol. i., No. 2) Captain Lloyd describes the anatomy of the gigantic marine isopod *Bathynomus giganteus*.

The April number of the *Emu* is illustrated by a reproduction from a photograph of a nest of the brown flycatcher (*Micraeca fascinans*) containing two eggs laid by

Nest and Eggs of Brown Flycatcher, with Egg of Square-tailed Cuckoo. (Nearly natural size.)

the rightful owner, and a third deposited by the square-tailed cuckoo (*Cacomantis variolosus*). The size of the nest admits of only three eggs; and it is stated in the same issue by Mr. E. M. Cornwall that in the case of an allied flycatcher (or "flyeater") and the bronze-cuckoo, the former bird normally lays a clutch of three eggs, but only two of them are found in a nest containing a cuckoo's egg. What becomes of the third egg is not stated. In the case of the nest photographed, the difference between the colour of the cuckoo's and the flycatcher's eggs, as shown in the accompanying reproduction, is very marked, while the small size of both is very noticeable.

The third volume of Notes from the Royal Botanic Garden, Edinburgh, is devoted to a history of the garden and biographies of the principal gardeners from the year

1756. The concluding portion now issued is mainly concerned with William M'Nab, who was deservedly esteemed both for his capabilities as a gardener and for his personality. He was a noted authority on heaths and hard-wooded plants. The papers he published on the planting of hardy evergreens and the cultivation of Cape heaths are printed as an appendix to his biography.

THE list of new garden plants introduced during the past year has been issued in the usual form of an appendix (No. 3) to the *Kew Bulletin* for 1908. The record includes new species of Bulbophyllum and Eria from Malaya and India; species of Lewisia are products of the United States, and a large number of cactus specimens under the genera Echinopsis, Echinocactus, Mamillaria, and Phyllocactus have been introduced from Mexico, Argentina, Paraguay, and other States of South America. Among the small quota from China there occur species of Rhododendron, Viburnum, and Berberis.

WITH the view of making known the results of investigations upon tropical American ferns as they are undertaken in the National Herbarium at Washington, it is proposed to issue a series of studies similar to the series "Studies of Mexican and Central American Plants." The work is being entrusted to Mr. W. R. Maxon, and the first part is published as vol. x., part vii., of Contributions from the United States National Herbarium. The part contains critical notes on uncertain genera and species. The limits of *Asplenium salicifolium* and the identity of *Asplenium rhizophyllum* are discussed. A number of new species are diagnosed, and the new generic name Ananthacorus is suggested for *Pteris angustifolia*.

AN article contributed by Mr. F. Ramaley to the University of Colorado Studies, vol. v., No. 2, describes the plant distribution in the north-east of Latimer County, in Colorado. The altitude varies from five to six thousand feet; the soil of the district is derived from sedimentary rocks, largely Red Sandstone, except in parts where granite rocks occur. The prevailing formation is a scrub of *Cercocarpus latifolius*, dotted in parts with *Pinus scopulorum*; grasses and species of Artemisia clothe the valleys, but along the streams bushes and trees, such as species of Pseudotsuga and Salix, find a congenial habitat. The Cercocarpus scrub grows densely on the sandstone soil, but is almost absent on the granite; lichens and Selaginella, on the contrary, prefer the granite areas.

IN *Man* for May Mr. D. I. Bushnell describes an ancient site at Kimmswick, Missouri, with curious remains of an ancient salt factory. The vessels used are remarkable as having an impression of cloth on the outer surface. It is supposed that a depression was first made in the earth or sand of the size and form of the vessel desired. The hollow was then lined with cloth, over which was spread a thin layer of clay previously mixed with pulverised shell and sufficient water to make it of the proper consistency. When the vessel became dry and was taken from the mould the cloth would be removed, the impression of which, however, would remain on the outer surface. The extensive cemetery adjoining the factory seems to belong to a branch of the Shawnee tribe, who probably made salt on this site.

THE March number of *Buddhism*, the organ of the International Buddhist Society, which advocates the propagation of the faith in the West, contains a remarkable article by Mrs. Rhys Davids on "The Value of Life in Buddhism." The more advanced school of Buddhists have come to see that the current conception of Nirvána as the cessation of sentient existence is a fatal obstacle to the acceptance of the Dharma in Europe. As the writer observes:—"It is hardly conceivable that the West will call such a creed anything but pessimistic, so long as the West retains its peculiar view of life, and its conception of the essential immortality of the self." Hence she proposes to define Nirvána as "the perfected state of the individual mind and heart, emancipation from all taint of lust, ill-will and illusion." She endeavours to show that Buddha, "in judging human individuals capable of realising, now and again, a perfected humanity independently of any transcendental outlook, raised life, or the possibilities of life, to a very high value." The editor, in a very cautious criticism of this theory, seems to prefer to believe that "Buddha and his advanced hearers beheld an interminable series of lives, with Nibbána as the goal." It seems unlikely that this attempt to put new wine into old bottles will be accepted by the orthodox thinkers of the East. But in view of the current belief in the immobility of eastern faiths, the new development is certainly interesting.

MR. F. COHEN, of Bonn, has published a beautiful contoured map of the Eifel, including Aix-la-Chapelle, Coblentz, and Trèves, on the scale of 1 : 200,000, prepared from the Government Survey by Dr. H. Rauff. The height-zones are shown in clear shades of colour, the contours being drawn at every fifty metres. For geographers and cyclists, who may often be happily combined, this large sheet, published at 3 marks, is a really notable achievement.

PROF. H. POTONIÉ has issued a fourth and enlarged edition of his brochure entitled "Die Entstehung der Steinkohle" (Borntraeger, 1907, price 4 marks). This is illustrated in the best sense by a number of landscape views of actual vegetation in swamps, bogs, and forests, with examples of stems found *in situ* in Coal-measures. A strong case is made out for the theory of the production of coal-seams in place and not by flotation, and stress is laid on deposits of "sapropelite," from the decay of various water-loving organisms and their excrement. A form of carbonaceous rock results which in turn provides petroleum. All who have to do with coal may read this little book with pleasure, and they will be especially grateful for the care with which the illustrations have been brought together and reproduced.

THE results of the meteorological observations made at Mount Tsukuba (Japan) during 1903 have recently been received; at the peak station (869·5 metres) and at the base hourly observations are given, at the middle station (240 metres) for every two hours. The volume contains an interesting discussion by Mr. T. Okada of a typhoon that swept over the eastern part of Japan on September 28, 1902, with a violence that had not been experienced for many years. An interesting fact is that the storm centre passed very near Mount Tsukuba (lat. 36° 12′ N., long. 140° 5′ E., approximately), so that the atmospheric condition at the summit and base stations could be determined. On the same day another violent cyclone appeared over the western part of the islands.

THE *Denkschriften* of the Vienna Academy of Sciences, vol. lxxxi., contain a very valuable contribution to the meteorology of west Turkestan, compiled (at the suggestion of Dr. J. Hann) by Heinz v. Ficker from the Russian meteorological year-books and other sources, and based on observations between 1894 and 1903 at seventeen stations. The area, which embraces $8\frac{1}{2}°$ of latitude and

$17\frac{1}{2}°$ of longitude, and differences of altitude amounting to 3600 metres, is subject to great contrasts of climate, *e.g.* at Pamirski Post, in the south-east, the mean yearly temperature is 29°·8 F., and at Termez, in the south, 63°·9; the mean yearly variation (difference of warmest and coldest months) is 68°·2, at Kasalinsk, in the north-west, and 40°·9, at Prschewalsk, in the north-east. The whole country has a very small rainfall, averaging from about 5 inches on the Steppes to $14\frac{1}{2}$ inches in the districts of the Naryn and Lake Issykul. The author states, with reference to the cultivation of the land, that the small rainfall and rapid evaporation give rise to the gravest fears for the future of the country.

Dr. A. Stock announces in part ii. of the *Verhandlungen der deutschen physikalischen Gesellschaft* for 1908 that he has succeeded in producing a material which, while porous to air and other gases, will not allow mercury to pass through it at pressures less than 1 atmosphere. It is composed mainly of clay, water-glass, and gum burnt together, and can be substituted for the taps and other appliances used in the manipulation of gases. The material withstands acids and boiling water, can be fused directly to glass, and is about five times as porous as that used by Dr. K. Pritz for the same purpose two years ago.

In France the Société d'Encouragement granted a subvention for a research on the gases occluded in steels, and the results of the work, by Dr. G. Belloc, of the University of Caen, are published in the current issue of the Bulletin (vol. cx., No. 4) of the society. The gases, he finds, consist of mixtures of carbon dioxide, carbonic oxide, hydrogen, and nitrogen, and the liberation of the gases is in intimate relation with the critical points of iron. Carbon dioxide is liberated first at about 550° C., and forms the great bulk of the volume present. Nitrogen begins to appear at 550°. More gases are given off by the steel taken from the centre of an ingot than from samples nearer the surface.

The *Physical Review* for April contains a study of the changes of the electrical resistance of selenium cells by Messrs. F. C. Brown and J. Stebbins, of the University of Illinois. They find that pressure diminishes the resistance at a rate nearly constant up to about 400 kilos. per sq. cm., and that the cells are somewhat less sensitive to light at high than at low pressures. Increase of temperature in the neighbourhood of 20° C. produces a rapid decrease of resistance, which becomes less marked as the temperature gets higher. The sensitiveness to light decreases as the temperature rises, and appears to be a function of the resistance of the cell, whether that resistance is determined by the temperature, pressure, or illumination of the cell. Radium and hydrogen peroxide both decrease the resistance of a cell to a remarkable extent.

Messrs. Macmillan and Co., Ltd., have published the forty-fifth annual issue of "The Statesman's Year-book," that for 1908. Its character is described excellently by its subtitle—"Statistical and Historical Annual of the States of the World for the Year." The volume has been enlarged again; more space is devoted to the British Empire and the United States. An account of the changes in the organisation of the British Army has been included, and the returns of the recent French census of 1906 are given. Some thirty pages of additions and corrections contain the most recent available statistics, among others those of public education in England and Wales. The maps and diagrams are, as usual, a very attractive feature. Three diagrams deal in a luminous manner with important matters in connection with the British Navy, and some interesting comparisons with the naval strength of other countries are shown graphically. It would be valuable and instructive if next year the editor, Dr. J. Scott Keltie, could provide similar diagrams comparing the United Kingdom with Germany, the United States, and other great countries, so far as the provision of higher education is concerned. We know of no subject in which statesmen stand more in need of instruction; and we are sure that a graphical comparison of the expenditure on higher education and scientific research, of the percentage of the population receiving higher technical instruction, and similar matters would show that while we apply the two-power standard to the arts of war, we are behind other progressive nations in the provision made for the arts of peace through higher education and science.

A fourth edition of Prof. E. Hammer's "Der logarithmische Rechenschieber und sein Gebrauch" has been published by Mr. Konrad Wittwer, of Stuttgart. The volume deals with methods of using logarithms and the slide rule, and their application to various forms of calculation. No tables are provided. The price of the book is one mark.

We are glad to see a column devoted to science of the week in the *Standard of Empire*, the first number of which appeared on Saturday last. The new periodical, which is published at the *Standard* office, will appear as a gratis supplement every Thursday in that newspaper, and will also be issued separately as a weekly journal devoted to Imperial affairs.

We have received from Mr. Robert Sutton, 43 The Exchange, Southwark, S.E., the fourth part of the first volume of Dr. E. Howard Adye's "Studies in Micropetrography." This fasciculus contains pages 29–36 of the first volume, and two full-page plates. The rocks dealt with are ophitic diabase, andesitic dolerite, fine olivine-basalt, and ophitic olivine-dolerite.

Messrs. A. and C. Black are publishing a second edition of "Studies in Fossil Botany," by Dr. D. H. Scott, F.R.S. The work, the first edition of which was reviewed in Nature of November 15, 1900 (vol. lxiii., p. 53), will in future appear in two volumes. The first, dealing with the Pteridophyta, is now ready, and its price is 6*s.* net; the second volume will be published, it is expected, next autumn, when we propose to review the complete work.

Messrs. Cassell and Co., Ltd., have commenced the publication, in twenty-four fortnightly parts, price 7*d.* net each, of "The Nature Book." The work is to be a popular description by pen and camera of the beauties of outdoor nature. Among numerous contributors we notice the names of Messrs. Walter Crane, Richard and Cherry Kearton, and Dr. W. J. S. Lockyer. The first part reaches a high standard of excellence. The letterpress is interesting and accurate, while the illustrations are abundant and beautiful. The publication should secure a wide popularity, and prove of real service to teachers of nature-study.

The first volume of the fifth edition of Prof. Wundt's "Grundzüge der physiologischen Psychologie" appeared in 1902, and was noticed in Nature of November 6, 1902 (vol. lxvii., p. 2). The second and third volumes of the same edition were reviewed in 1905, with Prof. Titchener's translation of the work (vol. lxxi., p. 529). The first volume of the sixth revised edition of this elaborate work has now been received from the publisher, Mr. W. Engelmann, Leipzig. Nearly two hundred pages have been added, the increase being necessitated by the rapid growth of experimental or physiological psychology during the past few years. The character of the work remains the same, and has been sufficiently described in reviews of earlier editions. The price of the present volume is thirteen marks.

## OUR ASTRONOMICAL COLUMN.

DANIEL'S COMET, 1907*d*.—A continuation of Herr H. H. Kritzinger's ephemeris for Daniel's comet appears in No. 4245 of the *Astronomische Nachrichten* (p. 345, April 29). From this ephemeris we see that the comet is now apparently travelling very slowly through the constellation Virgo, nearly parallel to, and some 15′ south of, the equator. Its positions on June 1 and 13 will be $\alpha=13h.\ 52 \cdot 1m.$, $\delta=-0^\circ\ 14' \cdot 3$, and $\alpha=13h.\ 48 \cdot 1m.$, $\delta=-0^\circ\ 20' \cdot 2$, respectively. The comet is now a little brighter than the twelfth magnitude, and crosses the meridian about 9.30 p.m.

SPECTROSCOPIC BINARIES.—For some time past the observers at the Dominion Observatory, Ottawa, have been endeavouring to complete their set of observations of the spectroscopic binary $\iota$ Orionis by obtaining spectrograms at a critical part of the velocity curve where it changes its form rapidly. According to a note in No. 2, vol. ii., of the Journal of the Royal Astronomical Society of Canada (p. 106, March-April), the necessary spectrograms were secured at the end of January. The following principal elements have been calculated from measurements of 107 plates:—period = 29·136 days, eccentricity = 0·75, longitude of the apse 110°, projected length of semi-major axis = 29,680,000 km., and velocity of the system = +20·7 km.

Elements for $\psi$ Orionis, of which the radial velocity has a remarkably short period, have also been obtained; they are:—period = 2·5259 days, $e=0 \cdot 063$, $\omega=186^\circ$, and $a \sin i =$ 5,103,000 km.

Mr. Harper has recently discovered that the star $\delta$ Herculis has a variable radial velocity with a fairly wide range; this star has therefore been added to the observing list at Ottawa.

RECENT OBSERVATIONS OF JUPITER.—Some interesting observations of Jupiter were reported to the March meeting of the British Astronomical Association by the Rev. T. E. R. Phillips, who directed attention to the fact that the great south tropical disturbance was once more passing the great Red Spot. The dark material of the disturbance was observed to be passing round the south side of the Red Spot by the south temperate belt, leaving a sharply defined oval in which the Red Spot lay; the latter feature was very difficult to see, and appeared at times to be distorted and irregular in form, as though clouds were passing over it. Since the beginning of the apparition the disturbance has increased considerably in length, from about 60° in September to 115° at the end of January. The rotation period of the Red Spot was less during the earlier part of the apparition, but the diminution was not so marked as it was during the conjunction of 1906, when it amounted to 14° between April and August. At each conjunction of these two features, since the first appearance of the south tropical disturbance in 1901, the Red Spot has, for the time being, appeared to be pushed forward (the *Observatory*, May, No. 396, p. 196).

DOUBLE-STAR OBSERVERS.—In continuing his series of articles on double-star observers in the May *Observatory* (No. 396, p. 205), Mr. Lewis gives a very interesting account of the work performed by Baron Dembowski between 1852 and 1878. With a telescope of 5 inches aperture, and fitted with neither position circle nor driving clock, Dembowski commenced a revision of the brighter pairs given in the "Mensuræ Micrometricæ," and did most excellent work. After mentioning the double-star work of Schiaparelli and other observers, Mr. Lewis proceeds to the consideration of what he calls the third period of double-star astronomy, which began when Burnham submitted a catalogue of eighty-one new double stars to the Royal Astronomical Society in 1873; all these doubles had been observed with a 6-inch refractor mounted in Burnham's back yard. In 1900 this same observer published a catalogue of 1290 doubles discovered by himself between 1871 and 1899. Mr. Lewis also gives a long list of observers of this third period, and the sizes of the instruments with which they worked.

In the note on the relative accuracy of various double-star workers, which appeared in these columns last week, the mean value given in the last line should, obviously, be $0'' \cdot 0698$, and not $0'' \cdot 698$ as printed.

THE COLOUR FILTER AND ISOCHROMATIC PLATE IN ASTRONOMICAL PHOTOGRAPHY.—An important paper by Mr. R. J. Wallace, on the function of a colour filter and "isochromatic" plate in astronomical photography, appears as a reprint from the *Astrophysical Journal* for March. Mr. Wallace discusses at length the use of various filters and stained plates, and shows, by reproductions of some of his photographs taken at the Yerkes Observatory, the immense gain in definition resulting from such use.

In the course of his discussion Mr. Wallace also refers to the results recently published by Prof. Lowell in his paper on the sharpening of celestial photographic images, and states a number of points whereon he disagrees with the conclusions arrived at by Prof. Lowell.

A NEW ASTRONOMICAL JOURNAL.—The first number of a new journal, printed in Japanese characters, has just appeared under the title of the *Astronomical Herald*, and is published by the Astronomical Society of Japan. This first number is dated April, and contains, among other articles, a note on sun-spots by Mr. S. Hirayama, and one on ancient astronomy.

## ALTERNATE CURRENT MEASUREMENT.

THE ordinary dynamometer is as well adapted for direct as for alternate current measurements; but while it is generally regarded as the best available instrument for alternate currents, its use with direct currents is almost restricted to standard instruments of the ampere balance type. This is due to the immensely greater sensitiveness obtainable with direct current instruments constructed on the heterostatic principle, as exemplified in galvanometers with permanently magnetised needles or magnets. The latter instruments, due originally to Kelvin and Maxwell, and first developed commercially by Ayrton and Perry, have been brought to a high state of perfection in recent years, with the result that ordinary measurements on direct current circuits are much more precise and satisfactory than those on alternate current circuits.

The only likely way at present of improving alternate current instruments is to use iron-cored electromagnets to increase the strength of the field acting on the moving system. The well-known difficulties due to the varying permeability, hysteresis, &c., of the iron cannot be overcome, but may be entirely avoided by exciting the electromagnet in shunt.

The excitation of an electromagnet can be governed either by controlling the current through the exciting coil or by controlling the voltage applied to the winding. On direct current circuits the two methods are identical owing to the operation of Ohm's law, but with alternate currents the two modes of control lead to widely different results if the resistance of the winding is made small compared with the impedance. With current control, the magnetism produced depends on the properties of the core, but is independent of the resistance of the winding. The reverse is true of the voltage controlled magnet, for, if this is suitably designed, the magnetic flux is connected with the applied voltage by a strict mathematical law not dependent on the physical properties of the core, except for a small correction term due to the resistance of the winding. The shunt magnet in another way contrasts sharply with the series magnet. In each case the strength of the magnet is increased by diminishing the air gap, but the smaller this is made the more accurate the shunt magnet becomes and the less accurate the series magnet. The field due to the shunt magnet is not in phase with the applied voltage, so that special means must be used to supply the moving coil of the instrument with a suitable current if the deflection is to indicate truly the quantity to be tested. But this difficulty, it is found, can readily be overcome. All measurements with alternate currents relate to mean values. It is not necessary to make the instantaneous value of the torque exerted on the moving system of the instrument a measure of the simultaneous value of the quantity tested, as, for instance, is the case with ordinary dynamometers. All that is needed is proportionality between the mean values. With the aid of this principle it can be shown that the shunt magnet offers for instrument purposes great advantages, one of these being that the density of the air-gap flux, without loss of accuracy, can be increased to a value far exceeding that obtainable in permanent magnet instruments.

The ordinary modes of analysis used for the solution of alternate current problems rest upon several convenient but inaccurate assumptions, such as sine law wave form, proportionality of magnetic flux to magnetising current, &c. Such methods can be used to give an approximate explanation of known results, but are not adapted to predict precisely the action of a new type of instrument in terms of measured data relating to its parts. In a paper read before the Royal Society[1] on January 16, a simple form of analysis, previously pointed out by the present writer, is further developed. This method is free from

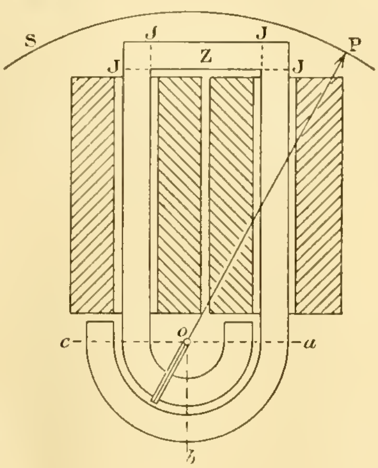


FIG. 1.

assumptions such as those mentioned. It rests upon the theorem that each one of a number of known cyclic quantities, however different these may be in wave form, can be expressed as a linear function of an equal number of other cyclic quantities, the latter being such that the mean square of each is unity, and the mean product of any two is zero. This theorem leads naturally to a vector method of representation, which in many cases closely approximates to that usually adopted for alternate current investigations, but there is the important difference that when the results obtained are independent of assumptions such as sine law wave form this fact can be proved, while if such independence does not hold good a superior limit can be found to the error involved in results obtained by the ordinary method.

One of the instruments of which the behaviour has been investigated theoretically and fully confirmed experimentally is illustrated in Fig. 1. The magnetic circuit consists of a block of thin iron stampings shaped so as to have only one narrow air gap, the section of which is increased by suitably extending the poles. The field windings are shown in section, and are liberally supplied with copper. By this construction the ratio of resistance to impedance is made small. The moving coil is rectangular, one side turning in the air gap, the opposite side acting as an axis perpendicular to the figure, and shown at *o*. The instrument becomes a voltmeter if the moving coil is placed in series with a condenser across the voltage applied to the field coil. It becomes a wattmeter if the main current is passed through an induction coil the secondary of which contains a large resistance and the moving coil. If the resistance of the field coil were zero, the flux through the core would simply depend on the applied voltage, whatever the magnetic properties of the core; and if this coil were short-circuited the core flux could not be varied. The chief points to be investigated were the effect of the actual resistance of the field coil, the influence of the E.M.F. induced by the field in the moving coil circuit, and the precise meaning and influence of the self-inductance of the moving coil. Exact formulæ have been established and verified for all these effects, some of which may be illustrated by the following tests. If the field coil be open-circuited and a current be passed through the moving coil, this will turn so as to enclose the greatest flux, but this position will not be *oc* because of the portion of the flux crossing the air gap twice, this part being greatest for the position *ob*. For feeble currents the resulting position will be near *ob*, but will tend to approach *oc* for larger currents, owing to the corresponding increase in the permeability of the core. If, however, the field coil be short-circuited, an alternating current through the moving coil will invariably turn it to the position *ob*, because such current cannot produce a flux through the long limbs of the magnet. If the field coil be excited by an alternating voltage and the moving coil circuit be closed through a small resistance, this coil, owing to its self-inductance, will turn to *oa* so as to enclose the minimum flux, while if under the same conditions the moving coil circuit be closed through a condenser, the coil will turn to *oc* so as to enclose the maximum flux.

A thorough analysis of these effects, confirmed by actual tests, shows that the instrument can be so constructed that for most purposes its errors are negligibly small, and also that it is possible to eliminate precisely these errors for any specified frequency by using a special winding round the magnet with its ends joined up to a condenser the capacity of which is determined by the frequency and the winding. None of the errors arise from the variable magnetic properties of the core. In connection with alternating current work, the voltage-controlled magnetic field thus offers great advantages for investigating purposes.

W. E. SUMPNER.

[1] "Alternate Current Measurement." By Dr. W. E. Sumpner. (Communicated by Prof. Perry, F.R.S.)

## NEW LIGHTS ON THE ANTHROPOLOGY OF CALIFORNIA.

THE anthropological department of the University of California, thanks to Mrs. Hearst's munificent endowment, is able to issue a further series of studies on the native races of that State. The most voluminous contribution is that of Mr. S. A. Barrett on the "Ethno-geography of the Pomo and Neighbouring Indians," a group of tribes numbering at present about 1000 souls, and occupying the region known to geographers as the Coast Range Mountains immediately north of San Francisco Bay, and running eastward to the Sacramento River. These people are now partially civilised, and support themselves by farming and labour. But sufficient is known of their primitive condition to show that they had no totemic clans or groups, and that their tribal organisation was weak, there being no chief in the commonly accepted sense of the term. There was a sort of council of minor chiefs presided over by a chief captain, whose authority was strictly limited, and who was elected by the community. The inferior chiefs, on the other hand, held their offices by hereditary right, and the succession passed from one incumbent to the family of that sister who was nearest to him in age, kinship and descent being in the female line.

In regard to culture, these people fall into three divisions:—the ocean tribes, who depended for food upon the fish and molluscs which abounded in the sea, and derived the material for their food and clothing from the redwood forests of the coastal districts; secondly, the valley tribes, who occupied in severe weather round grass-thatched houses, while during the summer they wandered along the streams and lived in temporary brush shelters, but used no canoes, as the rivers are of inconsiderable volume; lastly, the tribes of the inner lake region, who built elliptical huts thatched with the tule rush, which also supplied them with materials for nets, mats, and slings with which they killed water-fowl, using for the purpose of fishing canoe-shaped rafts of the tule. The materials for the study of this civilisation now extinct are found in the ancient village sites which have been carefully examined by Mr. Barrett. The greater part of his elaborate report is occupied by a survey of the tribal dialects, which adds largely to the information recorded by Schoolcraft, Powell, Bancroft, and others. In another and less elaborate report Messrs. S. A. Barrett and A. L. Kroeber give an account of the Miwok tribe.

Of more general interest and importance is the investigation conducted by Mr. W. J. Sinclair into the question of the existence of relics of prehistoric man in the auriferous gravels of the Sierra Nevada. The evidence of the early existence of man in California has been hitherto almost entirely based on the well-known report issued in 1880 by Prof. J. D. Whitney in the course of the geological survey of the State. The present inquiry has been devoted to a further investigation of the sites from which the human remains and objects alleged to be the work of man are said to have been derived. The result is seriously disconcerting to those who have relied on the evidence collected by Whitney. Mr. Sinclair points out that, though these gravels and the intercalated volcanic outflows are admittedly of various geological periods, Whitney made no attempt to indicate from which series of gravels the relics were obtained. In the case of the discoveries made in mines worked by hydraulic machinery the provenance of the vast majority of objects can no longer be verified, and there is good reason to suspect that many, if not all, the specimens have been washed down from modern Indian village sites situated on bluffs overhanging the pits, which were disintegrated by the powerful water currents. Mr. Sinclair reviews in detail all the more remarkable "finds" in this region. One large mortar is said to have been found in association with "a small oval tablet of dark coloured slate with a melon and leaf carved in bas-relief." But it exhibits no signs of wear from gravel friction; the scratches are all recent defacements, and the carving is said to show very evident traces of a steel knife-blade.

Special attention is naturally given to the Calaveras skull immortalised by Bret Harte, which is now a cherished possession of the Harvard Museum. Mr. Sinclair asserts that the substance adhering to it is not a gravel, but a cave breccia, and that the skull was not obtained in the gravels beneath the rhyolite, or from any other gravel of the rhyolitic epoch, none of which exhibits any trace of the stalagmitic cementation which has been recognised in the skull matrix. He suggests that the skull was derived from a comparatively modern Indian cave interment. If, he adds, man of a fairly high developed type was in existence during the deposition of these gravels, he must have been "a contemporary of the three-toed horse and other primitive forms of the late Miocene and early Pliocene, a thesis to which all geological and biological evidence is opposed." His conclusion is that the evidence is insufficient to prove the presence of the remains of men in the auriferous gravels; that there have been abundant opportunities for such relics to be accidentally mixed with these gravels; and that the local geological conditions render it improbable that such implements and bones have been found in the assumed sites.

It would be premature to attempt to criticise this important report in detail. Doubtless those authorities who assert the genuineness of these relics will not allow the case to go by default. English anthropologists have always adopted an attitude of reserve in relation to the Calaveras skull. If the question of the antiquity of the human race depended on the authenticity of these Californian discoveries, the position would perhaps be serious. But even if Mr. Sinclair's indictment survives the criticism to which it is inevitable that it must be exposed, the abundant evidence from other unquestioned sources which now exists renders a challenge of one set of relics a matter of little importance. Whatever may be the result of the controversy, the necessity of caution in dealing with evidence which has been collected without rigid scientific supervision is sufficiently obvious.

## *METEORIC PHENOMENA IN JUNE.*

In June there are few meteors seen which leave streaks. Possibly the twilight is responsible for this; it must partially be so, but I do not think that it will wholly account for the seeming rarity of meteors of the same type as the August Perseids or November Leonids.

Yet there are a few noticed by vigilant observers, and especially in the morning hours. These are directed from radiants in Pisces, Andromeda, Aries, Perseus, and other constellations in the same general region of the sky. There are the $\alpha$–$\beta$ Perseids, $\delta$ Cassiopeids, $\pi$, $\mu$, and $\gamma$ Andromedids, $\beta$ Triangulids, $\alpha$ Arietids, $\beta$ and $\epsilon$ Piscids, and many others. In 1887 I saw several fine streak-leaving meteors from a radiant near the position of the August Perseids at about $\eta$ Persei. All the centres referred to, however, stand in need of corroboration, as they are supported on very slender evidence indeed.

Fireballs are not uncommon to June, though few real paths appear to have been hitherto determined in this month.

When we have such excellent atmospheric conditions as prevailed in June, 1887, it is possible to discern a large number of showers. Some of these are directed from places south of the equator; for instance, there are radiants at $252^\circ-21^\circ$, $269^\circ-24^\circ$, $283^\circ-13^\circ$, $305^\circ-12^\circ$, &c.

Occasionally there are some late Virginids and Serpentids noticed in June, and a sprinkling of Ursa Majorids will be recorded by the careful observer.

The weather usually prevailing is excellent, and the sky, though light, is attractive. The writer has often been struck with the prominent aspect of the Milky Way on midsummer nights. It stretches nearly overhead, and the rich regions in Cassiopeia, Cepheus, and Cygnus are often beautifully displayed at this season of the year, notwithstanding the lack of suitable darkness.

W. F. Denning.

## *VISION AND COLOUR-VISION.*

The difference in physiological effect between incident and reflected light is a commonplace to those who have investigated the influence of surroundings on sensitive animals. The *influence du fond* is a function of the altered light reflected from these surroundings upon the eyes or skin of animals capable of assuming variable coloration. The direct incident light has little or no effect in producing the result.

In a series of papers (*Zeit. f. Augenheilkunde*, Bd. xvi., pp. 448–463; *Wiener medezinische Wochenschrift*, No. 46, 1906, No. 48, 1907) Prof. Raehlmann asserts that the light perceived by vertebrates is reflected from the plane separating the outer laminated limb of the rods and cones into the inner homogeneous limb of the same. He now claims that colour-vision is due to the reflected light setting up "stationary waves" in the inner limb of these retinal elements. To support this view he proceeds to show from recent work that if a Lippmann gelatin film (placed between a mirror and a source of light) be exposed to different parts of the spectrum, and then cut into microscopic sections and examined under a high power, the substance of the film is seen to be traversed by zones of black granules separated by colourless intervals, the interspaces equalling the wave-length of the light used, and, therefore, whilst perceptible in the case of red and yellow light, are so crowded together in green and blue light as to be almost continuous. This result is claimed by Prof. Raehlmann as confirmatory evidence of the truth of his hypothesis. The sensitive film is represented by the morphologically inner portion of the rod or cone, the mirror by the membrane separating this from the outer refractive portion, and the case would be complete if any arrangement of black and colourless zones comparable to that set up in the film could be discovered in the inner portion of the cone, but though Prof. Raehlmann has used the ultra-microscope after a given monochromatic exposure, he can discover nothing in the inner cone-limb but a perfectly uniform granulation, and though the length of the cone is known to vary with that of the light-waves used, yet he has not been able to correlate the somewhat different appearance of the granulation in the case of cones exposed to red and blue light with the qualities of the light. This argument from Lippmann's direct colour photography, therefore, is at present unconvincing in its most essential feature.

The second argument in support of the view that colour arises from "stationary waves" set up in the inner segments of the rods and cones is the ready explanation it affords of colour-blindness. On the usual theory that light traverses the outer dioptric limb of the rods and cones and is arrested by the retinal pigment, the origin, and especially the variations of the colour-sense, are difficult to explain, even with the aid of the retinal purple. Prof. Raehlmann, however, has no difficulty in pointing out that disturbance of the reflecting power of the outer rod-limb, such as might readily ensue without causing loss of sharpness of sight, would cause variation and even loss of colour-vision, whilst the much commoner reverse condition would be due to dislocation of the rods by choroidal or pigmentary disturbances from a vertical into an oblique position such as is found normally at the weak-sighted periphery of the eye. Other phenomena of vision—adaptation, the dazzling effect of contrast, after-images, and the interesting structural variations shown in the rods of animal retinas (for example, the coloured globules of many birds, the retina of deep-sea cephalopods)—are also touched upon, and an attempt is made to show that on this hypothesis a fuller explanation may now be given than has hitherto been possible. Direct proof of this view, however, has not yet been obtained, and the analogical or indirect evidence advanced in support of it cannot yet be said to be of a convincing nature.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

Cambridge.—On the occasion of the installation of the Chancellor on June 17 it is proposed to confer degrees upon the following, among others:—Hon. C. Algernon Parsons, C.B., F.R.S., Sir Andrew Noble, Bart., K.C.B., F.R.S., Sir William Crookes, F.R.S., Prof. Horace Lamb, F.R.S., and Prof. G. D. Liveing, F.R.S. It is understood that, according to precedent, the new Chancellor has nominated the recipients of the honorary degrees which will be conferred at his installation.

Dr. Guillemard, Dr. Haddon, and Mr. H. Y. Oldham, of King's College, have been nominated to represent the University at the International Congress of Geography to be held at Geneva next July.

The special board for mathematics has nominated Mr. H. F. Newall, of Trinity College, as a member of the board of electors to the Plumian professorship of astronomy, and the special board for physics and chemistry has nominated Dr. W. N. Shaw as a member of the board of electors to the professorship of mechanism and applied sciences.

The Vice-Chancellor announces that he has received from Prof. Liveing an intimation of his intention to resign the professorship of chemistry an Saturday, June 20.

Edinburgh.—Prof. Crum Brown will resign the chair of chemistry on July 25. Applications for the chair, the patronage of which is vested in the curators, should be sent, with relative testimonials, on or before July 4, to Mr. R. Herbert Johnston, 4 Albyn Place, Edinburgh.

Leeds.—Prof. W. H. Bragg, F.R.S., professor of mathematics and physics in the University of Adelaide since 1886, has been appointed to succeed Prof. Stroud in the Cavendish chair of physics. Prof. Bragg will enter upon his duties at Leeds next February.

Oxford.—Mr. C. F. Jenkin has been elected to the newly constituted professorship of engineering science.

Mr. Benjamin Kidd will deliver the Herbert Spencer lecture on Friday, May 29, at 4 p.m., in the Sheldonian Theatre, the subject being "Individualism and After."

Dr. Joseph F. Payne, hon. fellow of Magdalen College, has been appointed by the delegates of the common university fund to deliver a course of six lectures in the next academic year on the history of medicine, dealing specially with Greek medicine.

Prof. E. B. Poulton and Mr. A. H. Church have been appointed to represent the University on the occasion of the Linnean Society's celebration of the fiftieth anniversary of the reading of the Darwin-Wallace memoir on the origin of species.

---

Mr. J. P. Griffith, Rathmines Castle, Dublin, has just contributed 100*l.* towards the new buildings of the North Wales University College.

The Association of Technical Institutions has awarded the prize of 25*l.* for the best essay on "The Bearing of Technical Education on Industrial Progress" to Dr. John Ryan, Milltown, co. Dublin, and the prize of the same amount for the best essay on "The Bearing of Technical Education on Agriculture and Industries of a Rural Character" to Mr. Edgar Chamberlain, Municipal Technical School, Lincoln.

Messrs. Swan Sonnenschein and Co., Ltd., have now published "The Girls' School Year-book" for the year April, 1908, to April, 1909. This is the third year of publication of a very useful work of reference. A hundred and thirty public secondary schools for girls in different parts of England and Wales are described in some detail, and a fairly complete list of similar schools in the United Kingdom is provided. It is not always easy to see the reasons for the choice of schools receiving extended treatment, but the year-book is still young, and the editors will probably extend their selection in future issues. The second part of the volume deals chiefly with careers for girls, but provides other useful information also. The book is certainly gratifying evidence of the improvement which has been accomplished in the education of girls during recent years, and it is satisfactory to notice that it is proposed in next year's issue to deal with instruction in domestic science and housecraft, for it is in this direction that there is real need of experiment and observation if our girls' schools are to be successful in preparing their pupils for one of the most important parts of a woman's life.

We learn from the *Pioneer Mail* that a letter has been sent by the secretary of the Government Education Department to the registrar of the University of Bombay stating that the Governor in Council has had under consideration the nature of the provision at present made in Government colleges affiliated to the Bombay University for the teaching of science. The committee appointed by the syndicate of the University in 1906 to inspect these colleges indicated many points in which the instruction in chemistry, physics, and biology could be improved. The letter points out that it is necessary to meet the requirements of two distinct classes of students—those who specialise in science with the view of making it their life work, and those who take an elementary course to qualify them in part for a degree in arts, or for admission to the medical profession. It is proposed to concentrate the higher teaching of science in the College of Science at Poona, which will be equipped thoroughly for the purpose. Steps have been taken to obtain a full staff of highly qualified professors, and when the college is in full working order it will afford facilities for the study of science such as have hitherto been unattainable in Bombay. For the second class of students it is proposed to provide a laboratory in Bombay at which students from different colleges may pass through a course of elementary science. A similar course would be provided at the College of Science for Poona students, and for the present the science departments of Gujarat and Sind Arts Colleges would be retained. This elementary course will consist almost entirely of practical work, and it is hoped in this way to supply a deficiency in the ordinary course of study of Indian students by providing a training in observation and the accurate recording of facts.

The Scotch Education Department is publishing at short intervals memoranda on the teaching of various school subjects. The teaching of English, arithmetic, languages, drawing, history, and, most recently, nature-study and science, have been dealt with in this way. The sixth memorandum (Cd. 4024) is divided into two sections, concerned with nature-study and science respectively. Nature-study as here described is a very comprehensive branch of knowledge, related in its various aspects with many other subjects, designed primarily, as the introduction to the Blue-book points out, to overcome the divorce between school and home life, which is nowadays a serious defect of education. Nature-study justifies its place in the curriculum only when it brings the pupils into direct contact with natural objects and phenomena, and develops in their minds habits of correct observation and intelligent discrimination. The guidance provided in the memorandum is practical, and preeminently designed to assist teachers, so that the pupils may derive from these lessons the advantages the study can ensure when rightly pursued. School gardens, excursions, collections, calendars, weather observations, and the care of animals, are some of the subjects selected for treatment, and the teachers who work in the spirit of the hints and suggestions which enrich these pages will have no reason to fear failure to develop in their pupils open-eyed interest in nature. An appendix by Prof. J. Arthur Thomson shows teachers in detail how the subject may be studied seasonally, and the difficulty of obtaining material obviated. The second section of the memorandum explains how the work in nature-study should develop later in the curriculum into a more formal study of experimental science, with the object of encouraging the habit and spirit of accurate investigation. Individual work on the part of the pupil is insisted upon, and the importance is pointed out of truthful and clear records of results. Outlines of work are put forward as indicating suitable courses of study for an intermediate school devoting three hours a week, in two equal periods, to the subject, as well as for higher schools. It is satisfactory to find it laid down that the value of the work will depend upon its spirit and method, and upon the power of initiative and self-reliance developed in the pupils, rather than upon the amount of examinable knowledge acquired.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Royal Society**, February 20.—"On the Osmotic Pressure of Compressible Solutions of any Degree of Concentration. Part ii. Cases in which both Solvent and Solute are Volatile." By Prof. A. W. **Porter**. Communicated by Prof. F. T. Trouton, F.R.S.

In a former paper (see NATURE, September 5, 1907, vol. lxxvi., p. 487) the author found an exact relation between vapour pressures and osmotic pressure in the usual case in which the solute may be taken as involatile. The case now considered is the more general one, in which both solvent and solute are volatile.

The author has considered several cases in which the vapour pressure is changed, and found that in each case it is only necessary to know the partial pressure of the pure solvent the vapour of which is referred to in order to calculate what the change in the vapour pressure amounts to. The same method might presumably be applied to other cases also, such as magnetisation, &c.

March 19.—"On Vapour Pressure and Osmotic Pressure of Strong Solutions." By Prof. H. L. **Callendar**, F.R.S.

The foundation of the vapour-pressure theory of solutions laid down in this paper is the assumption of a simple relation between the vapour pressure and the molecular constitution of the solution. That there should be a simple relation of this kind appears extremely probable when we consider that the concentration of the vapour phase in the solutions here examined is very small, and that such relations generally take a very simple form at extreme dilution. That such a relation should serve as a key to many of the phenomena occurring in solutions is not surprising in view of the fact that equality of vapour pressure is one of the most general conditions of equilibrium in physical chemistry. The relation of this assumption to the gas-pressure theory, or the hydrate theory, or the capillary pressure theory, as already indicated, is that it involves them all, since they may be regarded as merely different aspects of the same phenomena. An equivalent assumption may be formulated, at least approximately, in terms of partial pressure, or capillary pressure, or chemical attraction, but it would merely be putting the same thing in different words. The vapour-pressure method appears to be the most direct line of attacking the problem. If, for instance, we regard the changes of capillary pressure in relation to vapour pressure as defined by the relation $UdP=vdp$, we should arrive at nearly the same result by similar approximations. But this method does not appear to be so convenient, because it involves the volume U, which is generally unknown and variable in an uncertain manner, whereas the volume of the vapour $v$ at low pressures may be regarded as conforming very closely with the laws of gases.

There is no doubt that further experimental work may be required to establish the vapour-pressure theory generally, since accurate data for strong solutions are comparatively scarce. The interpretation of the ionisation factor, and its relation to the heat of dilution, requires further elucidation. Analysis of nearly all the data at present available, in addition to the examples above cited, fails to show any serious disagreement with the vapour-pressure theory. The theory cannot pretend to be exact for all ranges of temperature and concentration, but it seems likely to serve, at least as a second approximation, for coordinating results which have hitherto appeared discordant.

March 26.—"Comparison of the Board of Trade Ampere-standard Balance with the Ayrton-Jones Current Weigher; with an Appendix on the Electromotive Force of Standard Cells." By T. **Mather**, F.R.S., and F. E. **Smith**.

The paper describes experiments by which the relation between the Board of Trade ampere and one-tenth C.G.S. unit of current, as realised by the Ayrton-Jones instrument (Ayrton, Mather, and Smith, Phil. Trans., A, vol. ccvii., p. 463), was determined.

The comparison was carried out by aid of a combination of standard cells and resistances used as a secondary standard of current. This combination was evaluated by the Ayrton-Jones current weigher at the National Physical Laboratory on each of the three days during which experiments were made at the Board of Trade Laboratory, so that if any change occurred in the secondary standard it would be detected.

Two methods of comparison were employed, both giving concordant results, viz. one Ayrton-Jones ampere = $1{\cdot}0003_3$ Board of Trade ampere, the latter ampere being, therefore, smaller than the former by about 1/30 per cent.

A difference of this order was anticipated, for a recent determination of the electrochemical equivalent of silver (Smith, Mather, and Lowry, Phil. Trans., A, vol. ccvii., p. 579) by the Ayrton-Jones instrument gave 1·11827 milligrams per coulomb, whereas the Board of Trade balance was adjusted to correspond with 1·118 milligrams.

According to these experiments, the Board of Trade ampere will deposit silver at the rate of 1·1179 milligrams per second, so that *the Board of Trade ampere is equal to the international ampere, as defined by silver deposit, to within 1/100 per cent.*

The above experiments, combined with figures given by Prof. Ayrton and the authors (Phil. Trans., A, ccvii., p. 536), enable the E.M.F.'s of standard cells to be expressed in terms of the Board of Trade volt, this being defined as the P.D. between the terminals of a resistance of one Board of Trade ohm when one Board of Trade ampere is passing. The results are:—

E.M.F. of normal Weston cadmium cell = $1{\cdot}0186_8$ Board of Trade volts at 20° C.
E.M.F. of normal Clark cell = $1{\cdot}433_0$ Board of Trade volts at 15° C.

The Reichsanstalt value for the cadmium cell is 1·0186 at 20° C., and that for the Clark cell, determined directly by Mr. Trotter, 1·4329 at 15° C.

April 30.—"On Scandium." By Sir William **Crookes**, F.R.S.

Scandia is one of the rarest and least known of the recognised rare earths. It was discovered in 1879 by Nilson, who separated it, together with ytterbia, from erbia extracted from euxenite and gadolinite. Later in the same year Cleve extracted scandia from gadolinite, yttrotitanite, and keilhauite, and described the scandium sulphate, double sulphates, nitrate, oxalate, double oxalates, selenate, acetate, formate, oxide, and hydrate, and gave some of the chief reactions of the new body.

In the course of the author's twenty years' work on the fractionation of the rare earths, he has repeatedly tested his products by examining their photographed spectra, using the dominant lines of the various elements as tests for their presence. Scandium has an extremely characteristic group of lines in its spectrum, situated between wave-lengths 3535·864 and 3651·983, the strongest being at 3613·984, midway between two strong iron lines. By using a part of the spectrum in which this occupies the centre of the photograph, it is easy to see if scandium is present. Detecting the dominant line, the presence of scandium can be verified by reference to the other lines of the group.

The author found scandium in some of the fractions, but only in small quantities. A few years ago he commenced an examination of all the obtainable rare earth minerals in order to see if any of them showed more than a trace of scandium. The minerals examined were:—æschynite, allanite, alvite, auerlite, baddeleite (Ceylon), bastnasite, bröggerite, cerite, cleveite, columbite, cryptolite, eudialite, euxenite, fergusonite (Ceylon), fergusonite (Ytterby), fluocerite, gadolinite, hielmite, homolite, keilhauite, knopite, koppite, lanthanite, monazite, mosandrite, orangite, orthite, polycrase, pyrochlore, rhabdophane, samarskite, scheelite (Bohemia), scheelite (New Zealand), schorlomite, sipylite, tantalite, thalenite, thorianite, thorite, thorogummite, tscheffkinite, tysonite, urdite, wiikite, xenotime, yttergarnet, yttrialite, yttrocerite, yttrogummite, yttrotantalite, yttrotitanite, zirkelite (Ceylon, sp. gr. 5·0), zirkelite (Ceylon, sp. gr. 4·42).

Of the minerals examined, scandium was detected in auerlite, cerite, keilhauite, mosandrite, orangite, orthite, pyrochlore, thorianite, thorite, and wiikite.

Wiikite is a black amorphous mineral of specific gravity 4·85. Its hardness is 6. It is infusible before the blowpipe. It is imperfectly attacked by strong mineral acids, and breaks up easily when fused with potassium bisulphate. Heated to full redness in a silica tube, it gives off helium, water, and a distinct amount of sulphuretted hydrogen, followed by a white sublimate. The mineral begins to crack at a temperature a little below redness, and at the approach of redness gas is evolved with almost explosive violence, the mineral breaking up and flying about the tube. A fragment so treated examined under the microscope shows the surface covered with glistening points. With a high power these points are resolved into a mass of minute cubes, curiously regular in form and appearance. Heating drives off 5·83 per cent. of its weight; 5·82 of the loss is water and acid vapour, the difference, 0·01 per cent., consisting chiefly of helium, with a little hydrogen, carbon dioxide, and a mere trace of neon.

After the crude earths, chiefly yttria, ytterbia, and scandia, have been separated from the mineral, they are "fractionated" by methods described in the paper. Towards the end of the fractionation the chief impurity is ytterbium. Fortunately, the very strong dominant line of the ytterbium spectrum, wave-length 3694·344, occurs at a vacant part of the scandium spectrum, and near the characteristic group of scandium. A sample of scandia is not taken as satisfactory if the least trace of this line is seen on an over-exposed spectrum of scandium, and if the atomic weight is higher than 44·1. The atomic weight of ytterbium being 173, a very little of it as an impurity raises the atomic weight of scandium.

The author has prepared and analysed the following compounds of scandium:—scandium hydroxide, scandium carbonate, hydrated scandium chlorides, hydrated scandium bromides, scandium chlorate, scandium perchlorate, scandium bromate, scandium sulphates, anhydrous scandium sulphate, basic scandium sulphate, scandium and potassium double sulphate, scandium selenates, scandium nitrates, scandium formate, scandium acetate, scandium propionate, scandium butyrate, scandium iso-butyrate, scandium iso-valerate, scandium oxalates, scandium picrates, scandium pyromellitate, scandium camphorate.

**Royal Anthropological Institute**, May 5.—Prof. W. Ridgeway, president, in the chair.—Report on the Hythe crania: F. G. **Parsons**. An account was given of nearly 4000 measurements which the author made on 575 of the skulls under Hythe Church, Kent. The author reviewed the various historical facts in connection with them, as well as the numerous traditions and explanations which had from time to time been put forward to account for the presence of the crania. He declined to believe any of the numerous battle theories, and pointed out that skulls of women and children were plentiful, that earth was present in many of the crania, and that the injuries which have so often been referred to battle-axe and spear wounds were certainly inflicted many years after death, and were made probably by spades and pickaxes in digging up the skulls. From numerous details of collateral evidence the author argued that the bones probably must have come to their present place before the Reformation, and, as there were femurs of about 4000 people in the stack, must have represented the burials of more than a century. Mr. Parsons believed that the bones were of the thirteenth, fourteenth, and fifteenth centuries. The chief point of interest in the measurements was the shortness of the skulls, which averaged 17·9 cm. for the males. This is 1 cm. shorter than the two large London series lately recorded by Dr. Macdonnell, and goes far to disprove that observer's suggestion that the English head is gradually growing shorter and broader. The teeth were remarkable for their freedom from caries and for the wearing down of the crowns, pointing to hard, coarse fare. Many pathological specimens of bones were exhibited showing that osteo-arthritis and syphilis were very rife. The various abnormalities in the skull bones and sutures were classified, and their frequency recorded for future anatomical comparison.

**Chemical Society**, May 7.—Prof. E. Divers, F.R.S., in the chair.—The refraction and dispersion of triazo-compounds: J. C. **Philip**. A study of these constants shows that the contribution which the $N_3$-group normally makes to the molecular refraction is 8·91 units, and that to the molecular dispersion 0·36–0·37, but ethyl triazoformate, phenylazoimide, and α-naphthylazoimide show refractive and dispersive powers above the normal values. The bearing of these results on the formulation of the $N_3$-group is discussed.—The dissociation constants of triazoacetic and α-triazopropionic acids: J. C. **Philip**. The values found show that the introduction of the $N_3$-group into the molecule of acetic or propionic acid increases the strength of the acid nearly as much as the introduction of a bromine atom.—The fermentation of mannose and lævulose by yeast-juice (preliminary note): A. **Harden** and W. J. **Young**. Mannose is fermented by yeast-juice at almost the same rate as dextrose, whilst lævulose is fermented somewhat more rapidly. The peculiar influence of phosphates on the fermentation of these sugars by yeast-juice is described in detail.—The constituents of olive leaves: F. B. **Power** and F. **Tutin**. The following substances were isolated:—(1) a new monocarboxylic acid, $C_{22}H_{43}.CO_2H$; (2) a mixture of fatty acids containing oleic acid; (3) hentriacontane, $C_{31}H_{64}$; (4) pentatriacontane, $C_{35}H_{72}$; (5) oleasterol, $C_{20}H_{34}O$, a new crystalline alcohol related to the phytosterols; (6) a new crystalline alcohol, olestranol, $C_{25}H_{42}O_2$, which appears to be a hydroxyphytosterol; (7) homo-olestranol, $C_{27}H_{46}O_2$, a compound similar to olestranol; (8) *d*-mannitol; (9) a sugar which yields *d*-phenylglucosazone; (10) a trace of an essential oil; (11) oleanol, $C_{31}H_{48}O(OH)_2,N_2O$, which contains one alcoholic and one phenolic hydroxyl group.—The constituents of olive bark: F. B. **Power** and F. **Tutin**. The following crystalline compounds were obtained, together with some amorphous products:—(1) a new monocarboxylic acid, $C_{33}H_{67}.CO_2H$; (2) a new monocarboxylic acid, $C_{21}H_{43}.CO_2H$; (3) a new monocarboxylic acid,

$$C_{34}H_{69}.CO_2H;$$

(4) a new monocarboxylic acid, $C_{29}H_{57}.CO_2H$; (5) a substance, probably a tertiary alcohol, $C_{35}H_{68}O$; (6) pentatriacontane, $C_{35}H_{72}$; (7) a phytosterol, $C_{27}H_{46}O$; (8) a substance identical with ipuranol, recently isolated by Power and Rogerson from *Ipomoea purpurea*; (9) a new phenolic substance, olenitol, $C_{14}H_{16}O_6$; (10) *d*-mannitol; (11) a sugar which yields *d*-phenylglucosazone.—The reaction of diazonium salts with mono- and di-hydric phenols and with naphthols: K. J. P. **Orton** and R. W. **Everatt**. All diazonium salts couple quantitatively with

α- and β-naphthols in alcoholic media, but under similar conditions these salts do not combine with monohydric phenols. The dihydric phenols, resorcinol and orcinol, behave like the naphthols in alcoholic solution, but in aqueous solution only diazonium salts, with a preponderance of halogen atoms in the benzene nucleus, couple with the two dihydric phenols.—The condensation of benzoin with methyl alcohol: J. C. **Irvine** and D. **McNicoll.**—The mutual solubility of 2-methylpiperidine and water: O. **Flaschner** and B. **MacEwen.**—The melting points of the anilides, *p*-toluidides, and α-naphthalides of the normal fatty acids: P. W. **Robertson.** The irregularities in melting points in the series of anilides and *p*-toluidides seem to tend always in the reverse direction to those observed in the case of the amides. The disturbing factor appears to be a function of the lack of symmetry of the molecule, and is to a great extent eliminated on taking the mean melting points of the amides and anilides and of the amides and *p*-toluidides. In the fatty α-naphthalides, where the substituent group is heavier, irregularities tend to disappear.—The absorption spectrum of camphor: W. N. **Hartley.** The author confirms Baly, Marsden, and Stewart's statement that strong solutions of camphor in alcohol show a band in the spectrum due to the CO and $CH_2$ groups, but otherwise the substance is remarkably diactinic.—The viscosity of solutions: C. E. **Fawsitt.** A continuation of work on colloidal and alcoholic solutions.—The action of fused potassium hydroxide and of hydrogen peroxide on cholesterol (preliminary note): R. H. **Pickard** and J. **Yates.**—The volumetric estimation of silver: W. R. **Lang** and J. C. **Woodhouse.**—A criticism of Werner's theory, and the constitution of complex salts: J. A. N. **Friend.**—The action between potassium sulphite and potassium pentathionate: E. **Divers.** The author points out that the accuracy of Debus's investigation of the action between a sulphite and a pentathionate (Trans. Chem. Soc., liii., 278) is not affected by Colefax's quite recent work (*ibid.*, 1908, xciii., 798).—Note on phenolic thetines and their action with benzoyl chloride: E. de B. **Barnett** and S. **Smiles.**—The relation between dielectric constant and chemical constitution, part i., stereoisomeric compounds: A. W. **Stewart.** Examination of active and racemic compounds, and also of geometrical isomerides, shows that the influence of the spacial arrangement of atoms on the dielectric constants of isomeric substances is not clearly marked. In one case the active isomeride had a stronger absorptive power than the racemic form.—An apparatus for determining the specific inductive capacity of organic liquids: A. W. **Stewart.**—The influence of solvents on the rotation of optically active compounds, part xii., ethyl tartrate in aromatic halogen derivatives: T. S. **Patterson** and D. P. **McDonald.**—A new test for silver: A. W. **Gregory.** A solution of a silver salt to which has been added a mixture of aqueous ammonium salicylate with ammonium hydroxide furnishes on further addition of ammonium persulphate an intense brown colour. Lead does not give this reaction.—The spontaneous crystallisation of substances which form a continuous series of mixed crystals; mixtures of naphthalene and β-naphthol: H. A. **Miers** and F. **Isaac.**

**Linnean Society,** May 7.—Prof. W. A. Herdman, F.R.S., president, in the chair.—*Exhibits.*—Fruits of the "Buddha's Claw" variety of *Citrus medica* obtained at Easter from the gardens at La Mortola, formerly belonging to the late Sir Thomas Hanbury, also a normal fruit for comparison: Prof. F. E. **Weiss.**—Representation of the movements of Peripatus and other invertebrate animals by means of the Newman fire-proof kinematograph: F. Martin **Duncan.** The special feature of the apparatus used was that it enabled one to analyse all movement, picture by picture, instead of having to run the whole film through from end to end without a stop, as in ordinary kinematograph projectors. The effect of concentrated light upon different species of invertebrate animals had proved of interest and frequently a difficulty, so that colour filters and isochromatised negative film had in some cases to be used to obtain a satisfactory record.—*Papers.*—Colony-formation as a factor in organic evolution: H. M. **Bernard.**—Antipatharia from the voyage of H.M.S. *Sealark*: C. F. **Cooper.**—Fresh-water fishes, batrachians, and reptiles obtained by Mr. J. Stanley Gardiner's expedition to the Indian Ocean: G. A. **Boulenger.**—The madreporarian corals, part i., the family Fungidæ, with a revision of its genera and species and an account of their geographical distribution: J. S. **Gardiner.**

**Faraday Society,** May 12.—Mr. L. Gaster in the chair.—Apparatus for determining the boiling points of very small quantities of liquids: L. **O'Dowd** and Dr. F. Mollwo **Perkin.** This consists of a capillary tube which is placed in about 1/5 c.c. of the liquid the boiling point of which is to be determined. The liquid is contained in a small test-tube, which passes through a hole in the cork in such a way that the end containing the liquid comes in close contact with the thermometer also passed through the same cork. A stirrer is also provided. The heating liquid is contained in a flask capable of holding from 100 c.c. to 120 c.c., and may be either sulphuric acid, glycerin, or other suitable liquid. One end of the capillary tube is sealed, and the open end is so arranged as to be at the bottom of the liquid. On raising the temperature bubbles commence to give off from the end of the capillary tube, and when a constant stream of bubbles comes off the source of heat is removed. The thermometer is read at the moment the bubbles cease to be given off, that is, the temperature at which the temperature of the vapour in the capillary is equal to the atmospheric pressure and is the boiling point of the liquid. Numbers were given, showing for high boiling substances, and also for low boiling substances, that accurate results can be obtained.—Ozone, particularly in connection with water purification: Dr. F. Mollwo **Perkin.** After a historical introduction, the apparatus of Messrs. Siemens and Halske was described in detail. It consists of two concentric electrodes, the inside one of aluminium and the outside one of glass. The inner electrode is hollow, and is kept cool by a circulation of water. The outer one is also surrounded by water in order to prevent heating. The aluminium electrode is connected with one pole of the high-tension current (8000 volts). The containing vessel, which is filled with water, is of iron, and is earthed. This is thus the negative pole, and as water surrounds the glass pole it becomes electrified. Dried air is passed up an annular space between the two electrodes, and by means of the silent electric discharge becomes ozonised. From the ozoniser the air passes up towers filled with pebbles, over which water trickles. By this means a large surface of water is exposed to the action of the ozone; it thus becomes sterilised, and from here passes over cascades in order to remove any dissolved ozone. Messrs. Siemens and Halske have large installations dealing with the purification of water supply at Wiesbaden and at Paderborn. Other uses of ozone, such as the preparation of vanilla, the bleaching of flour, and other purposes of oxidation, were also mentioned. An apparatus for laboratory use was exhibited in working.—Dr. **Veley** showed an apparatus for the determination of dielectric constants of non-conducting liquids.

**Royal Meteorological Society,** May 20.—Dr. H. R. Mill, president, in the chair.—Upper air observations in Egypt: B. F. E. **Keeling.** The whole prosperity of Egypt is connected with the weather of the neighbouring country of Abyssinia. As the summer rainfall is greater or less in Abyssinia, so is the Nile flood, and in consequence the area of land cultivated and the general prosperity is greater or less. In years when a bad, low stage of the river is to be expected, following on a bad flood, the early spring showers in Abyssinia are then of very great importance. As, unfortunately, there is no meteorological service in Abyssinia, it is not possible to obtain information about the rainfall over that region, so steps have recently been taken to obtain observations on the upper air over Egypt by means of pilot balloons and kites. Mr. Keeling gave an account of the methods employed, and of the directions in which it was hoped in the near future to develop the work. He also stated that the observations of the anti-trade winds made by M. Teisserenc de Bort and Mr. A. L. Rotch have been confirmed. At Helwan the anti-trade wind is reached at a height of about 6500 feet above sea-level. The greatest height so far reached by a balloon was 54,000 feet, and on that occasion the south-west anti-trade wind was apparently penetrated and a north-west upper current encountered.—Balloon experiments in Barbados, November 6–8, 1907: Prof. J. P. **d'Albuquerque.**—Observations on the colour of lightning made at Epsom, 1903–7: S. C. **Russell.** The author had for the past five years kept a record of the colours or series of colours noted during each thunderstorm or display of sheet lightning, and tabulated them under their respective colour. He had thus results of observations of fork lightning made during fifty-seven thunderstorms, and seventy-eight observations of sheet lightning. It appears that in fork lightning red is the colour of the most frequent occurrence, and this is followed closely by blue, the least frequent colours being orange and green. White is of the greatest frequence in sheet lightning, red and yellow being next. It seems that the presence of hail, when occurring in association with a thunderstorm, is intimately connected with blue lightning.

**Institution of Mining and Metallurgy**, May 21.—Mr. Alfred James, president, in the chair.—The electrical equipment of gold mines: H. J. S. **Heather.** Continued discussion on this paper.—The behaviour of tellurium in assaying: Sydney W. **Smith.** An examination of the behaviour of this substance during pot-fusion, scorification, and cupellation in order that some reasons may be offered for taking the precautions which are generally regarded as necessary to ensure successful work. The paper describes a number of careful observations made with this end in view, and a summary of the conclusions arrived at is given.—The average rate of accumulation and absorption of gold amalgam by copper plates: Edward **Halse.** The absorption and accumulation of gold on copper plates: W. F. A. **Thomae.** These two papers deal with the same subject, the general conclusion of the two authors being that the absorption of gold by copper plates may be ignored by the mill-man in view of its small importance. In no case does the average rate appear to exceed a fraction of a grain per ton milled, and in the case of ore containing coarse gold it is practically nil. The authors look at this matter from somewhat different points of view, Mr. Thomae especially thinking that further data might be worth placing on record.—A journey to Central Asia: A. **Adiassewich.** This paper records the results of travels in Central Asia, with special reference to the position and prospects of the mining industry there. After a general description of the conditions of mining, the author passes in review the leading districts, Orenburg, the Khirgiz Steppes, &c., and gives details of the occurrence of gold, silver, copper, iron and other ores, coal, and petroleum.

PARIS.

**Academy of Sciences**, May 18.—M. H. Becquerel in the chair.—The hovering flight of birds: Marcel **Deprez.**—The turning of aëroplanes: Paul **Renard.** To turn an aëroplane requires that the apparatus should incline transversely a given amount; it will, in addition, usually have the effect of lowering the trajectory. Before making a turn it will therefore be necessary to rise if the original height is to be maintained at the end of the turn.—The profile of the polar masses of dynamos: Paul **Girault.**—The ultramicroscopic examination of charged centres in suspension in gases: M. **de Broglie.**—The re-combination of the ions in dielectrics: P. **Langevin.** On the supposition that in gases the re-combination of the ions with contrary signs is due to the attraction of their electric charges, the author has shown in an earlier paper that relation $\frac{\alpha}{4\pi(k_1 + k_2)} \leq 1 = \epsilon$ holds, in which $\alpha$ is the coefficient of re-combination, $k_1$ and $k_2$ the mobilities of the positive and negative ions. In the present paper the application of this formula to the case of solid dielectrics is considered, and a simple method described of determining $\epsilon$.—The influence of the surrounding atmosphere on the friction between solid bodies: F. **Charron.** The presence of moisture, benzene vapour, or alcohol vapour in the air reduces the friction, but no variation could be observed when the air round the moving parts was replaced by dry hydrogen, carbon dioxide, or ethylene.—The auto-excitation of a tri-phase alternator by means of electric valves: C. **Limb.**—The differences of contact potential between metals and liquids: L. **Bloch.** The apparent difference of contact potential between metal and liquid is smaller for alkaline solutions than for water, and smaller for water than for acid solutions. Salts give effects differing only slightly from water. The method is sensitive enough to detect traces of acid and alkali beyond the reach of detection by colour reagents.—The radiography of the lungs and stomach of the fœtus and still-born infants: M. **Bouchacourt.** In infants whose lungs have been filled with air, the lungs show definitely in the radiograph, but the usual practice of artificial inspiration in the case of infants apparently still-born may lead to the erroneous conclusion that the child has lived. The causes of the visibility of the stomach in the radiograph are also discussed.—Observation on the time required for the solution of substances: Gaston **Gaillard.** The substances studied were sodium thiosulphate, sugar, and sodium sulphate. The effect of the size of the crystal and rate of agitation have a great influence on the results, and it is only when these two factors are kept as constant as possible that comparative measurements can be obtained.—A photographic action of infra-red light: A. Gargam **de Moncetz.** The gelatinobromide plates were fogged by the X-rays previous to the exposure to the red rays, the light being filtered through a solution of iodine in carbon bisulphide capable of cutting off all rays between 800 λ and 4 λ. The plate showed clear effects of the exposure for wave-lengths between 920 λ and 1350 λ. The preliminary fogging of the plates by ordinary light instead of by the X-rays did not give these results.—The kinematographic study of the Brownian movements: Victor **Henri.** The path described by a particle, as shown by these experiments, was very complex; it varies from one particle to another, and is absolutely independent for each particle even when two particles only $2\mu$ apart are compared. The trajectory often shows abrupt changes of direction. The displacements measured for 0·05 second were compared with those deduced by Einstein's formula, and were found to be about four times greater than the latter.—The iodomercurates of thorium and aluminium: A. **Duboin.** The preparation and properties of $ThI_4,5HgI_2,18H_2O$ and $AlI_3,HgI_2,8H_2O$ are described.—The definite compounds of silicon and palladium: Paul **Lebeau** and Pierre **Jolibois.** Silicon and palladium unite directly with evolution of heat, giving rise to two definite silicates, $Pd_2Si$ and PdSi, the first of which has been separated and analysed. The existence of the other silicide has been deduced from the determination of the fusibility curve and the metallographic study of the ingots obtained. These silicides are analogous to the platinum silicides already known.—A method for the volumetric estimation of tartaric acid in argol and cream of tartar: Em. **Pozzi-Escot.** The method is based on the insolubility of barium tartrate in alcohol, and the solubility of barium bromide in the same solvent. The excess of barium used is converted into the oxalate, and the latter determined with potassium permanganate.—The elimination of carbon monoxide from coal gas: Léo **Vignon.** Details of laboratory experiments on three methods are given: the conversion into methane by reduced nickel, the transformation into carbon dioxide by heating with oxide of iron at definite temperatures, and the direct absorption with cuprous chloride. The question of the cost of treatment or the value of the gas after such treatment is not dealt with by the author.—Propargylcarbinol: MM. **Lespieau** and **Pariselle.** Starting with the ester $CH_2Br—CHBr—CH_2—CH_2.OCH_3$, this is successively converted into 1:2:4-tribromobutane by the action of hydrobromic acid, 2:4-dibromobutene, from the preceding by the action of potash, the alcohol, $CH_2{=}CBr—CH_2.CH_2OH$, and the sought for acetylenic alcohol,

$$CH \equiv C—CH_2.CH_2OH.$$

—The mixed trihalogen derivatives of methane: V. **Auger.** A description of the preparation and properties of $CHCl_2I$, $CHClI_2$, $CHBr_2I$, and $CHBrI_2$.—The constitution of the combinations of tetramethyl-diamino-benzhydrol with some methylenic derivatives: R. **Fosse.**—Some orthobenzylated colouring matters from triphenylmethane:

## SCIENCE IN FOLKLORE.

*Folklore as a Historical Science.* By G. L. Gomme. Pp. xvi+371. (London: Methuen and Co., n.d.) Price 7s. 6d. net.

AS its title leads us to suppose, this interesting volume is a plea for the recognition of folklore as a historical science. Seeing that the barrier between history and folklore is still unbroken, in spite of the efforts of Miss Harrison, Dr. Frazer, and others, the author has resolved to destroy it once for all, and has endeavoured to convince us that historical fact is often the essence of tradition, and that we must look to folklore for most if not all our light on the early stages of the psychological, social, and political development of modern man. In support of his argument, and by way of illustration, he has drawn on his vast store of instances, and discussed legends attached to places and historical persons, folk-tales such as Catskin, Faithful John, &c., which imply savage social conditions, and tribal laws and rules, rhythmical if not in verse, which have been handed down by word of mouth and preserved in historical times. Yet, in spite of the proofs at his command, he fears that the historians may refuse to admit the value of folklore as evidence, and believing that a change in their attitude must be preceded by a change in the attitude of the folklorists themselves, he urges on the latter a more rigid scrutiny of their data, and a more judicious use of the comparative method, than has been customary hitherto. Not only must they ascertain the position of each item of folklore in the culture area in which it is found, but must try to determine its correct relation to other items in that area, taking heed to compare like quantities alone. Only thus can they hope to discover the underlying facts, and to offer the historians materials they can use.

After indicating the relation of folklore to history, and the system to be followed by the folklorists, he discusses in the last half of the volume the aspects under which they must regard it, and the conditions they must take into account if their labour is to end in a real increase of knowledge.

The explanation of the folklore of a people should be sought, as Mr. Gomme thinks, in its anthropological history, especially in the stage of its development known as totemism, and as this is a topic on which opinion is divided he discusses it at considerable length. From totemistic survivals he passes on to speak of those which can be subjected to sociological and ethnological tests, and shows that certain differences in folklore are to be accounted for as the results of different race origins or a different social organisation. In discussing European folklore he emphasises the need of bearing in mind the introduction of a foreign religion, viz. Christianity, and the manner in which it affected and was affected by the existing beliefs.

For want of space we are unable to criticise the work in detail, and must content ourselves with a few general observations. Most of its readers will allow that folklore should be treated as a science, and that the principles of its study have been correctly laid down by the author. They will commend him, too, for rejecting the methods of the destructive school and laying stress on the value of popular beliefs. The scepticism of Voltaire and his followers was a natural reaction from mediæval credulity, and was bound to precede any real advance in historical writing. Our scholars of to-day are differently placed; as research has become closer and more extensive, their respect for tradition has been increased in many cases rather than diminished; they are no longer content to doubt; they must separate the truth from the overlying falsehood. In the light of our fuller knowledge, Voltaire's treatment of the myth of Romulus and Remus, for example, seems partial and unscientific; Mr. Gomme, in discussing, for instance, the story of the Frog Prince or the descriptions of Britain by classical writers, greatly surpasses him in breadth and acumen. To our mind, however, his conservative tendency is nowhere more happily expressed than in his refusal to dismiss as superstition the attempts of our savage ancestors to account for natural phenomena. He shows with admirable insight that their mental process was the same as that of their cultured descendants—"primitive myth is primitive science"—and the mistakes they made were but the natural outcome of severely accurate reasoning from insufficient data.

Yet, sensible as we are of his largeness of view and the excellence of his methods, we are not altogether satisfied as to the truth of his main contention; we are far from certain that "the gap in the heart of things" is not too wide to be bridged over by folklore. His analysis of the various folk-tales is masterly and suggestive, but he leaves us unconvinced that his results are worthy of his pains, that the data of folklore are matter for the historian, and not, as hitherto supposed, for the philosopher. It is only just to say that these doubts may not be felt by all, not to mention that they may be lessened or removed by his promised volume on "Folklore in Early British History." Be that as it may, we are less inclined to quarrel with him for mistaking the uses of folklore than for his attitude on certain other points, than, to take one instance, for his somewhat cavalier treatment of the mythologists. It is one thing to say that the key to folklore is anthropology; it is another to suggest that there are no traces of national gods among the European peoples, and that the objects of adoration were always of the tribe. Even if the European sky-god is a fabrication of "the Cambridge professor," even if Lud on the Thames and Nod on the Severn were distinct until the Romans united them, he is hardly justified in such sweeping generalisations; he has still to account for, *e.g.*, the cult of Lug in regions so far apart as Leyden and Lyons and County Wicklow, as well as at a host of intermediate places. It is possible that we shall receive greater satisfaction from the new volume; so far it cannot be allowed that the author has said the last word on the subject.

The book requires no praise from us. It is enough to say that it sustains Mr. Gomme's high reputation as a folklorist, and that those who devote time to its study will be amply rewarded. It possesses an additional source of interest in its well-chosen illustrations. "The Two Scenes from the Life of St. Guthlac" bring before us with peculiar vividness the unseen world as it presented itself to some of our forefathers.

## A ZOOLOGIST AS ÆSTHETE.

*Ästhetik der Tierwelt.* By Karl Möbius. Pp. v+128; 3 plates and 195 figs. (Jena: G. Fischer, 1908.) Price 6 marks.

AS director of the great zoological museum in Berlin, the late Prof. Möbius was naturally led to consider the æsthetic value of the various forms of animal life as well as their scientific interest. From time to time he published brief essays discussing different types of animals from the æsthetic point of view, and as he found the inquiry very profitable—increasing his delight in the animal creation—he gathered his reflections together in the beautifully illustrated book before us, which bears the pleasant title "Ästhetik der Tierwelt."

Certain animals cannot be seen without being greatly admired, others are regarded with complacency but without enthusiasm, others with entire indifference, and yet others with repugnance—which is often affectation. Prof. Möbius sought to discover some of the reasons for this diverse æsthetic value that animals seem to have, and his *à priori* method led him to judgments which it would be of great interest to test statistically, by collecting opinions from, say, 5000 of each of the following groups:—country children, men in the street, well-dressed women, naturalists, and artists. It is notoriously difficult, however, to get a frank expression of æsthetic emotion (especially in regard to animals), to allow for conventional prejudice and posing, for sheer uneducatedness of vision, and for entirely artificial associations which lead many people to recoil from forms of life which the artist admires. We find in this book many statements like this:—"Die Fledermäuse findet niemand schön," and the author tried to show that this universal disapprobation is justified according to certain canons of æsthetic criticism. So much the worse for these canons, it seems to us, not that we can believe in the universal disapprobation of bats.

Prof. Möbius pointed out that our æsthetic judgments as to animals rest on a complex objective and subjective basis; he went on to discuss the general qualities of a beautiful living creature—it must be a unity, it must be harmonious, it must have individuality, and so on. We regret that the illustrious author did not expand his reflections on these matters, instead of giving so much space to comparing the relative merits of crab and lobster, or analysing the alleged "Hässlichkeit" of hippopotamus and giraffe. It seems to us that just as we are pleased by a piece of carving, rude though it may be, which expresses the craftsman's mood, and shows him to be even a little bit of a creator, so, but infinitely more, are we pleased by the individuality of organisms—every one its own artist—no one of which uses its materials quite in the same way. An interesting short chapter is devoted to the æsthetic value of animals as parts of a landscape; thus what is not impressive in isolation gets its value in its natural setting. This is well illustrated by reference to the associations seen on a coral beach at low tide.

The volume attempts an analysis of beauty in animal architecture, but the treatment seems to us too dogmatic and aprioristic. We demand symmetry, it is said, yet what delights us more than a lop-sided shell from the shore? A Campanularian is not so beautiful as a Corallium, because the number of its tentacles is a distracting conundrum. A centipede makes us tired, it is said, with its monotony, "Man sieht nichts Neues, wird ermüdet und gelangweilt," whereas to many people a centipede quickly moving among the bark is in its way just as beautiful as a peacock. Spiders are not so much appreciated as butterflies, because their body has only two main parts, and the æsthetic unity is spoilt by the distractions of the abdomen when we are contemplating the cephalothorax, and *vice versâ*. It is unconventional for an animal to be broader than it is long, and, therefore, to use one of the author's examples, Geryon must take a back seat when Gammarus appears. But when it comes to ranking Peripatus among the animals with "langweilende Wiederholung," and putting Nymphon among the unsatisfactory because it lacks sufficient central mass to rivet the eye, we cannot but disagree. We may take shelter behind the eirenic maxim, "De gustibus non disputandum est," but we are not afraid of the responsibility of stating a counter-thesis, with which we think most artists will agree, that no natural animals are ugly or "hässlich" in the sense of being out of proportion or out of harmony, or "bad colour." It seems to us that the only ugly animals are such as prize pigs, on which man has laid violent hands. One of the delights of animal coloration is the daring as well as the subtlety of the experiments, but is any result ever a failure in the sense that a picture or a picture-hat may be?

J. A. T.

## FUNDAMENTAL PRINCIPLES OF CHEMISTRY.

*Stoichiometry.* By Prof. Sydney Young, F.R.S.; with an Introduction to the Study of Physical Chemistry by Sir William Ramsay, K.C.B., F.R.S. Pp. lxxi+381. (London: Longmans, Green and Co., 1908.) Price 7*s.* 6*d.* net.

THIS volume, as its unfamiliar title implies, is concerned with the fundamental principles of chemistry, and so forms logically the first of the "Text-Books of Physical Chemistry" edited by Sir William Ramsay; the introduction, which has appeared before, is appropriately reprinted in this volume. We are pleased to see that five more volumes of the series are in preparation.

Recent research on atomic and molecular weights, of which Prof. Young gives a clear and simple account, has proceeded mainly in two directions. D.

Berthelot, Lord Rayleigh, Leduc, Guye and his co-workers, from the study of gases have been able by a nice combination of exact theory and experiment to bring independent evidence as to the molecular weight of gases; at the same time, Morley, T. W. Richards, and others at Harvard have considerably increased the accuracy with which the more important atomic, or rather combining, weights are known. Prof. Young's own researches have been closely related to the former investigations.

The problem in the deduction of accurate atomic and molecular weights from the properties of gases is the precise application of Avogadro's hypothesis; that is, it is necessary to know the relative volumes (at 0° and one atmosphere) of the gas under consideration and oxygen, which contain equal numbers of molecules. When these volumes are known, the weight of the molecule of the gas can be found at once from its density relative to that of oxygen. Berthelot assumes that Avogadro's hypothesis is strictly true when gases are at small pressures; to apply this assumption, $pv$ has been observed at a small pressure and at one atmosphere for several gases, including oxygen. Guye uses the principle of corresponding states; for example, argon and oxygen have approximately the same critical pressure and temperature, so he assumes that equal volumes of these two gases (at 0° and one atmosphere) have the same number of molecules; and finally, the values of $a$ and $b$ in van der Waals's equation have been used directly to find the Avogadro volumes. The atomic weight of nitrogen obtained in this way is 14·01, as opposed to the formerly accepted 14·04; there is plenty of evidence that the smaller value is the more accurate one.

As was to be expected, the treatment of change of state, van der Waals's theory, the vaporisation of mixed liquids, &c. (where so much of the best work is that of Prof. Young himself), is at once clear, precise, and interesting.

The first chapter, of twelve pages, on "The Fundamental Laws of Chemical Combination," which also includes Dalton's atomic theory, seems to us entirely unsatisfactory, and falls much below the standard of the rest of the book. These fundamental subjects receive the usual inadequate treatment which mars so many elementary text-books of chemistry. The definition of an element, as a substance not decomposable *at will*, is artificial, and merely avoids the difficulties raised by the well-verified spontaneous change of radium into helium. Our complaint, however, is with the presentment of the laws of chemical combination. When a generalisation is raised to the dignity of being called a law, surely the value of science as a method of thought demands, (1) the definition of the law in clear and precise language, (2) a statement of the observations (with their accuracy) upon which the law is based? None of these is done for the law of definite proportions. It is high time the "law" of multiple proportions was omitted from text-books. The statement of it criticised ends with the words "vary in the different compounds according to very simple numerical proportions." Consider $C_{60}H_{122}$ and $C_8H_{14}$ (*i.e.* $C_{60}H_{105}$); can the ratio 122 : 105 be called "very simple numerically"? Few pairs of compounds obey the "law." Though Dalton's atomic theory was only accepted by chemists generally after half a century of controversy, and is at present rejected by a few, in the two pages devoted to it in "Stoichiometry" the difficulties of the theory are not even mentioned. It is to be hoped that these blemishes may be removed in a future edition from a book which gives such an up-to-date and adequate account of a large part of physical chemistry, and is one of the volumes most needed of a valuable series.

T. H. L.

## NEWTON'S PHILOSOPHY.

*La Philosophie de Newton.* By Dr. Léon Bloch. Pp. 642. (Paris: F. Alcan, 1908.) Price 10 francs.

THE subject of this book is Newton's "philosophy" in the large sense in which Newton himself understood that word, not in the narrower sense which is now usual. The author passes in review practically the whole of Newton's contributions to science, giving in each case their antecedents, their method, and their outcome. His historical accounts of previous discoveries, with the consequent estimates of Newton's contribution, are usually excellent, and in his exposition of Newton's ideas he is in general very faithful to his original.

M. Bloch's successive chapters, dealing with different parts of Newton's work, have a certain similarity of structure. They generally begin with Descartes, and show the element of arbitrary hypothesis in his views. Then, after some account of intermediate writers, they point out how Newton proceeded by the right inductive methods, collecting his laws and definitions from facts, and verifying their consequences by experiments. The hypotheses which he objected to, it is said, were not hypotheses used as such, but hypotheses used as though they were known to be true. It was still customary to object to a new theory, based on observation and experiment, not that it failed to explain the facts, but that it contradicted the maxims of the illustrious So-and-So. This attitude seems strange to us, because it has so completely died out in science. But it still survives in philosophy, where emphatic assertion is one of the accepted methods of proof; and from this analogy we can understand Newton's attitude and the progress it involved. M. Bloch's scheme involves some unnecessary repetitions, and one gets a little tired of the merits of induction. But substantially what he says on this subject seems just. While attributing to Bacon a great influence in forming Newton's ideas of method, he explains the two respects in which Newton surpassed Bacon's precepts, namely, that his methods were quantitative, and that he realised the part which deduction plays in induction.

Where the book is least satisfactory is on the side of logical analysis. Thus in regard to fluxions, he points out, very justly, how Newton conceived a fluxion physically, and how he often inferred the existence of limits, in problems where his mathematical apparatus was insufficient to prove it, from the fact that he was dealing with physical problems which must have definite solutions. But M. Bloch does not adequately discuss the postulates involved, or consider how, from a modern point of view, one could justify practically a procedure such as Newton's. He seems more or less unaware of the gulf which nowadays separates the pure mathematician's account of the calculus from the physicist's use of it, and therefore cannot deal thoroughly with the very interesting question as to how this gulf is to be bridged. To take another illustration; he gives an account of Newton's views on absolute space, time, and motion, and quotes the experiment of the rotating bucket of water, by which absolute rotations are to be discovered. But instead of endeavouring, after the example of many previous writers, to refute in detail the inferences drawn by Newton from this experiment, he contents himself with pointing out the dynamical irrelevance of absolute *translation*, and extending this by means of generalities to absolute *rotation*. The truth seems to be that he, in common with many moderns, is here indulging in an hypothesis of just that kind which Newton endeavoured to avoid: absolute rotation is impossible *a priori*; therefore, if the facts require it, so much the worse for the facts.

There are an unusual number of misprints, and some of them seem to be among the references. In spite of blemishes, however, the book is careful and erudite, and on the historical side very useful.

## OUR BOOK SHELF.

*The Common Bacterial Infections of the Digestive Tract and the Intoxications arising from Them.* By Prof. C. A. Herter. Pp. xii+360. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1907.) Price 6*s*. 6*d*. net.

THIS book forms a valuable summary of our knowledge of many of the bacterial infections of the digestive tract, and of the conditions resulting therefrom—valuable alike to the bacteriologist, the chemist, and the clinician. It commences with a review of the normal bacterial flora of the digestive tract, and the significance of the presence of bacteria is first discussed. It is shown that the intestinal bacteria are not required to carry on the ordinary digestive processes and normal nutrition, and the conclusion is formulated that the chief significance of the obligatory intestinal bacteria lies in their potential capacity for checking the development of other types of organisms capable of doing injury.

An interesting section deals with the differences in the bacterial flora of the intestine in nurslings and in bottle-fed infants; the number of bacteria is found to be considerably greater in the latter, and a majority of the organisms present are Gram-negative instead of Gram-positive, as is the case in nurslings. Another feature of interest which is well brought out is that in old age a greater number of putrefactive becteria are present than in youth. The origin and precise significance of this difference is not yet clear, but it suggests that intestinal infections stand in a causative relation to old age, an hypothesis recently advanced by Metchnikoff, and the author confidently states that the onset of senility may be distinctly accelerated through the development of intestinal infections in which putrefactive anaërobes are prominently represented. A number of details are given for the analysis of the intestinal contents, and of the significance of the data derived therefrom, together with hints as to treatment. R. T. HEWLETT.

*National Antarctic Expedition*, 1901-4. "The Charts of the *Discovery* Antarctic Expedition." By Lieut. G. F. A. Mulock. (London: Royal Geographical Society, 1908.)

THE charts illustrating the work of the National Antarctic Expedition, compiled by Lieut. G. F. A. Mulock, R.N., surveyor and cartographer to the expedition, have now been issued by the Geographical Society in the form of one of its supplementary publications. The series consists of a general chart of the Ross Sea and its coasts, and five on a larger scale showing the detailed geographical work of the expedition. The maps are clearly printed in three colours, the ice-coloured regions being shown in blue, the bare rocks in brown, and routes and altitudes in red; they are folded, and issued in a convenient cloth case, 10 inches high by 6¾ inches wide. They are accompanied by a short statement of eight pages recording the methods of survey and chief determinations, in which Lieut. Mulock gives credit to his colleagues for their contributions to the work, referring especially to Ferrar's survey of the Ferrar glacier, Bernacchi's determination of the longitude of the winter quarters, Dr. Wilson's sketches of the coast, and Lieut. Skelton's photographs.

The three charts of most interest are those including the Great Ice Barrier and the route of Captain Scott's remarkable sledge journey on to the plateau of southern Victoria Land. Lieut. Mulock retains the name the Great Ice Barrier, and adopts it for the whole ice sheet of which Ross discovered the northern face. Notes on the chart direct attention to the convincing evidence that the edge of this ice sheet is floating, and also of its recession at one place for twenty-three miles since it was discovered by Ross. Confidence in the latter fact is strengthened by Lieut. Mulock's testimony to the remarkable accuracy of Ross's positions. On a second chart the author shows the extension of Ross's Great Ice Barrier to the south, with the route of Scott and his two companions to their farthest south at the entrance to Shackleton Inlet, and of the face of the mountains on the western coast of that part of Antarctica.

Lieut. Mulock is to be congratulated on the skill and care with which he has incorporated all the observations of the expedition into this important series of charts, which are a most valuable addition to Antarctic cartography. J. W. G.

*Archhelenis und Archinotis. Gesammelte Beiträge zur Geschichte der neotropischen Region.* By Herman von Ihering. Pp. iv+350. (Leipzig: W. Engelmann, 1907.) Price 6 marks.

FEW and far between are the naturalists in South America. But there are exceptions even to this rule. Good work has been done of late years in Buenos Ayres and Parà, and the author of the present volume has not failed to avail himself of the abundant opportunities offered to him for research by the luxuriant fauna and flora of his adopted country. Dr. Herman von Ihering, the energetic director of the Museu Paulista at São Paulo, is well known to us in Europe by his essays on various subjects connected with the distribution of life in different parts of the world, particularly as regards the neotropical region. He has now collected these essays and reprinted them with additions in a uniform shape under the curious title which we give above. "Archhelenis" and "Archinotis" are names invented to designate the two principal continents which the author believes to have existed in the age of the Chalk, as shown in the map at the end of the volume. Three corresponding names (*Archiplata, Archibrasilia,* and *Archiguiana*) are proposed for the ancient bosses from which the whole continent of South America appears to have been developed, and are explained according to the author's views in his essay on the palæogeography of that region.

Three chapters of Dr. von Ihering's volume treat of the geographical distribution of river-mussels, and are also of some importance, as the author is a leading authority on this subject. Written in 1890, they were translated into English and re-published in the *New Zealand Journal of Science.* The fresh-water molluscs of Chili show many points of affinity to those of New Zealand, and the author agrees with Captain Hutton's views that in the Lower Cretaceous period a large Pacific continent must have extended from New Guinea to Chili, and sent out a peninsula to include New Zealand.

Those who are engaged in the study of the difficult problems presented by palæogeography will do well to consult the memoirs collected by the author in the present volume.

*The Moon, a Popular Treatise.* By Garrett P. Serviss. Pp. xii+248; illustrated. (London: Sidney Appleton, 1908.) Price 6s. net.

IN describing the Yerkes photographs of the moon Mr. Serviss has had a pleasant task, and has performed it with pleasing results. The text involves a selenologist, a lady questioner, and the excellent photographs of the moon taken on successive evenings throughout an entire lunation by Mr. Wallace with the 12-inch telescope of the Yerkes Observatory. The author has managed to keep the questions in the background whilst making the answers very lucid and impressive. In an introductory chapter the dialogue turns on the distance, size, motions, &c., of our satellite; thenceforward it takes each photograph of the moon in turn, and gives a simple, straightforward account, in popular language, of the various features, introducing, at well-timed intervals, asides on geometrical, photometrical, and such-like questions. Then follows a chapter (iv) dealing with some of the larger individual features of the lunar surface, as shown on the large-scale photographs taken by Mr. Ritchey with the Yerkes 40-inch refractor.

The exquisite photographs well reproduced—and the easily readable text of this volume should ensure it a welcome from all classes of readers, whether they be astronomers or not. There are twenty-one photographs in the first series and five of the enlarged portions, besides a number of diagrams in the text.

W. E. R.

*The Apodous Holothurians.* By H. L. Clark. Smithsonian Contributions to Knowledge. Part of vol. xxxv. Pp. 231. (Washington: Smithsonian Institution, 1907.)

THE author of this valuable memoir has had the advantage of studying more than two thousand specimens of the species included in the families Synaptidæ and Molpodadiidæ, and he has taken the opportunity of collecting together in the form of a handsome volume the information we possess concerning all the species of this interesting group. There are three coloured and ten monochrome plates of figures, illustrating the form and anatomy of the different species, of which several are original, and the others copied from the works of Semper, Theel, Sluiter, and other zoologists. Eight new genera are described, and a new generic name is proposed for an old genus. The monograph will undoubtedly be of great service to all those who are interested in the study of the Echinodermata.

### Elimination of Self-coloured Birds.

STATISTICAL data on the real value of colour markings in the survival of animals in the field are so uncommon that the publication of the following fragment may be excused.

At the Station for Experimental Evolution, about 300 chicks of from five to eight weeks of age on May 10 were running at large on a well-cropped pasture about three acres in area. For the most part, within the space of less than two hours, twenty-four of these were slaughtered by three crows which were caught in the midst of their work of chasing and killing the young poultry. A close estimate of the fowl as they ran at large shows that about 40 per cent. were of a white plumage, 40 per cent. black or nearly so, and 20 per cent. had a pencilled or striped marking more or less like that of the female jungle fowl or ordinary game. The interesting question arose, Was there any elimination on the ground of colour by the crows? Did any colour favour the escape from observation of any of the chicks?

Were there no selective elimination, expectation on the ground of chance is that of the twenty-four killed 9·6 would be white, 9·6 black, and about five pencilled. *Actually,* there were killed ten whites, thirteen blacks or prevailingly so, and one coarsely mottled grey and buff. No true pencilled bird was killed! The killed birds were largely Leghorns, Minorcas (both good fliers); the pencilled birds were partly games (good fliers), but mostly dark Brahmas (poor fliers). The race is not always to the swift! This fragment, then, so far as it goes, indicates that the self-colours of poultry, which have arisen under domestication, tend to be eliminated by the natural enemies of these birds, and the pencilled birds are relatively immune from attack because relatively inconspicuous.

### "Barisàl Guns" in Western Australia.

IN NATURE of October 31, 1895, Sir George Darwin, in a letter on "barisàl guns," "mist pouffers," and allied noises, desires all those hearing such to record them from time to time. Recently an instance, which may be of this nature, came under my notice, the only apparent difference being that it was a single noise, and was not repeated several times.

It happened that in July, 1907, I was dispatched by the Government of Western Australia to a remote portion of the north-west of that State to carry out certain investigations. We were camped for two months on the Strelley River (lat. 20° S.)—which only runs in flood-time—sixty miles from Port Hedland, and the same distance from Marble Bar. The situation was a desert "spinifex" plain, with occasional low hillocks of granite boulders, and uninhabited, save by occasional sheep and cattle stations, between the two places mentioned. At approximately 8.35 p.m., mid-West Australian time, on Friday, August 9, I was lying in the tent when, in the words of my diary, "we suddenly heard a dull roar lasting several seconds, increasing in loudness and then decreasing. Everyone heard it and looked round. The sky was quite clear, and there were no signs of thunder clouds. There was no apparent tremor. I thought the noise came from the S.E., others from the N.E. Some suggested it was the rumble of a herd of cattle galloping over a clay pan with hollow ground beneath, as they hear similar noises in the Kimberley District (W. Australia). Mr. G. and I wonder if it is due to a volcanic eruption somewhere, as that of Krakatoa was heard not very far from here." Next day "some men camped twenty miles west from here inquired if we had heard the rumble last night: it appears their Afghans jumped up and said 'buggy coming.' Whatever the sound was, it was not caused by cattle galloping."

The sound resembled a distant, prolonged peal of thunder or the discharge of a far-away piece of ordnance or mine explosion. The nearest working mines would be about sixty miles away, the sea about fifty miles, and it is needless to say there is no artillery within hundreds of miles. No noticeable meteor was seen by anyone, and had the noise been due to this, would it have been heard at places twenty miles apart? It might have been due to an earthquake, but no tremor was noticed.

I have heard from ear-witnesses of dull sounds resembling this being heard in the Kimberley district of this State. At the time, a black-fellow said, "Hill tumble down," and next day they found that great masses of rock had fallen. This might, perhaps, be accounted for in part by the unequal temperatures between day and night—the day very hot, the night very cool. Though the days in August were hot (about 90° F. in the shade) and the nights very cool (requiring several blankets in the early morning), the nearest hill to us was four miles at least away to the east.

Was this, then, an instance of the phenomenon known as "barisàl guns" on the Brahmaputra and "mist pouffers" off Belgium?

Mr. W. E. Cooke, the Government astronomer, to whom I forwarded an account of the phenomenon with the above inquiry, advised me to record it according to the wish of Sir George Darwin. J. BURTON CLELAND.

Department of Public Health, Perth, W. Australia, April 16.

## Welsh Saints and Astronomy.

THERE were in Anglesey two contemporary saints who were in the habit of meeting together at a spot mid-way between their respective abodes. One was called Seiriol Wyn, "Seiriol the White or Bright," the epithet signifying his coming from the east, the region of sunrise. He had his abode on Puffin Island, on the extreme east of Anglesey. The other saint was called Cybi, and because he travelled to meet his friend from the west he was called Cybi Velyn, "Cybi the Yellow." He lived on Holy Island, at Caer Gybi, "Cybi's Camp," the Welsh name of Holyhead. Their place of meeting was in the parish of Llandyvrydog, where there are two springs called Ffynnon Cybi and Ffynnon Seiriol, which are referred to by Matthew Arnold.

> "In the bare midst of Anglesey they show
> Two springs which close by one another play,
> And 'thirteen hundred years agone,' they say,
> 'Two saints met often where these waters flow.'"

Cybi, known in Cornish literature as Kebie, seems to have reached Wales from Cornwall. His wanderings and settlements are curiously coincident with the distribution of the cromlech areas in Wales. On further inquiry one finds that Cybi and Seiriol were regarded as astronomers, and that their places or settlements in Wales may be regarded as observatories.

In an ancient poem, to an extract from which I find the reference "Archaiol. vol. ii. p. 38," they are numbered among the "seven cousin saints," the others being Dewi, Beuno, Dingat, Cynvarch, and Deiniol. "Those are the seven . . . who have been in (or who entered) the Stone (of round form? 'graen grynder'), and the seven who numbered the stars." The expression "a fu'n y Maen," "who have been in the Stone," must be taken in the sense that they had entered a stone chamber or circle, and it is hard to find any meaning to the phrase unless a cromlech or stone circle is meant, especially when read in connection with numbering the stars. Thus it may fairly be taken that the leading saint-astronomers of Wales are spoken of as having made an astronomical use of stone monuments. This inference is confirmed by the fact that the Cybi churches in Wales, and most likely churches associated with the names of the other six saint-astronomers, preserve in their relation to adjoining churches the cromlech astronomy, especially the May-November year. JOHN GRIFFITH.

## Meteors from $\kappa$ Draconis in May.

ON May 31, 10h. 40m., I saw amid the gathering clouds nearly overhead a very short third-magnitude meteor close to its radiant at $193°+74°$. I had never previously remarked any indication of this shower at the end of May or in June, though it seems continued in an intermittent manner from July to December, and on January 19, 1887, I recorded four meteors from $191°+72°$. There is another winter shower near, viz., at $194°+67°$, from which I saw seventeen meteors on December 18–28, 1886.

A bright, doubly observed meteor seen in 1893 by Corder and myself had a radiant at $186°+74°$. This shower is one of the most interesting of those in the circumpolar region. It is, unfortunately, omitted in the diagram of Ursid radiants facing p. 292 in the Gen. Cat. Radiants, vol. liii. of the Memoirs.

The straggling constellation Draco contains many showers, and some of these are visible over long periods. Thus meteors continue to fall from a centre at about $261°+63°$ during the whole year.

Bristol, June 1. W. F. DENNING.

## FORMATION OF GROUND- OR ANCHOR-ICE, AND OTHER NATURAL ICE.

THE formation of ice on the bottom of a river or stream has occasioned much comment and often scepticism in the minds of scientific men. Instead of ice forming on the surface of the water and growing downwards, we find, in circumstances now well understood, ice forming on the bottom and growing upwards. The phenomenon has been observed in all countries where ice is formed, and has been given various names. In Europe it is called ground-ice or bottom-ice (glace-du-fond, grund-eis), but we often find local names, such as ground-gru and lappered-ice. The term anchor-ice evidently originated in America, for the first record of its use seems to be by a writer in the "Encyclopædia Americana," published in 1831. The term is universally used in the United States and in Canada.

There are many early records of the appearance of ground-ice. It was seen by Hales in 1730 in the Thames. Ireland, in his "Picturesque Views" of the Thames, published in 1792, speaks of ground-ice, remarking, "the watermen frequently meet the ice meers or cakes of ice in their rise, and sometimes in the underside enclosing stones and gravel brought up by them ad imo." It was observed in the Elbe as early as 1788, in the Rhine at Strassburg in 1829, and in the Seine, by Arago, in 1830. So much interested was Arago in the ice that, for the benefit of the doubting savants of his time, he published in France, and in the *Edinburgh New Philosophical Journal* for 1833, an account of his observations. Other interesting papers on the same topic were published about that time. In the same Edinburgh journal we find, in 1834, a paper by the Rev. Mr. Eisdale. Two very interesting and instructive papers were published in the Phil. Trans. for 1835 and 1841 by the Rev. James Farquharson, F.R.S., of Alford, of his observations on the Don and the Leochal.

In Canada the formation of anchor-ice has been given much study, largely owing to its great abundance and economic aspect. For the same reason, much attention has been devoted to it in Russia by prominent engineers, notably by M. Leon Wladimirof in his study of the ice conditions in the Neva.

Nowhere can be witnessed a more wonderful sight of the delicate poising of the forces of nature than in a river like the St. Lawrence, with the advent of the winter season. In November, when the temperature of the water arrives at or near the freezing point, the manufacture of ice begins, and for a period of nearly five months the temperature of the water remains almost stationary. During this time a tremendous struggle goes on between water and ice, growing more severe as the air temperature falls further from the freezing point. The outward calm of the ice-bound river gives no indication of the contest beneath, but it is only during the annual spring break-up that the volume of existing ice is realised. At that time the river frees itself from its icy burden in a few days by a mighty shove, which is viewed by thousands along the river shore at a safe distance from the relentless piling of great ice-blocks.

In all the quieter parts of the river, surface-ice forms into a sheet, and protects the water from excessive loss of heat. Wherever the water flows too swiftly for the surface sheet to form, the comparatively warm water is exposed to the winter weather with all its severity. Ice-crystals are produced all along its surface, and are carried under by the currents, to be whirled about for miles, until finally swept under the barrier-ice at the beginning of quiet water. There they rise and become attached to the under-side of the surface sheet, building downwards immense hanging dams, which form as effective a barrier to the flow of the river as so much rock. Winter floods and ice shoves are the result of this packing of the ice, and, in one part of the St. Lawrence, the damming is so complete as to change the course of the river every year. The natives call this fine ice "frazil," meaning cinder-ice, and this term has now come into general use in Canada.

During the ice survey of the river by the Montreal Flood Commission in 1886, it was revealed that the packing of the frazil extended to the bottom in many places, giving an unusual amount of solidity to the surface sheet. In one case, a depth of 80 feet of solidly packed frazil was measured. Hanging dams of the ice are observed to a greater or less extent for a distance of twelve miles below the barrier-ice at the foot of the Lachine Rapids, and the magnitude of the ice accumulation may be realised when it is stated that the winter level of so mighty a river as the St. Lawrence, which is two miles wide at Montreal, is twice as high as in summer.

A careful study of the winter river temperature by means of very delicate instruments has revealed the fact that the formation and growth of the ice is an accompaniment of a minute temperature depression in the water of the order of a few thousandths of a degree. When the temperature equilibrium of water and ice is upset by this minute amount, fresh ice-crystals are formed, and, being supercooled, adhere to anything in their path which is likewise supercooled. In this way large quantities of anchor-ice are formed on the stones and boulders over which the ice-laden water sweeps. The crystals themselves stick together and form frozen masses. When carried through the rack or screen at the intake of a power-house they freeze to it, and rapidly choke the free water-way. They stick to the turbines, and glue the wheels fast in a short time. When the temperature equilibrium of the river is restored, the ice no longer adheres, and a rise of a few thousandths of a degree above the freezing point changes the ice to a mass of a soft and spongy consistency, capable of passing easily through the most delicate machinery.

It may be said that the whole condition which determines the rapid formation of ice in its harmful adhesive condition hinges on this temperature balance in the water. Since this important fact has been recognised, effective means have been devised for the judicious application of heat about the vulnerable parts of a power-house during such time as supercooling exists. There is no need to melt the ice or to warm the total volume of water flowing, so long as the machinery itself is prevented from falling in temperature with the water. The ice is as effective as water in producing a head. What the engineer has to guard against is that the ice does not stick in its passage through the turbines.

Fig. 1 shows the interior of a penstock, or wheel-pit, after it has been completely blocked with frazil ice. At the time of this photograph the stop logs had been introduced at the rack, the water removed, and more than one-half the frazil-ice shovelled out. This condition is a result of the slight supercooling of the machinery by the water. Where artificial heat is used, conditions like this no longer occur.

The greatest factor for preventing this minute supercooling in the water is the absorption of the sun's radiant heat. During the sunny hours of the day no ice troubles are ever experienced, no matter how low the air temperature may be. Nocturnal radiation, on the other hand, is one of the most effective agencies in supercooling the water and objects immersed in it. Anchor-ice is formed by this means in large quantities, and it has been known to grow on the river bottom before the temperature of the water itself had reached the freezing point. During cold, clear nights

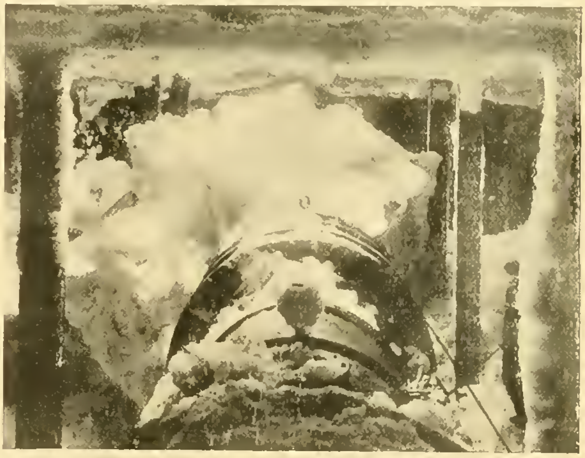

FIG. 1.—Interior of a penstock or wheel pit after the water has been removed, showing the accumulation of adhesive frazil ice.

anchor-ice forms in large quantities. When the air is cold enough to produce supercooling in the water, frazil crystals adhere readily to the anchor-ice and assist in building it up. On cloudy nights, anchor-ice does not usually form, unless the supercooling is great enough to bring the bottom of the river into a supercooled condition. A bridge is found to protect the river bottom from anchor-ice, and even in the severest weather the anchor-ice is always less thick under such a covering.

Anchor-ice is never found to grow under surface-ice. When produced previous to a surface sheet, which in some places does not form until the severest weather, the masses are detached by the natural heat of the earth, and rise to the under-side of the sheet. This has been observed extensively by M. Wladimirof, who has found in such cases an exact correspondence between the line of attached masses under the surface-ice and the river bottom.

Farquharson observed, in the small Scotch streams, that overhanging weeds protect the bottom from the frost, just as a tree will protect the ground from the dew or hoar-frost deposited at night.

The sun's rays are effective in detaching the anchor-ice from the bottom. On a clear morning in winter, as soon as the sun rises, the open surfaces of the St. Lawrence become dotted over with large masses of anchor-ice, which rise high out of the water by the impetus they attain, and sink back with a characteristic noise. Large boulders frozen to the masses are frequently brought up and carried in the currents.

FIG. 2.—Anchor-ice grown up from the rocks and protruding above the surface of the Ottawa river.

When the day is cold and cloudy, anchor-ice does not rise, but builds from the frazil in the water.

Boatmen are careful not to cross the river when anchor-ice is rising for fear of having a mass come up under the boat and carry it helplessly into a rapid or over a waterfall.

The limit of depth below the water-level where anchor-ice will form appears to be roughly about 40 feet, but in the clear waters of the Gulf of St. Lawrence it has been observed as deep as 70 feet. Twenty feet below the surface, anchor-ice will often attain a thickness of 5 or 6 feet during prolonged cold weather. When seen through the water, the growth resembles nothing more closely than the weeds that are found in the shallower portions in summer. Anchor-ice grows in arborescent forms, and with more abundance on dark-coloured rocks, although when it becomes very thick the radiation takes place chiefly from the ice-surface itself. During mild weather, especially with rain, practically all the anchor-ice is detached from the bottom, and this has been shown to accompany a slight temperature elevation in the water above the freezing point.

Fig. 2 shows an ice bridge on the Ottawa River in the process of formation. The anchor-ice may be seen protruding above the water in the shallower parts, and frazil-ice may be seen floating in the current.

Fig. 3 shows the spillway and waste weir of a large power station. Anchor-ice to which frazil has adhered may be seen under the water surface and in places protruding above. The thickness of ice on the crest was from 18 to 22 inches at the time the photograph was taken. In the background men may be seen with long rakes scraping the frazil-ice off the rack-bars or screen through which the water passes to the turbines.

When turbines are operated under very high heads, the supercooling of the water is corrected by the heat generated during the fall and the lowering of the normal freezing point by pressure. Power-houses so situated are seldom troubled with adhesive ice. Many power-houses are fortunately situated so that water is drawn from deep ice-covered channels, where frazil or anchor-ice cannot form, but for nearly all there are times, at the outset of cold weather, before the surface-ice forms, when trouble is encountered. For these and for all water-works situated below permanently open water, steam or electric heating must be resorted to at times, if interruption to the operation is to be avoided.

Through the good work of Mr. John Murphy, M.A.I.E.E., of the Department of Railways and Canals, Ottawa, practical and effective devices are now available for overcoming ice troubles, and in place of expensive auxiliary steam plants for carrying the load during the frazil season, with their corresponding large consumption of coal, a modest steam boiler, or a small amount of electrical energy—usually available in excess—proves an effective means of keeping the plant running smoothly.

To the practical superintendent of a power-house the idea of a thousandth of a degree has little meaning, and yet there is no doubt that the ice problem, as it is presented in the development of "white coal" in northern countries, depends on just such minute changes of temperature.

FIG. 3.—Spillway and waste weir of a power station showing anchor-ice. The thickness of ice on the crest of the spillway is from 18 to 22 inches.

It has been thought that the ice conditions in Canada might detract from the value of the vast water powers available for power purposes, but, from a scientific study of the conditions underlying the formation of ice, it is safe to say that no such bar exists.

H. T. BARNES.

## TELEGRAPHIC PHOTOGRAPHY AND ELECTRIC VISION.

THE success achieved by Dr. A. Korn in the telegraphic transmission of photographs (NATURE, vol. lxxvi., p. 444) has been followed by a remarkable development of inventive activity in the same line. Among several new processes which have recently claimed public attention three of the most promising were described in detail at the April meeting of the Société Française de Physique. As in Dr. Korn's method, the reproduced picture is in all cases constituted by a close spiral line of varying intensity traced upon a photographic film, or other material, covering a cylinder which rotates synchronously with another cylinder in the transmitting instrument. The use of selenium for controlling the resistance of the circuit is, however, generally discarded, the requisite variations of current being effected by purely mechanical means; ordinary film negatives, therefore, cannot be used.

In M. E. Belin's process, which he calls "Téléstéréographie," the original picture is a thickly coated gelatin-bichromate print, which has the form of a relief, lights being represented by elevations of the surface, and shades by depressions. The print is wrapped around the transmitting cylinder, which rotates uniformly, and at the same time moves slowly in a direction parallel to its axis. A sapphire point attached to the short arm of a lever presses lightly upon the picture, and is caused to move in correspondence with the contour of the surface. At the end of the long arm of the lever is a contact piece which slides over the edges of a series of thin copper plates, separated by sheets of mica, and connected with resistance coils, the whole constituting a rheostat capable of interposing in the circuit a resistance ranging from 0 to 4000 ohms in 20 steps. The current, regulated in accordance with the undulations traversed by the sapphire point, passes at the receiving station through an aperiodic reflecting galvanometer, such as Blondel's oscillograph. A beam of light concentrated upon the galvanometer mirror is reflected to a convex lens so placed as to project an image of the mirror over a small hole in the side of a light-tight box, inside which rotates the receiving cylinder covered with a photographic film. Between the hole and the lens, and close to the latter, is inserted an "optical wedge," consisting of a sheet of glass tinted by gradations from perfect transparency at one end to opacity at the other. A slight deflection of the mirror displaces the reflected rays from the centre of the lens towards the edge, and causes them to pass through a different part of the optical wedge; thus the intensity of the projected image of the mirror, and therefore of the photographic action upon the film, is varied in correspondence with the strength of the current. Photographs measuring 13 cm. by 18 cm. were transmitted by this apparatus over a double-wire telephone line in 22 minutes.

For use in Carbonnelle's instrument, the "Téléautograveur," the photograph is submitted to a treatment, details of which are not published, whereby the electrical conductivity is varied locally, being greater in the shades than in the lights. The picture is mounted upon the transmitting cylinder, and a stylus bearing upon the surface is joined to one of the line-wires. The receiving cylinder is covered with a sheet of soft metal, gelatin or celluloid, or simply by several sheets of white paper separated by carbonic paper. The sheet is acted upon by a graving point attached to the diaphragm of a telephone, which is in circuit with the transmitting apparatus. This process is said to give very satisfactory results, and to be remarkably rapid, a portrait 9 cm. by 7 cm. having been reproduced over a distance of 90 kilometres in 88 seconds.

A picture adapted for transmission by M. Pascal Berjonneau's "Téléphotographe" is prepared as a cylindrical half-tone block, the surface consisting of a multitude of metallic points, the density of which varies with the lights and shades. The block rotates under a stylus in the usual way, regulating the current which passes over the line. At the receiving station a galvanometer actuates a shutter which allows more or less light to pass through a small aperture to the photographic film. It is claimed for this apparatus that it is the only one which can be operated satisfactorily on an ordinary telegraph line, all others requiring a telephone line with metallic return. The time occupied in sending a portrait from Paris to Enghien by a single wire is said to have been 247 seconds.

The problem of telegraphic photography is often associated in the popular mind with that of distant electric vision, or "seeing by electricity," as it has been called. According to a telegram from the Paris correspondent of the *Times*, dated April 28, the latter problem is now engaging the attention of M. Armengaud, president of the French Society of Aërial Navigation, who "firmly believes that within a year, as a consequence of the advance already made by his apparatus, we shall be watching one another across distances hundreds of miles apart." It may be doubted whether those who are bold enough to attempt any such feat adequately realise the difficulties which confront them. The telegram referred to seems to contemplate the transmission of optical images over an ordinary telegraph or telephone line by a method in which advantage is taken of visual persistence. A necessary condition would be that the sensitive substance—selenium or other photoelectric body—should pass at least ten times per second over every unit of the surface upon which the image to be transmitted is projected, while at the distant station electrical connection is established, also ten times per second, between the line wire and every individual element in succession of the apparatus illuminating the receiving screen; and the synchronism of the arrangement must be so perfect that at the moment when the sensitive substance occupies any given unit area on the surface of the transmitter, connection must be made with the corresponding unit in the receiver. The difficulty imposed by this condition depends chiefly upon the necessarily large number of the units of area to be dealt with. Suppose that the image is received upon a screen no greater than 2 inches square; if its definition is to be as perfect as that presented by the eye or by a good photograph, the number of elements required would amount to about 150,000, and the synchronised operations to a million and a half in every second. If we are satisfied with a definition equal to that of the coarse half-tone pictures to be found in some of the daily newspapers, the necessary number of elements might be reduced to 16,000, and that of the synchronised operations to 160,000 per second. Even this would be wildly impracticable, apart from other hardly less serious obstacles which would be encountered. The number of operations might, of course, be greatly diminished by employing an oscillating or rotating arm, carrying a row of sensitive selenium cells, as was proposed by Profs. Ayrton and Perry nearly thirty years ago. For a coarse-grained picture 2 inches square 120 of these might suffice; but such an arrangement would require 120 line wires, and would also introduce a new series of troubles.

But although the problem is apparently incapable of solution upon the lines indicated, there is no reason beyond that of expense why vision should not be electrically extended over long distances. The only method which can be regarded as feasible (unless, indeed, M. Armengaud has made a revolutionary discovery) is that suggested by the structure of the eye itself; the essential condition is that every unit area of the transmitter screen should be in permanent and independent connection with the corresponding unit of the receiving screen. This idea would naturally present itself to anyone approaching the subject for the first time, but would probably be rejected in favour of something apparently more simple. Such an apparatus could, however, be constructed without any serious complexity apart from that arising from the mere multiplication of its components. I have made a rough estimate of the cost, assuming the stations to be 100 miles apart, the received picture to be 2 inches square, and the length of a unit to be 1/150 inch. Of each of the elementary working parts—selenium cells, luminosity-controlling devices, projection lenses for the receiver, and conducting wires—there would be 90,000. The selenium cells would be fixed on a surface about 8 feet square, upon which the picture would be projected by an achromatic lens (not necessarily of high quality) of 3 feet aperture. The receiving apparatus would occupy a space of about 4000 cubic feet, and the cable connecting the stations would have a diameter of 8 or 10 inches. The thing could probably be done for 1,250,000*l.*, but not for much less. By an application of the three-colour principle it would be possible to present the picture in natural colours, like that shown upon the focussing screen of a camera. The cost would in that case be multiplied by three.

SHELFORD BIDWELL.

## *ARISTOTLE AND NATURAL SELECTION.*

A PASSAGE of Aristotle's "Physics," in which he alludes to the theory of natural selection, has been frequently quoted and almost as frequently misinterpreted. It may therefore be worth while to devote a short space to a careful consideration of its import.

The passage in question is in the "Physica Auscultatio," ii., 8, §§ 1–6. In it Aristotle begins by asserting the existence in nature of final causes (*ἕνεκά του αἰτία*). He next considers objections that may be brought against this view, as, for example, that rain falls simply in obedience to natural law (*ἐξ ἀνάγκης*) and not for the sake either of making the corn grow or of spoiling it when cut. So, too, the supposed objector proceeds, with the parts or organs of animals; what is to prevent us from saying that the teeth originate in their various forms of incisors and molars simply by the operation of natural law? That they are serviceable respectively for cutting and grinding is not purposeful, but coincidental (*οὐ τούτου ἕνεκα γενέσθαι, ἀλλὰ συμπεσεῖν*). The existence of these apparent adaptations, the objector adds, can be accounted for by the fact that, as Empedocles has pointed out, those organisms that are unfitted for their conditions do not survive, but perish.

It will be seen from the foregoing that Aristotle does not advance the theory of natural selection as part of his own explanation of adaptation in nature, but as a principle that might be used to reinforce an alternative view.

We may now turn to his answer. The objection, he replies, will not hold, because things that arise naturally (*φύσει*) always, or nearly always, come about thus; *i.e.*, like the teeth, already adapted and fit to survive; while beings such as the unadapted monsters imagined by Empedocles originate, if at all, by chance or spontaneously (*ἀπὸ τύχης καὶ του αὐτομάτου*), and are, Aristotle would say, outside the ordinarily observed course of nature. It cannot be alleged, he goes on to point out, that such phenomena as rain and warm weather are altogether dependent on chance or coincidence (*ἀπὸ τύχης οὐδ᾽ ἀπὸ συμπτώματος*). Warm weather is the rule in the dog-days, and rain in winter. Everyone admits that things of this kind are in accordance with the ordinary course of nature; and if they occur in this regular way neither of themselves (like monsters) nor by mere coincidence (like unseasonable rain) it remains that they must exist for some purpose (*ταῦτ᾽ ἕνεκά του ἂν εἴη*). It must then be concluded that final causes exist in reference to natural products (*ἔστιν ἄρα τὸ ἕνεκά του ἐν τοῖς φύσει γιγνομένοις καὶ οὖσιν*).

Whatever may be thought of Aristotle's argument, it is clear that his general object throughout this passage is to defend his doctrine of final causes (it is to be observed that he does not say that final causes are of universal operation). He is unable to fall in with the view of natural selection as propounded by Empedocles, because, as it appears to him, adaptations are produced ready-made; the non-adapted is not merely eliminated, but seldom comes into existence at all. He seems, however, to admit that for those who believe (as he does not) in a purely fortuitous origin of natural objects, the hypothesis of natural selection affords a feasible explanation of adapted structures.

The erroneous views that have been taken of this passage by various writers have been due, I think, to the general failure to recognise that the whole of sections 2, 3 and 4 are devoted to Aristotle's statement of a possible objection to his own opinion. Thus Gomperz ("Griechische Denker," xiv., pp. 103, 104; Leipzig, 1908), although he clearly states Aristotle's position with regard to the Empedoclean monsters, nevertheless quotes the sentence about the rain and the growing corn as if it gave Aristotle's own explanation instead of the plea of an opponent. Osborn ("From the Greeks to Darwin") falls into the same error; the author of a pamphlet (*Αἱ τῶν* Lamarck *καὶ* Darwin *Θεωρίαι παρὰ τῷ Ἀριστοτέλει*), lately published at Athens, has similarly missed the point; nor has Darwin himself escaped the like misapprehension, for which probably the translator on whom he relied was responsible ("Origin of Species," note to "Historical Sketch" in the later editions). On the other hand, the general drift of the passage was rightly appreciated by G. H. Lewes, though the confusion of ideas with which he taxes it belonged, perhaps, rather to his own mind than to that of Aristotle.

F. A. DIXEY.

## *NOTES.*

WE notice with deep regret that Sir John Evans, K.C.B., F.R.S., died at his residence, Britwell, Berkhampsted, on Sunday, May 31, in his eighty-fifth year.

SIR GEORGE DARWIN, K.C.B., F.R.S., and Prof. E. B. Tylor, F.R.S., have been elected corresponding members of the Vienna Academy of Sciences.

THE twenty-fourth Congress of the Royal Sanitary Institute will be held at Cardiff on July 13–18, under the presidency of the Earl of Plymouth. In addition to sectional meetings, there will be a number of conferences on various aspects of sanitary science, among the subjects being spring cleaning and its sanitary significance, and the sorting and grouping of school children for educational purposes.

We learn from the *Times* correspondent at St. Petersburg that on Monday, June 1, the Grand Duke Michael opened the International Congress on Navigation, which is being held for the first time in St. Petersburg. Three thousand delegates from all countries have assembled, including Sir John Murray, K.C.B., F.R.S. Regret is expressed by the organisers of the congress at the small representation of Great Britain.

Under the direction of Prof. Loomis, an exploring party will leave Amherst College, Mass., on June 12 to work in the western States. The party will first examine the Indian quarries in Converse County in search of stone implements, and will then look for horse, camel, and rhinoceros bones in the Lower Miocene in Nebraska. The party will then go southwards to the Upper Miocene of north-eastern Colorado, where it is expected to find the later stages of the same groups of animals. Prof. Lull, of the Yale Museum, will probably camp with this party, but will make an independent collection.

The death is reported, in his fifty-seventh year, of Prof. Leslie Alexander Lee, who held the chair of biology in Bowdoin College, Maine, since 1876. In 1887 he was chief of the scientific staff on the voyage of the U.S. Fish Commission's steamer *Albatross* through the Strait of Magellan. The results of his work on this expedition were preserved in a large number of biological, geological, and ethnological memoirs published by the Smithsonian Institution. He was also director of the Bowdoin expedition to Labrador in 1891, when large collections were made, and the Grand Falls, 316 feet high, were rediscovered.

On May 15 there was held in Cracow, at the Academy of Sciences, a celebration of the twenty-fifth anniversary of Prof. Olszewski's work on the liquefaction of gases, his first researches in that direction having been commenced during the spring of 1883 with the late Prof. Wróblewski. The celebration was an unofficial one, and only the members of the mathematical and natural history class of the academy took part in it. The president of the academy, Prof. Count Tarnowski, congratulated Prof. Olszewski in an address, after which an album containing photos of the members of the mathematical and natural history class was presented to him. As the intention of the academy to celebrate the work of its distinguished member was not publicly made known, only a few letters and telegrams reached him, including those of several learned societies in Warsaw and of the professors of chemistry and of physics in the University of Fribourg.

A poll has just been taken by the Geological Society to ascertain the opinion of the fellows resident in the United Kingdom as to the admission of women to the society. The number of voting papers sent out was 870, and 477 replies were received. An analysis of the votes shows that 248 fellows were in favour of the admission of women as fellows and 217 against their admission, but of this number only 133 voted against the admission of women at all, the remaining eighty-four being in favour of their admission as associates. The fact that there was a majority of thirty-one in favour of the admission of women as fellows should be an encouraging sign to the increasing number of women who are taking up scientific work and in other ways contributing to the extension of natural knowledge.

The council of the Institution of Civil Engineers proposes to award annually a prize, of the value of about 33*l.*, to be called the Indian premium, to the author, being a corporate member of the institution in practice in India, of the best paper received during the year on a subject connected with Indian engineering. The council further proposes that the income of a legacy of 1000*l.* bequeathed by the late Mr. L. F. Vernon-Harcourt to the institution be applied, in general accordance with the testator's wishes, to provide for a biennial lecture on some subject relating to rivers, canals, or maritime engineering, to be delivered before meetings of students of the institution in London and before such of the provincial associations of students as the council may determine from time to time. The council recently accepted, on behalf of the institution, a legacy of 1000*l.*, bequeathed by the late Mr. F. W. Webb, to be applied to establish a "Webb prize" for the best paper submitted to the institution on railway machinery, or upon some branch of railway machinery which may be prescribed.

The thirteenth annual congress of the South-eastern Union of Scientific Societies will be held at Hastings on June 10–13 under the presidency of Sir Archibald Geikie, K.C.B., Sec.R.S., who will give his presidential address at the Royal Concert Hall, St. Leonards, on Wednesday, June 10, at 8 p.m. Papers are promised by Mr. E. A. Martin, on some considerations concerning dew-ponds; Messrs. Ruskin Butterfield and W. H. Bennett, a contribution to the spider fauna of the district round Hastings; Mr. W. H. Mullens, Gilbert White and Sussex; Mr. Edward Connold, local sponges; Mr. J. E. Ray, mediaeval timbered houses of Sussex and Kent; Mr. Wintour F. Gwinnell, the reptile monsters of Mesozoic times, with especial reference to the iguanodon; Mr. Lewis Abbott, Pleistocene vertebrates of the south-east of England; Mr. W. M. Webb, Darwinism as applied to dress. There will be a loan museum under the superintendence of Mr. E. W. Swanton. Excursions, geological or antiquarian, will take place to Hastings Castle and Caves, and the salient physical features of the district, Battle Abbey, Rye, Bodiam Castle, and Dungeness. The local secretary is Mr. W. Ruskin Butterfield, Corporation Museum, Hastings, from whom tickets and all information can be obtained.

Captain Ejnar Mikkelsen has returned, we learn from the *Times*, to Copenhagen after his two years' sojourn in the regions north of Alaska. The chief object of the expedition was to decide whether there is land to the north of Alaska or a deep sea. Captain Mikkelsen's ship arrived on September 17, 1906, at Flaxman Island, where she was soon frozen in. The whole of that autumn was spent in mapping the surrounding country and observing the tide. About forty miles from the coast the party found mountains from 10,000 feet to 12,000 feet in height, hitherto not marked on any map, and Mr. Leffingwell, the companion of Mr. Mikkelsen, undertook some geological researches. In March, 1907, Captain Mikkelsen, Mr. Leffingwell, and the mate started in three sledges with eighteen dogs on a trip over the ice towards the north. The thermometer showed −56° C.; nevertheless, they often came across big crevices among the ice floes. About fifty miles from shore they found water which they sounded to the depth of 800 metres without reaching bottom. Sixty miles further on no change was recorded, until at last, turning towards the south-east, they found bottom. They followed this edge of the continental shelf towards the east, but had soon to return owing to the strong current. Captain Mikkelsen was thus able to prove that deep water exists north of Alaska to a great distance.

On May 31, in Rome, M. Delagrange made successful experiments with his aëroplane. According to the *Times* correspondent, at the request of M. Delagrange the Italian Society of Aviation prepared the ground in the Piazza d'Armi for an officially authenticated trial. The Piazza was marked with flags, the four sides measuring in all 1300 metres. At 5.40 a.m. M. Delagrange set his machine going. The aëroplane ran for fourteen seconds, and then rose easily, remaining in the air for the whole of the rest of the flight, and keeping a distance from the ground varying between three and five metres. The actual flight lasted for 15m. 26s., and during that time the aëroplane made the circuit of the marked course $9\frac{3}{4}$ times. The actual distance travelled, measured by the milometer of an automobile, which naturally took closer curves than the aëroplane, was more than 15 kilometres, or there was a flight through the air without touching ground of 15 kilometres in something more than 15 minutes. M. Delagrange steered and controlled the aëroplane with ease, and could have continued the flight if the power of the engine had permitted. The problem of stability has still to be solved; M. Voisin, who made the aëroplane, hopes to overcome instability by increasing the number of planes. Other trials were made in the evening, in one of which M. Delagrange travelled five times round the Piazza in six minutes at a height of between five and six metres. On June 1 a final trial was made in the presence of the Queen-Mother. In preventing a possible collision with the Royal stands, M. Delagrange stopped the aëroplane too suddenly, and it fell from a height of about four metres to the ground. The aëronaut was unhurt, but the aëroplane sustained slight damage.

Just now, when consideration is being given to a proposal to effect an arrangement which shall ensure the utilisation of a larger number of hours of daylight in the summer time, it is not without interest to direct attention to a paper, which Mr. G. V. Hudson read before the New Zealand Institute in 1898, a copy of which the author has forwarded to us. The scheme differs from that now before a committee of the House of Commons in being of a more drastic character, and being free from the frequent irritating interferences with the regular record of time, which is one of the most objectionable features of the present Bill. Writing for the southern hemisphere, it was proposed to put the clock forward two hours on the first of October, and to put it back the same amount in the following March. Here the scheme has the merit of boldness, and if any breach in continuous time reckoning is to be tolerated, it may be excused on the ground that a considerable advantage is promised. In the paper are discussed the advantages and many of the objections with which we have become familiar from the evidence that has been given before the Parliamentary Committee, and sufficiently reported in the daily Press. There is no necessity to discuss these either as they appear in the original pamphlet or in a more modern dress. To substitute mid-European time as some of the witnesses have suggested is a noticeable improvement on the original plan, and one that would meet many objections. But, notwithstanding the amendment, it may be pointed out that, since the Bill does not contemplate any alteration of time as employed in navigation and nautical matters, one can conceive that in seaport towns, where the influence of shipping makes itself felt in the general conduct of business, very considerable confusion can arise. For instance, in most seaport towns a time signal is used for the convenience of vessels in port. That signal is also valuable to the public, and serves to regulate time. It seems that under the Bill the interests of one party must be sacrificed. Either the seaman or the public loses the time signal. It is easy to say that is a mere detail, but the whole objection to the scheme turns on details, and the final acceptance or rejection of the Bill will depend on the importance that details may acquire by accumulation.

The Alliance Franco-Britannique, Littéraire, Scientifique, et Artistique, held a conversazione at the Grafton Galleries, Grafton Street, London, on May 28, in the course of which M. Yves Guyot delivered a lecture on "Les Rapports Intellectuels de la France et de l'Angleterre." Sir Archibald Geikie, K.C.B., F.R.S., chairman of the council, introduced the lecturer. Referring to French and English science, M. Yves Guyot said, from the point of view of pure science, the English have changed the French system of natural science completely. In France the theocratical conceptions of Cuvier's "Révolutions du Globe" were still held when in 1830–3 Charles Lyell substituted for them the real and conclusive theory of "actual causes." The Frenchmen Lamarck and St. Hilaire had anticipated evolution, but when in 1858 Darwin expounded the theory of the struggle of life he brought about a total transformation in the study of biology. Herbert Spencer boasted of having given a systematic explanation of the universe, and of having propounded the conditions of evolution. Almost all his works have been translated into French, and they have continued to exercise upon French thought the beneficent influence which all English thinkers since Locke have had over it. Almost all Frenchmen are sons of Plato, who are apt to take words for deeds. University literary teaching in France has encouraged this tendency. This method of procedure allows scope, on one hand, for all the subtleties of scholasticism, and on the other for all the literary and oratorical explanations which hide the emptiness of the idea under assertions and metaphors. The English mistrust generalisations, and make a constant appeal to facts. They have the primary qualification for all scientific research—honesty. They do not try to dazzle by sophistry; their objective is truth, and by their example they force the men of research in all countries to subordinate all other considerations to this end. Not only have they enriched the world with the experimental method, but they make everyone practise it conscientiously. Hence it is easy to recognise in France those authors, professors, publicists, and *savants* who have come under English influence. Later, M. Yves Guyot remarked that among the useful forms under which English influence has been exerted upon the French intellect, the first is scientific. Bacon against Plato, Newton against Descartes, Lyell against Cuvier; the movement was continued through Darwin and Herbert Spencer. It was confirmed also by Adam Smith. It is the inductive method as opposed to intuitive conceptions. It is reality opposed to the assertions and subtleties taught by the Greek sophists.

From the East Kent Scientific and Natural History Society we have to acknowledge the receipt of a copy of the report and transactions for 1907.

Fishes of the Rocky Mountain region form the subject of the only zoological paper—by Prof. T. D. A. Cockerell—in No. 3 of the fifth volume of the University of Colorado Studies. Extinct as well as living species are discussed, and it is pointed out that the contrast between the generic types respectively characteristic of the Gila and the Rio Grande basins suggests re-consideration of the theory of a recent depression of the continent in the region of southern New Mexico and Arizona.

The second part of vol. xx. of the Proceedings of the Royal Society of Victoria contains two papers on the geology and palæontology of that colony, Prof. E. W. Skeats discussing the Palæozoic strata of Mooroodue, in the Mornington peninsula, while Mr. F. Chapman describes a number of new or little-known Victorian fossils. The same issue contains the first part of a paper by Miss Georgina Sweet on the anatomy of certain Australian amphibians, of which we have been favoured by the author with a separate copy.

To the May number of the Zoologist Mr. Charles Oldham contributes a paper on the birds frequenting the well-known "gullery" at Ravenglass, on the Cumberland coast. The most notable species nesting there are the black-headed gull and the common and the Sandwich tern, of which the last-named is more numerously represented than in any other of its few English breeding-places. The Sandwich terns breed in colonies of from five or six to fifty or more pairs. These colonies, often at some distance from one another, are chiefly in the southern part of the gullery, and most frequently on the dunes next the sea or the estuary. There the nests are grouped within a few inches of one another, sometimes hard by those of the common terns and the black-headed gulls. Unlike those of the latter, the nests are never in thick herbage, but take the form of mere shallow depressions, with or without a lining of bents, amid the sparse marram-grass.

The first part of the third volume of the Journal of the Federated Malay States Museum is devoted to an account of the exploring expedition to Gunong Tahan, the great mountain to the northward of Pahang, undertaken in 1905 by Messrs. Wray and Robinson, followed by descriptions of the zoological collections. The narrative, which is illustrated by reproductions of photographs of the general scenery and the vegetation, shows that the explorers had to undergo some rough experiences, although the admirable arrangements made by the authorities in the matters of supply and carriage prevented the occurrence of any difficulties. The collections, so far at any rate as vertebrates are concerned, proved, perhaps, a little disappointing. The new mammals, for example, comprised only a couple of squirrels, one of which is merely a subspecies, and a bat, albeit of a rather rarely represented genus, while of new birds there were seven, among which a woodpecker (Gecinus), an owl (Heteroscops), and a Cissa are, like one of the squirrels, illustrated in coloured plates.

The sensory reactions of the lancelet are discussed by Mr. G. H. Parker in vol. xliii., No. 16, of the Proceedings of the American Academy of Arts and Sciences. The creature, it seems, is but very slightly receptive to light, responding, indeed, to a rapid increase of illumination, but taking scarcely any notice of a corresponding decrease; the only known light-receiving organs are the eye-cups in the wall of the nerve-tube. Temperatures below 5° C. and above 39° C. are fatal to its existence. Mechanical stimulants affect the skin, more especially the tentacles and oral hood, and sound-vibrations likewise produce an effect on the organism. Tactile organs exist in the skin, but there are no derived structures corresponding to ears and the lateral line of fishes. To locomotion-inducing stimulants the lancelet responds by forward movements when these are applied to the tail, and by backward movements when they touch the middle or fore-part of the body. The creature generally buries itself tail-first in the sand, and probably swims in a similar manner, although in both cases the movement may be reversed.

To the May number of the *American Journal of Science* Mr. R. S. Lull contributes an interesting paper on the head-muscles of dinosaurs, with special relation to the origin of the neck-shield in the horned group (Ceratopsia). Such evidence as can be obtained with regard to the cranial musculature can, of course, be gleaned only from the form and proportions of the skull, coupled with, in some cases, the marks of the attachments of the muscles themselves. From the analogy of chamæleons, which, although insectivorous, masticate their food, it is inferred that horned dinosaurs had powerful temporal and feeble pterygoid muscles, thereby differing markedly from crocodiles, in which, owing to the absence of mastication, the conditions in these respects are reversed. It is also pointed out that the neck-shield or frill of the Ceratopsia presents a remarkable analogy or parallelism to the so-called casque of the chamæleon's skull, both structures being essentially a backward extension of the parietal segment designed to afford extra space for the origin of the great temporal muscles. It is added that Owen's chamæleon from the Cameroons presents a curious "mimicry" of the Triceratops type in carrying three horns situated very much as in the dinosaur, although these horns are entirely dermal structures, devoid of bony cores. "In the chamæleon they seem to be the result of sexual selection, and are certainly not for aggressive warfare in a creature which moves with the utmost caution; while in Triceratops the presence of efficient weapons in both sexes was an imperative factor in the struggle for existence."

In the *Travaux de la Société Impériale des Naturalistes de St. Pétersbourg* (vol. xxxviii., part i.) there appear two contributions to the "Flora Caucasica Critica." Mr. N. Kusnezow contributes addenda and a summary of various cohorts allied to the Ericales, and Mr. A. Fomin is responsible for a fascicle on the Campanulatæ.

The first number of the Proceedings of the Field Club and Natural History Society of University College, Exeter, has been received, in which the inception of the Field Club and records for previous years are chronicled. A list of plant formations on Dawlish Warren is contributed by Mr. J. L. Sager. Mr. J. Stevens supplies a catalogue of Rotifera collected in the Exeter district, among them a new species, *Brachionus sericus*, taken on Hell Tor.

A pamphlet dealing with the red-rot of the sugar-cane stem is issued as Bulletin No. 8 from the experiment station of the Hawaiian Sugar Planters' Association. Up to the present this disease, that is ascribed with a tolerable degree of certainty, although not quite definitely, to *Colletotrichum falcatum*, has not been credited with causing much damage in the Hawaiian Islands, so that the account is in the nature of a premonitory warning. Being a wound parasite, the fungus enters readily where the canes have been penetrated by borers, and is liable to be perpetuated by planting of diseased canes. A resistant variety appears to have been found in the yellow Caledonia.

The short list of new diagnoses, "Decades Kewenses, xxiii.," published in the current number of the *Kew Bulletin* (No. 4), contains Chinese species of Sterculia, Euonymus, and Rheum, also a new Rheum from Tibet. Mr. J. Burtt-Davy communicates some notes on Transvaal trees and shrubs. The group of Acacias is very numerous, and includes the species *caffra, Catechu, Giraffae, horrida,* and *spirocarpoides*, the last-named being a common species of the "umbrella" type in the Waterberg district. Evidence is adduced in favour of referring the Pretoria

"Wonderboom" to *Ficus caffra*. The determination of species in the orders Rubiaceæ, Ebenaceæ, and Celastraceæ is provisional. On the subject of the South African locust fungus, *Entomophthora Grylli*, Mr. G. Massee concurs in the opinion that it does not provide a remedy for exterminating locusts. Mr. T. A. Sprague collates the information regarding the occurrence of rubber in species of Gymnosporia.

Mr. R. G. Thompson, in the May number of *Man*, describes the ancient gold mines at Gebét, in the eastern Sudan, some eight days' march from Suákim. The works on this site, which is still occupied by miners, consist of an extensive series of underground tunnels excavated with metal tools, such as an iron scraper found in one of the workings. The scanty remains of pottery found indicate that these mines were worked about the beginning of the Christian era. The most noticeable relics are a number of querns of a rude form in which the quartz was ground, the gold being subsequently extracted by the action of water.

In the April number of the Journal of the Gypsy Lore Society Dr. G. A. Grierson contributes an interesting note on the philology of Romani. The Indian Gypsies, most of whom are of south Indian origin, have little to do with it, although some of them have borrowed words which are closely connected with it. He accepts Prof. Peschel's suggestion that the linguistic home of the Romani is to be found mostly beyond the northern frontier of India, in Kashmir, Gilgit, and Chitral, among the Doms of that region. Their language is one of the Pisáca group, a name which represents an Aryan tribe which reached India from the Pamirs over the Hindu Kush. As they entered the Punjab their speech became partially mixed with those of the other Aryan tribes who entered India from the west, but it can still be traced down the Indus valley into Sind, across Gujarat into the country of the Bhils, and as far as the central Vindhyan range, where it has affected the local dialects of Mahratti.

The *Australasian Traveller*, the journal of the Commercial Travellers' Association of Australasia, issued as its last Christmas number a richly illustrated folio volume of nearly 200 pages entitled "Australia To-day." It contains accounts of the resources, industries, and attractions of each of the Australian States and of British New Guinea. It directs attention to the enormous value of Australian production, with its output of 474,000,000*l*. of gold and its pastoral and agricultural produce, which together give it a greater output per head of population than any other continent. In addition to a collection of recent statistics, it describes pictorially the working life of the Australians and their industries, and the series of large photographs gives an excellent idea of the varied and beautiful character of Australian scenery.

It is stated in the *Engineer* of May 29 that in sinking for the sump at the new collieries at Bentley, near Doncaster, where the Barnsley seam was reached six weeks ago at a depth of 624 yards, a further fine seam of coal has been discovered twenty-four yards below the Barnsley seam. It is 5 feet thick, and is known in Derbyshire as the Dunsil seam. Hitherto it has not been found in workable thickness in Yorkshire.

The new museum of safety devices installed in December, 1905, at the Conservatoire des Arts et Métiers, in Paris, is described by Mr. J. Boyer in the *Engineering Magazine* for May. Its purpose is to indicate the precautions to be taken and the devices to employ to protect workmen against risks of all kinds—unhealthy atmosphere, dangers from machinery, harmful dust, high electric voltages, and poisoning.

The summary of the weather for the closing week of May, issued by the Meteorological Office, shows that the conditions had generally become more settled and summer-like over the entire country. In the north of Scotland the shade temperature rose to 80°, and almost equally high temperatures occurred generally over the United Kingdom. The spring, covered by the period of thirteen weeks ending May 30, was wet over the entire country, the aggregate rainfall being everywhere in excess of the average. In the north-west of England and in the Midland counties the excess of rain was more than 2 inches, and the number of rainy days was everywhere more than the normal. The temperature for the season was below the average, and there were fewer hours of bright sunshine than the normal. June opened with high summer temperatures, and sharp thunderstorms were experienced on the night of June 1 in most parts of England.

Dr. F. Eredia, of the Meteorological Office at Rome, continues in the Bulletin of the Italian Aëronautical Society his useful discussion of the winds of Italy, for places where trustworthy observations are available for the years 1891–1900. We have received memoirs relating to five provinces, in which he deals with the frequency of wind-direction referred to eight points, for months and seasons, illustrated by diagrams and wind-roses. In all cases the principal results are summarised in an interesting textual discussion.

We have recently received from Prof. Hergesell a copy of the observations relating to the meteorological service of Alsace-Lorraine for 1903, one of the series of year-books published on a uniform plan by the various States of the German Empire. The tables include monthly and yearly results for a large number of stations, hourly means for Strassburg, and five-day means at fourteen selected places. There is also a valuable appendix by Dr. Kleinschmidt containing monthly and yearly rainfall values for lustra, extending in some cases from 1876 to 1905. Some of these data have been compiled from Dr. Hellmann's great rainfall work and other trustworthy publications.

The May number of the *Jahrbuch der Drahtlosen Telegraphie und Telephonie* contains two contributions by Prof. J. A. Fleming and Dr. L. Mandelstam, respectively, to the discussion as to the correct deduction and interpretation of Prof. Fleming's formula for the radiation in different directions of the bent antennæ used in wireless telegraphy.

The *Physikalische Zeitschrift* for May 15 contains an article on the daily variation of the potential gradient in the atmosphere, by Dr. D. Smirnow, of the Central Observatory of St. Petersburg. He shows that the daily variation on clear days may be explained, qualitatively at least, and possibly quantitatively, by the production at sunset of a colder and relatively moist stratum of air in contact with the ground, which, owing to the reduced mobility of the ions and consequent decrease of electrical conductivity, causes positive electricity to collect on the ground, and thus reduces the electric field above the cool layer. At sunrise the layer disappears and the field increases to its former value. During the day the ascending air carries with it positive electricity, leaving negatively charged dust particles behind, and so the field is reduced. The direct action of sunlight in producing negative charges in the upper atmosphere seems to have little effect on the potential gradient near the surface.

## OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JUNE:—

June 6. 5h. 37m. to 9h. 20m. Transit of Jupiter's Sat. III. (Ganymede).
7. 4h. 24m. Conjunction of Mercury and Mars. Mercury 0° 19′ N.
,, 13h. 0m. Mercury at greatest elongation, 23° 58′ E.
13. 9h. 57m. to 13h. 39m. Transit of Jupiter's Sat. III. (Ganymede).
14. 10h. 13m. to 11h. 24m. Moon occults 4 Sagittarii (mag. 4·6).
19. 11h. 10m. Minimum of Algol (β Persei).
21. 8h. 19m. Sun enters Cancer and Summer commences.
22. 8h. 32m. Venus in conjunction with Mars, Venus 2° 4′ S.
28. Eclipse of the Sun partially visible at Greenwich. Begins 5h. 14m.; Middle 5h. 38m.; Ends 6h. 2m. Magnitude (Sun's diameter = 1) 0·065. At the time of greatest obscuration nearly one-fifteenth of the Sun's southern limb will be occulted.

THE RETURN OF ENCKE'S COMET.—A telegram from the Kiel Centralstelle announces that Encke's comet was found by Mr. Woodgate, of the Cape Observatory, on May 27. Its position at 17h. 49m. (Cape M.T.) on that date was R.A. = 2h. 59·3m., dec. = 7° 29′ S. This is situated about half a degree north of ρ Eridani, and is, at present, unobservable in these latitudes.

THE RADIAL VELOCITY OF ALGOL.—No. 22, vol. ii., of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo* contains a very full discussion by Prof. Belopolsky of the radial-velocity observations of Algol made at the Pulkowa Observatory during the years 1905–7. The results obtained from each line on each spectrogram are discussed in detail, and the following elements are finally derived:— $\omega$ 42°·5 ± 1°·35, $e$ = 0·0476 ± 0·0037, T = 2·509 ± 0·00019 days, $a$ = 1,693,523 ± 100 km., and $i$ = 90°.

THE RADIAL VELOCITY OF ε URSÆ MAJORIS.—From two spectrograms obtained at Potsdam in 1889, Profs. Vogel and Scheiner found the radial velocity of ε Ursæ Majoris to be −30·4 km., the measurements being made on the Hγ line. But from nine very consistent plates, secured with the Bruce spectrograph in 1902–3, Prof. Adams derived the value −9·4 km., and in 1903 this was confirmed by measurements of seven plates obtained at Potsdam, the mean value being −9 km. Vogel and Eberhard then re-measured the original plates, and confirmed the first value. The comparison of these results suggested that, possibly, the radial velocity of ε Ursæ Majoris is variable. That the star is of peculiar interest is shown by the fact that its spectrum is given as type I. *a* 2 in Vogel's classification, as VIII. P. in the Harvard classification, and that Sir Norman Lockyer, whilst classing it as "Sirian," has pointed out that it has several well-marked peculiarities.

For these reasons Messrs. Baker and Schlesinger, of Allegheny Observatory, obtained—during March and April, 1907—and the former measured, seven spectrograms taken with the Mellon spectrograph, which gives a measurable spectrum of 21 mm. in length between λ 3925 and λ 4750. The resulting mean value was −7·1 km. ±0·46 km., and as this agrees so closely with that obtained by Prof. Adams and with the later value of Prof. Vogel, the matter must still be considered as requiring further investigation (Publications of the Allegheny Observatory, vol. i., No. 4, p. 23).

OBSERVATIONS OF JUPITER'S SATELLITES.—Some interesting observations of eclipses and occultations of Jupiter's satellites are recorded by M. S. Kostinsky in No. 4249 of the *Astronomische Nachrichten* (p. 14, May 20). On April 3 photographic and visual observations of a partial eclipse of J. ii. by the shadow of J. i. were secured; the brightness of J. ii. was diminished about 0·3–0·4 magnitude according to the eye observations, and the minimum brightness occurred at 11h. 52·3m. (Pulkowa M.T.). On February 24 an occultation of the second satellite by the first was observed at 10h. 45·5m., and on March 27 and 30 two series of photographs of the second and third satellites were secured during their eclipse by the planet's shadow.

A partial eclipse of the second by the third satellite was observed by Herr Fauth at the Landstuhl Observatory at 8h. 17m. 55s. (M.E.T.) on February 20.

THE ORBIT OF α ANDROMEDÆ.—The following elements for the orbit of α Andromedæ are published by Mr. Baker in vol. i., No. 3, of the Publications of the Allegheny Observatory (pp. 17–22):—P = 96·67 days, $e$ = 0·525, T = 1907 November 2·40, $\omega$ = 76°·21, K = 30·75 km., $\gamma$ = −11·55 km., A = 34·60 km., B = 26·90 km., and $a \sin i$ = 34,790,000 km. The discussion of the orbit was based on the measures of eleven lines between λ 3933·789 and λ 4481·437 on ninety-four plates obtained with the Mellon (single-prism) spectrograph, and the results are compared with those previously obtained at the Lowell, Lick, and Potsdam observatories.

THE UNITED STATES NAVAL OBSERVATORY.—The annual report of the United States Naval Observatory for the fiscal year ending June 30, 1907, gives the usual data regarding the time-service, publications, &c., and a brief summary of the observations made with each set of instruments. The observation of each star in Sir David Gill's Zodiacal Catalogue of 2798 stars was nearly complete, but a few more observations remained to be made in the autumn of 1907. More than 3000 observations were made by different observers with the new self-registering transit micrometer installed in October, 1906, and the results again prove the efficiency of this instrument. Bad weather limited the number of photoheliograms obtained, records being secured on only 150 days; spots were shown on the negatives on 148 days. There are now 1455 solar negatives in hand, and in order to minimise the labour of reducing these it is proposed that a heliomicrometer, as devised by Prof. Hale, be installed.

## ON THE SHAPES OF EGGS, AND THE CAUSES WHICH DETERMINE THEM.[1]

THE eggs of birds and all other hard-shelled eggs, such as those of the tortoise and the crocodile, are normally simple solids of revolution, but they differ greatly in form according to the configuration of the plane curve by the revolution of which the egg is, in a mathematical sense, generated. Some few eggs, such as those of the owl or of the tortoise, are spherical or very nearly so; a few, such as the grebe's or the cormorant's, are approximately elliptical, with symmetrical or nearly symmetrical ends; the great majority, like the hen's egg, are ovoid, a little blunter at one end than the other; and some, by an exaggeration of this lack of antero-posterior symmetry, are blunt at one end but characteristically pointed at the other, as is the case in the egg of the guillemot and puffin, the sandpiper, plover, and curlew.

Various theories, based upon the principles of natural selection, are current and are very generally accepted to account for these diversities of form. The pointed, conical egg of the guillemot is generally supposed to be an adaptation advantageous to the species in the circumstances under which the egg is laid; the pointed egg is less apt than a spherical one to roll off the narrow ledge of rock on which this bird lays its solitary egg, and the more pointed the egg so much the fitter and likelier is it to survive. The fact that the plover or the sandpiper, breeding in very different situations, lays eggs that are also conical elicits another explanation, to the effect that the conical form permits the many large eggs to be packed closely under the mother-bird. The round egg of the tortoise and the elongated egg of the crocodile have been supposed to be developed in conformity with the shape of the creature that has afterwards to be hatched therein. Whatever truth there be in these apparent adaptations to existing circumstances, it is only by a very hasty logic that we can accept them as a *vera causa* or adequate explanation of the facts; and it is obvious to my mind that, in attempting to deal with the forms assumed by matter, whether in the organic or the inorganic world, we ought first to attempt to deal on simple physical lines with the forces to which it has been subjected, that is to say, the intrinsic forces of growth

1 A paper read before the Zoological Society of London on April 28 by Prof. D'Arcy Wentworth Thompson, C.B.

acting from within and the forces of tension and pressure that may have acted from without.

Certain elementary points in regard to the formation of the egg must be borne in mind :—

(1) The "egg," as it enters the oviduct, consists of the yolk only, enclosed in its vitelline membrane. As it passes down the first portion of the oviduct, the white is gradually superadded, and becomes in turn surrounded by the "shell-membrane." About this latter the shell is secreted, rapidly and at a late period.

(2) Both the yolk and the entire egg tend to fill completely their respective membranes, and, whether this be due to growth or imbibition on the part of the contents or to contraction on the part of the surrounding membranes, the resulting tendency is for both yolk and egg to be, in the first instance, spherical, unless otherwise distorted by external pressure.

(3) The egg is subject to pressure within the oviduct, which is an elastic, muscular tube, along the walls of which pass peristaltic waves of contraction. These muscular contractions may be described as the contraction of successive annuli of muscle, giving annular (or radial) pressure to successive portions of the egg; they drive the egg forward against the frictional resistance of the tube, while tending at the same time to distort its form. While nothing is known, so far as I am aware, of the muscular physiology of the oviduct, it is well known in the case of the intestine that the presence of an obstruction leads to the development of violent contractions in its rear, which waves of contraction die away, and are scarcely if at all propagated in advance of the obstruction.

(4) It is known by observation that a hen's egg is always laid blunt end foremost.

(5) It can be shown, at least as a very common rule, that those eggs which are most unsymmetrical, or most tapered off posteriorly, are also eggs of a large size relatively to the parent bird. We may accordingly presume that the more pointed eggs are those that are large relatively to the tube or oviduct through which they have to pass, or, in other words, are those which are subject to the greatest pressure while being formed or shaped. So general is this relation that we may go still further, and presume with great plausibility in the few exceptional cases (of which the apteryx is the most conspicuous) where the egg is relatively large though not markedly unsymmetrical, that in these cases the oviduct itself is in all probability large (or perhaps weak) in proportion to the size of the bird. In the case of the common fowl we can trace a direct relation between the size and shape of the egg, for the first eggs laid by a young pullet are smaller, and at the same time are much more nearly spherical than the later ones; and, moreover, some breeds of fowls lay proportionately smaller eggs than others, and on the whole the former eggs tend to be rounder than the latter.

We may now proceed to inquire more particularly how the form of the egg is controlled by the pressures to which it is subjected.

The egg, just prior to the formation of the shell, is, as we have seen, a fluid body, tending to a spherical shape and *enclosed with a membrane*.

Our problem, then, is: Given a practically incompressible fluid, contained in a deformable capsule, which is either (*a*) entirely inextensible, or (*b*) slightly extensible, and placed in a long elastic tube the walls of which are radially contractile, to determine the shape under pressure.

(1) If the capsule be spherical, inextensible, and completely filled with the fluid, absolutely no deformation can take place. The few eggs that are actually or approximately spherical, such as those of the tortoise or the owl, may thus be alternatively explained as cases where little or no deforming pressure has been applied prior to the solidification of the shell, or else as cases where the capsule was so little capable of extension and so completely filled as to preclude the possibility of deformation.

(2) If the capsule be not spherical, but be inextensible, then deformation can take place under the external radial compression, only provided that the pressure tends to make the shape more nearly spherical, and then only on the further supposition that the capsule is also not entirely filled as the deformation proceeds.

In other words, an incompressible fluid contained in an inextensible envelope cannot be deformed without puckering of the envelope taking place.

Let us next assume, as the conditions by which this result may be avoided, (*a*) that the envelope is to some extent extensible, or (*b*) that the whole structure grows under relatively fixed conditions. The two suppositions are practically identical with one another in effect.

(3) It is obvious that, on the presumption that the envelope is only moderately extensible, the whole structure can only be distorted to a moderate degree away from the spherical or spheroidal form.

(4) At all points the shape is determined by the law of the distribution of *radial pressure within the given region of the tube*, surface friction helping to maintain the egg in position.

(5) If the egg be under pressure from the oviduct, but without any marked component either in a forward or backward direction, the egg will be compressed in the middle, and will tend more or less to the form of a cylinder with spherical ends. The eggs of the grebe, cormorant, or crocodile may be supposed to receive their shape in such circumstances.

(6) When the egg is subject to the peristaltic contraction of the oviduct during its formation, then from the nature and direction of motion of the peristaltic wave the pressure will be greatest somewhere behind the middle of the egg; in other words, the tube is converted for the time being into a more conical form, and the simple result follows that the anterior end of the egg becomes the broader and the posterior end the narrower.

(7) With a given shape and size of body, equilibrium in the tube may be maintained under greater radial pressure towards one end than towards the other. For example, a cylinder having conical ends, of semi-angles $\theta$ and $\theta'$ respectively, remains in equilibrium, apart from friction, if $p\cos^2\theta = p'\cos^2\theta'$, so that at the more tapered end where $\theta$ is small $p$ is large. Therefore the whole structure might assume such a configuration, or grow under such conditions, finally becoming rigid by solidification of the envelope. According to the preceding paragraph, we must assume some initial distribution of pressure, some squeeze applied to the posterior part of the egg, in order to give it its tapering from. But, that form once acquired, the egg may remain in equilibrium both as regards form and position within the tube, even after that excess of pressure on the posterior part is relieved. Moreover, the above equation shows that a normal pressure no greater and (within certain limits) actually less acting upon the posterior part than on the anterior part of the egg after the shell is formed will be sufficient to communicate to it a forward motion. This is an important consideration, for it shows that the ordinary form of an egg, and even the conical form of an extreme case such as the guillemot's, is directly favourable to the movement of the egg within the oviduct, blunt end foremost.

(8)[1] The mathematical statement of the whole case is as follows:—In our egg, consisting of an extensible membrane filled with an incompressible fluid and under external pressure, the equation of the envelope is $p_n + T\left(\frac{1}{r} + \frac{1}{r'}\right) = P$, where $p_n$ is the normal component of external pressure at a point where $r$ and $r'$ are the radii of curvature, T is the tension of the envelope, and P the internal fluid pressure. This is simply the equation of an elastic surface where T represents the coefficient of elasticity; in other words, a flexible elastic shell has the same mathematical properties as our fluid, membrane-covered egg.

The above equation is the *equation of equilibrium*, so that it must be assumed either that the whole body is at rest or that its motion while under pressure is not such as to affect the result. Tangential forces, which have been neglected, could modify the form by alteration of T. In our case we must, and may very reasonably, assume that any movement of the egg down the oviduct during the period when its form is being impressed upon it is very slow, being possibly balanced by the advance of the peristaltic wave which causes the movement, as well as by friction.

The quantity T is the tension of the enclosing capsule—

[1] The mathematical statement is not my own; I am indebted for it and for other help in the editing of this paper to my colleague, Prof. W. Peddie.

the surrounding membrane. If T be constant or symmetrical about the axis of the body, the body is symmetrical. But the abnormal eggs that a hen sometimes lays, cylindrical, annulated, or quite irregular, are due to local weakening of the membrane, in other words, to asymmetry of T. Not only asymmetry of T, but also asymmetry of $p_n$, will render the body subject to deformation, and this factor, the unknown but regularly varying, largely radial, pressure applied by successive annuli of the oviduct, is the essential cause of the form, and variations of form, of the egg. In fact, in so far as the postulates correspond near enough to actualities, the above equation is the equation of *all eggs* in the universe. At least this is so if we generalise it in the form $p_n+\frac{T}{r}+\frac{T'}{r'}=P$ in recognition of a possible difference between the principal tensions.

(9) In the case of the spherical egg it is obvious that $p_n$ is everywhere equal. The simplest case is where $p_n=0$, in other words, where the egg is so small as practically to escape deforming pressure from the tube. But we may also conceive the tube to be so thin-walled and extensible as to press with practically equal force upon all parts of the contained sphere.

(10) If while our egg be in process of conformation the envelope be free at any part from external pressure (that is to say, if $p_n=0$), then it is obvious that that part (if of circular section) will be a portion of a sphere. This is not unlikely to be the case actually or approximately at one or both poles of the egg, and is evidently the case over a considerable portion of the anterior end of the plover's egg.

(11) In the case of the conical egg with spherical ends, as is more or less the case in the plover's and the guillemot's, then at either end of the egg $r$ and $r'$ are identical, and they are greater at the blunt anterior end than at the other. If we may assume that $p_n$ vanishes at the poles of the egg, then it is plain that T varies in the neighbourhood of these poles, and, further, that the tension T is greatest at and near the small end of the egg. It is here, in short, that the egg is most likely to be irregularly distorted or even to burst, and it is here that we most commonly find irregularities of shape in abnormal eggs.

(12) If one portion of the envelope were to become practically stiff before $p$ ceases to vary, that would be tantamount to a sudden variation of T, and would introduce asymmetry by the imposition of a boundary condition in addition to the above equation.

(13) Within the egg lies the yolk, and the egg is invariably spherical or very nearly so, whatever be the form of the entire egg. The reason is simple, and lies in the fact that the yolk is itself enclosed in another membrane, between which and the outer membrane lies a fluid the presence of which makes $p_n$ for the inner membrane practically constant. The smallness of friction is indicated by the well-known fact that the "germinal spot" on the surface of the yolk is always found uppermost, however we may place and wherever we may open the egg; that is to say, the yolk easily rotates within the egg, bringing its lighter pole uppermost. So, owing to this lack of friction in the outer fluid, or white, whatever shear is produced within the egg will not be easily transmitted to the yolk, and, moreover, owing to the same fluidity, the egg will easily recover its normal sphericity after the egg-shell is formed and the unequal pressure relieved.

## *GEODETIC INVESTIGATIONS IN THE UNITED STATES.*[1]

THE report of the U.S. Coast and Geodetic Survey for 1907 has just been received. For the details of the extensive cartographic work of the bureau in the United States proper, Alaska, Porto Rico, and the Philippines, as well as for the account of the progress of the primary triangulation and levelling of precision, the report itself must be consulted. Certain important work of the survey receives bare mention, as, for instance, the results of the investigation of the earth's figure, based on geodetic operations in the United States. This is owing to the fact that these results were communicated to the International Geodetic Association in a preliminary report which has been published.

Soon after the California earthquake of April 18, 1906, it became evident that the permanent horizontal displacements of large areas covered by triangulation in California had so changed the lengths and directions of the lines joining the triangulation stations as greatly to diminish the value of the triangulation for its primary purpose as a framework for future surveys. During the year, therefore, new triangulation extending from Point Arena to stations south of Monterey Bay was done, which serves to restore the value of the old triangulation by determining the new positions of sixty-one of the old triangulation stations. The triangulation included the Farallon Lighthouse, twenty-two miles to the westward of the great fault accompanying the earthquake, and the stations Mocho and Mount Diablo, thirty-three miles to the eastward of the fault. The new triangulation serves to trace the permanent distortions and displacements of the earth's crust for many miles back from the fault in each direction, and to show that they follow certain regular laws. This is the most extensive and accurate determination by triangulation of the effects of an earthquake which has yet been made anywhere in the world. Appendix 3 of the report gives a full report of this investigation.

A report on the measurement of six primary bases with steel and invar tapes in 1906 is printed as Appendix 4. The invar (nickel steel) tapes have a coefficient of expansion about 1/28th that of steel tapes, hence it is much less difficult to keep the temperature errors within the required limit with invar tapes than with steel tapes. Invar tapes had not been used in the United States until 1906 in primary base measurements. The thorough tests of these tapes, made by using them on six bases in conjunction with the steel tapes formerly used, showed that measurements may be made more conveniently, accurately, and at smaller cost per mile than with the steel tapes, and that the invar tapes are sufficiently durable and stable for safe field use. This demonstration is believed to be a distinct step in advance in base measurement.

The steady progress in the magnetic survey of the United States, and accumulation of magnetic observational data, as mentioned in Appendix 5 of the report, should be of special interest to the surveyor and the navigator, as well as to those pursuing the study of the science of terrestrial magnetism. Throughout the year the measurements of the earth's magnetism were made at places distributed over a majority of the States and territories of the United States, and at numerous places at sea along the Atlantic and Pacific coasts of North and South America, and in Porto Rico and the Philippines. Important information was secured in the equatorial regions. Numerous "repeat" observations were made throughout the country in order to follow as closely as possible the secular change in the magnetic elements. Five magnetic observatories were maintained in continuous operation, and important seismological data were also obtained. The facilities of the observatories were afforded to all investigators who desired to make standardisation comparisons of their instruments, and in response to numerous requests information or observational data was furnished for practical application or for use in special investigations of terrestrial magnetism and allied phenomena.

Appendix No. 6, constituting the concluding portion of a manual of tides, treats of the flow of water, of river tides, tidal currents, permanent currents, annual inequality, lake tides, seiches, and miscellaneous tidal matters. Charts of co-current lines are given for the principal marginal waters along the Atlantic coast of the United States. The numbers upon these lines show the times of the maximum flood current. The dependence of the permanent ocean currents and the annual height inequality upon the prevailing winds is briefly pointed out. Seiches are shown to exist in harbours and other tongues of water, as well as in lakes, but their character is fundamentally different in some respects. The analyses of observations upon the tides of Lake Superior show that they follow closely the equilibrium theory, although the

[1] "Report of the Superintendent of the Coast and Geodetic Survey showing the Progress of the Work from July 1, 1906, to June 30, 1907." (Washington: Government Printing Office, 1907.)

range is only $1\frac{1}{2}$ inches at Duluth and one-third inch at Marquette.

In Appendix No. 7 is given a detailed description, with appropriate illustrations, of the long wire drag, a device for detecting erratic obstructions of small extent in navigable waters. The method of operating can be understood from the simple statement that the drag is a wire varying in length from 480 feet to 1400 feet, supported at suitable intervals, and maintained at any desired depth below the surface of the water. This drag is towed over any given area by launches, and in the area so searched no elevation of the bottom above the depth at which the wire is suspended can escape detection. Buoys floating at regular intervals along the drag indicate to observers in the launches when and where an obstruction is touched, and the spot so indicated is then accurately determined.

This method of sweeping has proved a sure means of detecting pinnacle rocks and similar erratic obstructions which heretofore have eluded the hydrographic surveyor, since it is almost impossible to discover them by lines of soundings with the lead. Only the navigator in whose hands rest many lives and much property can realise the relief from mental strain that comes from knowing that the water in which he is sailing is absolutely free from hidden dangers, or that every menace is charted. The device has proved very satisfactory under widely varying conditions, and marks a decided advance in marine surveying.

The report, or any one of the appendices, may be obtained by interested persons, free of charge, upon application to the superintendent of the Coast and Geodetic Survey, Washington, D.C., U.S.A.

## *THE MECHANICS OF THE INNER EAR.*

THE University of Missouri has recently issued a memoir by Prof. Max Meyer, in which an interesting, instructive, and suggestive attempt is made to explain the mechanism of the cochlea without having recourse to the application of the principle of sympathetic vibration, or rather without the assumption that there exists in the cochlea, in the form of the organ of Corti, a vast number of delicate structures tuned, as it were, to tones of different frequencies. Prof. Max Meyer does not base his views on experimental data; his paper is a purely theoretical discussion as to how the cochlea may act, if we make six fundamental assumptions, none of which can, at present at all events, be tested by direct examination or by direct experiment. His inquiry begins with the movements, in and out, of the stapes at the oval window. The tube filled with fluid is divided into three compartments, the upper, the scala vestibuli, communicating at the apex of the cochlea with the scala tympani, at the foot of which we find the round window, while between the two scalæ we have the cochlear duct, or scala intermedia, composed, in its turn, on one side by the basilar membrane, on which rests the organ of Corti, and on the other by Reissner's membrane. When the base of the stapes is pushed inwards at the base of the scala vestibuli, pressure is communicated to the fluid in the scalæ (the scalæ communicating at the apex of the cochlea by a little opening, the helicotrema), and the membrane of the round window passes outwards, towards the tympanic cavity. It is generally held that with such pressure the fluid in the scalæ moves as a whole, and that pressure is communicated to the whole length of the scala intermedia, and especially to the basilar membrane, and that in this way the nerve-endings in Corti's organ are also submitted to pressure. The question then arises, is there any differentiating mechanism in the basilar membrane or in Corti's organ for tones of different frequencies, or, in other words, have we here an organ capable of analysis? Some deny any such property, while others, since the views of Helmholtz were first promulgated, are of opinion that there does exist an analysing mechanism.

The theory of Prof. Meyer essentially is that when the base of the stapes is pressed inwards a section of the membrana basilaris is also pressed in one direction until it reaches its limit of movement. On the basilar membrane rests the organ of Corti, the delicate hair cells being supported on the backs of the rods or arches of Corti. The membrane of Reissner may be regarded as merely protective, and a similar function Prof. Meyer awards to the arches of Corti, which are a kind of skeleton to prevent the delicate hair cells and nerve endings from being crushed by downward pressure on the membrana basilaris. No one can say what is the function of the membrana tectoria, the cushion-like structure that lies over the apices of the hair cells, and the nerve endings that, according to some histologists, lie between the hair cells. It may be a damper or it may be the arrangement by which pressures are made on the apices of the hair cells or nerve endings. There is thus, according to Prof. Meyer, a movement in one direction of a segment of the membrana basilaris, the direction being towards the scala tympani. When the base of the stapes has passed inwards to its fullest extent, the segment also moves to its limit, and then when the base of the stapes passes outwards the segment passes in the reverse direction, that is, towards the scala vestibuli. The rest of the basilar membrane beyond the segment is undisturbed. It is not known whether the basilar membrane is elastic or not; most probably it is non-elastic, but its backward swing has also its limits, and the velocity of the backward spring is probably slower than its forward swing, seeing that it is weighted on one side by the Corti cells, &c. The intensity of the tone will be determined by the amplitude of movement of the base of the stapes—the extent of the segment being greater as the amplitude is greater, and the reverse. Assuming that the number of nerve fibres in each segment is the same (which is unlikely), the greater the extent of the segment the greater will be the number of nerve fibres irritated, and the greater will be the intensity. The pitch will, of course, depend on the frequency of the movement of the segment, and there is no necessity for the assumption that either segments of the membrana basilaris, or structures upon these, are tuned to certain frequencies. When a compound tone or sound, say a fifth (the frequencies of the components of which are in the ratio of 3 : 2), is sounded, the base of the stapes makes a more complicated movement than that of a simple pendular vibration, and then this compound movement is resolved by two segments of the basilar membrane moving synchronously, in the ratio of 3 : 2, and the nerve endings in one segment would be irritated thrice during the time that the nerve endings in the other segment would be irritated twice. Still more, a segment at or near the base of the stapes would move once in the same time, and give rise to the differential tone, and so on.

Prof. Meyer thus recognises the cochlea as an analytic apparatus, without the necessity of any tuned mechanisms, and he works out his theory with great clearness, much ingenuity, and perfect fairness. His explanations of differential tones are in perfect consistence with his theory, and they are graphically delineated. He does not pretend that his theory is an ultimate solution of the problem attacked. Data are still wanting to found a final theory, and when we consider the minute size of the parts involved, it will probably be many a day before these data have been collected. But as experimental, and even observational, research must start from theory, however imperfect, Prof. Meyer has done good service in advancing his views.

The writer would only remark that he finds it easier to conceive the existence in the cochlea of arrangements adapted to frequencies, and consequently of an analysis by resonance, than to think of the membrana basilaris, short as it is, moving in segments when a complex mass of tones is objectively produced. Such a cochlea as Prof. Meyer has conceived might work in the way he thinks, and the writer would suggest that he should make a huge model, with a big piston, and ascertain whether a stout leather non-elastic membrana behaves as he expects it to do. The writer thinks that Helmholtz's resonance theory, with slight modifications, still holds the field, nor does it seem to him to be negatived (and the same remark applies to the theory of Prof. Meyer) even by the difficulties created by a consideration of differences of phase. The physiological effect produced by the relative *intensity* of a com-

[1] "An Introduction to the Mechanics of the Inner Ear." By Prof. Max Meyer. Science Series of the University of Missouri Studies. Pp. 140. (1907.) Price 1 dollar.

ponent of wave forms produced by components combined in different phases may enable us to distinguish one wave form from another, although, as has been proved experimentally, the forms must be different.

John G. McKendrick.

## COLOUR PHOTOGRAPHY.

The second annual exhibition of the Society of Colour Photographers will be open at 24 Wellington Street, Strand, until June 27. It includes about 230 examples prepared by the various methods that are now available. The section of transparencies on Lumière's autochrome plates is the largest; there are a few reproductions of autochromes, some pinatype transparencies, transparencies by the Sanger-Shepherd process, a good show of three-colour prints prepared with the Rotary Company's tissues and with the Autotype Company's tissues, some pinatype three-colour prints, and a few miscellaneous examples. It is clear that all these methods can be made to give good results, but in every section there is evidence that success cannot be expected without skill and practice.

There are no transparencies that surpass, if any equal, the examples of the Sanger-Shepherd process exhibited by Messrs. Sanger-Shepherd and Co., but we are glad to see some excellent autochromes, such as Nos. 108, 113, and 114 by Mr. J. C. Warburg, and No. 89 by Mr. Maurice Meys, as autochrome plates present the simplest method yet known for getting colour results. Many of the autochromes have an unpleasant coloured granulation obvious to anyone of keen vision when the plate is held at the normal distance from the eye. This is doubtless due to the grouping together into patches of the similarly coloured starch grains, and its absence in some examples may justify the hope that the makers can more thoroughly mix the differently coloured grains now than heretofore.

The application of autochrome plates to photomicrography is well exemplified by Drs. O. Rosenheim and H. R. Hurry. These gentlemen also show photomicrographs of the starch grain itself, and the area of the black filling between the coloured grains is larger than one would have expected, probably larger in the particular plate photographed than in many other plates. Mr. Welborne Piper's copies of autochromes on autochrome plates are very interesting as showing the result of attempts to multiply these colour photographs by exposure in the camera and also by superposition. It is clearly possible to use an autochrome that has not been reversed in the making as a negative from which to prepare other autochromes. Of the prints on paper, those by Mr. H. J. Comley, the secretary of the society, and by the Rotary Photographic Company are specially good, the latter showing excellent portraits of the German Emperor ar Empress and of Prof. Ostwald.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—Lord Rayleigh will visit Cambridge on Tuesday, Wednesday, and Thursday, June 16, 17, and 18, in order to be installed as Chancellor. At 4 o'clock on Tuesday, June 16, he will open the new extension of the Cavendish Laboratory. On Wednesday, June 17, the Chancellor will hold a levée of members of the Senate in the Fitzwilliam Museum at 11.30. On the same day there will be a Congregation at 3.15 p.m., at which honorary degrees will be conferred. The Chancellor will visit the colleges on the morning of Thursday, June 18, and will be received at the gate of each college at times which will be notified.

Mr. A. C. Pigou, King's College, has been elected professor of political economy in succession to Mr. Alfred Marshall, who has resigned the chair.

Dr. Hobson has been re-appointed as Stokes lecturer in mathematics, and Dr. Baker as Cayley lecturer in mathematics, each for five years from Michaelmas, 1908.

The Bradford City Council has resolved to extend the technical college at a cost of 19,000*l.*, including equipment and machinery.

A course of three lectures on "Plankton" will be given by Dr. G. Herbert Fowler at University College on June 10, 15, and 23 at 5 p.m. The lectures are to be addressed to advanced students of the University of London and to others interested in zoology; they will be open to the public without fee or ticket.

Mr. R. N. Rudmose Brown has been appointed to the newly instituted lectureship in geography in the University of Sheffield. Mr. Brown accompanied the Scottish Antarctic Expedition in 1902 as naturalist to the expedition. He acted in 1906 as Special Commissioner, under the Indian Government, for the investigation of the pearl oyster fisheries of the Mergui Archipelago.

The International Congress of Historical Science is to be held in Berlin on August 6–12. The work of the congress will be carried on in general and sectional meetings. Among the eight sections are sections on Oriental history; history of Greece and Rome; history of civilisation and the history of thought, mediæval and modern; sciences subsidiary to history (archives, libraries, chronology, diplomatic, epigraphy, genealogy, historical geography, heraldry, numismatics, palæography, study of seals). Copies of the programme can be obtained from the secretary of the congress, Dr. Caspar, Kaiser-Allee 17, Berlin W. 15.

A combined examination for twenty-three medical entrance scholarships and exhibitions of an aggregate total value of about 1500*l.*, tenable in the faculties of medical sciences of University College, King's College, and in the medical schools of King's College Hospital, St. George's Hospital, Westminster Hospital, and the London School of Medicine for Women, will be held in London by the London Inter-collegiate Scholarships' Board on September 22 and following days. Full particulars and entry forms may be obtained on application to the secretary of the board, Mr. Alfred E. G. Attoe, University College, Gower Street, London, W.C., or to the deans or secretaries of the medical schools concerned.

The establishment of the proposed university for Bristol and the west of England, to which frequent reference has been made in these columns, will make desirable a scheme of cooperation between the Bristol University College and the Merchant Venturers' Technical College. The Society of Merchant Venturers has had the matter under consideration from time to time, and the proposals of the society, signed by its treasurer, have been printed and circulated. The technical college is carried on in three departments, viz. a secondary school, adult day classes for the study of the higher branches of applied science and technology, and evening classes in technological and commercial subjects for artisans. Only a part of the work is of university standard, and such part the society proposes to submit to the control of the new university, but to continue as before the remaining larger part of the teaching not of university standard. The society has expressed its willingness to undertake the faculty of applied science and engineering in the proposed university, and to hand over this work to academic control, a scheme the society maintains would prevent friction and overlapping. These proposals differ in essential respects from those of the university committee, which appears to have thrown out the suggestion that the society's secondary school should be discontinued in connection with the technical college; that the college buildings in Unity Street should be transferred to the University and used only for applied science and engineering, and that another school of technology under a composite committee should be established. To provide a new site and new secondary school—as was done in the similar case of University College, London—would cost, it is said, some 28,000*l.*, and the money does not seem to be forthcoming. The other suggestions of the university committee fail at present to meet with the approval of the society, but we are hopeful that when the money necessary for the establishment of a new university is available it will prove possible by mutual concessions to develop a plan which, while utilising all work of university standing at present being done, will in no way interfere with other good educational work being accomplished in the city.

## SOCIETIES AND ACADEMIES.

### London.

Royal Society, January 16.—"On the Perception of the Direction of Sound." By Prof. C. S. **Myers** and Prof. H. A. **Wilson**, F.R.S.

Lord Rayleigh (*Phil. Mag.*, 1907, xiii., 214) has shown that the determination of the apparent direction of a sound is influenced by phase-differences between the vibrations at the two ears. In the present paper this influence is experimentally further investigated, and a theory is advanced which offers a possible explanation of the effects ultimately in terms other than phase-difference.

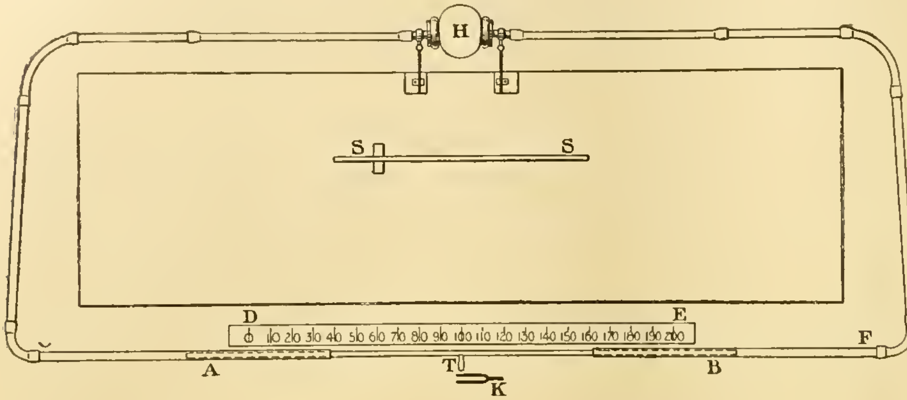

Fig. 1.

The apparatus (Fig. 1) used in these experiments consisted of a brass tube AB about 2·5 m. long and 2·5 cm. in diameter, at the centre of which a short T-piece T was soldered. This tube was freely movable within the two slightly larger tubes CD and EF, from the ends of which tubes were led to two softly padded caps, supported on retort stands, and applied to the ears of the observer H. Beside the tube AB was placed a graduated scale DE, which recorded the position of the T-piece. The sound entered the T-piece from a vibrating tuning-fork K held near it. By sliding the tube AB, so that the T-piece at different times pointed to different divisions of the scale, every kind of phase-difference between the vibrations reaching the two ears could be produced. A screen SS concealed the position of the T-piece from the observer.

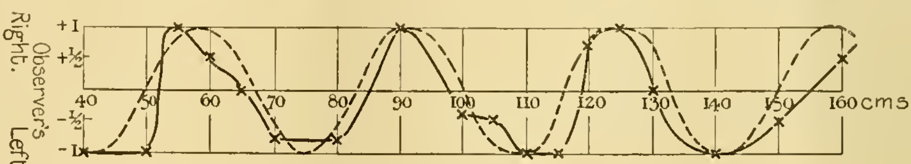

Fig. 2. (512)
(Observer facing towards fork)

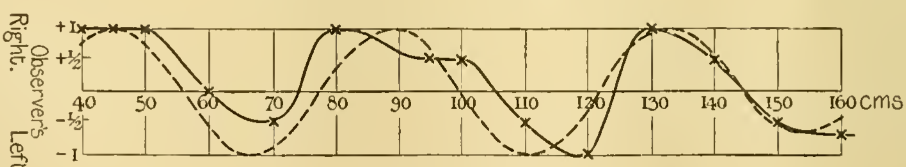

Fig. 3. (384)
(Facing towards)

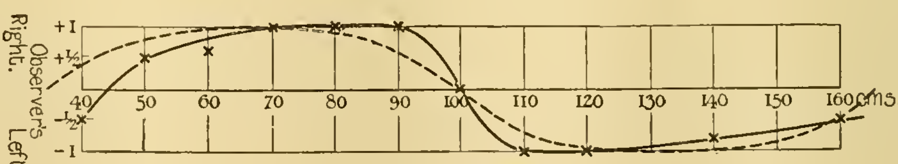

Fig. 4. (128)
(Facing towards)

One of the authors varied the position of the T-piece, sounding the tuning-fork before it at each position, while the other, acting as the observer, stated on which side the fork appeared to be sounding. The answers of the observer could be graded—"full right," "half right," "middle or half right," "middle," "middle or half left," "half left," "full left." At "half right" the lateral direction of the sound was only moderately clear; at "middle" or "half right" it was doubtful, while at "middle" there was no lateral effect at all.

If we call the lateral effect $\phi$, considering right effects positive and left effects negative, then, according to Lord Rayleigh's results, $\phi = A \sin(4\pi nx/v)$, where A is constant, $x$ is the distance in cm. of the T-piece from the middle point of the scale, $n$ is the number of vibrations per second, and $v$ the velocity of sound.

The results of the observations can be conveniently expressed in the form of curves, the abscissæ expressing the scale-readings and the ordinates the lateral effects. For this purpose a "full right" is reckoned as 1, a "half right" as a $\frac{1}{2}$, a "middle or half right" as a $\frac{1}{4}$, a "middle" as 0, the corresponding left effects having equal, but negative, values. Figs. 2, 3, 4 show the curves obtained with forks of frequencies 512, 384, 128. The dotted line in each figure is the curve $\phi = \sin(4\pi nx/v)$.

It is at once apparent that the theoretically and the experimentally obtained curves agree with one another remarkably well. The discrepancies which were sometimes met with were, with the aid of manometric flames, traced to the occurrence of resonance in one or other side of the tube. Interesting results were obtained from experiments conducted when the tubes were partially blocked or gradually pinched on one side. Other observations, of psychological rather than physical or physiological interest, are reserved for a future communication.

It is here suggested that the lateral effects thus produced by differences of phase at the two ears are really and ultimately due to the binaural differences of sound-intensity which must result, if the sound, entering one ear, is transmitted (as from psychophysiological data we know that it must be) across the head by bone conduction to the opposite ear. This suggestion receives support from a detailed mathematical consideration of the conditions. It may be added that the writers hope in a future paper to discuss the applicability of this explanation to the interesting experiments which Lord Rayleigh has brought forward.

March 5.—"The Relation between Wind Velocity at 1000 Metres Altitude and the Surface Pressure Distribution." By E. **Gold**. Communicated by Dr. W. N. Shaw, F.R.S.

It is a matter of common observation that the wind does not blow along the pressure gradient, but in well-exposed situations more nearly at right angles to it or along the isobars. It is equally well known that near the centres of anticyclonic or high-pressure areas the winds are very light, and it has been customary to attribute this fact to the coincident occurrence of small gradients of pressure. It appears, however, that these latter results, instead of being mutually explanatory, are both due to the effective centrifugal force arising from the earth's rotation, the admitted cause of the tendency to motion along the isobars.

If we express the fact that for steady horizontal motion in a path of curvature $1/r$, the part of the centrifugal force arising from the motion of the wind is balanced by the effective gradient of pressure, we obtain the equation

$$\frac{(wr\sin\lambda \pm v)^2}{r} = \frac{1}{\rho}\frac{\partial p}{\partial r} + \frac{(wr\sin\lambda)^2}{r},$$

where $p$ is atmospheric pressure, $\rho$ density, $v$ velocity of moving air, $\lambda$ latitude, and $w$ the angular velocity of the earth about its axis. If there is no friction, the variation of $p$ along the path must be zero or the path must be an isobar. If $\partial p/\partial r$ be negative, corresponding to a path concave towards the higher pressure, $v$ and $wr\sin\lambda$ must have opposite signs, or the air must rotate in a clockwise direction. Further, in this case $\frac{1}{\rho}\frac{\partial p}{\partial r}$ cannot exceed $\frac{(wr\sin\lambda)^2}{r}$ numerically, and $v$ cannot exceed $wr\sin\lambda$, so that for steady motion in anticyclonic regions there are definite limits to the gradient and velocity.

A general idea of the importance of this result is to be gained from the fact that at no point within 100 miles of the centre of an anticyclonic system of circular isobars in latitude 50° can the theoretical steady wind velocity exceed twenty miles per hour.

It is shown by analogy with the motion of a particle on the earth's surface that the time necessary for bringing about the state of steady motion is small enough for us to expect it to be the general state except where obstacles set up eddies. It is proved that the velocity calculated from the above equation is, for a given surface-pressure distribution, independent of the altitude provided there is no horizontal temperature gradient and the necessary corrections are given for the case of varying temperature when the direction of the horizontal isotherms does not change with altitude. The values of the theoretical steady velocity can by this means be calculated for any altitude from the surface observations. This was done for Berlin for 8 a.m. on each day of the year 1905, the temperature correction being disregarded. The results were compared with the actual velocities observed at 1000 metres' altitude in kite and balloon ascents. The theoretical and observed values showed a striking agreement both in direction and in magnitude, proving that the effect of surface irregularities on the horizontal air motion is practically obliterated at 1000 metres, and that we can obtain definite values for the wind velocity at moderate altitudes from the surface observations of pressure and temperature with a good degree of accuracy.

April 2.—"The Alcoholic Ferment of Yeast-juice. Part iii. The Function of Phosphates in the Fermentation of Glucose by Yeast-juice." By A. **Harden** and W. J. **Young**. Communicated by C. J. Martin, F.R.S.

(1) The addition of a phosphate to a fermenting mixture of glucose and yeast-juice not only produces a temporary acceleration in the rate of fermentation, but, in addition to this, an increased total fermentation.

(2) This last effect is due to the fact that the hexosephosphate formed during the period of temporary acceleration is continually hydrolysed by an enzyme, with production of free phosphate, which again enters into reaction, and thus brings about an increased fermentation.

(3) It appears probable that the presence of phosphate is essential for the alcoholic fermentation of glucose by yeast-juice, the reaction which occurs being the following:—

$$(1)\ 2C_6H_{12}O_6 + 2R_2HPO_4 = 2CO_2 + 2C_2H_6O + C_6H_{10}O_4(PO_4R_2)_2 + 2H_2O.$$

This reaction is only realised in the presence of the ferment and coferment discussed in previous communications, phosphate alone being unable, in the absence of coferment, to bring about fermentation in a mixture of ferment and glucose.

The hexosephosphate thus formed is then hydrolysed:—

$$(2)\ C_6H_{10}O_4(PO_4R_2)_2 + 2H_2O = C_6H_{12}O_6 + 2R_2HPO_4.$$

The rate at which this second reaction occurs determines the rate of fermentation observed when glucose is fermented by yeast-juice.

(4) An optimum concentration of phosphate exists which produces a maximum initial rate of fermentation. Increase of concentration beyond this optimum diminishes the rate of fermentation.

**Entomological Society**, May 6.—Mr. C. O. Waterhouse, president, in the chair.—*Exhibits*.—A. H. **Jones**: An example of the melanic ab. *nigra* of *Tephrosia consonaria* bred from the ovum from a wild ♀ taken near Maidstone, and a living larva of *Sesia andreniformis* feeding in the stem of *Viburnum lantana*.—R. **Shelford**: Specimens of insects in amber showing several forms closely allied to those of existing insects, one orthopteron being very near to *Ectobia lapponica*.—**President**: A living example of Blatta found in bananas from Mexico. Mr. Shelford said he thought the species to be *Pandora niveus*, Lin.—H. M. **Edelsten**: A living larva of *Nudaria senex*, and living larva and pupa of *Calligenia miniata*.—O. E. **Janson**: A white aberration of *Epinephele jurtina*, taken in Holme Park, Sussex, in June, 1904.—Lieut.-Colonel N. **Manders**: A collection of butterflies from Bourbon demonstrating examples of mimicry and the effects of the interaction of species.—W. J. **Lucas**: (1) A glow-worm found at Oxshott on May 4, inside the shell of the snail *Helix cantiana*. There was no doubt that the larva was feeding on the snail, for on breaking away parts of the shell the moist remains of it were found near the apex. (2) The ♂, ♀, and nymph of the dragon-fly *Oxygastra curtisii*, first described by the late J. C. Dale, and at that time supposed to be confined to the British Islands.—H. St. J. **Donisthorpe**: An example of the beetle *Xantholinus distans*, Kr., taken at Helton, near Dumfries, on May 1, a species new to the British list.—*Papers*.—The British dragon-flies of the "Dale collection": W. J. **Lucas**.—The distinctness of several species of Everes, determined by their genitalia: Dr. T. A. **Chapman**. The author announced as the result of his investigations that *Everes argiades*, Pall., and the so-called var. *coretas*, were separate, though very nearly allied species.

**Geological Society**, May 6.—Prof. W. J. Sollas, F.R.S., president, in the chair.—Solution valleys in the Glyme area of Oxfordshire: Rev. E. C. **Spicer**. This area is part of the gently tilted great oolite limestone plateau, indented by sunken valleys, principally with a strike-and-dip trend, that appear to be subsidence valleys. They begin suddenly, and descend with sinuous curves to a main valley. The main valley likewise enters a stream valley. The stream valley develops into a broad, sinuous river valley, over which a small river stream meanders. The plateau area is free from drift and from marks of surface denudation; there are no marks of marine currents or of ice, no wind-gaps suggest beheaded streams, nor is there evidence of vanished heights. At the mouths of the dry valleys issue streams impregnated with carbonate of lime. It is suggested that percolating water, forming an underground course along joint-lines, removes enough material in solution to weaken a long, winding area over which the surface subsides. Solution widens the stream banks into bowls of soakage, and leaves insoluble material to build up a level valley floor, which rises above and obscures the valley outlet streams, these then forming marshes.—The stratigraphy and structure of the Tarnthal mass (Tyrol): Dr. A. P. **Young**; with a note on two cephalopods collected on the Tarnthal Köpfe (Tyrol): G. C. **Crick.** The occasion for this paper is the discovery of fossils which appear to throw new light on the relations of the rocks of this mountain. The rock series is divided into three parts, and the succession summarised. An explanation of the structure is then suggested. A petrographical note is furnished on the amphibolite of Gufidaun.

**Physical Society**, May 8.—Dr. C. Chree, F.R.S., president, in the chair.—A modified theory of gravitation: Dr. C. V. **Burton.** If we are to regard gravitational attraction as exerted through the medium of the æther, it appears to the author difficult to avoid the conclusion that the very great (or possibly infinite) velocity with which such attractions are propagated is due to the very great (or complete) incompressibility of the æther. This conception is embodied in the pulsatory theories of Hicks and of subsequent writers; the chief outstanding difficulty has lain in providing for that agreement of phase which must be assumed to subsist amongst the centres of pulsatory disturbance associated with the mutually attracting masses. This difficulty is avoided if we suppose that primary waves of compressional-rarefactional type are being propagated through the æther with a velocity enormously transcending that of light. These primary waves may be travelling in directions indifferently distributed, or predominantly or exclusively in one direction; but an essential point is that all effective wave-lengths should be very great, measured even by astronomical standards. Thus the pressure changes will be sensibly in the same phase over considerable regions, and if the ætherial compressibility is locally increased (or diminished) by the presence of electrically neutral matter, every particle of such matter will act as a centre of pulsatory motion. For the electron, so far as concerns this modification of ætherial compressibility, a specification is assumed which involves no restraint on the free mobility of the electron through the æther. Incidentally, the dynamics of the problem assumes a relatively simple form, and a value which could be quite insignificant attaches to a "gravitational (or non-electromagnetic) term" appearing in the expression for the total inertia of an electron.—An examination of the formulæ for the grading of cables: C. S. **Whitehead.**—Illustrations of geometrical optics: R. M. **Archer.** Light from a narrow rectilinear source is allowed to pass through a slit and fall upon a flat white surface at almost grazing incidence. It is easy to obtain upon the surface a long narrow streak of light with sharp edges, and if a mirror be placed with its plane approximately normal to the surface another streak corresponding to the reflected ray can be seen. Similarly, the path of the beam after its emergence from a glass block or prism may be traced. Interesting effects can be obtained by using many slits and casting the beam from a distant optical lantern upon them. This mode of illumination is useful in demonstrating the formation of caustics. Quantitative results can be obtained comparable in accuracy with those given by an ordinary optical bench.

**Zoological Society**, May 19.—Dr. F. DuCane Godman, F.R.S., vice-president, in the chair.—*Exhibits.*—Preparations of a new gland found in certain teleostean fishes: W. **Woodland.** This new gland is quite distinct from the gas-gland, and consists of rows of huge columnar cells, which are situated in close connection with the blood-vessels, which possess large nuclei and nucleoli, and are packed with numerous large spherical granules derived from the red-corpuscle disintegration concerned in the generation of the oxygen contained in the swim-bladder. These granules, thus abstracted by the gland-cells from the blood, are carried away by special ducts appertaining to the gland. The discovery of this gland confirms Jæger's view as to the mode of generation of the bladder oxygen. This gland exists in Gobius, Syngnathus, Peristedion, Box, and some other genera.—Specimen of a petrel, *Œstrelata neglecta*, Schleg., picked up dead, yet in a quite fresh condition, at Tarporley, in Cheshire, on April 1, 1908: T. A. **Coward.** This bird is a native of the southern Pacific, and has almost certainly never been recorded from the northern hemisphere, and certainly never from Europe before.—The tanned skin of a wild cat, obtained by the Hon. Mason Mitchell, of the American Consular Service, in Sze-chuen: R. **Lydekker.** Mr. Lydekker had compared the skin with a light-coloured skin of *Felis temmincki* from Sikkim, and described it as a new local race of that species.—Specimen of chert from the Middle Culm-measures (Carboniferous) of Christon Down, near Doddiscombe Leigh, Devonshire, showing numerous large and well-preserved Radiolaria: C. Davies **Sherborn.**—*Papers.*—The Cyril Crossland collection of Calcarea from Zanzibar and Wasin (British East Africa): C. F. **Jenkin.** Notes on the Australian fossorial wasps of the family Sphegidæ, with descriptions of new species: R. E. **Turner.** Eighty species were described as new, and the absence of the genera Oxybelus and Philanthus, otherwise of world-wide range, from Australia was commented on. —The heredity of secondary sexual characters in relation to hormones; a contribution to the theory of heredity: J. T. **Cunningham.** The paper contained an examination and criticism of the most important recent investigations and theories on the subject by evolutionists of various schools, namely, the theory which attributes such characters to constitutional causes, such as male katabolism, Prof. Karl Pearson's biometrical investigation of sexual selection in man, Castle's Mendelian theory of the heredity of sex, and Geoffrey Smith's views on dimorphism of males and parasitic castration in Crustacea. The author maintained that all these contributions were more or less inconsistent with the known facts concerning the connection between the development of secondary sexual characters and the functional activity of the primary gonads. He directed attention to the recent discovery and experimental proof on the part of physiologists that the development of the characters was due to the stimulus of a chemical substance or hormone produced by the testis or ovary, and passed into the blood, and suggested that conversely hormones from parts of the soma might affect the gametes in the gonads. In this way the hypertrophy of a part of the body due to external stimulation might modify the corresponding determinants in the gametes so as to produce some hereditary effect in succeeding generations. Mr. Cunningham added that his theory was an interpretation in terms of modern physiology of Darwin's theory of pangenesis.

**Chemical Society**, May 21.—Sir William Ramsay, K.C.B., F.R.S., president, in the chair.—Hydro-aromatic ketones, preliminary note: A. W. **Crossley** and C. **Gilling.** A description of the condensation products obtained from 5-chloro-1 : 1-dimethyl-$\Delta^4$-*cyclo*hexenone-3, with ketonic esters.—The sulphides and oxysulphides of silicon: I. G. **Rankin** and S. M. **Revington.** Berzelius's sulphide is shown to be $SiS_2$, and the compositions of the monosulphide and the oxysulphides, SiSO and $SiSO_2$, have been definitely established.—Apparatus for experiments at high temperatures and pressures, and its application to the study of carbon: R. **Threlfall.** A simple and comparatively inexpensive steel apparatus for the investigation of reactions at high temperatures and pressures was described, and the results obtained by melting carbon under a pressure of about 100 tons per square inch were detailed. In every case soft, crystalline graphite was obtained, and the view is taken that for the formation of diamond under these conditions other substances must be present, and the nature of these will probably be determined by the constituents of diamond ash.—Acids as accelerators in the acetylation of amino-groups: Miss A. J. **Smith** and K. J. P. **Orton.** It was shown that minute quantities of sulphuric and other mineral acids greatly accelerate the acetylation of such substances as anilines with two negative groups in the ortho-positions with respect to the amino-group.—The chemical action of radium emanation, part iii., on water and certain gases: A. T. **Cameron** and Sir W. **Ramsay.** The decomposition of water and the re-combination of hydrogen and oxygen under the influence of radium emanation have been confirmed. Carbon dioxide decomposes into carbon, oxygen, and the monoxide, and the last is changed into carbon, oxygen, and the dioxide. Ammonia breaks up into its components, as does also hydrogen chloride. The rate of change in these reactions is in all cases proportional to the rate of change of the emanation.—The chemical action of radium emanation, part iv., on water: A. T. **Cameron** and Sir W. **Ramsay**. The formation of neon from radium emanation in presence of water is confirmed.—Titani-dihydroxymaleic acid, and the detection of titanium: H. J. H. **Fenton**. Dihydroxymaleic acid in aqueous solution gives an intense red-brown colour with quadrivalent titanium compounds. The reaction is sensitive enough to be used as a test for titanium, and serves to distinguish it from vanadium.—The preparation of diselenides. Dibenzyl diselenide, preliminary note: T. S. **Price** and L. M. **Jones**. The diselenides are prepared by the addition of a solution of sodium selenosulphate to a solution of the alkyl chloride.—The optical and sensitising properties of *iso*cyanine dyes: S. E. **Sheppard**. The results of an examination of the absorption spectra, &c., for gelatinobromide plates are given.—The polarimetric study of intramolecular re-arrangement in inactive substances: T. S. **Patterson** and A. **McMillan**. The authors have applied their method (Trans. Chem. Soc., 1907, xci., 504) to measure the rate of inversion of piperonal*syn*oxime and similar substances.—Mercuric zinc cyanide: W. R. **Dunstan**. The formula $Zn_3Hg(CN)_8$ is now given to this substance instead of $Zn_4Hg(CN)_{10}$, as formerly proposed (Trans. Chem. Soc., 1892, lxi., 666).—Ethyl 6-methyl-2-pyrone-3:5-dicarboxylate and its derivatives: J. L. **Simonsen**.—Contributions to the chemistry of the amidines, part ii., 2-anilinobenzoxazole and the supposed anilodihydrobenzoxazole: G. **Young** and A. E. **Dunstan**.—The slow decomposition of ammonium chromate, dichromate, and trichromate by heat: W. C. **Ball**. The dichromate evolves nitrogen, water, and ammonia, and leaves eventually a black compound, $3CrO_2,H_2O$. At an intermediate stage a black product having the formula $2CrO_3,Cr_2O_3,2NH_3,H_2O$ is formed.

**Royal Microscopical Society**, May 20.—Mr. A. N. Disney in the chair.—A series of lantern-slides of old microscopes that the society will exhibit at the Franco-British Exhibition was shown on the screen. Mr. **Rousselet**, the curator, in giving a description of the instruments, said the collection was illustrative of the history of the microscope, and would consist of twenty-eight microscopes mostly taken from the society's collection, several others being lent for the purpose by Sir Frank Crisp and Mr. E. M. Nelson. The collection included, with others, a model of Leeuwenhoek's microscope, date about 1673; microscopes by Musschenbroek, 1702; Wilson, 1702; Culpeper, before 1738; Lieberkuhn, 1738; John Marshall, 1744; John Cuff, 1744; Benjamin Martin, 1760, and one made for George III., 1771; Dellebarre, 1777; Jones's "Most Improved," 1798; Lister-Tulley, 1826; Cuthbert's reflecting microscope, 1827; Chévalier, 1834 and 1840; Hugh Powell, 1839 and 1841; Jas. Smith, 1841; Andrew Ross, 1842; Dr. Edwin Quekett, 1844; and Powell and Lealand, 1848.—An old photomicrographic apparatus designed by Dr. Maddox for Dr. Lionel S. Beale: J. E. **Barnard**. There were two points of interest about it, the first being the application of an arrangement between the objective and the stage for excluding extraneous light, the other was that the illuminating apparatus was carried on a triangular bar, which had the apex inverted, thus losing the advantage to be derived from the application of the principle of the triangular bar.

Cambridge.

**Philosophical Society**, May 4.—Dr. Hobson, president, in the chair.—The geographical distribution of the acarine family Oribatidæ: C. **Warburton**. It seemed likely that if ever the Oribatidæ of the world should be widely investigated they would prove to be a very characteristic fauna of the various zoological regions, for they seem to possess none of the facilities for extensive distribution exhibited by most of the other Arachnids or by insects. They are highly specialised mites, not parasitic on animals like the ticks and Sarcoptidæ, nor attaching themselves to other creatures for purposes of distribution like the Tyroglyphidæ. They are, of course, wingless, nor have they the power of spinning silken parachutes like spiders so as to utilise the wind. They are slow moving, vegetable-feeding mites, and in England their distribution is very local. Samples of moss containing the living mites have been received from certain widely separated localities, and the results are not at all what were expected. On the whole there is a great resemblance between all the collections, and some species seem to be practically cosmopolitan. Moreover, these species are not primitive in appearance, nor are they among the most active of the group. The almost world-wide distribution of certain forms seems difficult to account for unless the creatures have remained unaltered for a very long period of time.—Some new and obscure species of the genus Hæmaphysalis of the Ixodidæ: C. **Warburton**. This paper was an attempt to remove the confusion which had arisen with regard to the species *Haemaphysalis flava*, *H. bispinosa*, and *H. papuana*. Four species had been confused under the name of *H. flava*, and two of these were now described as new—*H. japonica* and *H. campanulata*. Neumann's *H. bispinosa* was restored and separated from *H. hystricis*, of which he considered it a synonym. A species confused by Neumann with *H. papuana* was described as new under the name of *H. crassa*.—The fauna of the Bradford coke bed effluent: Dr. A. **Meixner**.

Manchester.

**Literary and Philosophical Society**, April 7.—Mr. Francis Jones, vice-president, in the chair.—The occurrence of quartz crystals in limestone, columnar coal, marble, &c.: R. **Pettigrew**. Photographs, microscopic and lantern-slides, were exhibited showing microscopic crystals of quartz obtained from mountain limestone, columnar coal from Airdrie, in Lanarkshire, and ordinary statuary marble.—Note on the action of oxalic acid on cellulose: Prof. E. **Knecht**. It appears that the action of oxalic acid on cellulose simply constitutes one example of a general mode of formation of acidyl celluloses.

April 28.—Prof. H. B. Dixon, F.R.S., president, in the chair.—Some observations on the chemical effect of tropical sunlight: Dr. G. J. **Fowler**. The results show that the greatest photochemical effect is obtained on the sea, the highest record being on the Arabian Sea (lat. 16° 31′, long. 54° 8′) in the vicinity of the Arabian coast. Here the chemical intensity of the sunlight was forty-two times what has been recorded on a bright sunny day in winter in Manchester, and three times the highest summer record in Manchester. The average record for Calcutta was about double the highest for Manchester in 1892. There does not appear to be any relation between the photochemical effect of sunlight and the liability to cause sunstroke, the records in the Mediterranean being as high as in Calcutta, and one record furnished by Dr. Bailey from Pontresina being higher than the average for Calcutta. Evidence is also mentioned which suggests that sunstroke is not purely a heat effect. In the same way sunburn does not seem to depend entirely either on the photochemical or heat intensity of sunlight. The full explanation of these phenomena has not, it is believed, been yet given. The results of the observations recorded show generally that the photochemical effects of tropical sunlight do not differ in kind from those observed under European conditions; indeed, in certain favoured European localities equally striking effects may be obtained.

Paris.

**Academy of Sciences**, May 25.—M. H. Becquerel in the chair.—The recent eruption of Etna (Taormina, May 15, 1908): A. **Lacroix**. This eruption broke out in a region quite distinct from that of the eruptions of 1883, 1886, and 1892. Details are given of the formation and appearance of the new crater, of the lava, and the erosion phenomena caused by the lava.—The stimulating properties of the serum of healthy and tuberculous animals, and of animals treated with tuberculin, on cobra poison: A. **Calmette**, L. **Massol**, and C. **Guerin**. A description of experiments on the production of lecithin in blood serum by experimental tuberculosis.—A method of M. Goursat in Monge's problem: P. **Zervos.**—The general problem of probabilities in repeated trials: L. **Bachelier.**—The secondary rays from the $\alpha$ rays: William **Douane.** The production of the secondary rays ceases almost entirely when the radium salt is removed more than 2 cm. from the slit; this distance is precisely that which was found in earlier experiments for the charge of the $\alpha$ rays.—The potential difference and stability of the alternating arc between metals: C. E. **Guye** and A. **Bron.** The contradictory results of earlier workers are largely due to the difficulty of maintaining the stability of the arc. The authors have obtained arcs of high stability by bringing the electrodes to a temperature near their melting points, and having a large reserve of potential (20,000 volts) in open circuit. For metals which are slightly volatile the potential difference, under equal conditions, tends to a lower limit, approximately the same (about 470 volts) for all metals.—The existence and origin of harmonics in the self-induction spark: G. A. **Hemsalech.**—The impossibility of diagnosing death by the radiography of the abdominal organs: Maxime **Ménard.**—Contribution to the study of the oxidation phenomena produced by iodic and bromic acids: H. **Baubigny.** Bromide of silver in ammoniacal solution is stated to be converted at 100° by iodic acid into silver iodide and ammonium bromide; this statement is now shown to be erroneous, the reaction in reality being quite different. A small proportion of the ammonia is oxidised by the iodate at 200°, nitrogen, water, and ammonium iodide being produced.—A new volumetric method allowing the simultaneous estimation of carbonic acid and other acids in atmospheric air: H. **Henriet** and M. **Bouyssy.**—The estimation of tungstic acid and its separation from other substances by the use of a mixture of chlorine and chloride of sulphur: F. **Bourion.** The method proposed is described in detail, and its accuracy proved by the results of analyses of sodium tungstate, silicotungstic acid, ytterbium, silicotungstate, and a mixture of silica and tungstic acid.—The triboluminescence of mineral substances: Adrien **Karl.**—The syncytial nature of the intestine of Rhabdocœles: Paul **Hallez.**—The comparative action of simple salt solutions and artificial serums with complex mineral contents on the blood and circulation: C. **Fleig.**—The action of acids on the coagulation of milk by vegetable ferments: C. **Gerber.**—The experimental study of the cutting of twigs for slips: A. **Imbert.**—The study of the bactericidal action of anti-virulent serum on the adventitious germs of vaccine: L. **Camus.**—The transmission of syphilis to the cat: C. **Levaditi** and T. **Yamanouchi.**—The different levels of alluvium at the confluence of the Yonne and the Cure: Paul **Lemoine.**—Two causes of error in experiments on fluorescein: F. **Dienert.** A fluorescent substance occurs naturally in certain waters, and this may cause difficulty when fluorescein has been used to trace the passage of underground water. The added dye may often travel very slowly, and by its appearance cause confusion when a second experiment is being carried out in the same district.—The temperature of the thermal waters of the eastern Pyrenees: O. **Mengel.**

## SYSTEMATIC EXPLORATION AT DEIR-EL-BAHARI.

*The Eleventh Dynasty Temple at Deir-el-Bahari.* Part i. By Eduard Naville, with chapters by H. R. Hall and E. R. Ayrton. Pp. ix+75; 31 plates. (London: The Egypt Exploration Fund, 1907.) Price 25*s*.

IN 1893, Prof. Naville undertook for the Egypt Exploration Fund the work of clearing Queen Hatshepsut's celebrated temple at Deir-el-Bahari at the foot of the cliffs bounding the western side of the necropolis of Thebes. This work was completed in 1903, but during the progress of the clearing certain relics of the eleventh dynasty were unearthed which led M. Naville to believe that under the sand and rubbish mounds on the south side of Hatshepsut's temple lay concealed a building or cemetery of the Early Middle Kingdom. In these southern mounds of Deir-el-Bahari, Prof. Naville and Mr. H. R. Hall began to excavate in 1903, and they soon brought to light the platform of what they conjectured to be another and an earlier temple. Continuing their excavations, they found a number of slabs of stone and columns bearing the cartouches of King Neb-hatep-ra Mentu-hetep, and it was not long before they had cleared enough of the building to show that the ruin before them must be the mortuary temple of that eleventh-dynasty King. The clearing was steadily continued during the winter seasons until 1907, and the volume before us is the first part of the record of a patient and thoroughly systematic piece of exploration. In the writing of the memoir Prof. Naville has been assisted by Mr. H. R. Hall, of the British Museum, and by Mr. E. R. Ayrton, one of the Egypt Exploration Fund officers.

In the first chapter Prof. Naville deals with the difficult question of the sequence of the eleventh-dynasty kings. The Royal Canon of Turin preserves the names of only the last two: (1) Neb-hatep-ra (Mentu-hetep) and (2) Se-ankh-ka-ra (Mentu-hetep) The order of three other kings of this dynasty is now established from a newly acquired stele in the British Museum quoted by M. Naville; this gives (1) Uah-ankh Antef-aa, (2) Nekht-neb-tep-nefer Antef, and (3) Se-ankh-ab-taui Mentu-hetep. The only other well-authenticated sovereign of this Theban line of princes is Neb-taui-ra Mentu-hetep, whose place is probably between Se-ankh-ab-taui Mentu-hetep and Neb-hatep-ra Mentu-hetep. To this list of six kings Prof. Naville would add another Mentu-hetep whom he calls Mentu-hetep III., but the separate existence of this sovereign is extremely problematical; he only differs in his "Horus" name from Neb-hatep-ra (M. Naville's Mentu-hetep II.), his prenomen and nomen are the same, and the difference in the Horus-name may well be due to his further territorial conquests. Another King Mentu-hetep discovered by M. Naville (pl. xii. i) certainly belongs to the later intermediate period between the end of the twelfth dynasty and the beginning of the eighteenth; the prenomen cannot be read on the published fragment Se-kha-en-ra as the explorer suggests, although that prenomen certainly occurs on another block found in the temple (pl. xii. j). Se-kha-en-ra, it may be pointed out, is the prenomen of a Hyksos king, and to the Hyksos period or thereabouts also belong the vassal Kings Dudu-mes (p. 3) and Senb-ma-iu (Naville in E.E.F., Arch. Report, 1906–7, p. 6), monuments of whom M. Naville and Mr. Hall have found in the eleventh-dynasty temple at Deir-el-Bahari.

In the second chapter Mr. Hall deals with the temple and its excavation. He points out that although the mortuary temple of Neb-hatep-ra has been found, the actual *tomb* of the king, which we know from the Abbott Papyrus was intact as late as the time of Rameses IX., has as yet eluded the explorers' search. The name of the temple was Akh-asût-Neb-hatep-ra, "Brilliant are the seats of Neb-hatep-ra," and it is often mentioned in the hieroglyphic inscriptions. The second mortuary temple, named Men-asût, "Firm are the seats," referred to on p. 11, was that of Queen Ahmes-nefret-ari, and was discovered in 1896 on the edge of the desert at Kurneh—a fact which seems to have escaped Mr. Hall's notice. Dating from the beginning of the Middle Empire, this temple discovered by the officers of the Egypt Exploration Fund is the earliest Theban temple known to us, and it is consequently of great interest. It seems to have been the prototype of Hatshepsut's temple, for, like it, it is constructed in terraces, the approaches to which are a ramp or inclined plane flanked by colonnades of square pillars having the cartouche of the king. The ramp leads to a platform which supported the front part of the temple, while the rear portion was cut out of the living rock. In the middle of the upper court is a large superstructure of rough stones which bore a small pyramid—a mere architectural erection—about sixty feet square at the base. This was surrounded by an ambulatory of octagonal sandstone columns, many of which still remain in position. The walls were covered with painted reliefs of religious and civil scenes, and at the back of the central superstructure were found remains of shrines of certain priestesses of Hathor under the eleventh dynasty. The painted reliefs discovered have a curious archaistic appearance. Some depict men gathering reeds, driving animals, sowing and reaping, and so forth, for the maintenance of the royal funerary cult. Others give scenes from the ceremonies of the Sed-festival, and show processions of priests and warriors. The most important, however, are those which relate to a campaign of Neb-hatep-ra against the *Aamu* (pls. xiv., xv.) and the *Reten-reru* (pl. xv. F), both peoples of Asia. The patron goddess of the temple was Hathor, and it is curious that Amon does not appear to find a place in the reliefs, although Set is represented on the wall of the western court in his traditional guise.

In the third and fourth chapters the authors describe very carefully the various tombs found during the course of the excavations: "they are all, with one possible exception, of the eleventh dynasty, and therefore contemporary with the temple," though certain of them contained secondary burials. The sarcophagi of the Princesses Kensit and Kauit will henceforth rank as important examples of the eleventh-dynasty workmanship.

The fifth chapter, by Prof. Naville, is devoted to the twelfth-dynasty monuments found in the temple area, and to the worship, in the later periods of Egyptian history, of King Neb-hatep-ra, the founder of the temple. The most important monument of the twelfth dynasty unearthed was a red granite stela of Senusret III. (why do the authors retain the obsolete transliteration Usertsen?) recording a royal decree to the priest of Amon and to the officials of Thebes, "ordering rations of bread, and beer over and above what had been given before, in order to increase the offerings of his forefather Neb-hatep-ra." This stela, more than one and a half metres high, has since been removed to the Cairo Museum.

In the last chapter, M. Naville deals with his discovery of the famous Hathor Shrine containing the Cow-statue, at present one of the chief objects of interest in the museum at Cairo. This splendid specimen of the Egyptian sculptor's work M. Naville believes dates from the reign of Thothmes III., but it bears the name of his son, Amenhetep II. A fine coloured reproduction of it is given in pl. i., from a water-colour drawing by Mr. Reach.

Several of the photographic plates are poorly reproduced, but a word of praise ought to be given to the line drawings of Madame Naville, which, as always, are excellent.

## BIOGRAPHY OF AN INVENTOR.

*Thomas Alva Edison: Sixty Years of an Inventor's Life.* By Francis Arthur Jones. Pp. xvi+375; with 22 illustrations. (London: Hodder and Stoughton, 1907.) Price 6s. net.

"IT is estimated," so Mr. Francis Arthur Jones tells us, "that if everything that has ever been written and published about Edison were collected and re-published in book form, it would make a library of a thousand volumes—each volume containing an average of a hundred thousand words." The present biography is a most readable and interesting book, which gives a very good insight into Edison's life in the space of 375 pages. It is written for the general rather than the scientific reader. It would be a capital book to place in the hands of schoolboys, and if juvenile readers were to play at setting up make-believe printing presses in railway trains in emulation of Edison's first attempts at educating himself the amusement would be a harmless and instructive one, if they did not reproduce the fiasco which first put the youthful inventor "down on his luck."

This biography should do much to disillusion the impressions which are so commonly formed about successful men, that they only have to invent something in order to make a fortune. It shows clearly that the only road to success is through failure. His career as telegraphic operator was most precarious, and one of his first inventions—a vote-recording machine for election purposes—was refused, really because it was too ingenious and perfect; in fact, it could not be tampered with. His resolve never to invent anything which was not wanted by the community at large helped him greatly, but still the telegraph companies would not seriously consider his systems of multiplex telegraphy until he had done something more. That something was to help them out of difficulties when a breakdown occurred. His successes in obtaining his first cheque from the Gold Indicator Company, and in securing the adoption of his improvements in telegraphy, were only achieved when he had shown his capacity of being handy man in an emergency. Then the success of his inventions in connection with the telephone and phonograph was only bought at the cost of long and patient attempts at trying first one substance and then another for the transmitter of the former and the cylinder of the latter. As to the continual litigation which fell on Edison's shoulders in order to protect his patents, Mr. F. A. Jones's information regarding the large staff of solicitors employed in Edison's legal department bears abundant testimony.

In the later chapters we see how even success brought troubles with it in the form of a crowd of reporters, interviewers, cranks and faddists, and it cannot be doubted that Edison's good humour and ready wit, of which we have here many amusing instances, no less than his indomitable energy and perseverance, were greatly needed in order to enable him to cope with all the work that fell on his shoulders. His biographer is also at considerable pains to disillusion the reader as to the wild and fantastic inventions attributed by unscrupulous newspaper reporters to "the wizard of Menlo Park," and to which the name "Munchausen science" has been given. Unfortunately, many of these tall stories have been read and widely believed in England, and no one is stronger in his condemnation of such fictions than Edison himself.

It would be very desirable that a further book should some day be published dealing more especially with the scientific aspect of Edison's work. It would undoubtedly be a difficult task to write such a book. If Edison did not study at a university in the accepted meaning of the term, he certainly appears to have made a university for himself in his workshops, in which he was his own professor, and it cannot be denied that the training he underwent under these conditions was fully as efficient, and in many ways better, than a course modelled on conventional lines. His education was undoubtedly thoroughly scientific in the best sense of the word, but it was different in the matter of technicalities from that of the ordinary science student. Consequently Edison nowhere figures as a contributor of papers in transactions and periodicals. Some evidence is given in this book that results published elsewhere as "researches" were well known to him years previously. His "notion books," couched though they be in a mysterious language of their own, must contain a lot of important new results, and it will be a pity if no steps are taken to render these results accessible to scientific workers at some future time, if not now. The statement that Edison is now devoting himself exclusively to pure science thus becomes welcome news.

The book is illustrated in the approved style with "Edison at the age of four," "Edison at nineteen," "Edison at forty," and so forth, also "Mr. and Mrs. Edison in the laboratory"; altogether more than a score of illustrations.

We think that one person is kept rather more in the background than is really necessary in this book, that person being Mr. Francis Arthur Jones. He shows such an intimate knowledge of and friendship with Mr. and Mrs. Edison that some further reference to his personal relations with them would not only be justifiable, but would give an added interest to the biography.

We must, however, direct attention to the statement on the last page:—

"Of the force hidden in coal about 15 per cent. only is available, the other 85 per cent. being wasted That is why it requires so many hundreds of tons o coal to propel a liner across the Atlantic. When the problem of generating electricity direct is solved, then two or three tons of coal only will be needed for the same purpose."

"Many hundreds of tons" is, of course, a somewhat elastic term, and we do not know whether Mr. Edison or Mr. Francis Arthur Jones is responsible for the above statement, but taking, say, five hundred tons by way of argument, it is surely a little unnecessary for either of those gentlemen to imperil his reputation for the sake of seventy-two tons of coal.

G. H. BRYAN.

## A FRENCH TREATISE ON GEOLOGY.

*Traité de Géologie. I. Les Phénomènes géologiques.* By É. Haug. Pp. 536; 195 figs., 71 plates. (Paris: Armand Colin, 1907.) Price 12.50 francs.

AMONG the most important of the perpetual needs of geology is the frequent renewal of the international supply of advanced text-books, from which the general conclusions of foreign authorities and the outlines of the geology of foreign lands may be learnt apart from the now overwhelming mass of original literature. In such books the interests of the local students, to whom illustrations of normal phenomena are most important, to some extent conflict with the requirements of foreign geologists, who will profit by the description of exceptional occurrences; but fortunately most authors of advanced works may be trusted to enliven their books by a sufficient number of special cases to make them useful to foreign geologists. The issue of an extensive treatise on geology by Prof. Émile Haug, of the University of Paris, is, therefore, to be warmly welcomed by British geologists, as we may expect it to give an instructive account of geological phenomena in France, a guide to the original literature, and a clear exposition of the current state of geological thought in that country.

Prof. Haug's first volume deals with geological processes and materials. In his statement of the relations of geology to allied sciences he lays stress on the essential importance in geology of the succession of phenomena; and this idea finds frequent expression in the book, from the first chapter on the geological cycle to the last on theories of orogenesis The volume opens with an account of the general morphology of the earth, and he says that "the geological history of our planet is nothing else than the history of its successive cycles"; and he regards the three main subdivisions of geological history, for which he uses the names Primary, Secondary and Tertiary, as each a great cycle beginning with very active sedimentation, followed by intense crustal movements, and closing with a period of great consequent denudation. He suggests that the "preprimary" was a similar cycle, and that the "post-tertiary" will be another."

In his description of rocks he follows the guidance of the same principle by describing them under the headings of lithogenesis, orogenesis, and glyptogenesis, *i.e.* their formation, modification, and destruction. He then proceeds to biological geology, discussing the life of the continents and the distribution of botanical and zoological provinces. The author attaches no value to the theory of the permanence of oceans and basins; and although he notices the objections of Koken and Frech to the assumed Pacific continent, he warmly maintains its former existence. According to Prof. Haug, there were five great continents in Secondary times—the North-Atlantic continent, the South Atlantic or Brazilio-African continent, the Sino-Siberian continent, the Austral-Indian-Madagascan continent, and the Pacific continent. He maintains the Mesozoic existence of these continents, and the fundamental difference from the present distribution of land and water, as a necessary consequence, both of the tectonic structure of the earth and of the distribution of animals and plants. He maintains that:—

"The enigmas of zoological geography are absolutely insoluble if one regards only the existing state of things. But as soon as one admits that the distribution of lands and seas was not, in geological epochs anterior to our own, the same as it is to-day, all these facts become clear in a new light."

After three chapters dealing with the sedimentary rocks, and one on mineral-fuels, the author discusses tectonic geology, crustal movements, and the phenomena of volcanoes and earthquakes. The chapter on fuels shows the author's thorough chemical knowledge of his subject. The excellent chapters on mountain structure are illustrated by numerous clear diagrams to explain the views and terms of Suess, and by artistic photographs of those French Alpine regions where the author has made important researches.

In the treatment of so wide a range of subjects there are naturally a few slips; thus the author four times refers to Ceratodus as living in Tasmania instead of Queensland, and he follows another important recent text-book in the statement that the New Zealand geysers were destroyed by the eruption of 1884. That eruption, however, though it destroyed the sinter terraces of Rotomahana, actually increased the activity of the New Zealand geysers, until they culminated in the eruptions of Waimangu, the greatest of known geysers. Some of the opinions expressed by the author may not be generally followed. He holds that the diamond-bearing block of nickel-iron found in the Diablo Canyon was of volcanic origin, and not a meteorite. According to him, the lateral secretion hypothesis "ne compte plus guère d'adeptes"; and he refers to the impregnation theory for the banket of the Rand as if it were universally accepted, although during recent years the majority of the Rand mining engineers who have had previous experience of placer deposits have rejected the theory.

Each chapter is followed by a bibliographic list, of which one striking feature is the rarity of reference to British geologists even when dealing with British rocks and problems. Thus the chapter upon coals and lignites includes several references to British materials, but there is no mention of British authors on palæobotany or its problems; and though the rock classification accepted follows the lines established by the British school of petrography, a student might read the chapter on igneous rocks and its bibliographic list without a suspicion that any British author had ever taken any interest in petrography.

At the close of the volume the author discusses the displacement of shore lines, the possible instability of sea-level, and the views of Prof. Suess, and he gives an interesting statement of the tetrahedral theory. Though he confesses that the bases of this theory are still uncertain, he thinks that tetrahedral deformation of the earth may be the solution of the hitherto unsolved problems of orogenetic movements.

J. W. G.

## *BOTANICAL PHOTOGRAPHS.*

*Vegetationsbilder.* Edited by Dr. G. Karsten and Dr. H. Schenck. Series iii. (parts 4–8), iv. (parts 1–8); v. (parts 1–8). (Jena: Gustav Fischer, 1906–7.) Price 20 marks each series, or 4 marks for separate parts.

NOTICES of earlier series of this excellent publication, that is due to the enterprise of the publishing firm of Gustav Fischer, appeared in NATURE of November 2, 1905 (vol. lxxiii., p. 4). Any doubts that may have existed as to the success of the venture have been dispelled, and it may be expected that series will follow series for some time to come. Each number containing one or more parts is complete in itself, and the various numbers in a series refer, as a rule, to different countries.

Dr. H. Schenck contributes the photographs reproduced in series iii., part 4, of trees characteristic of the Mediterranean region, of which the olive and cypress are the most important. The island of Socotra furnishes the subject of the next part. Although explored with successful results by the Forbes-Ogilvie expedition, Austrian botanists on a more recent visit also obtained many new plants. About one-third of the flowering plants are endemic, including the curious trees *Dendrosicyos socotrana* and *Adenium socotranum*, with conical swollen stems. Dr. E. Zederbauer provides the illustrations of the dry inner regions of Asia Minor. A typical scene shows scattered cushions of Astragalus and Acantholimon with interspersed plants of *Verbascum olympicum*. A double number is devoted to the small island Koh Chang, near Bangkok, where Dr. J. Schmidt obtained very successful photographs of the pneumatophores of Avicennia, Sonneratia, and Xylocarpus; a singular plant is the orchid *Eria semiconnata*, bearing button-like tubers that are studded over the rocks.

The fourth series opens with an account of myrmecophilous plants found by Mr. E. Ule in the Amazon region; species of Cecropia, Triplaris, and Tachigalia are illustrated. Two separate parts referring to German territory in West Africa are contributed by Dr. W. Busse. The former deals with primitive forests and modern steppe formations in the southern part of Togo; the other depicts economic trees such as the oil palm and shea-butter tree. Mr. C. Skottberg is responsible for a double number in which Tierra del Fuego, the Falkland Isles, and the island of South Georgia are illustrated. On the mainland, trees of Nothofagus give form to the landscape; on the islands the umbelliferous plant *Bolax glebaria*, tussock-grass, *Poa flabellata*, and *Acaena adscendens* furnish characteristic formations. Photographs of algal vegetation in the Færöe Islands have been supplied by Mr. F. Börgesen. Scenes from Arizona represent the work of Mr. C. A. Purpus. They include photographs of pines and some markedly xerophytic types, such as *Cereus giganteus*. Mr. A. Th. Fleroff has selected the water and swamp vegetation of mid-Russia for reproduction in the last part of the series.

A double number containing a continuous ecological account of the formations in the districts of the Eifel and Venn begins the fifth series. The authors, Drs. M. Koernicke and F. Roth, have shown great skill in their photographs of the ground vegetation. A number made up of three parts is devoted to photographs in northern Russia, some representing conditions in the coniferous region, others taken from the subarctic zone, that depict *Rubus chamaemorus*, *Senecio arcticus*, and "tundra" moors. Photographs of Spanish vegetation by Dr. M. Rikli illustrate the only indigenous European palm, *Chamaerops humilis*, the date palm, and esparto-grass, *Macrochloa tenacissima*. The dry season in the country around Ugogo, in German East Africa, furnishes the subject of another part contributed by Dr. W. Busse. Commiphora trees, bushes of *Adenium obtusum*, and *Acacia spirocarpa*, one of the "umbrella" Acacias, are selected for illustration. The final number in the series deals with the vegetation of the Mexican mountains Ixtaccihuatl and Popocatepetl. The author, Mr. C. A. Purpus, has selected illustrations of *Pinus Hartwegii* growing at the tree limit, and of *Senecio calcareus* and grasses in the subalpine region. *Draba Pringlei*, *Arenaria bryoides*, and *Alchemilla pinnata* are shown in the photographs of the higher Alps.

## PAINTS AND PIGMENTS.

*Analysis of Mixed Paints, Colour Pigments, and Varnishes.* By Dr. C. D. Holley and Prof. E. F. Ladd. Pp. xii+235. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1908.) Price 10s. 6d. net.

*Modern Pigments and their Vehicles.* By Frederick Maire. Pp. xi+266. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1908.) Price 8s. 6d. net.

THE book written by Dr. Holley, with the assistance of Prof. Ladd, on the analysis of mixed paints, colour pigments, and varnishes, should prove of considerable practical value, especially in America, and should be of assistance to analysts who have work of this kind to do, as it brings together much information which is otherwise scattered, and contains a good deal which is not to be found in the well-known manual by the late Mr. Hurst. Owing to the very large development of the ready-mixed paint trade in the United States, and the recent legislation there dealing with adulteration, the analysis of ready-mixed paints is of far more frequent occurrence than it is in this country, where it is very rare for a public body or an architect to have a proper examination made of the pigments and varnishes that they use.

The part of the book which deals with the determination of the covering power and tinting power of a pigment might certainly have been more developed. For a great many practical purposes this is a most important question. If, for instance, we take an ochre which is going to be used either to cover a surface by itself or to be mixed with white, the analysis of the ochre gives us little information of any practical value compared with its careful examination for covering power and tinting strength, yet comparatively little is said in the text-books about this method of assaying pigments. The most useful practical instrument for this purpose up to date has been the Lovibond tintometer, which enables the whole matter to be reduced to the plotting of comparative curves of tinting power, and also enables the actual covering power of a white lead to be exactly and accurately measured. The Lovibond tintometer is, however, an instrument which requires a great deal of practice before accurate results can be obtained, and recently Mr. Ives has introduced a new tintometer which may possibly replace the Lovibond tintometer for such purposes. The experiments that were made in this direction by Captain Abney resulted in the development of a most ingenious application of the spectrum, but in practice the Lovibond tintometer has so far proved the more useful instrument.

There is another direction in which the information in the book is somewhat imperfect, and that is the practical testing of varnishes, although the authors can hardly be blamed for this, as so little has yet been done to make the testing of varnishes thoroughly complete and efficient. The practical difficulties are great, and weather tests in the hands of different observers have proved to be very delusive. One of the most important questions on which there is need for far more accurate information is the durability of paints, prepared from different pigments and with different vehicles, when used for the protection of iron and steel structures. This is rapidly becoming a very serious question, as the use of steel in construction is greatly on the increase, and it is not yet possible to give very accurate information upon this matter. While, therefore, this book by Mr. Holley and Prof. Ladd may be regarded as bringing up to date the information both on the analysis of pigments and vehicles, and on the practical testing of their properties, to which the attention of chemists might well be directed, it reveals very clearly that in this department of applied chemistry a great deal more information is required to enable us to determine the facts upon which the suitability and durability of various vehicles depend.

The little book by Mr. Maire does not pretend to be a scientific treatise, but merely brings together much helpful information about modern vehicles and pigments, which is stated in a simple manner, without going into chemical details, and it should therefore prove of use to architects and house-painters and decorators who wish to have some general information as to the materials they use from day to day, and who are yet unable to understand a thoroughly scientific treatise. A fair number of the pigments which are mentioned by Mr. Maire belong rather to the artist's palette than to painters and decorators, but there is no reason why these should not be included and some reference made to them. The main difficulty of the modern decorator is, however, due to the introduction of a large number of pigments which are prepared from coal-tar dyes, fresh ones constantly coming into the market, which may be fugitive or have the property of bleeding, and about which he necessarily has no information. These pigments are introduced with fancy names, each colour maker choosing such names as may suit himself, and consequently a great deal of trouble has resulted in the painting and decorating trade. It is hardly possible for any text-book to deal efficiently with this subject, beyond giving certain general warnings that before using any new pigments, outside those already recognised, careful tests should be made by the architect and decorator.

Both these books can be regarded as thoroughly useful, the one for the analyst and the other for the architect and decorator, and should do something to encourage a more scientific study of these questions in this country.

A. P. LAURIE.

## OUR BOOK SHELF.

*A Dictionary of Spanish and Spanish-American Mining, Metallurgical, and Allied Terms, to which some Portuguese and Portuguese-American (Brazilian) Terms are Added.* By E. Halse. Pp. xiii+380. (London: C. Griffin and Co., Ltd., 1908.) Price 10s. 6d. net.

IN view of the magnitude of the mining industries of Spain, Mexico, Central America, Peru, Chile, Bolivia, and other South American countries, there can be no doubt that there is a large and increasing number of English and American mining engineers who will appreciate a good dictionary of mining terms, and certainly the author has spared no pains to make his dictionary as complete as possible. He has diligently studied the Spanish literature of mining and metallurgy, and his long residence in Mexico and in the United States of Colombia has enabled him to include a very full list of the terms used in these republics. Some Portuguese and Brazilian terms are also added.

It is curious to note that many terms have different meanings in different districts of South America. Thus, the well-known term *Caliche*, applied in Chile and Peru to the impure native nitrate of soda which is mined on a vast scale, denotes in the Uco district of Peru a thin layer of clayey soil capping auriferous veins, in Mexico felspar, and in Antioquia, Colombia, a recently-discovered mineral vein. It is probable that with the development of railway intercommunication many of these terminological differences will disappear, and that the most convenient terms will survive. In all cases the locality where a particular term is in use is noted by the author, and the authority is duly recorded. Small sketches, seventy-six in number, are added when necessary to elucidate a definition. The whole work has been compiled with scrupulous accuracy, and deserves unstinted praise. It is perhaps to be regretted that an English index to the Spanish terms has not been included in the scheme of the work.

*Immanuel Kants Metaphysik der Sitten.* Herausgegeben von Karl Vorländer. Price 4.60 marks.
*Kirchners Wörterbuch der philosophischen Grundbegriffe.* Neubearbeitung von Dr. Carl Michaëlis. Price 8 marks.
*B. de Spinoza's kurzgefasste Abhandlung von Gott, dem Menschen und dessen Gluck.* Übersetzt von C. Schaarschmidt.
*G. W. F. Hegel's Phänomenologie des Geistes.* Jubiläumsausgabe. Herausgegeben von Georg Lasson. Price 5 marks. (Leipzig: Durr'schen Buchhandlung, 1907.)

The first three of these volumes are new editions of works that have been reprinted at various times in the "Philosophische Bibliothek," a series which does for the German student of philosophy what Ostwald's well-known "Klassiker der exakten Wissenschaften" do for the German student of the sciences. Hegel's famous treatise has been added to the series in celebration of the centenary of its original publication in 1807.

The books are admirably printed, and are provided with excellent introductions, often by men of first-rate authority. Many of them are, in addition, briefly but helpfully annotated, while most are equipped with a useful index. More conspicuously moderate in price even than Ostwald's reprints, these wonderful volumes, by their very existence, render almost unthinkable any English series comparable with them in scope and importance.

*The Spectroscope: its Uses in General Analytical Chemistry.* By T. Thorne Baker. Pp. viii + 130. (London: Baillière, Tindall and Cox, 1907.)

This volume contains a fair amount of information useful to those wishing to purchase and set up spectroscopic apparatus for chemical research, but it seems to us to be ill-assorted and indifferently arranged. The author plunges straightway into the elementary mathematics of the prism and plane and concave gratings, and then describes the various parts of spectroscopes; yet on p. 78 it is thought necessary to inform the reader that a 12-inch focus telescope lens will give a much shorter spectrum than an 18-inch focus lens. There are, however, in the various discourses on adjustments, refractive indices, resolving power, the methods of producing radiation, sensitive plates, &c., numerous hints which will be found useful by those who have only a general knowledge of physics and wish to take up spectroscopy. It is for such readers that the book is intended. The notes on "series" and the Zeeman effect would probably be better left to the more advanced works on spectroscopy. There are a few uncorrected misspellings and one or two curious terms, which suggest that the author's acquaintance with real, practical laboratory work has been either too brief or too restricted. The astrophysical side of the subject is not dealt with at all, the idea being to restrict the book entirely to the chemical side. W. E. R.

*Der Bedeutung der Reinkultur. Eine Literaturstudie.* By Dr. Oswald Richter. Pp. viii + 128. (Berlin: Gebrüder Borntraeger, 1907.) Price 4.40 marks.

This essay, with true German thoroughness, gives a very complete, though necessarily brief, survey of the various microscopic organisms that have been obtained in pure cultivation. The organisms are dealt with in groups (and not individually), partly according to their biological position, partly according to the changes they produce. The green and blue algæ and diatoms are first considered, then the bacteria—the nitrifying forms, cellulose fermenters, sulphur bacteria, &c.—and lastly the yeasts and protozoa. In the final portion of the book the subjects of pleomorphism and systematic position of these organisms are discussed. The bibliography is a very full one, and it is probable that this part of the compilation will be most appreciated. R. T. H.

## LETTERS TO THE EDITOR.

*[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.]*

### The Coloration of Birds' Eggs.

In Nature of May 14 Mr. R. L. Leslie asks if it is known how and why birds' eggs become coloured, and whether they illustrate Mendelian phenomena.

Something is known as to the nature of the pigments from which the colours are derived. The late Dr. H. C. Sorby in 1875 investigated their origin by means of the spectrum analysis. He discovered seven substances in the pigments accounting for every form of coloration. These substances are oorhodeine (red), oocyan, banded ooycan (blue), yellow ooxanthine, rufous ooxanthine (yellow and reddish-yellow), a sixth substance of a brown tint, and lichenoxanthine, found in many plants, lichens, and fungi, and perhaps due to microscopic fungi. According to older theories, the pigments were secretions from the blood and bile, and in the case of the first three Sorby was disposed to agree (*cf.* the origin of pigments in coloration of molluscan shell). The ground-colour is laid on the shell just before the extrusion of the egg, and in eggs not of a purely uniform colour the markings are then superposed, being originally rounded, but by movement of the bird they become blurred and blotched. The intensity of coloration varies with age up to a certain point. Eggs of young birds are often unspotted. No doubt absence of markings is due to deficiency of pigmentation. The last egg or eggs of a second brood, in fact, often lack normal coloration or markings. Age and health thus control coloration, which is brilliant in a healthy but indistinct in an unhealthy bird's egg. Whether albino birds lay eggs differing from those of birds typical in every way has not been noticed apparently.

Little is known definitely as to why eggs are coloured.

In the early days of ornithology oology played its part in classification, but though the eggs of plovers, gulls, &c., characterise their suborders, this is rather exceptional than otherwise, and Huxley has settled the question of avian taxonomy upon a sound morphological basis. Coloration of eggs seems to have no connection with inherent hereditary tendencies, nor is it apparently the result of acquired characters in the birds themselves. In a large number of cases it can be traced to the necessity for a protective resemblance, just as in shells of mollusca. This would serve to ensure escape from the jaws or beaks of natural enemies, *e.g.* hedgehog, snakes, and egg-sucking birds and mammals, or (in recent times) from the collecting instinct of man. Where eggs exhibit brilliant or conspicuous markings, for no purpose apparently, we may perhaps assume that the nesting-site has been modified, or that, like the colour of the plumage, that of the egg is a source of attraction, and connected with courtship, or, more probably, as a means of identification by the individual of its own nest and eggs, when the process would naturally be hereditary (memory and heredity being intimately allied), the instinct employed in distinguishing similar clutches characterised by merely slight differences being likewise acquired.

No two clutches of eggs of the same species are exactly alike, particularly amongst birds nesting in colonies, *e.g.* guillemots, penguins, &c., but each bird knows its own egg. A few general principles may be recognised in the coloration of birds' eggs. Usually white eggs are laid by birds nesting in holes in trees or in dark situations, where light seldom penetrates, as by the barn owl, woodpeckers, and some pigeons, which build sometimes in the open, though usually in dark woods (wood-pigeon), sometimes in holes in trees, or in rabbit-burrows (stock-dove). Though all owls lay white eggs, not all of them nest in holes in trees, *e.g.* long-eared owl, snowy owl. This rule, then, holds good in a large number of cases, but not invariably. Most birds nesting on or near the ground lay eggs of a uniform olive-green or brown ground-colour, *e.g.* pheasant, partridge, nightingale, &c., the eggs harmonising with the ground or vegetation.

The eggs of grouse, ptarmigan, &c., resemble the heather amongst which they are hid. Those of the ringed plover, little tern, and oyster-catcher resemble sand and shingle on the beach. The lapwing's eggs closely simulate bare soil or dried bents. In these eggs secondary markings break up the ground-colour, and further help to render the eggs quite invisible except to an eye trained to detect slight differences. The experienced field naturalist can find his way to the immediate whereabouts of a nest by noticing the existence of some distinctive mark in the surroundings, *e.g.* a stick, boulder, bush, mole-heap, &c., indicating to the birds themselves at a distance the vicinity of the nest, and thus enabling them to return quickly and stealthily without laying themselves open to observation by long searching for the nest. The same protective resemblance occurs amongst the chicks of these birds. Adaptation to external surroundings, now or in the past, seems to explain this matter of coloration in a large number of cases, and exceptions to the rule are usually simply examples of reversions to, or rather survivals of, ancestral traits before protection was called for. In seeking for the causes of variation, &c., the influence of environment or external conditions seems to have been largely overlooked, too great prominence having been given to the influence of the inherent tendency to vary. In the case of the colours of birds' eggs we have an instance in which, I think, external conditions have played the greatest part.

Whether all birds' eggs were originally white, and the pigmentary layer has since been added to aid in concealment or to counteract the heat of the sun's rays, is not definitely known. The number of eggs ornamented with spots, &c., is very great. The creepers, nut-hatch, &c., lay spotted eggs in holes in trees, &c., possibly after originally having had some other nesting-site.

Summing up the general conclusions drawn from the coloration of birds' eggs, we find different species of birds of the same genus in a large number of cases lay eggs of much the same type, *e.g.* warblers, tits, nut-hatches, creepers, plovers, ducks, pigeons, gulls, terns, &c. In very many cases, however, this is not the case, and an exception in any genus may generally be traced to influence of environment. Amongst the Turdidæ, the eggs of the missel-thrush, thrush, and blackbird are very dissimilar, though their nesting sites are much alike. Variation in the colours of eggs goes, in fact, largely with difference in nesting-site. The starling and jackdaw lay blue eggs like the three last-named birds in holes in trees. Probably these birds have only recently betaken themselves to such nesting quarters. The influence of man and his habitations, and the conversion of dark forests into fields simply enclosed with *lines* of trees into which light readily penetrates, may have induced alterations in some instances, if not in coloration of the egg, at least in nesting-sites, of many birds intimately associated with human undertakings.

## Electrical Action of Sodium.

IN a recent letter (NATURE, May 28) I directed attention to the fact that a negatively electrified body lost its charge in air when held near to a clean surface of sodium.

I have now ascertained that different portions of the same rod may show the effect to a greater or less extent owing to inequalities of temperature. Diminishing the oxidation by cooling the metal produced a more complete diselectrification, and this result seemed, at first sight, to point to a cause other than chemical action. The influence of a current of air, as well as the fact that even a soap film stopped the discharging action, supported the view that an electrified gas was emanating from the metal. A bright surface of potassium gave no appreciable discharging effect when cooled with a mixture of ice and salt. In all cases the surfaces could be seen in the dark to be glowing strongly.

Further experiment has shown that no active gas can be driven from sodium by heat, and that the true explanation of the action lies in the positive electrification of the air surrounding the freshly cut surface. With warm sodium it is seen that the gold leaf falls rapidly for a very short distance, while after cooling the action is more prolonged. It is clear, therefore, in the first case, that the action, although violent, is so transient, owing to the whole surface being rapidly oxidised, as to appear of small amount. The far larger discharging action was obtained with reduced oxidation owing to the effect being more prolonged.

## Tabular Accuracy.

I DO not know whether you will consider the following suggestion suitable for publication. Though obvious, I do not remember meeting with it.

All are agreed upon the enormous importance of securing accuracy in mathematical tables, and of making known any errors, but I am not aware of any definite centralised method of registering mistakes, and publishing, in an easily accessible form, corrections of them.

What I venture to suggest is that, in connection, say, with the National Physical Laboratory, there should be a department dealing with mathematical tables. When an error is discovered in any recognised table, the discoverer should at once send a note of the fact to this department, which would duly investigate the matter. Then, at suitable intervals, the department would publish a list of errors, with their corrections, in a form purchasable by those interested. By some such arrangement he might hope in time to secure the accuracy so essential to the numerical data employed in scientific calculations.

## The "Sky-coloured Clouds."

THERE was a very feeble display of "sky-coloured clouds" here on May 27 from 10 to 11.15 p.m. This is the first time I have seen this phenomenon since July 19, 1906. Since May 27 the sky has not been clear enough for them to be visible.

## SOME SCIENTIFIC CENTRES.

### No. XIII.—THE MECHANICS LABORATORY OF THE IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY.

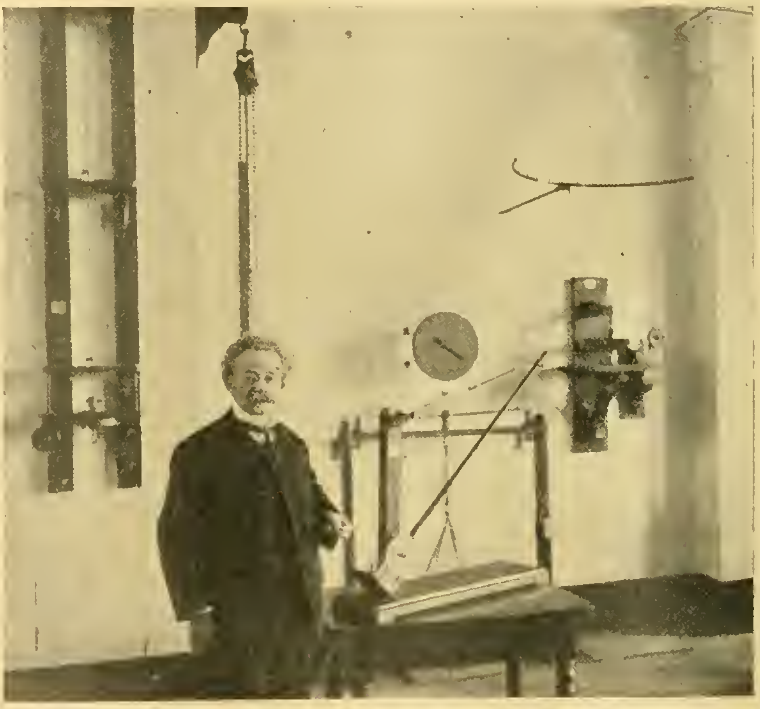
THIS description of the mechanics laboratory of the Imperial College of Science and Technology may not improbably appear to some readers as premature, in consideration of the fact that the college was so recently founded and the new rector, Dr. Bovey, appointed only within the last few months. It was as the mechanics laboratory of the Royal College of Science that until lately it was known, and under that name it achieved the great success that time and Prof. Perry brought to it. What that laboratory has been for the past ten or more years to engineering students in London will not readily be forgotten by Prof. Perry's old students, and a piece of creative work of this kind is too valuable to be lost. It is therefore a matter for congratulation that the laboratory has found a place in the new Imperial College, and in doing so it has, we hope, taken a new lease of life and usefulness.

The new Imperial College will assume also the control of certain engineering laboratories, but it must be remembered that the study of mechanics is not the same thing as the study of engineering. Not all who attend a mechanics course become engineers, though, while they are pursuing that study, the more they conform to the engineer's mental attitude, the better will they understand what they are doing, and the more effective use will they make of the time spent on this subject.

Engineering laboratories are now so numerous that they must be familiar to all who are interested in scientific work. As a type, probably the best example is to be found in the University of Cambridge. In that laboratory, for instance, there are steam engines, dynamos, motors, gas engines, boilers, oil engines, storage cells, indicating instruments, and all the hundred-and-one accessories. The atmosphere is far more nearly that of the power-station or the test-bench of a works than that of the college class-room. To complete an engineering course it is necessary to spend some time in these surroundings at Cambridge or elsewhere, but unless the student has some preliminary training in mechanics the soil will be but ill prepared for the seed.

When in 1896 Prof. Perry was appointed to the chair of mechanics and mathematics in the old Royal College of Science, he set himself to organise and equip a laboratory for the study of mechanics. It was extraordinary how the course could have prospered before without something of the kind, and the new departure meant a good deal of hard work in getting it carried out. In spite of all difficulties, however, the scheme was successfully carried through, and visitors to the college have for some years been able to see what is the model mechanics laboratory of this country. Prof. Perry himself states that his laboratory methods of teaching are based on those introduced by Prof. Ball (now Sir Robert Ball, of Cambridge University) when at the Royal College of Science in Dublin, and were gradually developed by him at Clifton College between the years 1870 and 1874. A further opportunity of development occurred during his tenure of an engineering chair in Japan from 1875 to 1879, with the consequence that by the year 1880 they blossomed out into a matured scheme of teaching at the Finsbury Technical College. It is a remarkable fact that almost all the technical institutes in this country now have, or are in process of forming, mechanics laboratories which, like the one which forms the subject of this article, are based upon the model of "Finsbury." The idea at the basis of this teaching is that students should test for themselves the truth of the theories they learn, and not get into the frame of mind which looks on all theories as equally true because all are put forward with a generally similar show of authority.

To take a simple instance of this, the problem presented by the phenomenon of friction may be cited.



Prof. Perry in his laboratory at the Imperial College of Science and Technology.

In the days before engineering had become a scientific study, the phenomenon of friction was part of the domain of the mathematical physicists, who, being chiefly desirous of finding quickly relations between different variables which would enable the data to be put into the mathematical mill to the end that results might be ground out, did not scrutinise with nearly sufficient care the results of their experiments. This was not altogether their own fault, as the apparatus used was rarely well designed to give accurate results, and their own training was extremely ill fitted for such work. For good or ill, however, the theories, such as they were, were formulated, received the name of "laws," and then there came into being those curious survivals known as the "laws of friction," so familiar to all who were still students ten or more years ago. In the early days of scientific engineering education, let us say during the 'fifties and 'sixties of last century, when the Prince Consort gave so nobly his assistance to the furtherance of the new movement, young engineers found themselves required to learn for the purpose of examinations "facts" which they were well aware from their own experience to be misrepresentations of the real state of affairs. Among the men who have since helped to put these students into the right path and to help them on the way, none were more prominent or are more deserving of praise than Prof. Perry.

In his laboratories the phenomenon of friction, to take this same instance, is dealt with in such a way as to give the student opportunity to exercise all his knowledge of mechanics. Thus he has to test the effects of friction in every part of a mechanism—he is not allowed to forget its existence or to have his mind taken away from it, as may happen so easily when working among the large and complicated machines of the engineering laboratory. Even in so simple a case as that of the spinning of a horizontal fly-wheel by means of the unwinding from its axis of a rope which passes over a pulley, and carries a weight at its far end, the number of problems that arise is very numerous. To instance the variety of information which can be derived even from such a simple experiment as this, we may quote the following from Prof. Perry's "England's Neglect of Science":—

"Let us take this well-used fly-wheel. The M of a fly-wheel, multiplied by the square of its number of revolutions per minute, gives the kinetic energy stored up in it in foot-pounds. You are asked to measure experimentally the M of this fly-wheel; the loop at the end of a cord goes over the pin A on the spindle, and is wrapped $n$ times round the spindle, then goes over the pulley B, and has a weight W at its end. At time O the wheel is let go; in $t_1$ minutes—carefully observed—the cord drops off; in $t_2$ minutes from starting the wheel has been brought to rest again by friction. The weight W lb. multiplied by the height in feet through which it has fallen gives the energy stored up in the wheel at time $t_1$, so that if the speed were then known M could at once be calculated. But as we have no speed indicator, we take it that the motion is uniformly accelerated till the cord drops off or we take $2\frac{n}{t_1}$ as the revolutions per minute at the time $t_1$. The corrections are of more interest. We have first to deduct the kinetic energy of W when the cord drops off. Then we must make experiments on the friction of the pulley B, for the pull in the cord at C is less than what it is at D, and these experiments are themselves very interesting, for they are made with the two parts C and D vertical, so that the parallelogram of force principle must be brought in to make them available. Next we correct for the friction at the pivots E and F. And here we observe that the average speed from $t_1$ to $t_2$ is the same as from O to $t_1$, and hence that from $t_1$ to $t_2$ the motion is uniformly retarded, and hence that there is as much energy wasted in any one revolution as in any other. If, then, we know the number of revolutions from $t_1$ to $t_2$ we know the energy wasted in one revolution, and we can correct for friction before the cord drops off, and so we make one correction after another, and there is hardly any limit to the amount of ingenuity required, as the corrections get less and less important. I remember that four grey-headed men worked together once at this piece of apparatus in the evening for five weeks, and when at length they had satisfied themselves with their corrections they had practically used many times every important principle of mechanics, and they had acquired a handy working knowledge of all these principles."

It is hardly possible to set bounds to the usefulness of such calculations as the above in making students think for themselves and, if they have even a moderate acquaintance with mathematics, in assisting them to find themselves, even unwittingly, engaged on what is really an original piece of research.

A mechanics laboratory is by its constitution less adapted than an engineering laboratory to research work of the usual kind, but during the last few years an important piece of original work on the air friction of rotating paper discs has been carried out. A note on the preliminary experiments was read before the Southport meeting of the British Association in 1904 by Mr. W. Odell. Mr. Odell's experiments consisted in measuring electrically the torque necessary to keep in uniform rotary motion circular discs of paper which were mounted on a horizontal shaft. These discs were 15, 22, 27 and 47 inches in diameter, and the torque was measured for (1) different speeds, (2) different diameters. The very interesting result was found that, once the critical speed was passed, the torque was proportional to the $n$th power of the speed, and that $n$ was about 2·5. It was further found that the critical speed was roughly proportional to the square of the diameter when different discs were used. For a given speed the torque increased with the 5·5th power of the diameter, and this striking result leads to the deduction that, 6 watts only being required to keep a 27-inch disc moving steadily at 550 r.p.m., no less than 32 h.p. would be necessary to keep a 9-feet disc rotating at the same speed. This deduction has a very important bearing on the design of high-speed generators and other machines in which the rotating parts have considerable diameter. Roughly, a one per cent. increase in diameter would lead to an increase in the necessary torque for the same speed to be obtained of no less than $5\frac{1}{2}$ per cent.

A similar plan is followed in the laboratory with regard to problems connected with the torsion of shafts, the flow of water, the bending of beams, the efficiency of mechanisms, the swinging of pendulums, and others of the same kind. The result of such a training on students is that they acquire a kind of instinct in mechanical matters, one which is difficult to describe, but which develops alertness, and would, for instance, lead such a student to doubt immediately the accuracy of the usual measurement of horse-power by means of the average indicator. Even with such a well-made instrument as the Hopkinson reflecting indicator he would not omit to make calculations as to the effect of inertia lag when rapid explosions were being recorded, the effect of damping, and other points. After doing this he would appreciate the more the modest claim of the inventor of a 2 per cent. accuracy, and contrast it with the far more heavily drawn claims of instruments much less carefully designed. To instil this attitude of mind into young students, that they should "test all things" and take nothing for granted, is to lay the basis of a scientific way of thinking which is of fundamental importance to them in after years.

H. E. W.

## THE MILKY WAY.[1]

It may be that the limitations imposed upon us by restrictions in time and space will never allow a complete solution of the problems offered by the study of the sidereal universe. But the effort to comprehend the processes that have contributed to its structure, or

[1] (1) "La Distribution des Étoiles par rapport à la Voie lactée d'après la Carte et le Catalogue photographiques du Ciel." Par Paul Stroobant. Extrait des Annales de l'Observatoire royal de Belgique, Annales astronomiques, Tome xi., Fascicule ii.
(2) "Die Milchstrasse." By Prof. Max Wolf. Pp. 48. (Leipzig: J. A. Barth, 1908.) Price 4 marks.

to penetrate the mystery that conceals its destiny, will not be abandoned on account of the difficulty of the problem or the dearth of pertinent facts. There may be little hope that our observations and those of our predecessors will prove adequate to the task of reading the riddle, but the human mind needs very little information to tempt it to form conjectures concerning the order of creation in its widest extent. In this department of science, history unfortunately bears witness rather to the richness of our imagination than to our skill in securing facts. But in recent times, as the contents of the two works under notice show, the tendency has been to limit our excursions into the unknown, and to substitute exact inquiry directed to a definite end, in place of the loose, but possibly plausible, suggestions that did duty for critical examination. In the first-mentioned work M. Stroobant is content to count the stars the positions of which have been recorded in connection with the scheme for the construction of the photographic chart of the heavens. Such work is no doubt tedious and unheroic, but it is eminently useful, and more welcome than any random speculations, however brilliant or startling they might be. The object the author had in view in undertaking this wearisome task was to determine the law of stellar distribution, both on the chart and in the catalogue, according to variation of galactic latitude. For the present the research is limited to the stars in the zones taken at the observatories of Paris, Bordeaux, Toulouse, Algiers, and San Fernando. Of the star charts 879 have been used, containing the total of 985,430 images; and of the catalogue negatives 535, which show the places of 163,009 stars. The celestial surface scrutinised contains 4126 square degrees, approximately one-tenth of the entire surface of the sphere.

One of the by-products of the research is to indicate that the mean magnitude of the faintest stars recorded on the catalogue plates is 11·5 mag., and that of the faintest stars on the chart 13·5 mag., or taking into account the loss of images, unavoidable in reproduction, 13·7 mag. These figures show, so far as this inquiry is trustworthy, that the original proposals for the construction of the international chart have been adhered to very faithfully. A further conclusion is that the total number of stars we may expect to find in the complete catalogue is 2,676,000, and on the chart 9,854,000. These totals are more modest than early and less informed estimates, and M. Stroobant gives reason to think that these numbers will be exceeded when some of the unpublished charts become available. The data supplied from each observatory are discussed separately and fully, but space will not permit more than the reproduction of the final result, which exhibits the conclusions drawn from the whole material under discussion :—

| Galactic Latitude | No. of stars in square degree | | Stellar density | |
|---|---|---|---|---|
| ° ° | Chart | Catalogue | Chart | Catalogue |
| +90 to +70 | 91 | 30 | 0·14 | 0·19 |
| +70 ,, +50 | 83 | 29 | 0·13 | 0·18 |
| +50 ,, +30 | 140 | 48 | 0·21 | 0·30 |
| +30 ,, +10 | 337 | 90 | 0·51 | 0·57 |
| +10 ,, −10 | 660 | 159 | 1·00 | 1·00 |
| −10 ,, −30 | 344 | 83 | 0·52 | 0·52 |
| −30 ,, −50 | 130 | 39 | 0·20 | 0·25 |
| −50 ,, −70 | 111 | 24 | 0·17 | 0·15 |

The want of exact regularity in the change of these numbers with the latitude is doubtless due to insufficient data, but considering the number of stars involved and the care taken to secure uniformity, the result is probably more trustworthy than that drawn from Herschel's gauges, which indicate a much more rapid increase in stellar density as the latitude diminishes. Further examination shows that the number of stars on the chart increases uniformly in both hemispheres, but that if the faintest stars be excluded and the research limited to those that appear in the catalogue, the density is more marked in the northern than in the southern hemisphere. It is not possible to make any complete inquiry as to the variation of density depending on galactic longitude, but from a preliminary investigation of those regions of the Milky Way where it cuts the celestial equator, M. Stroobant shows that at the ascending node of the Galaxy, the northern border is richer in stars than the southern, and that at the descending node this relation is reversed. It is further pointed out that the increase in the number of stars on the photographic chart does not correspond with the contour lines drawn in naked-eye representations of the Milky Way, and in conclusion the author directs attention to regions of the sky which are very rich in stars, though fairly remote from the central line of the Milky Way, to the pole of which are assigned the coordinates $\alpha = 12h.\ 46m.$, $\delta \pm 28°$.

Prof. Max Wolf addresses himself to a scientific congress, mainly composed of medical men, and necessarily his paper is of a more popular character. He frankly admits that we have but very little knowledge of the true construction of the Milky Way, and that speculation has supplied the place of exact information. By means of excellent photographs he shows the great variety of structure running throughout the Galactic Belt, and indicates the difficulties which any theory of the Milky Way has to surmount. Prof. Max Wolf is intimately acquainted with the literature of the subject, knows the strength and the weakness of the various hypotheses that have been advanced, and treats the many problems that arise in a luminous and interesting manner.

He glances at the various studies that have been made to solve the problem of the possible geometrical form of the Galaxy, from the time when Herschel began his laborious task of counting the stars visible in the field of his telescope, down to that later period when the resources of photography have supplied more information, but at the same time revealed a more complex structure, offering fresh difficulties for solution. Of the different attempts that have been made to represent its true shape, concealed as it is by the curious bifurcations, rifts, condensations, and lacunæ, that suggested by Dr. Easton, of Amsterdam, meets with the greatest favour. In this scheme the Spiral Nebula in Ursa Major has admittedly supplied the model. A nucleus is placed in the constellation Cygnus, and from this central condensation radiate streamers, which can be arbitrarily arranged so that the combined effect can be made to resemble the general aspect of the Milky Way. The objection the author raises to the scheme is that Cygnus does not present that close agglomeration of stars which such an hypothesis requires. It might further be added that in the sketch given, the sun occupies too much the place of a detached spectator, and is apparently quite disconnected from the system.

A feature of great prominence in many photographs of nebulæ is the comparative scarcity of stars in the immediate neighbourhood of the nebula, and Dr. Max Wolf discusses the probable physical connection between the dark lacunæ and the brilliant condensations adjoining. This effect is real, and not due to contrast, for by counting the stars on a photograph within a definite area, and shading the different parts of that area according to the number of images impressed on the film, it is possible to exhibit statistically the relative density of stars surrounding the different nebulæ. This plan has been adopted with great success in the most important nebulæ and clusters, and the diagrams reproduced show the completeness of the connection. The most conspicuous, as it is one of the most interesting instances, is that known as the "cocoon" nebula, where the complex nebulous structure lies concealed at the end of a long channel, extending more than two degrees into the luminous clouds. The author suggests that we have here to do with an absorptive phenomenon, and certainly the appearance warrants the suggestion. But such instances, if less pronounced, are not rare, and therefore it is legitimate to imagine that the whole heavens are more or less hidden by the results of processes still in progress. In that case the Milky Way itself may be regarded as a remnant of an earlier much more extended universe. This hypothesis, as any other we may form, may be quite misleading, but into whatever errors our assumptions may conduct us, it is certain that the Milky Way offers a grand and sublime problem, indicating the action of processes and forces for the adequate description of which we still lack rudimentary conceptions. We stand face to face with a great mystery without the partial unveiling of which our pictured scheme of the cosmos must remain an imperfect patchwork.

## *SIR JOHN EVANS, K.C.B., F.R.S.*

BY the death of Sir John Evans, British archæology has lost one who was amongst its foremost figures for more than fifty years. The son of the late Rev. A. B. Evans, D.D., he was born at Britwell Court in 1823, educated at Market Bosworth School, and entered the business of his maternal uncle, Mr. John Dickinson, F.R.S., the founder of the famous paper factory at Nash Mills. From school young Evans brought with him a genuine love of classical literature and history, and presently he developed a no less strong taste for science, whilst he at once showed business capacity of no ordinary kind. Very soon he directed his attention to geology. Practical reasons may have hastened a natural tendency, as he was led to this study by a dispute respecting the water rights of his uncle's firm, and in a comparatively short time he mastered the principles of that science. He became an active member of the Geological Society, of which he was elected president in 1874.

Sir John Evans's scientific training had a very important bearing on his work as an archæologist, and in no little degree enabled him to make those great advances in British archæology which that science owes to him. Scientific method, combined with his love of historical literature, gave him an equipment for antiquarian studies possessed by but few of his contemporaries. Evans's interests were of the widest, but in his early years they chiefly lay in the coins of the ancient Britons. Though from Camden onwards much had been written about them, Evans for the first time coordinated the entire mass of material, and worked out systematically the evolution of the British types, as Lelewel had done for the Gaulish series and partially attempted for Britain. When, in 1864, Evans published his "Coins of the Ancient Britons," it was at once recognised, not only as a masterly example of learning and minute accuracy of detail, but also as a model of method. He published a supplement to it in 1890, and though his chronology, based on the time supposed to be necessary for the degradation of the original type of the gold stater of Philip II. of Macedon, may not now commend itself, the book must always remain one of our chief authorities for the early history of this island.

But his attention was not confined to the period between the occupation of south-eastern Britain by the Belgæ and the Roman conquest. He worked incessantly at the remains of prehistoric man both on the Continent and in these islands, following the method of the great Scandinavian archæologists. The first results of these labours were embodied in "The Ancient Stone Implements," &c., of Great Britain, published in 1872 (second edition in 1897). Here, of course, his geological knowledge came into play, more especially in reference to the relics left by Palæolithic man in the fluviatile gravels of our own island. Yet all this time he had been working incessantly at the first beginnings of the use of metal, and the fruits of his work in this all-important field were put forth in "The Bronze Implements of Great Britain and Ireland," in 1881. All his three great works are largely based upon and illustrated from his own magnificent collections in the several departments, though these were but a fraction of his vast treasures, which comprised a great series of Greek, Roman, English, and other coins, medals, rings, enamels, and most other classes of antiquities. At a time when so many objects which form an integral part of our national history are constantly finding their way across the Atlantic, it is pleasant to think that the collections amassed at Nash Mills are not to be dispersed under the auctioneer's hammer.

Besides his three master-works, Evans wrote innumerable papers in *Archaeologia*, the *Numismatic Chronicle*, and various other journals, all of which are distinguished by the same rigorous accuracy and keen insight as his larger publications. It is hard for us in this generation to realise clearly all that he did to advance the study of archæology in this country. Though Worsaae and his school had already firmly laid down the principles of archæology in Scandinavia when Evans began his career, in this country such studies were almost entirely in the hands of the Oldbucks and the Simpkinsons, whose fatuities, credulities and wild speculations were scorned by serious historians and mocked at by the general public. Evans's strong common sense, his scientific training, and his instinctive love of historical records soon made him a powerful steam-hammer which pulverised mercilessly the trivialities and inanities of the old antiquarians. To his influence is due in no small degree the hold which scientific archæology has been able to get on the respect of men of science, historians, and the general public. The fact that he was a most successful man of business, and at the same time took the lead in the public affairs of his county, contributed in no small degree to this result. It was felt by men of the world and men of science alike that if so powerful and practical a mind could find its chief interests in the pursuit of archæology, these studies deserved better than to be the mere pastime of pedants or enthusiasts.

Evans's great characteristics were his strong common sense, his courage, and his extraordinary mastery of details, though the last became sometimes even a weakness. Thus, whilst his books on the Stone and Bronze ages are vast storehouses of facts and minute and accurate details, he sometimes lost sight of the general principles, and did not always lay sufficient stress on the importance of associated groups of objects to which the younger generation attaches so much value. But make what deductions we may, the fact remains that Sir John Evans must always hold his place along with John Kemble, Wollaston Franks, Greenwell, and Boyd Dawkins in the front rank of those who have set British archæology on a scientific basis. Vigorous in defence of his own views, yet from his innate love of truth ready to modify them and accept those of others when his reason was convinced, his strong and masterful disposition made him a leader of men, and thus he became in due course president or chairman of almost every society, association, or public body of which he was a member. His delightful humour and inexhaustible fund of good stories made him the best of companions. Time dealt with him kindly; he bore lightly his burden of more than four-score years, and to the last his mind retained its youthful spring. The sturdy old oak continued green and vigorous until the axe was laid to its root. His genial presence will long be missed at the British Association and numberless other bodies at which he has been a familiar figure for more than half a century. W. R.

## *NOTES.*

THE Albert medal of the Royal Society of Arts for the present year has been awarded to Sir James Dewar, F.R.S.

ON May 30 Her Majesty the Queen of Holland nominated Sir William Ramsay, K.C.B., as a member of the Dutch Academy of Amsterdam in succession to the late Lord Kelvin.

IN the House of Commons on June 3 Sir William Anson asked the President of the Board of Education whether, having regard to the insufficiency of the present temporary buildings at South Kensington for the housing and display of the collections of scientific instruments and apparatus belonging to the Government, and to the importance of making these collections useful to teachers and students of science, and to the Imperial College of Science and Technology, he would consider the advisability of erecting a suitable building for a science museum on the site of the existing temporary galleries. In reply, Mr. McKinnon Wood said:—"I think it would be eminently desirable that there should be a science museum properly housed in immediate propinquity to the Imperial College of Science and Technology, and if the Commissioners of the 1851 Exhibition feel themselves in a position to cooperate, I should be happy to bring the matter under the notice of the Chancellor of the Exchequer; but it is obvious that any steps requiring the financial assistance of the Government could only be undertaken with due regard to the general calls upon the Exchequer."

IT was announced some time ago that the Zoological Society of London was arranging for a special exhibition of Australian and New Zealand animals in the society's gardens. Dr. P. Chalmers Mitchell, F.R.S., now informs us that the Governments of New Zealand and New South Wales have each made presents to the society of some of their peculiar birds, mammals, and reptiles, and a very fine collection has been got together from the various Australian colonies. Mr. Seth-Smith, a member of the council of the society, proceeded to Australia last December to make the final arrangements for getting the collection together, and two keepers followed him early in the year to take out a number of animals from the gardens in Regent's Park for the Australian gardens, and to take charge of the returning collection under the direction of Mr. Seth-Smith. The animals left Australia in the White Star liner *Persic* in April, and arrived at Tilbury on Saturday evening. The detailed list is not yet to hand, but from advices the society has received it is certain that the collection will be the most representative one of marsupial mammals and peculiar birds and reptiles of Australia ever got together either in Australia or in Europe.

BY the death of Admiralitäsrath Carl Koldeway, which occurred at Hamburg on May 19, Germany has lost a distinguished seaman whose scientific investigations have proved of great practical value. Captain Koldeway was born on October 26, 1837, at Bücken, Hanover, and commenced his career as a sailor in 1853. In 1866 he studied at the polytechnic at Hanover, and in 1867 at Göttingen. He commanded two German North Polar Expeditions during the years 1868–70, the first to Spitsbergen, and the second, with two ships, to north Greenland, where he wintered and made important discoveries. In 1871 Captain Koldeway was appointed first assistant to the Seewarte at Hamburg, and four years later became director of the second section for magnetism, and for the testing of nautical and meteorological instruments. He was specially interested in magnetism, and was entrusted with the compensation of compasses for deviation on board ships of the mercantile marine. In addition to the accounts he published in reference to his voyages to the Arctic regions, he was the author of many valuable papers on magnetism, meteorology, and oceanography, among which may be mentioned "Change of Magnetism in Iron Ships, based on Observations for Deviation" (*Deutsche Seewarte Arch.*, 1879), "Results of Meteorological Observations at Spitsbergen and East Greenland" (*Zeitschrift Meteorol. Vienna*, 1876), "Surface Temperature in the Equatorial Regions of the Atlantic Ocean" (*Annalen Hydrogr.*, 1875).

A LETTER by Dr. W. N. Shaw, F.R.S., in Saturday's *Times* contains some cogent reasons against the adoption of the proposals in the Daylight Saving Bill, to which reference has been made in these columns on several occasions. In the first place, Dr. Shaw remarks that a large number of meteorological instruments in many parts of the country are designed to record continuously day and night. Are these instruments to run an hour wrong for six months or are meteorologists to use a time system different from that in use in the country? All the operations of meteorological observers would be affected by the change contemplated by the promoters of the Bill, and the passing of an Act to change the standard time twice a year would have to be followed by an instruction to meteorological observers to adhere to the old times for their observations, whatever it might be called according to the clocks. Part of the work of the Meteorological Office, Dr. Shaw points out, is represented by a system of daily telegraphic reports of synchronous observations upon which the weather reports are based. The system is an international one, and this year an important step is being made towards the ideal of international as well as national synchronism. It is important, therefore, that there should be no misunderstanding as to the time standards employed. Dr. Shaw writes feelingly when he says that no one who is concerned with the preservation of records for long series of years to be consulted when all possibility of clearing up ambiguities has passed away can regard the idea of a dual time system with anything but blank dismay. It is curious that in this connection he does not refer to the impossibility of comparing thermometer readings in summer and winter if the change were adopted. The seasonal meddling with the clocks cannot, in fact, be justified from a scientific point of view, and would lead to hopeless confusion in records in which time is a factor. There is no reason why individuals should not practise self-deception to the extent of putting their clocks back or forward as they wish, but for a nation to be compelled to do this by legislation would be the height of folly. It is too much to expect that men of science busy with their own affairs should have to devote their time to the preparation of evidence to show the Select Committee upon the Bill the disturbing nature of the scheme proposed; but as to the weight of competent opinion against the Bill there can be no question.

The Institution of Electrical Engineers will hold a conversazione at the Natural History Museum, South Kensington, on Thursday, June 25.

To a new species of amphipod crustacean inhabiting sand at the roots of trees at Punta Arenas, Costa Rica, the Rev. T. R. R. Stebbing (Proc. U.S. National Mus., vol. xxxiv., p. 241, No. 1609) gives the name *Orchestoidea biolleyi*.

As the result of recent legislation for regulating the importation of wild animals which might possibly become acclimatised in the United States, the Zoological Society of Philadelphia, according to its report for 1907, finds a marked diminution in the number of specimens received during the year. Although, runs the report, the wisdom of preventing the introduction of objectionable animals is not to be questioned, "regret may be expressed that the minute and vexatious details which must be complied with on bringing into the country even single specimens by casual travellers or steamship-employes, imposes this serious limitation upon zoological gardens."

From America we have received a batch of pamphlets dealing with the protection and encouragement of birds. Among these is one issued by the National Association of Audubon Societies on the winter-feeding of wild birds, and a second on the best methods of constructing and placing artificial nesting-places. Statutory bird-protection in Massachusetts forms the subject of a pamphlet sent out by the Board of Agriculture for that State, while some of the commoner birds of Oregon are described and figured in a tract issued by the Oregon State biologist. The claim of the Virginian quail to considerate treatment by the agriculturist is urged by Miss E. A. Reed in a leaflet published by the aforesaid association under the title of "Bob White the Farmer's Friend"; while, finally, we have the first annual report (illustrated by an excellent coloured plate of the wood-duck) of the good work by the Audubon Society of South Carolina during its (at present) short career.

To the *Century Magazine* for June, Mr. G. H. Thayer contributes an article on the concealing (protective) coloration of animals. The article, which discusses the problem from the point of view how and to what extent—and not why—animals are protected by their colouring, is mainly based on the experiments conducted by the well-known artist Mr. Abbott H. Thayer, which were reviewed in Nature in April, 1902, and are represented by a case with models in the natural history branch of the British Museum. The author re-asserts the claim of this artist to have discovered that the arrangement of light and dark colours on the upper and lower surfaces of the bodies of animals is a factor of much more importance in rendering them invisible than is an agreement between their own colouring and that of their environment. This is graphically illustrated by means of photographs.

Nearly the whole of the April number of the *American Naturalist* is taken up with the report of a "symposium" on the species-question which took place at a meeting of the American Botanical Society held at Chicago in January last, where various speakers discussed the topic from the point of view of their own special line of study. The first speaker urged that we are in danger of destroying the usefulness of taxonomy in our zeal for describing every differing form as a separate species. We have lost sight of the primitive reason for the formation of species, namely, that we should have fewer things to hold in mind. A second referred to the statement made by ornithologists to the effect that a species may differ by characters which cannot be put into words, so that it can only be recognised when placed alongside specimens of its nearest relatives. In opening a general discussion on all the papers submitted to the meeting, Prof. J. M. Coulter remarked that all the speakers seemed in accord as to the need for action of some kind, and that the idea of a species must be modified. He himself favoured the plan of continuing to name easily recognised forms, calling them species if desired, and then to indicate minor distinctions by numbers. By this the excessive multiplication of names would be avoided, while an exact record would be established. This plan is to a great extent a modification of trinomialism—with the important difference that the third term in the name is discarded in favour of a number.

The degree to which trees, especially in the seedling stage, will flourish under shade is a consideration of some importance in the regeneration of forests. Mr. R. S. Pearson contributes to the *Indian Forester* (April) a list of Indian trees roughly classed in five sections, according to their light-demanding requirements. Teak, *Terminalia tomentosa*, *Bassia latifolia*, and *Boswellia serrata* are noted as strong light demanders, while the ironwood tree, *Xylia dolabriformis*, *Nyctanthes arbor-tristis*, and *Aegle marmelos* are placed among the heavy shade bearers. A note appended by the editor to an article on Eucalyptus trees offers the practical hint that leaves of the blue gum and other species boiled in cylinders or boilers will be found useful in removing any hard incrustation of lime.

Opinions with regard to the limits, sources, and possibilities of Indian cottons are so widely divergent that nothing short of detailed experimental cultivation undertaken by an experienced specialist seems likely to meet with general acceptation. Mr. H. M. Leake publishes in the Journal of the Asiatic Society of Bengal (vol. iv., part i.) a short account of some experiments in the nature of an introductory note. The criterion selected is a "leaf-factor," according to which a leaf may be distinguished as narrow or broad-lobed. Crosses were made between *Gossypium arboreum* or *Gossypium neglectum* and *Gossypium indicum*. The conclusion is arrived at that plants with an intermediate leaf-factor are crosses, and other facts are cited tending to support the view that natural crosses between cotton plants do occur.

It is always a difficult matter to identify the trees that yield the timber imported from new countries. In this connection it may be said that the sources of West African mahogany have been mainly conjectural, so that it is useful to have the identifications based on the authority of Mr. H. N. Thompson, conservator of forests in northern Nigeria, that are published in the *Kew Bulletin* (No. 4). The three species *senegalensis*, *grandifolia*, and *Punchii* of the genus Khaya furnish "Benin" mahogany; similar timber from *Entandophragma Candollei*, and "Sapeli" mahogany from a species of Pseudocedrela, are also in demand. "Batum" mahogany is obtained from *Mimusops multinervis*, and a red ironwood said to resist white ant and terido worm is derived from a species of Lophira. Other trees furnish timber that is classed as mahogany, satinwood, cedar, and greenheart.

The April number of the Journal of the Gypsy Lore Society is mainly devoted to a protest against the action of the Continental Governments who are starting a crusade against vagrancy, and against the attempt in this country, under the Movable Dwellings Bill, to enforce the registration of caravans and to compel the residents in them to send their children to school. This action will, it is said, if pushed too far, drive the Gypsy into city slums, where he will suffer from ill-health and lose his national identity. At the same time, the useful chronicle in the same number of the adventures during the year 1906 of the bodies of Continental Gypsies who took refuge in this country demonstrates the necessity of bringing such people under control. It is difficult to see how any system of regulation, such as that proposed, is consistent with the maintenance of the nomadic life, a picturesque phase of our social system which few would wish to destroy.

In the Journal of the Franklin Institute (vol. clxv., No. 5) Dr. C. B. Thwing describes a new radiation pyrometer based on the measurement of the total energy of radiation by means of the current generated in a sensitive thermocouple by the radiations concentrated upon it. In the same number Mr. C. L. Huston gives the results of experiments undertaken in order to secure for practical purposes a more accurate knowledge of the interior character and structure of steel.

The Queensland Geological Survey has issued a second report (Publication No. 204) on the West Moreton (Ipswich) coalfield, with special reference to the Bundamba district. The report, which has been written by Mr. W. E. Cameron, covers thirty-seven pages, and is illustrated by two large coloured geological maps, one plate, and eight illustrations in the text. The West Moreton coalfield is at present the chief producing coalfield in Queensland, its importance being due to the generally useful character of its coal and to its proximity to the chief industrial centre and most important shipping port of the colony. The investigations described in the report show that the resources of the area under consideration will be sufficient to meet any increase likely to occur in the demand for some years.

The past week has experienced weather changes of an exceptional character. Sharp thunderstorms occurred in nearly all parts of the country. In London and the suburbs the storm experienced on June 4 was unusually severe, and was accompanied, over the southern parts of the metropolis especially, by a heavy fall of large hail and a copious downpour of rain. At Croydon the rainfall exceeded an inch in half an hour. The shade temperature in London on June 4 rose to 81°, and on the following day there was a sharp fall of the thermometer over the entire country. On Saturday, June 6, the highest temperature in London was 59°, 22° lower than two days previous. The colder weather was brought about by the setting in of a northerly wind over the whole of the British Islands, the supply of air being drawn from the neighbourhood of Iceland. On the night of June 6 the exposed thermometer fell almost to the freezing point in the south-east of England.

The frequency of different forms of clouds during the years 1903–5 is discussed in Appendix i. to the observations made at Batavia Observatory in 1905. The general results of the observations, made four times a day during the three years, show that the percentage of occurrence of cumulus was 35·3, of cirrus 21, and of strato-cumulus 11·3. With reference to the diurnal period, attention is directed to the predominance of stratus and cirrus forms and of clear sky in the morning, of the cumulus forms about noon, and of nimbus forms at the close of the day. The daily change in the amount of each cloud form is nearly the same for both dry and wet seasons, except that during the latter period (October–March) there is a greater prevalence of the nimbus forms in the morning. Also the cirro-stratus form preponderates during the wet season.

In another interesting appendix to the above-mentioned volume, Dr. W. van Bemmelen (acting director) discusses the influence of days of bright sunshine on the various meteorological elements at Batavia (1889–1906 August 1). Among the results arrived at, he finds that the clearness of the sky decreases the fluctuation of air-pressure in the early morning and emphasises it during the day; in the case of temperature, as one would naturally expect, the air is greatly cooled in the early morning and heated (to about the same degree) in the early afternoon, but the maximum is not retarded. The daily oscillation of relative humidity is strongly emphasised, especially in the wet season. The sea-breeze is much stronger, and the predominance of northerly components is much more conspicuous, but there is no evidence of a strengthening of the feeble land-breeze.

A North Wales branch of the Mathematical Association has lately been formed. Three meetings have already been held in Bangor, and have proved highly successful in stimulating discussions between those engaged in teaching mathematics in secondary and elementary schools in North Wales. The secretary of the branch is Mr. T. G. Creak, Bron Eryri, Llanberis.

Several papers on aëronautics and on meteorological experiments of aëronautical interest have reached us lately. Prof. L. Palazzo has sent a reprint from the *Bolletino della Società aeoronautica Italiana* describing the results of experiments with kites and *ballons sondes* in the Gulf of Genoa, conducted on board the torpedo-boat *Fulmine*. Prof. Cleveland Abbe has suggested somewhat original methods of studying atmospheric circulation by means of models as well as maps (Bull. Amer. Math. Soc., xiii., 10, and *Monthly Weather Review*, December, 1907). The winds in the Straits of Messina are dealt with by Dr. Filippo Eredia in the *Rivista marittima* for March.

The International Association for promoting the study of Quaternions and allied Systems of Mathematics has issued its annual report (Lancaster, Pennsylvania: New Era Printing Co., March, 1908). The president, Dr. A. Macfarlane, gives an interesting biography of his predecessor, the late Prof. Charles Casper Joly, with especial reference to his work on quaternion methods. An important feature of the report is the bibliography of recent and recently catalogued literature classified under the heads of matrices, linear substitutions, quadratic forms, bilinear forms, complex numbers, equipollences, vector analysis, commutative algebras, quaternions, biquaternions, linear associative algebras, and general algebra and operations.

Mr. E. Stanhope Kitchin, Woodford Green, Essex, writes to us directing attention to the prevailing lack of true scientific method on the part of those who are engaged in aëronautical experiments. He gives instances in which experiments have been described on air resistance of rotating planes, where the author of the paper has entirely ignored the necessity of specifying the conditions, and has failed to appreciate the difference between maintaining the torque or the power of the motor constant.

He also mentions that such statements as that the drift is proportional to the velocity, and not to its square, as demonstrated by Langley, find their way into print and are allowed to pass unchallenged. That inaccuracies such as Mr. Kitchin mentions are far too common in papers on aëronautical subjects is probably well known, with the result that the problem of flight is being worked out at the cost of a greater number of failures than would be necessary if more mathematical accuracy could be brought to bear on the work.

IN an article on the discharge of electricity through gases in the May number of the *Journal de Physique*, M. P. Villard, after a critical examination of the present view that the luminous phenomena are due to ionisation or recombination, comes to the conclusion that the opposite is the case, ionisation producing darkness rather than light. His own experiments lead him to the further result that the positive column is not an assemblage of independent particles, but an object of the nature of a vortex filament behaving like a flexible and extensible conductor, only capable of existing in gas ionised to an extent lying between certain limits, but within these limits becoming more prominent and stable as the current is increased. The arc and electric spark, according to M. Villard, are intense discharges in which the positive column plays the most important *rôle*, the negative phenomena having disappeared, while in the vacuum-tube discharge the opposite holds.

IT has been recognised for some time that when an electric discharge passes through a gas the product of the length of the spark into the pressure of the gas at which the spark passes most easily is a quantity characteristic of the particular gas used, and very nearly proportional to the mean free path of the molecules of the gas. Dr. E. Lohr, of Vienna, finds, further (*Sitzungsberichte der Wiener Akademie*, 1907, p. 1281), that the above-named product is inversely proportional to the refraction constant $n-1$ of the gas. Since the mean free path is proportional to the viscosity of the gas, Dr. Lohr draws the somewhat startling conclusion that the velocity of propagation of light in a gas is a function of the viscosity of the gas, and is, *ceteris paribus*, the greater the greater the viscosity.

So many experimenters are now interested in the accurate measurement of the alternating currents used in wireless telegraphy that it may be worth while to reproduce a portion of a table of relative sensitiveness of some of the best known of the instruments suitable for such work, given by Von Espinosa in the "Jahrbuch der drahtlosen Telegraphie," p. 328:—

| Instrument | Resistance in ohms | Watts necessary to give standard deflection |
|---|---|---|
| Hot wire air-thermometer with thin copper wire ... ... ... ... ... | 0·8 | ... $2{\cdot}5 \times 10^{-2}$ |
| Hot wire air-thermometer with thin manganin wire ... ... ... ... | 34 | ... $2{\cdot}0 \times 10^{-2}$ |
| Bolometer with iron wire in air ... | 1·8 | ... $2{\cdot}5 \times 10^{-4}$ |
| ,, ,, vacuum | 2·2 | ... $9 \times 10^{-6}$ |
| Thermo-couple of iron-eureka (Konstantan) in vacuum ... ... ... | 5·1 | ... $2 \times 10^{-4}$ |
| Duddell thermo-galvanometer ... | 18 to 100 | ... $5 \times 10^{-6}$ |

THE Board of Education is endeavouring to encourage practical work in the geography teaching of schools, and has suggested exercises of various kinds suitable for the pupils themselves to work. These exercises include a daily record of the pressure and temperature of the atmosphere the amount of rainfall, the direction of the wind, and so on. To assist teachers in securing a permanent record of these observations, Messrs. George Philip and Son, Ltd., have published a Meteorological Calendar consisting of fifty-two weekly sheets, each of which includes suitable barometer, thermometer, and rainfall tables, and a chart for recording wind direction. The calendar costs 2*s*. net, and the publishers are prepared to supply the sheets in quantity for the use of pupils. The sheets should prove useful in schools.

THE volume of "Extracts from Narrative Reports of Officers of the Survey of India" for the season 1905–6 deals, as usual, with a variety of topics. The progress made with the magnetic survey under the immediate direction of Captain R. H. Thomas, R.E., has been slower than in recent years, owing to the greater remoteness of the districts dealt with. It is hoped, however, that by the end of 1908 the "preliminary" survey will have been completed; by this apparently is meant a survey sufficient to indicate the general magnetic character of India, leaving for the future a detailed survey of any districts that may prove to be specially disturbed or otherwise of exceptional interest. A variety of magnetic information is given in tabular form, including the diurnal variation from selected "quiet" days for the observatories at Dehra Dun, Barrackpore, Kodaikanal, and Toungoo. As usual, considerable space is devoted to the comparison of instruments and their various defects. Pendulum observations were made, as previously, under the direction of Major Lenox Conyngham, R.E. To eliminate so far as possible the disturbing effects of temperature, observations were never taken, as in previous years, in a tent, but only where a house of some kind was available. Notwithstanding all precautions, irregularities still arise which it seems difficult to account for. During the year nine stations had self-recording tide gauges at work. The observations for 1905 were reduced by harmonic analysis at Dehra Dun, while full particulars of the observed values during 1904, with values of the tidal constants for 1908, were transmitted to the National Physical Laboratory, where the tidal predictor is at work. Particulars are given of the comparison of observed and predicted tidal results for 1905. Levelling operations were carried out by two parties, but call for no special remark.

THE Clarendon Press, Oxford, has published "A Chart of English Speech Sounds, with Key-words and Notes," by Mr. Daniel Jones, lecturer in phonetics at University College, London. The pronunciation of the key-words is that usually adopted by educated people in London and the neighbourhood. The price of the chart is 4*d*. net.

MESSRS. MACMILLAN AND CO., LTD., have published a third English edition of Prof. Wilhelm Ostwald's "Scientific Foundations of Analytical Chemistry treated in an Experimental Manner." The work has been translated by Dr. George M'Gowan from the fourth German edition, with further alterations and additions by Prof. Ostwald. The price of the volume is 6*s*. net.

A SALE by auction will take place in Berlin on June 20 next of scientific and mathematical manuscripts and books of the sixteenth to the eighteenth centuries. We have received a catalogue of the sale from Mr. W. Junk, Berlin W., Kurfürstendamm 201, with whom those persons unable to attend the sale, yet anxious to procure books or manuscripts, should correspond.

## OUR ASTRONOMICAL COLUMN.

BRIGHT METEOR.—Mr. Denning at Bristol saw a bright meteor of about first magnitude at 11h. 12m. on June 2 with path from 301°+50° to 265°+55°, and directed from the shower of Pegasids at 334°+28°, to which he recently directed attention in NATURE. The meteor left a streak of about 10° amongst the stars of Cygnus and Draco. At Bristol the midnight sky of June 2 was magnificent, the stars being unusually bright and the firmament remarkably dark, and comparable with some of the evenings of early autumn.

THE TOTAL SOLAR ECLIPSE OF MAY 8, 1910.—In a letter to the *Observatory*, Mr. J. F. Tennant points out the availability of Tasmania as an observing station for the eclipse of the sun due to take place on May 8, 1910. The duration of the total phase will be something like three minutes, but the sun will, at most places, apparently be at a low altitude; in fact, except at the extreme N.W., the sun sets partially eclipsed. Particulars as to times are given in the letter, and the writer states his intention to obtain particulars concerning the climatic probabilities, &c. (the *Observatory*, No. 397, p. 250, June).

THE DARK $D_3$ LINE IN THE SUN.—In the June number of the *Observatory* (p. 250) Mr. Buss returns to the discussion anent the presence of the helium absorption line in the solar spectrum. Among other things, he points out that, according to Mr. Evershed's recent letter, the position of the dark $D_3$ line is now given as being on the red side of the bright chromospheric line, whereas it was previously stated to be on the more refrangible side.

Mr. Buss adds that of 358 observing days in 1906 and 1907 he made spectroscopic observations on 317 days, and was able to detect the $D_3$ absorption on 236 days, or on about 75 per cent. of the total number. This indicates that the phenomenon of helium absorption over active solar areas is not so rare as has been thought, and Mr. Buss suggests that, with a more refined equipment than his, a practical permanency of the phenomenon over such areas, with or without spots, might be established.

It is interesting to note with regard to this that at the meeting of the British Astronomical Association held on April 29, Father Cortie expressed the opinion that for this class of work a telescope of not very large aperture and a spectroscope of moderate dispersion were required.

POSITION OF THE AXIS OF MARS.—In No. 4251 of the *Astronomische Nachrichten* (p. 39, May 29) Prof. Lowell gives the results obtained from his measures of the position of the axis of Mars during 1907. Between September 23 and December 16, 1907, 198 determinations of the position-angle of the south polar cap were made by Prof. Lowell and seventy-nine by Mr. Lampland. The measures were made in three different ways:—(1) with the micrometer thread cutting off equal segments below the cap; (2) with the thread tangent externally to the cap; and (3) with the thread tangent internally to the cap, and on collating the results it was seen that each method is subject to systematic errors. To throw some light on the question of these errors, an artificial planet was devised by Mr. Lampland on which measures were made by both observers, under conditions as far as possible identical with the true conditions. The results of these observations showed that the dichotomy measures are more trustworthy than the tangential, that they are decreased by phase, and that the tangency measures are too large.

Combining the results for the measures made during 1901–7, Prof. Lowell obtains as the general mean for the position of the axis R.A.=315° 38′, dec.=54° 39′, and for the obliquity of the Martian ecliptic 23° 8′. He then gives a table comparing his results with others obtained since 1781, and points out that there is apparently a steady decrease in the obliquity if Cerulli's observations of 1896–7 be excepted; of this phenomenon he offers no explanation.

THE ORBIT OF α ANDROMEDÆ.—From spectrograms taken at the Potsdam Observatory during the period 1901–7, Herr Ludendorff determined an orbit for the spectroscopic binary α Andromedæ, and now publishes his discussion in No. 4250 of the *Astronomische Nachrichten* (p. 23, May 21). For the period he finds 96·7 days, a value which he considers certain to within 0·1 day. In the discussion he confirms Sir Norman Lockyer's remarks as to changes in the spectrum, and records that he has on several plates observed the Mg line at λ 4481 doubled.

THE ECCENTRICITIES OF COMET ORBITS.—In No. 113, vol. xix. (pp. 67–71), of the Publications of the Astronomical Society of the Pacific, which we have just received, there is an interesting address by Prof. Leuschner on the probable general form of comet orbits. Prof. Leuschner raises strong objections against the prejudice which assumes all cometary orbits to be parabolic unless it can be proved very certainly that they are elliptic or hyperbolic. In support of his suggestion that the parabola may be the exception, and not the rule, he gives two tables, the first of which shows the percentage of parabolic orbits of comets appearing in three different periods. For the last period (1846–95) only 54 per cent. of the determined orbits had the eccentricity 1·0, and therefore it seems no more probable that a comet's path should be parabolic than that it should not. The second table classifies the orbits according to the duration of visibility of the comets, and here it appears that the longer the comet is observed the more probable it becomes that the orbit cannot be satisfied by a parabola. Of comets observed for more than 240 days, it is doubtful whether any had parabolic orbits.

## THE ROYAL OBSERVATORY, GREENWICH.

THE annual visitation by the Board of Visitors of the Royal Observatory, Greenwich, was held on Wednesday, June 3, when the customary report was presented by the Astronomer Royal dealing with the work carried out during the twelve months ending 1908 May 10. A summary of the chief points of the report is given below.

Among other matters, it is interesting to note that various national undertakings of importance were, or are being, facilitated by the loan of instruments by the observatory authorities. Thus the observers attached to the British Antarctic Expedition (1907) are using the 4-inch Simms' telescope No. 2, Captain Monro, R.N., used the transit instrument D in the determination of the longitude of Ascension, whilst a very interesting collection of historical and modern astronomical and meteorological instruments, models, photographs, &c., illustrating the past and present work of the observatory, is being exhibited in the Science Section of the Franco-British Exhibition.

Referring to the work done with the transit circle, the report states that the system of inclined wires formerly used has been replaced by a system of two close vertical wires and one horizontal wire, and the method employed for illuminating the field has been changed to that applied so successfully to the altazimuth last year. A series of observations is now being carried out in order to compare the results obtained under the respective conditions of illumination, and it is hoped that a discussion of the results may throw some light on the question of the magnitude equation in the observation of the fainter stars.

The transit was employed for the usual observations of the sun, moon, planets, and fundamental stars, the working list being made up by the inclusion of stars of the ninth magnitude and brighter between the parallels of north declination +24° to +32°, which will serve as reference stars for the Oxford astrographic zones. Eight thousand seven hundred and twenty-three transits and 7960 circle observations were taken during the year.

From the observations made in 1905, applying Bessel's refractions, 38° 31′ 21″·70 was determined as the co-latitude, whilst those made in 1906, with Pulkowa refractions, gave the value 38° 31′ 21″·67. The reduced solar observations of 1906 show the correction to the tabular values for the obliquity of the ecliptic to be −0″·09, and the observations of the summer and winter solstices indicate that the mean of the observed distances from the pole to the ecliptic is apparently 0″·005 too great.

Each day, when practicable, three or more observations of level and nadir were made, and it was found that the diurnal changes of level ranged from +0″·13 at noon, to 0″·00 at 6 p.m., to +0″·18 at midnight; the corresponding values for the nadir were found to be +0″·17, 0″·00, and

$+0''.14$. The mean error of the moon's tabular place, determined from eighty-two observations and computed from Hansen's tables with Newcomb's corrections, was $-0.383$s. in R.A. and $+0''.15$ in N.P.D. for 1906. From 104 observations in 1907 the error is $-0.401$s. in R.A.

Part i. of the Second Nine-year Catalogue, epoch 1900, dealing with fundamental and zodiacal stars, is already in the printer's hands, and part ii., giving the astrographic reference stars, will be ready for the press shortly.

The new method of illuminating the altazimuth field, as described in the previous report, has proved very satisfactory, and has now been adapted to the transit instrument. The altazimuth was used for meridian and extra-meridian observations throughout the year, and the observations of the lunar crater Mösting A, commenced in 1905, were continued whenever practicable; these serve to connect the observations of the first and second limbs made before and after full moon, and, when discussed with the similar observations that are being made at the Cape Observatory, will provide data for the determination of the lunar parallax. Forty-three observations of the N.P.D. and of the R.A. of the crater were made during the year. That both the transit-circle and altazimuth observations are satisfactory is shown by their agreement.

From the altazimuth observations in 1907 the mean errors of the moon's tabular place are:—moon's limb, in meridian, $-0.36$s.; Mösting A, in meridian, $-0.35$s., moon's limb, extra meridian, $-0.42$s.

The larger scheme of reflex-tube observations, mentioned in the preceding report, was prosecuted throughout the year, 1545 double and forty-four single observations being made; the total number of stars observed, including $\beta$ and $\gamma$ Draconis and $i^2$ Cygni, which are observed throughout the year, was eighty-five. With the view of determining the variation of latitude, the discussion of the observations from 1903 onwards has been commenced, but owing to the variation of the instrument's scale value from night to night, caused by minute alterations in the distance between the mercury surface and the object-glass, there are serious difficulties to be overcome in the discussion. This distance can be adjusted to within about 0.01 inch by means of the focussing rod, but an error of that amount would introduce errors quite inadmissible in the deduced zenith distances of the stars at a distance from the centre of the field. For example, in the case of $\beta$ Draconis, which is $53\frac{1}{2}'$ from the zenith, the error would amount to $\pm 0''.56$.

The 28-inch refractor was employed for observing double stars, primarily those pairs discovered by Mr. Hough, and measures were made on 105 nights as compared with eighty-six nights last year; $\kappa$ Pegasi was measured on fifteen, $\delta$ Equueli on thirteen, and 70 Ophiuchi on sixteen nights. Complete sets of measures of the polar and equatorial diameters of Jupiter were made, first with the filar and then with the double-image micrometer, on seventeen nights, whilst with the filar micrometer the diameters of the satellites were determined on two nights.

It was mentioned in the last report that a system of twelve lignum-vitæ wedges had been employed to fix rigidly the mirror of the 30-inch Thompson reflector. Whilst the method has proved very satisfactory in fixing the mirror, there is a tendency to produce slight distortion, so it is proposed to introduce a further modification of the support the next time the mirror is dismounted for re-silvering. Cast-iron blocks, shaped to fit the steel supporting band round the edge of the mirror, are to be introduced, the pressure being applied by screws passing through the cell; in this way the strain may be adjusted as required.

Thirty-one photographs of Neptune and its satellite were secured with the 26-inch refractor, using the occulting shutter as in previous oppositions, on sixteen nights; photographs of Saturn's, and of Jupiter's distant, satellites were also taken. In regard to the latter, Mr. Melotte and the Greenwich observers generally are to be heartily congratulated upon the discovery of Jupiter's eighth satellite, first noted on a photograph taken on February 28. Altogether twelve photographs showing this object were secured between January 27 and April 24, and the measurements show that the newly discovered satellite is very much more distant from Jupiter than the sixth and seventh satellites, and is perhaps not quite so faint as the seventh. Of J. vi. and vii., respectively, thirty-eight and twenty-two photographs were secured during the opposition.

The 30-inch reflector was also used to photograph fifty-four minor planets, and comets 1907*d* and *e*. Several long exposures on comet 1907*d* (Daniel) produced negatives in which the structure of the tail is of great interest. Four long exposures were made in an unsuccessful search for Halley's comet, and this search, for which an ephemeris, based on the perturbations calculated at Greenwich, has been prepared, will be resumed during the coming autumn.

With the astrographic equatorial, 128 satisfactory plates were taken during the year to replace plates which, although satisfactory in other respects, are unsuitable for reproduction of large prints. Positives have been made and passed for 192 plates which cover the zones $75^\circ-78^\circ$, and 109 plates in zones between $79^\circ$ and the pole. Only fifteen chart plates remain for reproduction, and these have to be replaced by more suitable negatives.

The work of the Greenwich section of the Astrographic Catalogue is complete so far as the publication of the measured rectangular coordinates and the data necessary to convert them into Right Ascension and Declination is concerned. The conversion of the coordinates of such stars as are in Carrington's Catalogue has been commenced. Vol. ii. of the Greenwich Astrographic Catalogue was published during the year, and contains 98,738 stars. The report contains an interesting table, too large to reproduce here, comparing the number of stars which appear on the plates for each zone and for the three different exposures, and also comparing these numbers with the number of stars shown in the same zones of the Bonn Durchmusterung; the total number of stars shown on the forty-minutes' plates is 719,088, or 344.4 per square degree.

The perturbations of Halley's comet, which are being computed by Messrs. Cowell and Crommelin, and the data necessary for determining the time of next perihelion passage, are nearly complete, but some further investigation of the close approaches of the comet to Jupiter in 1834 and 1837, when the perturbations appear to have been considerable, is necessary; 1910 April 8 appears to be the most probable date for the occurrence of the next perihelion passage. Mr. Crommelin has confirmed Dr. Hind's identifications of the comet with three exceptions (1223, 912, and 837), and the perturbations have been carried back to 760.

Photographs of the sun were taken with the Thompson photoheliograph on 210 days, and with the Dallmeyer photoheliograph alone on two days.

Some remarkable fluctuations of the solar activity during 1907 are reported. From July onwards an increased activity occurred, and several naked-eye groups were observed.

The usual magnetic observations were carried out during the year, and the principal results for the magnetic elements for 1907 are given as follows:—

| | |
|---|---|
| Mean declination ... ... | $15^\circ$ $59'.8$ West |
| Mean horizontal force ... | 4.0195 (in British units)<br>1.8533 (in metric units) |
| Mean dip (with 3-in. needles), | $66^\circ$ $56'$ $4''$ |

In 1907 there was one day of great magnetic disturbance and sixteen of lesser disturbance.

The meteorological results show that the summer of 1907 was exceptionally windy, and that the mean temperature of the year was $49^\circ.4$, or $0^\circ.2$ below the average of the sixty-five years 1841–1905. The rainfall of the year ending 1908 April 30 was 23.14 inches, being 0.98 inch below the sixty-five-year average.

The testing of chronometers and chronometer watches showed a serious falling off in the performance of the former and an improvement in that of the latter instruments.

The danger which threatened the observatory from the working of the L.C.C. generating station on the northern meridian has been averted to a great extent by the two years' working agreement with the Council. Apparently the close, double-star observations with the 28-inch refractor are not affected prejudicially, but it is still desirable that the trouble arising from the outflow of heated gases, which interfere with the observation of northern stars on the meridian, should be mitigated.

## VISUAL ILLUSION AND FIXATION.

A REMARKABLE new visual illusion is described by Dr. James Fraser in the *Journal of Psychology* for January. In the first form of the illusion a word (such as "LIFE") is printed in capital letters on a chequered background of black, grey, and white squares. The double outline of the letters is not traced in continuous lines, but is constituted by a band consisting of short lines, alternately black and white, slightly inclined to the direction of the limbs of the letter. This band may conveniently be regarded as representing a cord made of two strands, black and white, twisted together. In these circumstances the letters appear, in general, to be inclined several degrees from their actual directions, the sense of the deviation varying with the direction of the constituent lines of the

Fig. 1.

illusory band (see Fig. 1). A number of figures are given illustrating variants of this form of the illusion, and facilitating a study of the limits within which it persists.

In a second form of the experiment concentric circles or ellipses made of the "twisted cord," and laid upon a chequered surface of peculiar construction, are shown to suffer apparent distortion of an extraordinary character (see Fig. 2).

The paper (which is excellently illustrated) concludes with a short discussion in which the author points out the factors which appear to him to determine the presence and disappearance of the illusion.

Fig. 2.

[1]Upright letters of appropriate size and concentric circles of appropriate diameter, drawn on tracing paper and superimposed upon the figures, will demonstrate the character of the illusion in each case.

The *Psychological Review* has published, as a monograph supplement (November, 1907), an account of an experimental study of visual fixation conducted by Prof. Raymond Dodge in the psychological laboratories of Wesleyan University. The main result of this careful and interesting work is to render untenable the traditional assumption of an identical anatomical and functional centre of the retina, to which all visual processes are referred or referable. Prof. Dodge shows (following, in part, Delabarre and McAllister) that during supposed fixation there is continuous movement of the point of regard over a variable area of appreciable extent. This is the result of uncompensated disturbances produced by the pulse and respiration, and by irregular head and body movements. On the other hand, the investigation has brought to light a number of eye-movements compensatory of movements of head and trunk, the perfection of which (since the reaction time of the eye is relatively slow) points to the existence of highly organised motor systems embracing both ocular and somatic muscles. The discovery that there is, strictly, not a fixation point, but merely a fixation area, renders improbable the current hypothesis that assumes a tendency to transfer every peripheral stimulus to the centre of the fovea. Actual experiment shows, in fact, that when a given word is read the point of regard may rest indifferently in many situations. These observations have, obviously, an important bearing upon the question of retinal space-perception, and Prof. Dodge uses them to discredit the theory that the motor-impulse by which a peripheral object of regard would be brought to a supposed constant intra-foveal fixation point is a "local sign" differentiating the retinal point stimulated from every other. He proposes to substitute for it the conception of a differentiated organisation of the retinal groups, and shows how such an organisation might be brought about by the agency of the fixation movements.

## SOME RECENT PETROLOGICAL PAPERS.

A DETAILED study of the granite of Brixen has been contributed by Herr Bruno Sander to the *Jahrbuch der k.k. geologischen Reichsanstalt*, vol. lvi. (1906), p. 707, which involves many interesting questions of the intimate penetration of sediments by igneous rocks, and directs fresh attention to the marginal facies known as tonalite-gneiss (pp. 726–34). The author shows that a foliated structure existed in this rock before deformation by pressure occurred. Dr. Trener, on the other hand (*ibid.*, pp. 415 and 458), in a paper on the Presanella group, containing many petrographic details, treats tonalite-gneiss as a product of pressure, and the basic inclusions in it as segregations. One of Sander's most suggestive observations is the finding of amphibolites, closely resembling the tonalite-gneiss, in the old limestone series that has been invaded by the granite; and he is led to ask (p. 734) whether the occurrence of tonalite-gneiss does not in some way depend on the horizon selected by the granite for its intrusion continuously from Meran to Mauls.

Dr. Trener's paper, just referred to, contains (p. 484) a valuable appendix on graphite, in which Luzi's "graphitite" and Sauer's "graphitoid"—a graphite in metamorphic rocks—are both opposed as mineral species.

Mr. Joseph Barrell's "Geology of the Marysville Mining District, Montana" (U.S. Geological Survey, Prof. Paper No. 57, 1907) is also "a study of igneous intrusion and contact metamorphism," dealing particularly with a great batholithic inflow of granite among pre-Cambrian strata at the opening of Cainozoic times. Various igneous rocks, from gabbros to aplites, appear as subsidiary intrusions. The contact-phenomena have been studied to advantage in mine-sections down as far as 1300 feet. A strong case is made out for the occurrence of "stoping," by the falling in of blocks "10 to 200 feet or more in thickness and of considerably greater length" (p. 172), and the consequent rise of the granite into its former cover of Algonkian rocks.

Mr. R. A. Daly, another strong advocate of "stoping," in a paper on the Okanagan composite batholith of the Cascade Mountain system (Bull. Geol. Soc. America, vol. xvii., 1906, p. 329), urges that this batholith actually replaces an equal or approximately equal mass of the older solid rock. Those of us who have been maintaining this somewhat natural view from field-observations on batholiths in our own islands must join with Mr. Daly in hail-ing its growing acceptance, though many will still hesitate before his conclusions (p. 373) as to the profound modification of a gabbro-magma by absorption of pre-existing acid masses. He admits, with other writers, a "gravitative differentiation of the compound magma of assimilation," and urges that at each stage in the intrusion of the Okanagan batholith a magma more basic than the average of the rock invaded became enriched with silica by assimilation, and also by this gravitational draining away of the denser material. Dynamic and accompanying hydrothermal actions are said to have produced gneisses from the intrusive Okanagan "granodiorite," and it is held that in many places mineral material, especially from the more basic constituents, "has been leached out from the granulated rock and has re-crystallised in strong shear zones to which the solutions have slowly travelled" (compare pp. 345–6). This would seem in accord with Lehmann's view of the development of biotite along shear zones; and, as even a tentative explanation of the formation of a strikingly banded gneiss out of a homogeneous "granodiorite," it has considerable petrographic interest.

Messrs. E. C. Andrews and J. C. H. Mingaye, assisted by the careful petrographic descriptions of Mr. G. W. Card, discuss the granites of northern New England in part iv. of their description of the New England plateau of New South Wales (Records Geol. Survey N.S.W., vol. viii., 1907, p. 196). They conclude that their granitic masses are mostly "bathyliths." At Hillgrove they find a diorite (p. 232) that passes insensibly through a fine-grained granite rich in biotite into silicified slates, which further pass into true black slates. "The biotite-granite is thus possibly a compromise between the slates and the diorite." The authors urge (pp. 234 and 237) that the "bathyliths" have occupied their present positions at the expense of the older rocks, and they are advocates of stoping as a means of carrying away derived material. In part v. of the memoir (*ibid.*, p. 239), Mr. Andrews explains the structure of the deposits of wolfram, cassiterite, and molybdenite as a "replacement of granite by [the products of] solutions and gases rising along the intersecting joints" (p. 241), and spreading at times from "an incredibly small core." Mr. Card contributes "Mineralogical and Petrographical Notes, No. 10" (*ibid.*, p. 257), referring his rocks to the American system of classification, on the basis of the thorough analyses provided by Mr. Mingaye's laboratory. We hope that some day these notes may be brought together into a general petrographic study of the colony, so that we may learn the part that each rock has played in the broad sequence of geological events.

A fine example of that rare rock, orbicular granite, is described from the Transvaal Bushveld by Mr. W. J. Gau (Trans. Geol. Soc. of S. Africa, vol. ix., 1906, p. 70).

The mining district of Pitkäranta on Lake Ladoga, in Finland, has been thoroughly investigated by Mr. Otto Trüstedt from a mineral and petrographic point of view (*Bull. de la Comm. géol. de Finlande*, No. 19, 1907). His fine memoir, written in German, of more than 300 pages, lays special stress on three zones of "skarn"—a somewhat forbidding word in Swedish—which here means a calciphyre formed from crystalline and usually dolomitic limestones. These limestones are part of an ancient amphibolitic and sedimentary series, now highly metamorphosed, into which granites and pegmatites intruded in early pre-Cambrian times, followed in much later, but still pre-Cambrian, times by the great mass of Rappakiwi-granite. The "skarn," chiefly composed of salite and garnet, is believed (p. 91) to have arisen through the influence of magmatic waters circulating from the earlier intrusive bodies. Earth-movements then broke it up in many places into blocks, round which singular modifications have taken place. Serpentinisation, acting through a long period, has spread inward from their surfaces (*e.g.* pp. 218 and 235), producing an eozoönal structure, built up of salite, serpentine, and calcite. This banded structure is well shown in the photographic plates and figures. The Rappakiwi-granite ultimately invaded the whole series of rocks, and became solid. During the last phases of the eruptive activities of which it forms the climax, metallic ores, including cassiterite, were deposited in its zone of contact. Magnetite, zinc-blende, and sulphides of iron and copper now began to replace certain layers of the "eozoön," and the outer portions of some of the lumps of "skarn," or "Salitaugen," pass into pure ore. Even garnets (p. 138) have been dissolved away along certain of their zones of growth, and these zones have been replaced by metallic minerals. The author agrees with Vogt (p. 315) that the Pitkäranta ore-deposits belong to the true contact-metamorphic type, and occupy a middle position between the iron and copper deposits of Christiania and the tin and copper deposits of Cornwall.

Mr. Curt Fircks's paper, written in English, on the occurrence of gold in Finnish Lapland (*ibid.*, No. 17, 1906), describes ferruginous veins traversing granulite as the mother-lodes of the alluvial gold; but it is not clear why they are called (p. 33) "a new type of gold veins, not yet observed in other parts of the world."

Messrs. Johnson and Warren (American Journal of Science, vol. xxv., 1908, p. 1) revive our interest in Wadsworth's "cumberlandite" in their account of the geology of Rhode Island. This rock becomes a "rhodose" in accordance with the new system of classification (p. 25); it has the high specific gravity of 4, owing to its groundmass of inter-grown magnetite and ilmenite, enclosing hyalosiderite (p. 19), an olivine rich in iron. The olivine has retained grains of the iron ore within it, and Mr. Warren suggests that these were prevented from joining the main mass by the decreasing mobility of the separating olivine, and he favours the supposition that the minerals became immiscible before their freezing point was reached (p. 22).

An unusual group of rocks, for which ultra-basic intrusive masses seem primarily responsible, is described from the Vizagapatam district of Madras by Messrs. T. L. Walker and W. H. Collins (Records Geol. Survey of India, vol. xxxvi., 1907, p. 1). The ultra-basic igneous border of a mass of granulites and garnetiferous granites (charnockite series) is believed to have mingled with sillimanite-schists. Rocks rich in green spinel and magnetite thus pass into others where the spinel is largely replaced by sapphirine, and sapphirine is regarded (p. 11) as a product of the interaction of spinel and sillimanite. A mineral hitherto described as hypersthene in the charnockite series, with a pleochroism "sky-blue to red or red-brown" (p. 14), is shown to have frequently oblique extinction. The authors seem to throw doubt on the existence of "a rhombic pyroxene with the properties usually assigned to hypersthene"; but surely they mean merely to ask whether rhombic pyroxene ever has a "sky-blue" axis-colour.

Before leaving ultra-basic igneous rocks, it may be mentioned that Dr. Corstorphine further defends his view, criticised in South Africa and elsewhere, as to the concretionary nature of the eclogite masses in the diamond-pipes of Kimberley (Proc. Geol. Soc. of S. Africa, 1907, p. lxi). The tenth volume of the Transactions of the Geological Society of South Africa, which these Proceedings accompany, contains contributions by Messrs. Voit, Merensky, and J. P. Johnson on the same subject, and an interesting rejoinder by Prof. T. G. Bonney to Messrs. Corstorphine and Voit, all being included in the part for July to December, 1907.

Mr. L. L. Fermor, in describing rhyolites and basalts from Pávágad Hill, Bombay Presidency (*ibid.*, vol. xxxiv., 1906, p. 148), points out differences between the former and the Maláni rhyolites of Rájputana described by Mr. La Touche, in spite of some points of striking resemblance. In consequence, he is able to suggest that the Pávágad rocks, both basic and acid, were poured out as differentiation-products from one caldron in Cretaceous times, the alternative being that the basalts form intrusive sills in a far older rhyolitic series. A vertical section of 2400 feet of rock is exposed, to which Mr. Fermor invites the attention of future visitors who can undertake its detailed exploration.

From five weeks' study in the field, Mr. James Currie has drawn up an illustrated list, arranged topographically, of the minerals in the basaltic Færöes, which will especially appeal to students of zeolites (Trans. Edinburgh Geol. Soc., vol. ix., 1906, p. 1).

Coming now to sedimentary deposits, Herr Meigen has continued his researches on calcium carbonate, which have been so practically fruitful (*Ber. naturforsch. Gesell. zu Freiburg i. Br.*, Bd. xv., 1907, pp. 38–74). His precipitates of aragonite globules or needles from various solutions pass for the most part into calcite, with characteristic rhombohedral forms, in periods varying from twenty-four hours to three months. A few, from dilute hot solutions, remain unaltered, at any rate for the period of observation, which in one case is as long as four months. Experiments to determine the composition of the coloured deposits produced by the action of calcium carbonate on salts of cobalt showed (p. 57) that calcite assumes a violet colour *when in the form of an impalpable powder* and treated in a distinct[illegible]e solution of cobalt nitrate. Ordinary fragments remain uncoloured, or become blue on continued boiling in a concentrated solution, while aragonite under all conditions becomes, as is now well known, violet. Though the violet colour arises in powdered calcite more slowly than in aragonite, this new discovery serves as a warning to be regarded in the application of Meigen's test. The author determines (p. 74) the violet precipitate on aragonite from a concentrated solution of cobalt nitrate as $2CoCO_3 + 3Co(OH)_2 + H_2O$, and the blue one on calcite as $CoCO_3 + 3Co(OH)_2$.

Prof. R. B. Young, in describing the calcareous rocks of Griqualand West (Trans. Geol. Soc. of S. Africa, vol. ix., 1906, p. 50), shows how oolitic dolomites have been converted into granular quartzites, and supports the late Mr. Rutley's views as to the origin of certain "metasomatic quartzites." Mr. G. Abbott illustrates many of the well-known forms of concretion in the Durham dolomite in a general paper on concretions (Trans. South-Eastern Union of Sci. Societies, 1907).

Messrs. T. M. Reade and Philip Holland continue their researches on our much-neglected sedimentary rocks with the analysis and discussion of a series collected near Ludlow. A full analysis of the Titterstone Clee dolerite is also given (Proc. Liverpool Geol. Soc., 1907).

Lastly, Mr. R. A. Daly's paper on the limeless ocean of pre-Cambrian time (Amer. Journ. Sci., vol. xxiii., 1907, p. 93) raises many important questions as to the mode of origin of pre-Cambrian sedimentary rocks. The author holds that the land-areas of Eozoic times were of insufficient extent to supply enough lime to the ocean for the demands of shell-forming organisms. The continuous decay of abundant soft-bodied animals precipitated, moreover, as calcium carbonate what little lime entered the seas; the magnesian limestones so frequently found in pre-Cambrian sediments were also deposited as inorganic rocks by the prolonged action of the ammonium carbonate after the lime salts had been dealt with. It was only when, in Cambrian times, land-areas became more pronounced that shell-forming animals could become common; hence the rather abrupt transition from beds almost devoid of fossils to those with an abundant fauna. All this gives the reader food for meditation, and brings the petrographer, as is fitting, into the field of evolutionary geology.

G. A. J. C.

## THE INSTITUTION OF MINING ENGINEERS.

THE forty-eighth general meeting of the Institution of Mining Engineers was held on June 4 and 5 in London in the rooms of the Geological Society. Mr. C. E. Rhodes read his presidential address, in which he stated that steps were being taken to transfer the headquarters of the institution to London. The main portion of his address was devoted to a consideration of some of the problems with which the rising generation of mining engineers will have to deal, namely, the sinking of deep shafts through water-bearing strata, the depth to which tubbing can be put in, improved methods of splitting the air which will be required at great depths for cooling down the working places, and the method of dealing with dust, which in all probability will be abundant in deep mines.

The first paper read described the mineral resources of Trinidad. The author, Mr. John Cadman, gave a brief account of the gold ore, iron ore, graphitic schist, limestone, and coal known to exist, and dwelt more fully upon the bituminous minerals, which are of great economic importance. In a mine of the bitumen known as manjak an explosion occurred in 1904, causing the death of seventeen miners. A sample of gas examined by the author contained 14·00 per cent. of oxygen, 11·10 per cent. of carburetted hydrogen, 1·60 per cent. of hydrogen, and 73·30 per cent. of nitrogen. It is suggested that the deficiency in oxygen is due to the absorptive properties of the manjak. During the meeting several other papers of scientific interest were read. Mr. J. B. Tyrrell described the recently discovered mineral veins of cobalt in Ontario. Mr. Greville Jones gave an account of the various types of calcining kilns for iron ore. Mr. C. B. Wedd and Mr. G. C. Drabble described the occurrence of fluor-spar in Derbyshire. The longest paper read was by Mr. S. L. Thacker, on winding-engine tests. He recorded the results of his own experience, pointed out some sources of loss, and suggested the lines on which winding-engine tests should be carried out.

In connection with the meeting, excursions were arranged on June 4 to a diving demonstration at Lambeth under the supervision of Dr. J. S. Haldane, on June 5 to the mining and metallurgical section of the Franco-British Exhibition under the guidance of Mr. Bennett H. Brough, and on June 6 to the South Metropolitan Gas Company's tar works. A new self-contained diving apparatus suitable for work in mines was exhibited for the first time. The supply of oxygen is automatic, and is furnished to the diver mixed with 60 per cent. of air. At the Franco-British Exhibition Sir Hugh Bell received the visitors in the Machinery Hall, and gave an account of the collective pig-iron exhibit and the other objects of interest in the iron and steel section. The French mining section, in which the scientific aspects of working are well shown, was much appreciated.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—On Monday, June 8, Mr. William Bateson, F.R.S., was elected to the chair of biology, which has been established for five years largely owing to the generosity of an anonymous benefactor. Mr. Bateson, who was born in 1861, is a son of the late Rev. W. H. Bateson, D.D., Master of St. John's College, and has been a fellow at the same foundation since 1885. He was educated at Rugby School, and held the Balfour studentship from 1887 to 1890; for many years he has been one of the leading workers in England on heredity and variation, and has published several important treatises on these subjects. In 1904 he received the Darwin medal of the Royal Society.

Mr. A. R. Hinks has been re-appointed chief assistant of the observatory for a period of five years from June 24, and Mr. W. E. Hartley has been re-appointed an assistant of the observatory for a period of five years from July 13.

Prof. Thomson gives notice that the new building of the Cavendish Laboratory will be opened by the Chancellor on Tuesday, June 16, at 4 p.m. In consequence of the limited accommodation, admission will be by ticket only.

In the forty-second annual report the museums and lecture-rooms syndicate records a gift of 500*l.*, made by Mr. Frank Smart, for the purchase of additional furniture and fittings in the museum of botany. The library in the department of physiology has been materially increased by many books formerly in the possession of Sir Michael Foster; the library of the medical school has also received many additions, including a large number of pamphlets and books presented by Sir T. Clifford Allbutt, K.C.B. The Woodwardian professor records several important additions to the museum, especially a fine series of slates, marbles, and rocks of economic value, which have been presented by Mrs. J. F. Walker, of York. The syndics' accounts for the year show a balance in favour of the maintenance fund of 33*0l.* 4*s.* 4*d.*

The prize of 50*l.* out of the Gordon-Wigan fund for a research in chemistry has been awarded to Mr. L. A. Levy for his research entitled "Investigations on the Fluorescence of Platinocyanides."

Notice is given that a prize of 50*l.* out of the Gordon-Wigan fund will be awarded at the end of the Easter term, 1909, for a research in chemistry, of sufficient merit, carried out in the University. The research may be in any branch of chemistry. The dissertation, with the details of the research, must be sent to the professor of chemistry not later than the division of the Easter term, 1909.

Liverpool.—At the graduation ceremony on July 11 the honorary degree of LL.D. will be conferred upon Sir John Brunner, Principal Macalister, and Prof. Vinogradoff; of D.Sc. upon Mr. Francis Darwin and Prof. J. L. Todd; and of D.Eng. upon the Hon. C. A. Parsons.

Manchester.—On the occasion of the installation of Viscount Morley of Blackburn as Chancellor of the University, on July 9, the honorary degree of Litt.D. will be conferred upon Mr. A. J. Evans, F.R.S., of D.Sc. upon Prof. Baldwin Spencer, F.R.S., and Prof. A. Gamgee, F.R.S., and of M.A. upon Mr. William Burton, for his scientific investigations and art productions in pottery. H.M. Treasury has allowed the grant of 12,000*l.* to remain at that figure for another year instead of reducing it to 10,000*l.* It is hoped that the grant will be continued on the higher basis, and possibly increased.

Oxford.—Dr. B. P. Grenfell has been appointed extraordinary professor of papyrology.

The Rolleston memorial prize for 1908 has been awarded to Mr. C. C. Dobell, Trinity College, Cambridge; Mr. W. K. Spencer and Mr. C. H. G. Martin, B.A., both of Magdalen College, Oxford, were honourably mentioned by the examiners.

The Romanes lecture for 1908 will be delivered by Canon Scott Holland in the Sheldonian Theatre on Saturday, June 13, at 5 p.m. The subject of the lecture is "Bishop Butler."

The Robert Boyle lecture was delivered by Prof. Rutherford on Friday, June 5, in Balliol College Hall, the subject of the lecture being "The Transformation of Radio-active Matter."

---

A conversazione will be held at the East London College (University of London) on Wednesday next, June 17. The college departments will be open from 8 to 9.30 p.m.

A Shaw studentship for research, the gift of Mrs. Bernard Shaw, of the value of 100*l.* a year for two years, will be awarded in July by open competition at the London School of Economics and Political Science, Clare Market, W.C. Particulars of the scholarship can be obtained from the director of the school.

The Bill "to make further provision with respect to the University of Durham" has now been printed. It proposes to appoint a body styled the University of Durham Commissioners. These Commissioners are to hold office until the end of 1909, but their powers may be continued by the King in Council, but not beyond the end of 1911. Their powers are to make statutes regulating the constitution of the University and the powers and duties of its authorities and constituent bodies and the disposition of its property in accordance with a scheme scheduled as an appendix to the Bill. Provision is made for the affiliation to the University in the faculty of science of the Sunderland Technical College, subject to its satisfying the conditions specified by the Senate of the University. The Senate is to consist of thirty-seven persons, namely, the Chancellor, six persons nominated by the Crown, the Dean and Chapter of Durham, together with so many other persons appointed by the council of the Durham colleges as shall make six in all, six appointed by such professors, tutors, and lecturers of the Durham division of the University as are not members of the Chapter, four appointed by the College of Medicine, Newcastle, four by the council of Armstrong College, and four by the professors of Armstrong College, and six appointed by Convocation, three being past students of the Durham division and three past students of the Newcastle division. Full powers are assigned to the Senate over the property, conditions of study, examinations, and degrees of the University. The Newcastle division of the University is to consist of the University College of Medicine and Armstrong College, Newcastle, but no council is set up for this division.

The twenty-eighth annual report of the council of the City and Guilds of London Institute, dealing with the work of 1907, has now been published. The reports of the dean of the Central Technical College, of the principal of the Finsbury Technical College, of the South London Technical Art School, and of the department of technology constitute important appendices. The total income of the institute for 1907 amounted to 46,036*l.*, as compared with 44,848*l.* in 1906. A table showing the amount of the donations and subscriptions to the funds of the institute since its foundation provides much interesting information. In 1878 the total amount of such donations and subscriptions was 12,102*l.*, while in 1907 the amount reached 22,343*l.*, a gratifying increase of more than 10,000*l.* Since its foundation the institute has received from this source the large sum of 778,365*l.*, to which the table shows there have been fifty-three contributors. The largest total benefactions received in the period mentioned are from the Goldsmiths' Company, 135,314*l.*; the Fishmongers' Company, 112,270*l.*; the Clothworkers' Company, 111,750*l.*; the Mercers' Company, 75,000*l.*; the Drapers' Company, 51,500*l.*; the Skinners' Company, 50,862*l.* Previous reports of the council have directed attention to causes which impede progress in the technical instruction of artisans, and in the report on the department of technology this year the matter is referred to again. The impediments which continue to exist are, first, the difficulty of finding competent teachers, and, secondly, the unduly large proportion of artisan students who enter technical classes without the preliminary knowledge necessary to take full advantage of the instruction they receive. We have referred on many occasions in these columns to the necessity for serious continuation-school work after the elementary school has been left if young artisans are to derive full benefit from technical courses later in life. It is quite clear that the gap between the day school and the technical institute must be bridged in some way if the money expended on technical instruction is to produce its best results.

---

## SOCIETIES AND ACADEMIES.

### London.

**Royal Society**, March 26.—"Note on the Ascent of Meteorological Balloons and the Temperature of the Upper Air." By **A. Mallock**, F.R.S.

The recent investigation of the upper atmosphere by means of india-rubber balloons has led to the discovery that an almost constant temperature is reached when the pressure has decreased to about 150 mm. The lowest pressure reached in England is a little under 50 mm., and the corresponding height about 20 kilometres.

The note examines from a theoretical point of view what the behaviour of balloons such as are used in meteorological work must be as regards the possible heights to which they might ascend and the variations of their velocity as they rise. The determining factors are:—

(1) The relative density of the gas in the balloon and of the outer air at the same pressure.

(2) The ratio of the dead weight of the balloon and fittings to the total lifting force at ground-level.

(3) The compression, by the elasticity of the balloon, of the gas it contains.

It is shown that the velocity of the balloon at first increases as the one-sixth power of the ratio of the density of the air at the elevation attained to the density at ground-level,[1] and that when the elastic compression is small the upward velocity reaches its maximum not far from the greatest elevation to which the balloon can attain.

The results of the equations are traced in Diagram I., the values for the ratio of dead weight to lifting force and the elastic compression being such as are likely to be met with in practice. It is remarkable how rapidly the velocity decreases as the minimum pressure is approached.

To connect the pressure with the height at which it is experienced, the temperature at every point of the ascent

[1] The reason being that the decrease in density rather more than compensates for the effect of the increased cross-section.

must be known, and this information is furnished by the automatic recorder attached to the balloon.

A comparison is made between the actual temperatures and the adiabatic temperatures, *i.e.* the temperature which a given volume of dry air would have if transported from ground-level to a given height and allowed to expand without receiving or losing heat.

The height at which the pressure $p$ is found in these circumstances is (if H = height of homogeneous atmosphere) $h = \mathrm{H}\frac{\gamma}{\gamma-1}\left(1 - m^{-\frac{\gamma-1}{\gamma}}\right)$. (where $m = p/p_0$), which gives a finite limit to the height of the atmosphere at 27 kilometres nearly. The ratio of the absolute temperatures at $p$ and $p_0$ is $\theta/\theta_0(1/m)^{\frac{\gamma-1}{\gamma}}$.

For isothermal expansion $dh = d\mathrm{H}p_0/p$, and if the arbitrary relation between temperature and pressure found from the balloon records is $\theta/\theta_0 = \phi(p)$, the actual value of

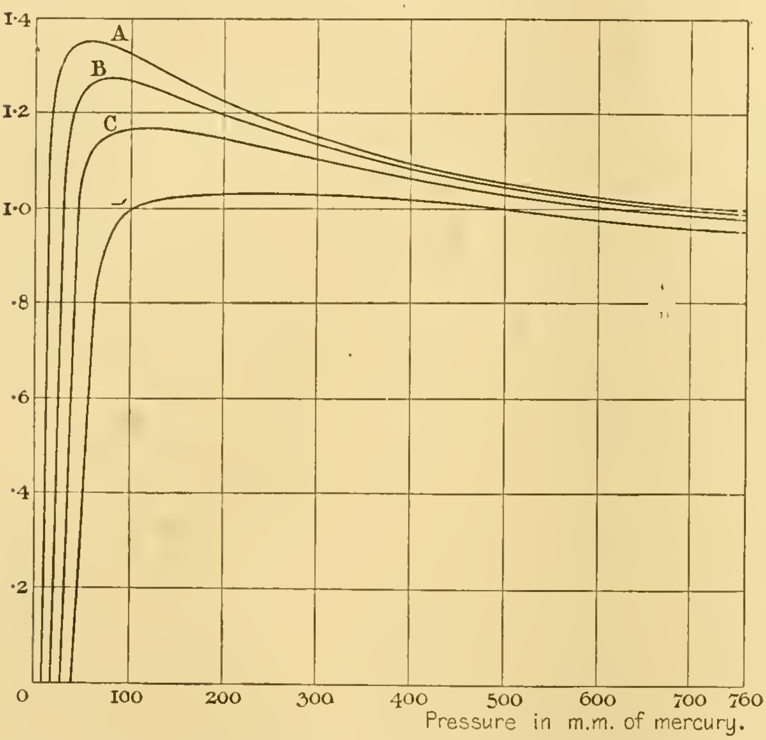


DIAGRAM I.—Velocity of ascent of balloons. The ordinates give the ratio of the velocity of a balloon in air at pressure $p$, carrying a load 0·6 $F_0$, and with internal pressure $= p + \frac{p_0}{n}\left(\frac{p_0}{n}\right.$ being the elastic compression and $F_0$ the total lifting force at ground level), to the velocity at $p_0$ of the same balloon if devoid of weight, and with the external and internal pressures equal. For A, $n = 100$; for B, C, and D respectively $n = 75$, 50, and 30.

$dh$ is $d\mathrm{H}\phi(p)p_0/p$, the integral of which can readily be found graphically.

The relations of the height corresponding to a given pressure on the supposition of (1) constant temperature, (2) temperature as observed, (3) adiabatic temperature are given, and it is noted that the observed decrement of temperature is almost exactly 0·7 time the adiabatic decrement down to a pressure of rather less than 200 mm., corresponding to a height of 11 kilometres.

Heights approaching 40 kilometres could probably be reached if the balloons were made more expansible, *i.e.* if the unfilled balloons were of thinner material and larger in volume than those at present in use, as this would allow of the same lifting force for the given quantity of gas and give more scope for expansion with diminished pressure.

Geological Society, May 20.—Prof. W. J. Sollas, F.R.S., president, in the chair.—Some fossil fishes discovered by Prof. Ennes de Souza in the Cretaceous formation at Ilhéos, State of Bahia (Brazil): A. S. **Woodward**, F.R.S. The Lower Cretaceous formation of Bahia extends along the coast to a point 130 miles south of the area previously described. The fish remains are referable to new species of the genera Mawsonia, Lepidotus, and Scombroclupea. Mawsonia seems to have been scaleless, and differs from all known Jurassic and Cretaceous cœlacanth fishes in lacking denticles on the fins. The Lepidotus resembles the European Wealden *L. mantelli* in proportions, but is more strongly ornamented. The Scombroclupea is peculiar, in exhibiting only scales where the anal finlets usually occur.—The Bala and Llandovery rocks of Glyn Ceiriog (North Wales): Dr. T. **Groom** and P. **Lake.** The authors have mapped the district around Glyn Ceiriog on the 6-inch scale. The succession of strata is tabulated, and the characteristics of each bed given. No indication of the overlap or overstep of the Wenlock, Tarannon, and Llandovery beds mapped by the officers of the Geological Survey or described by previous observers was found, although there is probably an unconformity at the base of the Fron-Frys Slates. The beds of the district dip northwards at an almost uniformly low angle, but the structure is complicated by a series of faults, most of which have hitherto escaped notice, some being very elusive. The most important east-and-west fault is the Ddolhir fault, which dips at an angle of 20° nearly with the bedding, and may be either a thrust-plane or a lag-fault. Of the N.N.W. and S.S.E. or N. and S. faults, the most remarkable is the Caemor fault, on the east side of which the rocks have been raised nearly a mile, and shifted horizontally to the south for nearly three miles.

Faraday Society, May 26.—Sir J. Swan in the chair.—*Presidential address:* Some aspects of the work of Lord Kelvin: Sir Oliver **Lodge.** The president commenced by pointing out the difficulty of doing justice in the course of a short address to a man who, from an early age to an old age, had turned out such a prodigious amount of work, embracing practically all branches of physical science. Lord Kelvin had calculated the age of the earth, worked in the domain of electrostatics, optics, elasticity, telegraphy, beside many other practical subjects. These, however, had been dealt with by other appreciators. Sir Oliver himself would not touch upon the practical side of Lord Kelvin's work, but upon the more recondite and abstruse branches of his activity. He was not entirely able to agree with some of Lord Kelvin's assumptions, neither did he always consider that his practical work entirely bore out his conclusions. For instance, in the case of the kinetic theory of solidity, Kelvin seemed to consider that solids could be made from fluids and fluids from solids, and that matter might be ether in motion. But more recently he seemed to have rather changed his views, or at any rate modified them, and seemed satisfied with the postulate of action at a distance through space without the intervention of a connecting medium. Sir Oliver Lodge himself was unable to accept the explanation of action at a distance without the intermediary of some form of matter. Nothing in Lord Kelvin's work was finer than his publications in 1851, or showed the extraordinary keenness of mind aided by the tremendous natural powers which he possessed. His prescience was, at that date, even greater than that of Helmholtz. Posterity will probably consider that the greatest of all his work was that upon the conservation of energy and his enunciations upon the laws of thermodynamics. This part of the discussion was illustrated on the blackboard by mathematical formulæ. Reference was also made to the importance of his work upon absolute measurements, and Sir Oliver Lodge pointed out that some persons appeared to think that absolute measurements meant the metric system, but it did not matter in the least what units were employed so long as they were understandable.

Zoological Society, May 26.—Prof. E. A. Minchin, vice-president, in the chair.—Mammals collected by Mr. C. H. B. Grant near Tette, Zambesia, being the tenth and last of the series of papers on Mr. C. D. Rudd's exploration of South Africa: Oldfield **Thomas** and R. C. **Wroughton.** The importance of this collection was due to the fact that Tette was the place where Dr. Peters obtained most of the specimens on which his "Säugethiere von Mossambique" (1852) was based, and the specimens now collected were therefore topotypes of his species, and in consequence of great value in working out South African mammals in general; 104 specimens were referred to, belonging to thirty-two species. The exploration had lasted five years, and its results formed the largest and most complete collection that the National Museum had ever received from any one source. Besides duplicates, 1541 specimens had been registered in the museum, a large number of new species and subspecies had been discovered and described, and many more old and inexactly described species were now represented by good series of well-prepared skins and skulls. The collection had, in fact, revolutionised our knowledge of South African mammalogy, and it was impossible to exaggerate the benefit that such an exploration was to zoology in general and to the National Museum in particular.—The small collection of terrestrial Isopoda made by Dr. Cunnington on the third Tanganyika expedition: Rev. T. R. R. **Stebbing.** The collection consisted of four species. For two of these the author instituted the new genus Anchiphiloscia, distinguished by more penicils on the mandibles and a different cleavage of the second maxillæ from Philoscia as founded by Latreille in 1804. The paper insisted on the need of some enthusiast able and willing thoroughly to revise all the forms which had clustered under and about the generic name Philoscia.—The anatomy of Antechinomys and some other marsupials, with special reference to the intestinal tract and mesenteries of these and other mammals: F. E. **Beddard.** With the aid of a series of diagrams, the author described four grades or types into which he divided the modes of suspension of the mammalian intestinal tract.—The dermal armour of the extinct reptiles of the genus Pareiasaurus: Prof. H. G. **Seeley.** The existence of a dermal armour in Pareisaurus had been doubted by some authors, but Prof. Seeley was able to exhibit some actual specimens of scutes which had been obtained by Mr. J. Van Renen south of Fraserberg, Cape Colony.—Prof. **Seeley** also exhibited the skull of an extinct reptile of the genus Diademodon, on which he proposed to found a new species, and gave an account of the further evidence which it afforded of the structure and dentition of these South African reptiles.—Descriptions of many new species of Siphonaptera: Hon. N. Charles **Rothschild.**

DUBLIN.

Royal Dublin Society, May 19.—Prof. Young, F.R.S., in the chair.—Mendelian characters among Shorthorn cattle: Prof. J. **Wilson.** The author showed that in the matter of colour Shorthorn cattle display Mendelian phenomena, and that the reds and whites are the parent races, while the roans are intermediate hybrids. In support of this he quoted data collected for another purpose by Miss Barrington and Prof. Karl Pearson, which were published in *Biometrika* (vol. iv.). For the purpose of his paper the author pointed out that Barrington and Pearson's data were not complete, inasmuch as they left out of account several factors that cause the registration of Shorthorn cattle to be inaccurate. The author collected new data, in which the inaccuracies are eliminated as far as possible. He also gave a short account of the origin of Shorthorn cattle and of the history of the three races of cattle now found in the British Isles, viz. the black Celtic race, the white Roman race, and the red Saxon race.—Injurious insects and other animals observed in Ireland during the year 1907: Prof. G. H. **Carpenter.** The paper included records of several insects feeding on tobacco, including the caterpillars of *Mamestra oleracea* and *M. brassicae*, and a springtail—*Isotoma tenella*, Reuter—new to the Britannic fauna. The storehouse beetle, *Ptinus tectus*, Boield., lately introduced into Great Britain, has now appeared also in the suburbs of Dublin.

PARIS.

Academy of Sciences, June 1.—M. H. Becquerel in the chair.—The fossils of Patagonia. Economy in nature: Albert **Gaudry.** A comparison of the remains of mammals of the Patagonian region with those of this hemisphere shows no reason for supposing that there were two centres of creation; but during Tertiary times evolution has taken place in the two hemispheres differently, continuing in the one and being arrested in the other.—New observations on Etna: A. **Lacroix.** The eruption has been studied from the observatory, situated at an altitude of 2942 metres, and at the foot of the terminal cone, 1 kilometre from the crater. The clouds emitted are compared with those of Mont Pelée, and details are given of the field within which fresh openings have been produced, and of the materials projected by the explosions of the central crater.—Some points relating to the pathogeny of congenital deformities of the face: M. **Le Dentu.** A general review of the theories of malformation is given, the statistics relating to the influence of heredity being considered in some detail.—The stability of auto-excited alternators working in parallel: M. **Dumoulin.** A study of the effect of adjusting the brushes of the rectifier supplying the inducing current.—Two different states of the iron arc: H. **Buisson** and Ch. **Fabry.** The first state of the arc, which is stable only when the current is intense, can be made to pass over into the other by introducing a large resistance into the circuit, the electromotive force being high, 220 to 440 volts. The phenomena observed are compared with those shown by the arc between carbon poles.—The hydrates of the fatty acids determined from measurements of the viscosity of their solutions: D. E. **Tsakalotos.** These measurements lead to the conclusion that there is no combination between formic acid and water, whilst acetic, propionic, and butyric acids form molecular combinations containing one molecule of water to one molecule of the acid.—The action of ammonia upon phosphorus chloronitride: MM. **Besson** and **Rosset.** With dry liquid ammonia the product of the reaction is $PN(NH_2)_2$; gaseous ammonia acting on a solution of the chloronitride in carbon tetrachloride gives a different substance,

$$P_2N_2Cl_3(NH_2),$$

soluble in carbon tetrachloride.—The acid phosphoric esters of guaiacol: V. **Auger** and P. **Dupuis.**—The mechanism of cyclic formation in the geranic series; the synthesis and structure of dihydromyrcene: M. **Tiffeneau.**—Researches on protoplasmic hydrolysis: A. **Etard** and A. **Vila.** It is pointed out that the current methods of separating and determining the nitrogenous products of the hydrolysis of protoplasmic substances entail unavoidable losses.—The relations between the microgranites and the diabases of the Meuse valley: J. **de Lapparent.** It is concluded that the eruption of the microgranites of the valley of the Meuse is of a later date than that of the diabases. At the moment of the eruption of the microgranites the magma of the diabases had not consolidated.—A new genus, *Lecythodytes paradoxus*, a parasite of the Chrysomonadineæ: P. A. **Dangeard.**—The propagation of some species of mosses of the genus Barbula under certain experimental conditions: Jacques **Maheu.**—The pallial defensive glands in *Scaphander lignarius*: Rémy **Perrier** and Henri **Fischer.**—The most recently discovered drawings in the Portel (Ariège) grotto: A. **Breuil**, L. **Jammes**, and R. **Jeannel.** In a branch of the main cavern, unnoticed until recently, a fresh set of palæolithic drawings has been found. These include pictures of a small bison and a horse, reindeer, and wild goat. Evidence of the presence of small bears in this cave has also been found.—The entoptoscope, an instrument for examining the macula: Paul **Fortin.**—Radioscopy in forensic medicine: F. **Bordas.** In determining whether an infant has breathed or not, radiography cannot be substituted for the methods in current use. It is, however, of service in furnishing the expert with a photographic document, which may be used as supplementary evidence.—A new thermo-pulveriser worked by means of compressed air: M. **Guyenot.** The various forms of apparatus in current use for producing sprays of aqueous solutions for therapeutic purposes cannot be used for a higher temperature than 25° C. In the apparatus described and figured in the present paper, any temperature up to 50° C. can be maintained at will.—Researches on the food of the typhoid bacillus: H. **Dunschmann.** A comparison of the nutritive effects of bile salts on the typhoid and coli bacilli.—The utilisation of concentrated saline solutions for the differentiation of bacteria. The separation of *Bacillus typhosus* from *Bacterium coli*: A. **Guillemard.** A strong saline solution, such as one containing 20 per cent. of sodium sulphate, causes differences in the growth of cultures of the typhoid and coli bacilli, by means of which they can be readily differentiated. Other bacilli have been studied from the same point of view.—The presence of Hippurite grit at Vence, Alpes-Maritimes: V. **Paquier.**—The Cretaceous and Tertiary strata in the region of Constantine, Algeria: E. **Joleaud.**—The use of Daguin's *acoustèle* for the detection of subterranean sounds: F. **Diénert,** A. **Guillerd,** and M. **Marrec.** An account of the application of this instrument to the tracing of currents of underground water by means of the sound produced by the stream. The method is only successful in a few limited cases.—The influence of the wind on the filling up of the bed of the ocean: M. **Thoulet.**—Contribution to the study of the Landwasser river and the Davos valley: Gabriel **Eisenmenger.**

## DIARY OF SOCIETIES.

*THURSDAY*, JUNE 11.

MATHEMATICAL SOCIETY, at 5.30.—Electrical Resonance: Prof. H. M. Macdonald.—Relations between the Divisors of the First *n* Numbers (second paper): Dr. J. W. L. Glaisher.—The Formation of Fundamental Harmonics: Prof. A. E. H. Love.

*FRIDAY*, JUNE 12.

ROYAL ASTRONOMICAL SOCIETY, at 5.—Considerations on the Form and Arrangement of New Tables of the Moon: Simon Newcomb.—On the Orbit of $\beta$ 416: J. Voûte.—An Example of Prof. Karl Pearson's Calculation of Correlation in the Case of Periodic Inequalities of Long Period Variables: H. H. Turner.—On the Parallax and Proper Motion of the Double Star Krueger 60: E. E. Barnard.—Observations of Daniel's Comet (*d* 1907): Radcliffe Observatory, Oxford.—The Lunar Bright Rays: H. G. Tomkins.—Observations of Helium $D_3$ Absorption in the Neighbourhood of Spots in 1907: Capt. R. A. C. Daunt.—The Radius of the Moon for Libration −4″·5: Walter Heath.—*Probable paper:* Report on Observations of the Total Solar Eclipse of 1908 January 3: F. K. McClean.

## CONTENTS.

THURSDAY, JUNE 18, 1908.

## THE FRESH-WATER FISHES OF CENTRAL AMERICA.

*Biologia Centrali-Americana. Pisces.* By C. Tate Regan. Pp. xxxiii + 203; with 26 plates and 2 maps. (1906–8.)

WE have to congratulate the editor of this magnificent work on the regularity with which the issue of the parts, now 200 in number, is proceeding, thus bringing its completion within measurable distance. Many a time, when, during its progress, collection after collection arrived, each bringing insects in tens of thousands, besides specimens of almost every other class of animals, the prospect of completing the work must have appeared almost hopeless, and this still more so when the editorial labours were thrown entirely upon Mr. Godman after the death of his coadjutor, Osbert Salvin. When the founders of the "Biologia" planned the work, now some forty years ago, they were moved to this grand enterprise by a clear perception of the important bearing which an intimate knowledge of the fauna of Central America, as a transition area between the Nearctic and Neotropical regions, must have upon the wider questions of the changing distribution of animals generally, and of their evolution since Tertiary times. But we believe that their original estimate, both of the number of species and of the extent of the work, was greatly exceeded in the course of those years. Nevertheless, their determination and energy have never failed them.

The volume with which we propose to deal on the present occasion is that containing an account of the fishes. Its appearance marks also the completion of the whole division of vertebrates. The preparation was entrusted to Mr. C. Tate Regan, who by his previous work on Neotropical fishes had shown himself eminently qualified for the task. The editor was most fortunate in his selection, for in the short space of two years he saw a work completed which was not only difficult in itself, but was rendered more laborious by the numerous contributions to Central American ichthyology which have appeared during the last two decades, and which, of course, had to be carefully consulted and studied.

The author has restricted himself almost entirely to fresh-water fishes and to such marine forms as are known to ascend rivers beyond the influence of the tide. In accordance with the plan generally followed in the "Biologia," detailed descriptions, with full references to previous publications, are given in the case of groups or species which to the author appeared to need revision, and for which the requisite materials were to be found in the British Museum. The remainder are merely mentioned by name, with the addition of such distinctive characters as may be compressed in a synopsis or key.

We find, then, that the number of species described is 330, including some truly marine forms which for comparison, or other reasons, had to be referred to. This is a surprisingly small number considering that about 700 reptiles and 200 batrachians are known from the same area—an area which has been peopled from two regions, the Nearctic and the Neotropical, and also by migrations from two oceans; offering every variation of physical condition most favourable to the development of fish-life; intersected by networks of river systems, without intercommunication; and with large expanses of water severally containing numerous representatives of the same genus. An area such as this must nourish a multitude of specific forms, of which only a fraction are as yet known to us. We can therefore fully concur with the author when he says that our knowledge of the fishes of Central America and Mexico must still be regarded as very incomplete. He directs attention to the fact that not a single fresh-water fish has as yet been described from Honduras or from Nicaragua north and east of the Great Lakes. He might have added that fishes, for obvious reasons, are not favourites with the generality of collectors. Extensive collections are only made by those who are especially interested in the subject; and we believe that since Salvin, assisted by Capt. Dow and Mr. Godman, formed his collection, no other of equal extent has been made, unless it be that of Mexican fishes, brought together by Dr. Meek. We must not omit to mention here that the acquisition by the British Museum of numerous types or co-types from various, especially American, sources is chiefly due to the efforts of Mr. Regan himself.

The systematic work has been carried out in every detail with painstaking care and accuracy. Generally we notice with pleasure that in nomenclature he has kept free from the crotchets of modern reformers, and has remained faithful to the classical spirit which one expects to find in a Cambridge graduate. With the rich materials at his disposal, and the additional information contained in the writings of his contemporaries, he has aimed at a precise definition of genera and species, by which their identification has been much more facilitated than if he had prepared those lengthy descriptions which too frequently prove a snare for the student.

We cannot enter more fully into the treatment of the subject in the systematic section of the work, involving in the case of almost every species questions of a purely technical nature. But there is one point which may be mentioned, if only as a suggestion to other authors engaging in similar work. Students would find it a great boon if direct references to good illustrations were always admitted in the "synonymy," instead of references merely to some recent publication, in which they learn for the first time that such illustrations exist. Furthermore, in the case of the "Biologia," it would have been particularly appropriate to give direct references to figures of species discovered by Salvin, and drawn from specimens collected by him. We allude, *inter alia*, to the genus Heros and its allies, for which Mr. Regan has adopted the Swainsonian name "Cichlasoma." [1]

[1] Should be superseded, according to modern nomenclature, by the prior Cichlaurus!

H

In his Introduction the author discusses some questions of more general interest. After having devoted a chapter to the classification of fishes, with special reference to the Central American families, explaining the grounds on which he differs from some of the generalisations proposed in recent years, he proceeds to summarise the conclusions at which he has arrived with regard to the geographical distribution of the fresh-water fishes. He begins with a description of the range of the ten Central American families and of many of their genera, tracing their origin and migrations. Thus he says of the Cichlidæ (*alias* Chromides):—

"The Mexican and Central American Cichlidæ are more specialised than the South American ones, and have certainly been derived from them; not one of the genera with three anal spines is found north of the Isthmus of Panama, and all the South American Cichlidæ have simple conical teeth."

He rejects the hypothesis of a northern origin of Cichlidæ and of their southward migration into South America, Africa, and Southern India, and adopts the view expressed by other zoologists that

"In early Eocene times Africa was connected by land with South America on the one side, and with India, *via* Madagascar, on the other."

On the other hand, he takes the Cyprinodontidæ to be an originally Holarctic group, which, moreover, was confined primarily to fresh water. His principal reasons for the latter assumption are:—(1) their absence from the Australian region, except for a species of Haplochilus in Celebes and Lombok[1]; and (2) the fact that all fossil Cyprinodonts known are from fresh-water or estuarine deposits. Singularly enough, while in the old world all the species retained their oviparous habit, a very large number of the American forms became viviparous; and it is in Central America that some of the most specialised genera were developed within comparatively limited districts. Anableps is considered to be endemic to South America, one Central American species being an immigrant from the South.

The Centrarchidæ are also a northern type which is making its way southwards into Central America. Of about thirty species, six extend southwards to the Rio Grande, and one a little further into Tamaulipas. We are glad to see that the author vindicates the North American integrity of this group from the attempt to associate with it the Indo-Pacific Kuhlia and its Australian fresh-water allies.

These brief extracts will suffice to direct attention to the many very interesting points on which the author's thorough acquaintance with the subject enables him to speak with authority. Several woodcuts accompany the text, illustrating the distribution of the Central American families over the globe; and on two plates the northern range of Neotropical and the southern range of Nearctic families and subfamilies are shown.

In the division of the Central American sub-region into provinces, the author does not carry us on firmer ground than had been reached by previous inquiries. However, he expresses it as his opinion that

"for fresh-water fishes the volcanic chain of mountains which stretches across Mexico from Colima nearly to Vera Cruz may be taken as the boundary between the Arctic and Tropical regions. This range has proved an insuperable obstacle to the northward migration of the Neotropical fishes."

Having thus established a northern and southern division, he distinguishes in the former three provinces, viz.:—

(1) Northern Mexico, west of the Sierra Madre.

(2) Rio Grande province.

(3) The Lerma system.

And in the latter:—

(1) The Rio Balsas system.

(2) Rio San Juan, with lakes Managua and Nicaragua.

(3) Guatemalan province.

(4) Isthmian province (Costa Rica and Panama).

The author cautiously adds that any division into provinces must be regarded at present as merely provisional, owing to our incomplete knowledge of the fish fauna of this area. We cannot help thinking that he would have much facilitated the labours of future inquirers had he followed the plan of other contributors and given a systematic index of species with a table showing their range so far as at present known.

Finally, in the last chapter of the introduction the author explains his views as regards the partial identity of the fish faunas of the two sides of the isthmus. He adopts the opinion of American ichthyologists that there are very few of the truly marine forms the representatives of which on the two sides cannot be shown to differ in some point; but on the present occasion he takes into consideration such only of the shore fishes as are known to enter fresh water. He has prepared a list of eighteen pairs of such fishes, each pair consisting of an Atlantic and a Pacific representative. The members of each pair differ from each other in various degrees; some of them differ in three or more "tangible," "substantive" characters (and no systematic ichthyologist would deny them specific rank), while others can scarcely be regarded "as more than subspecifically distinct." Thus, whatever method is followed by ichthyologists for taxonomic distinction, with the object of accentuating either the amount of differentiation that has taken place since the individuals were separated and isolated, or their previous and still more or less apparent identity, the similarity between species of both sides must be admitted by all to be so great as only to be explicable by a former communication between the two oceans.

The work is illustrated by twenty-six lithographic plates executed by Mr. J. Green in his usual excellent style, and we have to express our hearty thanks to Mr. Tate Regan for having contributed so careful and important a work to Godman and Salvin's great undertaking.

[1] Prof. Max Weber could hardly allow even this exception, having incontestably proved that the scanty fresh-water fauna of Celebes is merely an immigration from India.

## ROULETTE AT MONTE CARLO.

*La Loi des petits Nombres.* By M. Charles Henry. Pp. xiv+71. (Paris: Laboratoire d'Énergetique d'Ernest Solway, 1908.) Price 4 francs.

THE question discussed by the author may be given in his own words:—

"Est-il possible de prévoir une loi de séquence plus ou moins fragmentaire dans les phénomènes fortuits comme les arrivés de la rouge et de la noire à la roulette?"

He considers that the theory of probabilities is only verified in practice when the number of throws of the ball is indefinitely great, and that new principles are required when the period of play is short. He takes what he terms a psycho-physical point of view, and bases his researches on the ultimate vibrations of particles and the musical interval, the fifth—the ratio 3 : 2. He adopts the latter as governing the sequences at roulette without giving any scientific reason whatever.

It is difficult to take the author seriously, but as he pretends in chapter iv. of the work to give rules of play which will enable a player to win at Monte Carlo, it is necessary to inform the reader that the system of M. Henry is not based upon scientific truth, and can have no effect upon his winning or losing. It still remains true that the construction of the Monte Carlo roulette table gives an advantage to the bank, which, roughly, may be stated to be 1·35 per cent. on the even chances and 2·7 per cent. on the longer chances. The percentage refers to all the money placed upon the table that was originally in possession of one of the players. Should a player stake five francs on one of the even chances, the piece becomes immediately depreciated in value so as to be only worth four francs ninety-three centimes. Placed anywhere else on the table it is worth but four francs eighty-six centimes. If the stake be left upon the table for another coup, with or without previous winnings, a like depreciation takes place, and it is the sum of all these depreciations which in the long run constitutes the profit of the bank.

Statistics show that each table earns about 400*l.* per diem on the average. This shows that the amount staked at each table is about 20,000*l.* per diem. The nine tables in use during the winter months thus earn about 3600*l.* per diem, and the amount staked probably reaches the large figure of 180,000*l.* per diem. It may be regarded as certain that a large majority of the players leave off losers. Of these, certain individuals lose a small sum which they consider is sufficient to leave in the rooms; others a sum which they had previously determined not to exceed; others sums which are in excess of what they wished to lose. On the other hand, a minority of the players will be winners, but this minority becomes smaller as the average time during which the players remain at the table becomes larger.

Many of the players have probably been winners at some time or other during the play. They determined to become larger winners, with the final result that they were losers. Few players know when to stop the game and to hold their hands when a reasonable sum, reasonable in proportion to the playing capital, has been won. The consequence of a player with a moderate capital thus settling down to play the bank for immoderate winnings is in the long run certain ruin, whether the bank has between one and three per cent. in its favour or not.

The large capital of the bank gives it an advantage over the player, whose capital is relatively small, which is quite separate from the advantage derived from the design of the table.

The influence of capital can be well seen in an ordinary even game of rouge et noire. We may suppose Peter and Paul to be the players, and the stake to be 1*l.* at each coup. It is quite certain, whatever be the capital of each, that after a sufficient number of coups one or other will lose all his capital. Which of the two has the greatest chance of being ruined depends upon the ratio between the capitals. It can be shown that Peter's chance of ruining Paul bears the same ratio to Paul's chance of ruining Peter that Peter's capital bears to Paul's. If Peter's capital be 50*l.* and Paul's 40*l.*, it is 5 to 4 that Peter ultimately ruins Paul. The circumstance that the game, if continued long enough, will inevitably lead to the ruin of one of the players may seem surprising to one who has not given the subject special attention. There is a popular fallacy that in the long run Peter and Paul will win very nearly the same number of coups. The fact is that in the result of a large number of coups the ratio of the numbers of coups won by the players approaches unity, but that the difference between these numbers has a tendency to increase beyond any limit. Great as is the advantage of a large capital, it cannot be inferred that the bankers at roulette could afford to play with tables not constructed to their advantage, because then there would be nothing to hinder a combination of capitalists from placing themselves on more than even terms with the bank. So great is the advantage of the bankers due to their large capital that, failing a combination against them, they could afford to play with a table constructed against themselves and in favour of the players.

If the respective capitals of the bank and of a player be known, it is not difficult to design a table which will place the two sides on an exact equality as regards play on the even chances for an unlimited time. When the bank has practically an unlimited number of stakes the solution is very simple, and may be stated as follows:—If the player possess a certain number of stakes, he should be able, from the construction of the roulette, to win on the average a majority out of four times that number of coups. A player with fifty stakes should be able to win 101 coups out of 200. In this case the roulette should have one zero and 100 numbers, and the zero should be in favour of the player. On the existing roulette tables a player with nineteen stakes and the zero in his favour would be on even terms with the bank. There would not be more than an even chance of his final ruin.

The above facts should become known to intending players, so that they may not be misled into thinking that they will make their fortunes by following the advice given in M. Henry's book. That book adds nothing to our knowledge of the probabilities connected with roulette at Monte Carlo.

## THE THEORY OF LIGHT.

*The Theory of Light: A Treatise on Physical Optics.* By Richard C. Maclaurin. In three parts. Part i. Pp. viii+326. (Cambridge: University Press, 1908.) Price 9s. net.

THIS is the first instalment of a work on optics arranged on a somewhat novel plan. The volume treats mainly of the propagation of light in homogeneous media, isotropic or crystalline, and of the laws of reflection and refraction at plane boundaries. It is to be followed by a second dealing with the subjects of diffraction, dispersion, aberration, &c.; whilst a concluding volume is to be devoted to the history of optical theory. The method followed is deductive; a medium of the McCullagh type is postulated, and the laws of wave-motion are obtained by an application of the principle of Action. This is practically, of course, the electric theory of light in the form adopted by Larmor. The subsequent developments are naturally almost entirely mathematical, experimental methods being rarely referred to. For this reason the work cannot claim to be, indeed does not profess to be, a complete handbook of the subject; but this is hardly to be regretted, since the English student already has within his reach two masterly expositions from the physical standpoint in Lord Rayleigh's *Encyc. Brit.* article, and in Prof. Schuster's "Optics." A more serious matter is that some recent speculations of importance are ignored. For instance, we read on p. 29:—

"The answer forced upon us by the experimental evidence is that we must regard the [components of white] light as polarised elliptically . . . for an interval of time which is long compared with the period of vibration, but very short compared with the time required to make any impression on the retina or on a photographic plate."

This brings us back to the standpoint of Airy's "Tracts." It is to be hoped that the author will return to this question in his second volume, and that the bearing on it of Rayleigh's and Schuster's work on interference will receive due consideration.

The real value of the book consists in the systematic mathematical discussion of various classes of phenomena from a common point of view. In particular, many readers will be glad to have in an easily accessible form the author's own investigations of the effect of a thin transition layer in the phenomena of ordinary and crystalline reflection and refraction, and metallic reflection. Regard being had to the point of view, the style is clear and attractive, and the reader will appreciate the numerous excellent graphical representations of the somewhat complicated theoretical results.

In a lively introductory chapter the author discusses the methods and aims of science, the object being apparently to anticipate criticisms which might be directed against the special theoretical basis which he has adopted for his exposition. This discussion is pleasant reading enough, but it is to be hoped that future writers on mathematical physics will not always think it necessary to begin in this way. From the student's point of view the procedure has this disadvantage, that he may find the introduction much harder than the book, and perhaps even not intelligible until he has read the book. In the present instance the opening sentence tells us that "the first question in the catechism of every physicist" should be "what is the chief end of science?" The author's own reply to this question is interesting, and has the present writer's sympathy, but one cannot help wondering what degree of uniformity would be found among the answers which would have been given by, say, Archimedes, Galileo, Newton, Pascal, Laplace, Young, Maxwell, Kelvin. Fortunately history shows that the progress of science is not really conditional on the correct resolution of so formidable a question, any more than art has ever stood still for want of a definitive reply to the other secular question, what constitutes the Beautiful?

The remaining volumes will be looked forward to with interest, and the historical section in particular should prove of great value. H. L.

## GEOLOGICAL EPITOMES.

*Die Alpen.* By Dr. Fritz Machaček. Pp. iv+146. (Leipzig: Quelle and Mayer, 1908.) Price 1.25 marks.

*Eiszeit und Urgeschichte des Menschen.* By Prof. Hans Pohlig. Pp. viii+142. (Leipzig: Quelle and Mayer, 1907.) Price 1.25 marks.

THESE two books, bound in cloth and convenient for the pocket, are members of Dr. Paul Herre's series entitled "Wissenschaft und Bildung." They are printed in the older German type, presumably to give them a popular and untechnical aspect; and their cheapness prevents their half-tone illustrations from being more than suggestive. But the text is by no means of the "nature-study" order, or merely intended to lead a young reader on to better things; it is rather a summary of the results of a wide range of specialised research.

Dr. Machaček in his volume compares the views of various authors on the structure of the eastern and the western Alps, and discusses the origin of the present surface-relief. He accepts the theory of glacial erosion for the "Zungenbecken" of the North Italian lakes as a logical outcome of observations on the deepening of the main glaciated valleys further up among the Alps; and he attributes the rich variety of pictorial features (p. 56) in the central chain to the denuding activities of the Ice-age. Surely no one can nowadays deny the efficacy of "frost-nibbling" in producing crags and *cirques* and wild *arêtes*, when combined with the presence of glaciers, which carry off the débris from the scene of severest action. Nor can the modification in form of the original valleys excavated by streams be ascribed to anything but the eroding power of the glaciers themselves, well armed with materials gathered all along their course.

Dr. Machaček proceeds to describe the Alpine climate, the flora and fauna, and the influence of the topography upon human occupations. We cannot help thinking that a similar book for English readers would have been written with the view of attracting the ordinary tourist. Dr. Machaček, on the other hand, in pursuance of the plan of the series, aims at giving systematic information to those who may never see the Alps, but who regard them as features about which something should be known. There is a Teutonic touch in this; but to pursue this aspect of a cheap handbook, which is presumably meant to sell by thousands, would be to raise all manner of questions about the level of our own public education.

Prof. Pohlig has also a good deal to say about glaciation. His sketch of the geological history of the earth (pp. 2–4) leads up to the glacial epoch, and presumes with some audacity that the first continents appeared in Carboniferous times, and that the first marked differentiation of climatic zones took place in the later part of the Cainozoic era. An Ice-age affecting the whole globe seems a very chilly preparation for the coming of man, though Dr. Pohlig regards these occurrences as in some way connected. We are tempted to ask what organic change was heralded by the Permo-Carboniferous Ice-age, which does not seem to be referred to? The book is based on lectures by the author, and retains the vigour of style of one who is not afraid of controversy. There are even references, thinly veiled, to persons who have come off badly in the fray (pp. 74 and 96). The descriptions of the types of early man, and of the mammals associated with him, are of special interest. A larger number of specific names is employed for the latter than zoologists usually accept. From the description of the splendid Scandinavian boulders scattered over Holland and North Germany (which surely travelled more rapidly than the author suggests), down to the subdivisions of the giant deer, the book has an individuality about it which marks it out agreeably among compendiums of useful knowledge.

G. A. J. C.

## NEW ZEALAND PLANTS.

*Plants of New Zealand.* By R. M. Laing and E. W. Blackwell. Second and revised edition. Pp. xii+454; illustrated. (Christchurch, Wellington, and Dunedin, New Zealand; Melbourne and London: Whitcombe and Tombs, Ltd., 1907.) Price 15s. net.

WE are glad to welcome the second edition of this interesting book, which is essentially a popular account of the flowering plants of New Zealand, exclusive of the grasses. It appears that no less than 1400 species of flowering plants are now known to be indigenous within the limits of the dominion, and doubtless others remain to be discovered in the more remote mountain ranges and outlying islands. No less than three-quarters of the whole appear to be endemic, comprising many species of singular beauty and scientific interest. Thanks to the energy of local botanists, great strides have been made during recent years in our knowledge of this wonderful flora, and the earlier descriptive work of Hooker, based largely upon dry material, has been to a great extent supplemented by investigations of the living plants in their native environment.

The chief merit of the volume before us lies in the numerous beautiful photographic illustrations of the more conspicuous species, upon the selection and execution of which the authors are to be sincerely congratulated.

A general introduction gives a short account of the principal features of the vegetation of the open country, the fern land, the bush, the scrub, and the alpine regions. Throughout the work, indeed, a large amount of attention is devoted to œcological problems, very extensive use being made of the recent work of Dr. Cockayne in this direction. This feature, together with the frequent references to Maori legend and tradition, give to the work an unusual interest. The general introduction also includes a discussion on the affinities of the New Zealand flora, which is perhaps a little out of place in a work of this character, though interesting in itself. The relationship to Australia is emphasised by the statement that 80 per cent. of the genera are common to the two countries, and explained by the common origin of a large part of the two floras from the north by way of a northern extension of the land in Eocene times, which also accounts for the subtropical facies of the New Zealand flora as a whole. The absence of many of the most important Australian genera, such as Eucalyptus, Acacia, Casuarina, Hakea, is perhaps to be explained in accordance with Wallace's well-known theory of the separation of Australia into two islands in Cretaceous times, to the western of which the most characteristic Australian genera were confined.

Other important elements in the New Zealand flora are the South American and sub-Antarctic. The former, illustrated by the genera Fuchsia and Calceolaria, may perhaps be explained in accordance with the late Captain Hutton's theory of a Pacific continent connecting New Zealand and New Guinea with Chili in Cretaceous or early Eocene times, while the latter may be similarly accounted for by the existence of a number of islands in the Antarctic ocean in Pliocene times which have since disappeared.

A very short "Botanical Introduction" appears to us to require elaboration and illustration in order to make it really intelligible to the uninitiated, to whom it is apparently addressed. A considerable advance upon previous works on the New Zealand flora is made in the abandonment of the familiar system of Hooker and Bentham in favour of Engler's arrangement of families.

The book is well got up, but somewhat uncomfortably heavy, especially as a travelling companion, for which purpose it ought to be largely in demand. In future editions a little more care might advantageously be given to the page headings, several of which are at present very misleading.

A. D.

## OUR BOOK SHELF.

*Soils: their Nature and Management.* By Primrose McConnell. Pp. xii+104. (London: Cassell and Co., Ltd., 1908.) Price 1s. net.

In this little book the working farmer or gardener will find set out clearly and from his own point of view just that basis of the scientific knowledge of the soil that he ought to possess for the intelligent management of his land. The author, Mr. Primrose McConnell, is well known as a practical farmer, who has been trained in science and has shown a special interest in the application of scientific principles to the implements used for cultivating the land.

Mr. McConnell begins with an account of the origin of soils, their composition, classification, and distribution on the different formations of Great Britain, in which he gives some indication of where good and bad soils occur, and of their characteristic trees and weeds. The more valuable part of the book is, however, that which deals with soil physics and the effect of cultivation and management upon the all-important factor of the texture of the soil. The author is, as might be expected from a man accustomed to tillage operations, free from the temptation to regard the soil purely from the chemical point of view as a medium for the supply of the plant with certain salts; again and again he lays stress on the importance of tilth and the way it can be affected by the operations, both manurial and mechanical, of the farmer. In this direction it is very desirable that more experimental work should be done; the basis of the statements usually made as to the effect of various acts of husbandry upon the water content and temperature of the soil is astonishingly slight. For example, we should doubt a statement on p. 97 that rolled soil $1\frac{1}{2}$ inches below the surface may be 10° F. warmer than the same soil not rolled, as also the explanation which follows—but the experimental evidence we could bring against it is not so strong as the importance of the question would warrant.

Here and there throughout the book there are small mistakes and misreadings in dealing with scientific matters, but they are of small account, and do not touch the general course of the argument, so that we can cordially recommend the book to the class of readers for whom it was designed.

*The Life and Work of George William Stow, South African Geologist and Ethnologist.* By R. B. Young. Pp. vii+123. (London: Longmans, Green and Co., 1908.) Price 3s. 6d.

South African geology has yielded many results of world-wide interest, including the extinct fauna of the Karroo and the Palæozoic glaciation of South Africa. The debt due to George William Stow, the pioneer in the discovery of both subjects, will now be paid more easily owing to the admirable sketch of his career by Prof. R. B. Young. Geologists would, however, have been still more grateful for this biography if it had included a table of contents, an index, and a bibliography.

Stow was born at Nuneaton in 1822, and educated at a school on the Isle of Dogs. Though anxious to be an engineer, he was trained for medicine; but he did not qualify for practice, emigrated to South Africa in 1843, and lived there until his death in 1882. Considering the time and place in which his life was spent, it was apparently not rich in striking incidents or adventures. It was, however, during a trek to dodge the rebellious Kafirs in 1850 that he found in the Rhenosterbergen the first of the extinct reptiles of the Karroo. He fortunately reported his discovery to Prof. Rupert Jones, to whose help and encouragement Stow's services to geology are largely due. Stow's life was unsettled; he was thrice married, and in the search for a livelihood he was at different times teacher in the schools of the Colonial Church, book-keeper, trader at Queenstown, wine merchant at Kimberley, diamond merchant, geologist to the Orange Free State, and manager of the South African Free State Coal and Mineral Mining Association. His main scientific achievements were his discovery of the fossil reptiles of the Karroo, his recognition and proof of the glacial origin of the Dwyka conglomerate, his collection of Bushman drawings, his valuable memoir on the geology of Griqualand West, published by the Geological Society, and his two reports on the geology of parts of the Orange Free State, in which he described the geology of the area on the southern border of the Rand basin and part of the Vereeniging coalfield. Unfortunately, Stow's detailed account of the geology of Griqualand was never published, and the manuscript is now in the library of the Geological Society of South Africa.

Stow claimed the discovery of a second Cainozoic glaciation of South Africa, and in his glacial enthusiasm he described the diamond pipes of Kimberley as due to the action of ice. His view of a late Cainozoic glacial action in South Africa was at one time accepted in Europe, but is now discredited. His discovery, however, of the Upper Palæozoic glaciation has been confirmed, and will always give Stow's name an honoured place in the list of South African geologists.

J. W. G.

*Lessons in Hygienic Physiology.* By W. M. Coleman. Pp. ix+270. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1907.) Price 3s.

Of the many school physiologies, this is one of the best written, best arranged, and best proportioned. Since Huxley set the fashion more than a generation ago, the range of school physiology has remained pretty much the same; but there have been improvements in method. The method of this book is specifically adapted to the needs of teacher and pupil. All through, there are suggestions for making the teaching concrete, for "founding the study on facts and not mere words" (preface to the teacher). The illustrations are very varied, and set forth with many small original touches. The "review" and "thought questions" are obviously the careful work of an experienced teacher. Principles are never lost sight of, and the exposition never becomes mechanical or irrelevant, as so often happens when written examinations are the objective. But the book is admirably suited even for examinations. Taught as it may and should be taught, this little book should yield excellent results. Food and stimulants are specially discussed. The volume is one of a graded series.

*L'Aérobisation des Microbes Anaérobies.* By Georges Rosenthal. Pp. 107. (Paris: Félix Alcan, 1908.)

*Anleitung zur Kultur der Mikroorganismen.* By Dr. Ernst Küster. Pp. v+201. (Leipzig: B. G. Teubner, 1907.) Price 7 marks.

In his interesting essay, Mr. Rosenthal first describes the methods by which anaërobic microbes may be isolated and cultivated, then methods for measuring the degree of anaërobiosis, either by a pressure gauge fitted to an exhausted chamber or by the degree of growth occurring from above downwards in a tube containing a deep layer of culture medium, and, finally, the technique whereby different anaërobic organisms may ultimately be transformed into aërobic ones. This, according to the author, may be accomplished by simultaneously gradually admitting air and subculturing, so that a gradual acclimatisation to an aërobic condition is brought about; other methods are also described. The author then relates his experiences with such anaërobic organisms as the *Bacillus perfringens*, the bacillus of malignant œdema, and the bacillus of tetanus, and concludes with a critical examination of his results in order to detect fallacies.

Dr. Küster's little book will be very useful in the laboratory, as it gives a fairly complete summary, with bibliography, of the methods of isolation and cultivation of micro-organisms, including protozoa, myxomycetes, algæ, fungi, and bacteria, together with the formulæ and mode of preparation of the nutrient media. A book covering so wide a field will naturally be unequal, and the best sections are probably those dealing with the algæ, fungi, and special groups of bacteria.

R. T. HEWLETT.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### Distant Electric Vision.

REFERRING to Mr. Shelford Bidwell's illuminating communication on this subject published in NATURE of June 4, may I point out that though, as stated by Mr. Bidwell, it is wildly impracticable to effect even 160,000 synchronised operations per second by ordinary mechanical means, this part of the problem of obtaining distant electric vision can probably be solved by the employment of two beams of kathode rays (one at the transmitting and one at the receiving station) synchronously deflected by the varying fields of two electromagnets placed at right angles to one another and energised by two alternating electric currents of widely different frequencies, so that the moving extremities of the two beams are caused to sweep synchronously over the whole of the required surfaces within the one-tenth of a second necessary to take advantage of visual persistence.

Indeed, so far as the receiving apparatus is concerned, the moving kathode beam has only to be arranged to impinge on a sufficiently sensitive fluorescent screen, and given suitable variations in its intensity, to obtain the desired result.

The real difficulties lie in devising an efficient transmitter which, under the influence of light and shade, shall sufficiently vary the transmitted electric current so as to produce the necessary alterations in the intensity of the kathode beam of the receiver, and further in making this transmitter sufficiently rapid in its action to respond to the 160,000 variations per second that are necessary as a minimum.

Possibly no photoelectric phenomenon at present known will provide what is required in this respect, but should something suitable be discovered, distant electric vision will, I think, come within the region of possibility.

A. A. CAMPBELL SWINTON.

66 Victoria Street, London, S.W., June 12.

### Prominences and Coronal Structure.

PRESSURE of work in other directions prevented me from writing these lines before to-day. They have reference to an article contained in NATURE for April 2, in which Dr. Lockyer describes what he considers a triple concentric arc formation in the upper chromosphere similar to coronal structures observed during the eclipses of 1898, 1901, and 1905. Through the kindness of Prof. Hale, the British Astronomical Association is in possession of a photographic slide showing a composite calcium spectroheliogram taken of the sun's disc and chromosphere on July 17, 1907, *i.e.* the same date as the South Kensington one. Prof. Hale took the picture at 6.46 a.m. P.S.T., while Dr. Lockyer took his at South Kensington at 3.14 p.m. G.M.T. There is thus a difference of something like half an hour between the two exposures, that at Mount Wilson being the earlier one. Comparing the two spectroheliograms, it becomes evident that what Dr. Lockyer considers concentric coronal arcs, due to eruptive action either immediately in front or in the rear of the formation, constitute in reality the débris of an eruptive prominence. I happened to be observing the sun at the time, starting about 1.30 p.m. L.T., having also had the sun under observation early in the morning, and an extract of my notes reads thus:—

"July 17, 1907, 7 a.m.—In S.L.E. there is something hatching, the limb looking very uneven and the chromospheric lines contorted, with strong $D_3$ absorption effects being on view there from time to time.

"Ditto, 1.30 to 2.20 p.m.—Fine eruptive prominence in L.S.E., where something was preparing this morning. Great displacement of H$\alpha$ to red side, and the prominence seems to rush *en bloc* away from the observer and in an almost horizontal direction towards the south, rising radially but little, and dissolving from a stout, dense, and bright stem into a number of bright, more or less parallel layers or striæ."

Great activity continued in the S.E. quadrant for the next three days. The Mount Wilson picture shows what I observed in the spectroscope, viz. a strong dense stem breaking forth in lower L.S.E., curving immediately over to the south (as can be gathered from the great displacement observed, the real direction must have been *south-east*), the stem dissolving into a complicated structure of branches a good distance away to the south of the point of origin.

I had to leave the instrument at 2.20 p.m., when a few minutes later Prof. Hale in far-away California exposed his plate, to be followed soon after by Dr. Lockyer in South Kensington. It is quite feasible to think that when the exposure was made at South Kensington, the fragments, already in parallel arrangement when I left the instrument, partook also of some kind of concentric curvature, which is, indeed, indicated on Prof. Hale's spectroheliogram. As Dr. Lockyer mentions the absence of an *underlying* prominence to the concentric arcs he discerns in his picture, I deemed it in order to mention the above facts. I have not the slightest intention by so doing to doubt the great likelihood that concentric coronal arcs, such as those observed, for instance, by Mr. Wesley, are due to eruptive action from underneath, but in the case at present under consideration this seems not to have been the case in this more limited sense. I feel sure that Dr. Lockyer will come to the same conclusion when he compares the two spectroheliograms in the light of my observational notes given above.

ALBERT ALFRED BUSS.

2 Lansdowne Terrace, Grosvenor Square, Ashton-on-Mersey, near Manchester, May 28.

### The Action of Radium Salts on Glass.

THE letter of Mr. Phillip in NATURE of April 9 led me to examine some tubes containing radium salt which have been in my possession for some years. Some had become very purple owing to the action of the radium, whilst others were not coloured at all. The amount of coloration did not seem to depend upon the activity of the preparation; in fact, the deepest coloration—with one exception—was that due to a salt supposed to contain only one-thousandth of its weight of radium salt.

Certain kinds of glass when exposed to the bright sunshine of South Africa take a coloration similar to that produced by radium salt; I therefore thought that it might be interesting to observe the effect of sunlight upon a specimen of glass coloured by radium. With this object I exposed one of the coloured tubes to the action of the sunlight, and after twelve days' exposure the colour has been almost removed.

I have one tube which contained radium salt of about one million units activity; where the salt had rested against the tube almost black spots have developed. I shall expose this tube to the continued action of sunlight.

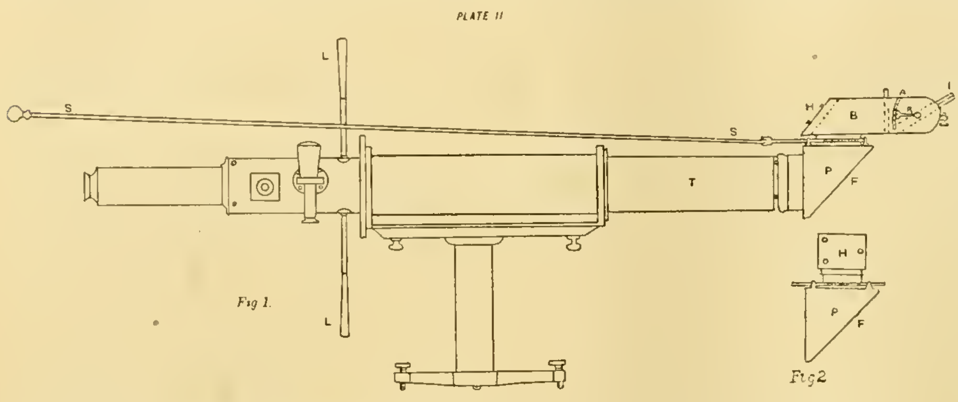
W. A. DOUGLAS RUDGE.

University College, Bloemfontein, O.R.C., May 14.

## *A FIELD METHOD OF DETERMINING LONGITUDES BY OBSERVATIONS OF THE MOON.*

A SHORT note appeared in these columns on April 23 (p. 590) with reference to a valuable paper by Mr. E. B. H. Wade, published by the Survey Department of Egypt. The paper, however, is one showing so much originality, and the instrument and method appears to be of such value, that a more extended notice is called for, the more so as the paper in question is by no means generally accessible.

Mr. Wade considers the case of field survey operations where at least one point, and preferably more, should be determined independently by a direct astronomical method. Latitudes are easy enough, and longitudes would be if telegraphic connection with an observatory were available. Until wireless time-signals are distributed over the world which might be picked up with portable receiving apparatus, the observer has to rely upon his chronometers, which become cumulatively misleading, or upon lunar observations. These latter, Mr. Wade points out, may be divided into two classes—those which depend directly upon the rotation of the earth, of which moon culmination observations serve as an example, and those which do not, for instance, lunar distances and occultations, and these have the advantage of being about thirty times less sensitive to errors of time.



The telescope T with its reflector F is mounted as an altazimuth, the motion in altitude being given by the handles L. B, the box-sextant, containing the horizon mirror H and index mirror I, is actuated by worm gear by means of the long handles, and so is made to turn about the reflected optic axis of the telescope, *i.e.* about a line at right angles to the axis of the actual telescope.

Mr. Wade has set himself to devise a method of making lunar distance observations with an accuracy outside the possible range of the sextant with apparatus that is easily portable. He refers to Talcott's method of determining latitude by observations of the equidistance of the zenith from two stars as compared with the actual measurement of its distance from a particular star. "In quite the same way" he suppresses "the graduated circle of the ordinary sextant and finds the moon's apparent position from the condition that it is equidistant from two or more stars, one of which, of course, must precede and the other follow the moon." By suppressing the graduated circle he removes the principal obstacle to the evolution of the sextant.

In order to arrive at this result, he starts with a good telescope of $2\frac{1}{2}$ inches aperture and magnifying 40 diameters, carrying a reflector set at 45° in front of the object-glass. The telescope is always horizontal, and can turn upon its longitudinal axis as well as upon its stand in azimuth. It therefore commands all points of the sky, and the observer can sit in comfort, a point essential for accuracy. The view of half the object-glass is intercepted by a second mirror set at 45°, which receives light from a third, which may be parallel with it or may be inclined at an angle of 10° or so, roughly indicated by a pointer. The real point is that at whatever angle it is set, it may be clamped infallibly until the observations are complete. The box containing these two last-mentioned mirrors is capable of slow rotation by means of a worm from the eye end of the telescope, so that if, for instance, these two mirrors were set at an angle of 5° and the worm were turned, the observer would see successively all points in a circle of 10° radius round the point to which the unintercepted part of the instrument was directed. Supposing now the moon to be observed directly, and a following star, which is just too far away to be brought into contact with the limb, to be seen by double reflection, then a slight sweeping motion may be given so as to ascertain the exact time of tangential contact. Similarly a preceding star which is just too near for a tangential contact may be observed until the moment at which this is seen also. Actually it is the star, not the moon, which is looked at directly, as by that means the moon's light after two reflections from unsilvered glass is sufficiently subdued to allow sixth-magnitude stars to be observed in contact. The designer has ingeniously introduced the equivalent of the spider lines of a transit instrument by providing a slightly prismatic plate which may be set in any one of three positions in one of the optical paths, thus making small but invariable differences in the apparent angle, so that three observations are possible for each star.

It will be seen, then, that the accuracy obtainable is only limited by the optical definition of the telescope.

Space is not available for following the author of the paper through his discussion of the observations or for referring to his excellent graphic methods for shortening the calculations where they are available. It is sufficient to say that with his apparatus he has found that the probable error of a single observation is of the order of 1·5 seconds of longitude.

C. V. BOYS.

## *THE CAVENDISH LABORATORY.*

ON October 10, 1870, the seventh Duke of Devonshire wrote to the then Vice-Chancellor of the University of Cambridge, offering to provide funds for a building and for apparatus for the teaching of experimental physics. The building was opened on June 16, 1874, when the Chancellor received the thanks of the University, and at the same time expressed his "wish to provide all instruments for the Cavendish Laboratory which Prof. Maxwell may consider to be immediately required either in his lectures or otherwise."

Twenty years later the laboratory was increased towards the south by a new building, running along Free School Lane, which contained, amongst other rooms, a spacious elementary laboratory. For this the University supplied the funds. The "Cavendish" is now, for the second time, being added to by a building which stretches along Free School Lane to the north, the new building being about 80 feet in length, and varying in width from 40 to 50 feet. The front to Free School Lane is of Weldon stone, with Ancaster dressings to the windows and where mouldings occur.

The new wing consists of three floors. The ground floor is occupied by a large class-room, two students' rooms, and two dark rooms. The lecture room, 40 feet by 30 feet, on the first floor, adjoins the preparation room containing a dark room, and there are also two other rooms, one for a library, the other for a common room for the demonstrators. On the second floor are nine students' rooms, a room for chemistry, and another dark room. Two floors of the new extension are thus devoted to research. There is ready access from all these rooms to the main laboratory.

The cost of the building will be between 7000*l*. and 8000*l*., and the University has only been enabled to undertake this work by the munificence of the Chancellor, Lord Rayleigh, who presented the whole of the Nobel Prize to Cambridge. Of this prize 5000*l*. is given towards the expense of the new laboratory, and Prof. Thomson has undertaken to provide 2000*l*., which has accumulated from laboratory fees. On Tuesday, June 16, thirty-eight years ago to the day, the first building of the Cavendish Laboratory was opened by the then Chancellor, and two days ago this latest addition to one of the most renowned institutions in the world was opened by a short ceremony by the new Chancellor, Lord Rayleigh, whose arms appear over the portal. It is appropriate that the first official act of the new Chancellor should be to declare open a building which his generosity alone has enabled the University to erect.

Owing to the room in which the Chancellor spoke being of limited dimensions, the number of those present at the actual ceremony was not large, but after the ceremony Prof. and Mrs. Thomson entertained a large company of guests at a reception. There was an interesting exhibition of scientific experiments and apparatus by students working in the laboratory.

New Wing of the Cavendish Laboratory, Cambridge. Elevation to Free School Lane.

## *LANDSLIP AT LYME REGIS.*

AN extensive landslip occurred at Lyme Regis on June 10, and was the occasion of many more or less inaccurate paragraphs in the daily papers. The account which was published in the *Western Morning News* of June 12 was, however, fairly full and accurate, being based upon information given by Mr. A. C. G. Cameron, late of the Geological Survey, and now resident at Uplyme. From this and from some additional particulars supplied by the same observer, we are able to state what really occurred on and previous to the date mentioned.

It is needless to say that no volcano or any kind of volcanic action is concerned in the phenomena. Spontaneous combustion took place at one spot on the cliff east of the town, owing, doubtless, to the decomposition of iron pyrites and the rapid oxidation of the iron. As some of the shales contain lignite, and others may be more or less bituminous, the conditions are favourable to the continuance of combustion, and the mound of smoking shale has been an object of great local interest from January to the present time. There is, however, no connection between it and the recent landslip.

The slip took place about 2 p.m. on June 10 below the road which leads from Lyme to Charmouth. The ground here consists of Greensand in the upper part, and of Lias shales in the lower part, the latter forming a succession of cliffs and terraces from a height of about 300 feet down to the beach. There are three tiers of cliffs, and it is the middle one for a distance of about 500 yards (rather more than a quarter of a mile) which is the scene of the slip. A great slice of this cliff suddenly gave way, and slid into the sea with a loud rumbling noise, and the production of semi-circular waves in the water. The slice intersected the mound of burning clay, and Mr. Cameron states that the interior of the mound thus disclosed resembled an old brick-kiln, from the baked appearance of the clays and shales. Falls from the cliffs continued all the afternoon, and the whole range of cliff is still in an unstable condition.

With regard to the cause of the landslip, it is somewhat remarkable that the fall should have occurred during a spell of dry weather, and not after heavy rain. This fact points to some other cause than rain or springs, and such a cause exists in the practice of digging out and taking away the cement-stones and layers of limestone which occur in the lower part of the cliffs. The abstraction of these must have weakened the cliff above, and have caused the cracks which have long been apparent in it; water issuing from the base of the Greensand would find its way into the cracks, and would still further loosen the cohesion of the masses. Finally, the dry weather caused contraction and widening of the cracks, with the result above described.

## *BRITISH COTTON CULTIVATION.*[1]

ABSTRACTS of a series of reports by Prof. W. Dunstan, F.R.S., Director of the Imperial Institute, on the quality of cotton grown in British possessions have been issued as a Parliamentary paper, which gives details with regard to the progress made in cotton cultivation in various parts of the Empire, other than India and Egypt, during the past two years. As instructive as the actual abstracts are brief statements prefixed to each, wherein the present position of cotton cultivation in the colony or protectorate referred to is reviewed.

It appears that the export of cotton from Cyprus, the only European possession dealt with, was much the same for 1905–6 and 1906–7, but that the figures for these years were more than double the figures for 1904–5.

As regards our East African possessions, the exports of cotton and cotton-seed from the Sudan during 1906 reached a total value of more than 45,000*l.*, as against some 23,000*l.* for 1905. From the East African Protectorate the exports during 1906–7 were valued at 1400*l.*, as against 1273*l.* for 1905–6 and 285*l.* for 1904–5. The increased export from Uganda was more marked, the figures for 1906–7 being more than 390,000 lb., valued at 11,400*l.*, as against 96,000 lb., valued at 1089*l.*, for 1905–6, and 21,566 lb., valued at 236*l.*, for 1905. From Nyasaland the exports for 1906–7 were 526,119 lb., valued at 15,345*l.*, a slight decrease on the figures for 1905–6, which were 776,621 lb., valued at 16,180*l.*, but a marked increase on those for 1904–5, when 285,185 lb., worth 5941*l.*, were exported.

As regards West Africa, we learn that exports of cotton from Gambia have ceased; the inhabitants will not take up cotton cultivation, the ground-nut industry being more profitable. The exports from Sierra Leone in 1906 were 87,800 lb., valued at 1829*l.*, as against 68,800 lb., worth 509*l.*, in 1905. A similar increase is recorded from the Gold Coast, whence the exports in 1906 were 92,886 lb., worth 1022*l.*, as against 29,200 lb., valued at 516*l.*, in 1905; also from Lagos, whence in 1906 the quantity exported was about 2,440,000 lb., worth 40,000*l.*, as against 1,281,000 lb., valued at 25,000*l.*, in 1905. On the other hand, the exports from southern Nigeria in 1905 only reached 85,000 lb., as against 285,000 lb. in the preceding year. In Lagos it is stated there are large areas suitable for cotton-growing, but the transport difficulties are great.

The reports dealing with the South African colonies show that Rhodesia and the Transvaal are capable of yielding cottons of excellent quality, and that experimental cultivation in the Orange River Colony, in Cape Colony, and in Natal has given results sufficiently encouraging to warrant further trial. Difficulties with regard to labour and to transport will, however, have to be overcome before an industry can be established. The reports regarding Seychelles and Mauritius indicate that much the same conditions obtain there as prevail in South Africa.

The reports from Asia refer to the Straits Settlements, where the climate is said to be not altogether favourable to the industry, and British North Borneo, where the conditions are expected to be favourable, and there is an ample supply of labour though the exports are small.

As to the Australian colonies and New Guinea, we learn that there are extensive districts in which the soil and climate are suitable for cotton cultivation, but that considerable difficulty is experienced with regard to the supply of labour.

The reports from our American possessions show that in British Guiana the industry is insignificant, and, small as it is, shows a steady falling off. In British Honduras, though the conditions are otherwise favourable, there is a lack of efficient labour; and in Bermuda, owing to the high price of land and labour, it is unlikely that a profitable industry can be established. But the exports from the West Indies show that cotton-growing is there being rapidly extended under the guidance of the Imperial Department of Agriculture, directed by Sir Daniel Morris. The estimated value of the exports of cotton and cotton-seed for 1905 was more than 63,000*l.*; for 1906, more than 90,000*l.*; for the half-year ending June 30, 1907, more than 167,000*l.*

One of the general conclusions on which Prof. Dunstan insists is that in most cases, and especially in West Africa, the best chances of success lie in the improvement of native cottons rather than in the introduction of foreign cottons; another is that every encouragement and facility should be given to the improvement of native cultivation. It is pointed out that the extent to which cotton-growing will be resorted to by native cultivators must depend largely on the price which can be offered by cotton-buyers, and on the competition of other occupations and other agricultural crops.

[1] Colonial Reports—Miscellaneous. No. 50, British Cotton Cultivation. Reports on the Quality of Cottons grown in British Possessions. By Prof. Wyndham Dunstan, F.R.S., Director of the Imperial Institute. (Cd. 3997.) Price 2½*d.*

## *NOTES.*

THE council of the London Mathematical Society has awarded the De Morgan medal for 1908 to Dr. J. W. L. Glaisher, F.R.S., for his researches in pure mathematics.

THE Belgium Academy of Science, Literature, and the Fine Arts has elected Sir James Dewar an associate in the section of mathematical and physical science.

THE inaugural meeting of the Research Defence Society will be held at the house of the Royal Society of Medicine, 20 Hanover Square, W., to-morrow, June 19, at 5 o'clock. The Earl of Cromer, president of the society, will occupy the chair.

THE executive committee and science committee of the Franco-British Exhibition are issuing invitations for a reception to be held in the Science Court of the exhibition on Tuesday, June 30.

AN exhibition will be held at Faenza from August 15 to October 15 to commemorate the third centenary of the birth of the Florentine physicist, Evangelista Torricelli. The exhibition will include international sections for meteorology and terrestrial physics, ceramics, and agricultural machinery. Prizes will be offered for competition in the two first-named sections. Inquiries should be addressed to Conte Cav. Carlo Cavina, president of the executive committee, at Faenza.

A monument to the memory of Boucher de Perthes was unveiled at Abbeville on June 8. Boucher de Perthes, who made important discoveries in prehistoric anthropology in the neighbourhood of Abbeville, died there in 1868. In 1832 he found at Thuison, near Abbeville, the first stone engravings, and in 1863, in the Moulin Quignon cave, the remains of Quaternary man with flint axes. The collections made by Boucher de Perthes were bequeathed to the State, and are preserved in the Museum of Saint-Germain-en-Laye.

The American Association for the Advancement of Science will devote a day during its meeting at Baltimore to the celebration of the centenary of the birth of Charles Darwin and the jubilee of the publication of the "Origin of Species." The programme includes, according to *Science*, arrangements for an introductory address by Prof. T. C. Chamberlin, of the University of Chicago, president of the association, and a number of discourses by American biologists and others. Among the latter we notice that Prof. E. B. Poulton, F.R.S., will speak on natural selection from the point of view of zoology.

A Reuter message from Auckland states that a remarkable volcanic outburst began in the island of Savaii, in the Samoan group, on May 10. The flow of lava was the greatest in the history of the island. It amounted to between 2000 and 3000 tons a minute, and streamed down in a great river from 6 inches to 6 feet deep, stretching in an almost continuous sheet over a width of eight miles. On reaching the coast it flowed over the cliffs into the sea, causing steam to rise in great quantities. The lava destroyed many native houses, and for a time threatened the town of Matatua.

At the General Conference on Weights and Measures, held at Paris in October last, a resolution was unanimously passed urging the universal adoption of a metric carat of 200 milligrams as the standard of weight for diamonds and precious stones. This proposal, which received a large measure of support on the Continent, especially in France, Germany, Spain, and Belgium, was brought under the notice of the principal diamond dealers in this country by the Board of Trade early in the present year, but it has not met with a favourable reception from the trade, and unless the proposed new standard is generally adopted abroad it is unlikely that any further action in the matter will be taken by the Government. The French Ministry is now introducing a Bill to legalise the "metric carat" of 200 milligrams in that country, and to prohibit the use of the word carat to designate any other weight. A recent resolution of the Bombay Chamber of Commerce shows that the proposal for an international standard carat is receiving favourable consideration in India.

The ninety-first annual meeting of the Société Helvétique des Sciences naturelles will be held from August 30 next to September 2 at Glaris. A provisional programme states that at general meetings on August 31 and September 2 the following addresses will be delivered:—Prof. K. Schröter, of Zurich, on an excursion to the Canary Islands; Prof. H. Schardt, of Montreux, on the great erratic boulders of Monthey and neighbourhood; Prof. A. Riggenbach-Burckhardt, of Bale, on gravity measurements of the Swiss Geodetic Commission; Prof. Ch. E. Guye, of Geneva, on the electric arc as a powerful aid to science and industry; Dr. H. Greinacher, of Zurich, on radio-active substances; and Prof. R. Chodat, of Geneva, on Palæozoic ferns, their significance in modern plant palæontology. September 1 will be devoted to sectional meetings and to the annual meetings of the Swiss Geological, Botanical, Zoological, and Chemical Societies. A more detailed programme of the meetings will be available in July.

The Sunday Society, which exists to obtain the opening of museums, art galleries, libraries, and gardens on Sundays, has been making attempts, though as yet unsuccessfully, to secure the opening on Sundays of the science and art collections at the Franco-British Exhibition. The experience gained during the last twelve years would appear to show that the Sunday opening of national museums and galleries has been greatly appreciated, and that there has been no abuse of the privilege. The last published returns show that in 1906 the number of Sunday visitors to the British Museum was 57,738, an average Sunday attendance of 1110; at the Natural History Museum for the same year the corresponding numbers were 61,151 and 1176. In 1905 the number of visitors to the Victoria and Albert Museum on Sundays was 93,005, an average Sunday attendance of 1755; the corresponding numbers in the same year for the Bethnal Green Museum were 74,990 and 1415.

On Saturday last Mr. E. W. C. Kearney gave a demonstration of his high-speed railway system in the temporary building on the east side of Aldwych. Mr. Kearney runs his car upon a single rail, supporting it upon a two-wheel bogey at each end. Above the car there is a second rail engaging a second two-wheel bogey at each end. The upper and lower bogeys are carried upon the same shaft, and so turn together. The intention is to run out of the ground-level stations down an incline of 1 in 7 until a speed possibly of 200 miles per hour is attained, then along the level, and so up to the next station. If this could be done safely and successfully, then, without question, much time would be saved; but nothing which was said or demonstrated on Saturday with the help of a scale model about one-fifteenth the full size in any way made it evident that this would be the case, or that the great economy in first and in running cost claimed would be attained in practice. While the steep declivity would be convenient in the case of tube railways, it hardly meets the requirements of elevated or of long-distance railways, for which the motors would have to provide the whole acceleration. Might it not be well to revive the old brachistochrone problem which the brothers Bernoulli invented before its time and travel on cycloidal routes from place to place? Even Mr. Kearney would find it difficult to compete with this.

After four months' canvassing among metal manufacturers and users, and two preliminary meetings held in Manchester, a new technical society called "The Institute of Metals" was formed at a meeting held at the Institution of Mechanical Engineers, Westminster, on Wednesday, June 10. Sir William White, K.C.B., F.R.S., who occupied the chair, has been for some years the chairman of the Alloys Research Committee, instituted by that body, which has concerned itself to some extent with the non-ferrous metals and their alloys. The following resolution was, after some discussion, adopted unanimously:—"That in view of the widely recognised need for a medium of communication for the advance of knowledge in connection with the production, manufacture, and use of the non-ferrous metals and their alloys, a society to be called 'The

Institute of Metals' shall be and is hereby constituted." Sir William White was unanimously elected the first president, and an interim council, composed of prominent metal manufacturers, ship-builders, marine and locomotive engineers, electric cable constructors, &c., and including representatives of pure science, was appointed to take the necessary steps to bring the institute into working order. The joint hon. secretaries are Prof. H. C. H. Carpenter, the University, Manchester, and Mr. W. H. Johnson, c/o Johnson, Clapham and Morris, Ltd., Manchester. Promises of support have been received from more than 200 persons.

The late Dr. Oswald Seeliger, professor of zoology in the University of Rostock, whose death in his fifty-first year has just been announced, was well known for his many valuable contributions to knowledge, and particularly for his writings on the morphology of the Tunicata. The articles on this group in Bronn's "Klassen und Ordnungen" and in Brehm's "Thierleben" were from his pen. The researches with which his name is most familiarly associated are upon questions connected with the process of budding in Tunicata, Cœlenterata, and other animals. His statement that the nervous system of the ascidiozooids of Pyrosoma is derived from the mesoblast of the parent Cyathozooid, undermining, as it seemed to do, the theory of the germ layers, gave rise to a long and interesting controversy. More recently he repeated Boveri's famous experiment of fertilising the enucleated egg of one species of Echinoderm with the spermatozoon of another, and, like Delage and others, came to the conclusion that the hybrid thus produced does exhibit some of the maternal characters, and that, in consequence, the theory that the hereditable characters are alone borne by the nuclei of the germ cells is untenable. Seeliger's writings were clear and forcible, and as he was free from the ordinary prejudice of orthodox opinion in biological matters, his loss to science is severe.

The second part of the Memoirs of the National Museum, Melbourne, is devoted to a monograph of the Silurian bivalve molluscs of Victoria, in the course of which the author, Mr. F. Chapman, palæontologist to the museum, describes and figures a number of new species.

With the June number *British Birds* commences its second volume, to which we wish every success. To that number Mr. W. H. Mullens commences a series of articles on the older British ornithologists, the first name on the list being that of William Turner, who was born just about 400 years ago, and was therefore a contemporary of the founder of Caius College, Cambridge. Previous to Turner's time, exact knowledge of British birds was practically *nil*, while ornithology was but little more cultivated on the Continent. Turner was the author of no fewer than thirty-nine works, among which the most famous is that dealing with the birds mentioned by Aristotle and Pliny. To this wonderful work may be attributed the rise of British ornithology.

We have received a separate copy of a paper by Messrs. Huene and Lull, from the February number of the *American Journal of Science* (vol. xxv., p. 113), on the Triassic reptile *Hallopus victor*, which was regarded by its original describer, the late Prof. O. C. Marsh, as a theropod dinosaur. In some respects the pelvis is, however, more like that of an orthopod dinosaur, although in the form of the pubis, the calcaneum, the extreme thickness of the astragalus, the contour of the scapula, and the height of the ilium, the skeleton differs from all known members of that group. In the opinion of the authors (the grounds of which are promised in a later memoir), the genus appears to be most nearly related to Aëtosaurus and its allies.

To the April number of *Spolia Zeylanica* Commander Boyle Somerville communicates a thoughtful paper on the submerged plateau surrounding Ceylon at an average distance of about a dozen miles from the coast, with depths shoaling from south to north from 40 to 20 fathoms. Everywhere there is a sudden drop to oceanic depths on the outer margin, but a slightly deeper channel or gully occurs in the centre, tapering off to the northward and ending in a marked shoaling, and the existence of banks, which begin at Mount Lavinia and extend northward. After referring to the occurrence of lakes or lagoons near the coast nearly all round the island, the author concludes that while the high-ground of Ceylon has existed as land for an extremely long period, the low-country has in the main been formed by the denudation of the central elevated area, and was laid down on a plateau of which the present fringe is a remnant. This accounts for the absence of coral reefs round most of the coast.

Stone implements from the Bulawayo district form the subject of an illustrated paper by the Rev. F. Gardner in vol. vii., part i., of the Proceedings of the Rhodesia Scientific Association. The account is based on the large collection in the Rhodesia Museum. Many of the implements are of well-defined shape and show workmanship of a high order, although not rising to the standard frequently noticeable in their corresponding (Neolithic) European prototypes. In the author's opinion, they represent a mixture, and are the product of many ages, some, perhaps, having been manufactured in quite recent times.

The latest issue (vol. iii., No. 1) of the *Journal of Economic Biology* is devoted to an investigation, by Miss J. S. Bayliss, of the basidiomycetous fungus *Polystictus versicolor*, that grows as a saprophyte on dead wood, causing it to rot and crumble. The bracket-like fruiting body is characterised by a velvety zoned upper surface. In laboratory cultures spore sowings produced oidia and conidia, and on infected blocks of wood incipient fruiting bodies were produced, but full development was only obtained when the blocks were exposed under natural conditions. Similarly, it was observed that the sporophores will not develop in the dark or when revolving on a clinostat. The zoning is shown to be due to changes in the rate of growth dependent upon the temperature of the air and the amount of moisture present.

The botanic station in St. Vincent occupies a portion of the site of the old botanic garden, established in 1765, that reached a high state of prosperity during the tenure of Dr. Anderson as superintendent. The station was re-established by Mr. H. Powell in 1890, who with the present curator, Mr. W. N. Sands, has contributed to its present standard of efficiency. A historical account, accompanied with reproductions of photographs taken in the gardens, appears in the annual report for 1906–7. Conditions in recent years have led to a remarkable increase in cotton cultivation, and a great reduction in the area devoted to sugar-cane. Arrowroot still supplies the most valuable asset of the colony, but the value of the cotton exported will shortly exceed that of the former product.

Two Bulletins received from the University of Illinois afford evidence of the value of the investigations carried on by the Engineering Experiment Station. Prof. A. N. Talbot (Bulletin No. 20) gives the results of tests of concrete and reinforced concrete columns, throwing light on the properties of plain and hooped concrete. The additional strength of the hooped column over that for an unreinforced column of the same quality averages for each 1 per cent. of hooping 955 lb. per square inch for spiral hooped columns and 669 lb. per square inch for band-hooped columns having a diameter of 12 inches. Tests of a liquid-air plant are recorded by Mr. C. S. Hudson and Mr. C. M. Garland (Bulletin No. 21). The tests were made for the purpose of determining the most economical conditions for operating the liquid-air plant belonging to the University.

We have received from the Rev. O. Fisher a letter commenting on the distinction drawn by Mr. R. D. Oldham between "earthquakes" and "earthshakes" in a communication published in the issue of Nature for May 28. Mr. Oldham on that occasion wrote:—"We may say that earthquakes, or at any rate severe earthquakes, are frequently, if not invariably, caused by rupture of the earth's crust and the formation of fractures or faults in the solid rock, but these fractures, which are the primary cause of the earthquake, are only the secondary result of the earthshake, the action of which arises at a greater depth, and the ultimate cause of which lies beyond our present ken" (vol. lxxviii., p. 78). Mr. Fisher read this to imply that Mr. Oldham applied the term "earthshake" to the deep-seated cause of the "snap and jar" caused by a rupture of the rocks, which gives rise to the vibratory movement constituting an earthquake, and suggests, as more probable, that the deep-seated cause is of the nature of an accumulating stress, which goes on increasing until the crust gives way suddenly, producing the "snap and jar" which produces world-shaking results. "What we want," says Mr. Fisher, "is a term to express the molar displacement of the ground as distinguished from the vibratory." Mr. Oldham informs us that in reality he is in agreement with Mr. Fisher. "The word earthshake," he writes, "was not intended to apply to the slowly accumulating stresses, but to the molar displacements accompanying the abrupt relief of the strain induced by these stresses." Mr. Oldham says "it might have been better to have suggested a wholly new word, such as bathyseism, carrying with it no connotation of meaning, but so many 'seisms' have already been suggested, and so loosely used, that I was chary of inventing yet another."

We have received from Prof. H. Mohn two valuable publications relating to the meteorological service of Norway for the year 1907:—(1) the year-book, containing complete observations or results at sixty stations, and (2) rainfall observations, containing daily measurements at 200 stations, with monthly or yearly amounts at a much larger number of places, for some of which the results are quoted so far back as 1867. These publications have been issued in the same excellent form for many years, and the data are of exceptional importance, due to the exposed position and topographical features of the country.

The report of the observatory department of the National Physical Laboratory for the year 1907 shows that the only very large magnetic disturbance was that of February 9–10, already referred to in Nature (February 14, 1907, vol. lxxv., p. 367); the mean declination for the year was 16° 23′ W. The largest seismological disturbances recorded took place on April 15 (the Mexican earthquake), maximum amplitude, 15 mm., September 2, and December 30. The lowest temperature, 23°·3, occurred on January 27, and the highest, 77°·7, on September 25; the total rainfall was 23·85 inches. The verification of instruments (exclusive of watches and chronometers), one of the most active branches of the useful work of the observatory, again shows a large increase, the total number of instruments tested being 34,700, or 5133 more than in the previous year, and was chiefly due to increased numbers of clinical and ordinary thermometers. A large part of the time devoted to experimental work has been occupied by observations on atmospheric electricity and on solar radiation.

In *Engineering* of June 5 there is an illustrated article on electric iron and steel furnaces, in which the leading types are described. At the present time, electric iron smelting is still in its infancy, while electric melting and refining furnaces have been added to many notable works. There is a good deal of electric melting, but, so far, little smelting. The reasons are not far to seek. All furnaces are wasteful; the electric furnaces do not form an exception, and electricity is not inexpensive, whether generated by water-power or by coal. The advantages of water-power have been much over-rated. When water-power begins to develop, it becomes subject to rates and taxes. Hydro-electric installations are by no means simple. The water may fail in summer owing to drought and in winter owing to frost, and reserve steam-power has to be provided; if a good load-factor is to be maintained, the reserve must be of ample capacity. Manufacturers are, moreover, becoming sceptical as to the advantages to be gained by installing works close to the mines and to the waterfalls, so as to secure cheap power and to avoid the transport of ores. The power item is not, as a rule, the decisive factor, and the crude ore transport may, after all, prove economical.

The practical value of the fascinating study of diatoms as a test of the powers of the microscope is illustrated by a note on *Biddulphia mobiliensis* contributed to the April Journal of the Royal Microscopical Society by Mr. Edward M. Nelson. The secondary structure of this diatom is so delicate that Mr. Nelson was unable to draw or even retain the image for any length of time, and in pointing out that the secondaries have only been seen with long-tube microscopes, the author states as his conclusion that "the ultimate appeal concerning any very minute structure must go to a long-tube microscope."

Prof. H. Fehr, editor of *L'Enseignement mathématique*, has reprinted from that journal the results of his inquiry on the work of mathematicians. It will be remembered that some time ago a circular was addressed to mathematicians containing thirty questions regarding their habits of life, the way in which they acquired an interest in mathematics, the advice they would give to a young mathematician, and other matters of a personal character. The classification of the answers has been undertaken by Profs. Th. Flournoy and Ed. Claparède, of the psychological department of the University of Geneva. Perhaps the diversity of the answers is one of the most noticeable features of the inquiry.

A new periodical entitled *Popular Electricity* has just been issued by the Electricity Publishing Co., of New York. The first number—for May—consists of thirty-six well illustrated pages dealing with such subjects of general interest as electric lighting in the house, how to read an electricity meter, the new metallic filament lamps, &c. The language is free from technicalities, and the treatment humorous on occasions. It would be interesting to know how far the electric milking machine and the electric shoeblack described are commercially successful in America.

THE March number of *Terrestrial Magnetism and Atmospheric Electricity* contains an article by Dr. L. A. Bauer on the question of the exact nature of the action of the earth on a magnet, which, according to our present ideas, should reduce to a couple. Most careful and accurate weighings of a magnet with its axis pointing in various directions have been made on a balance specially constructed to be free from magnetic material, and show that on the average for stations in Alaska, British Columbia, Kansas, Maryland, and Washington, the weight when the south pole of the magnet was to the north exceeds that when the magnet is reversed by 1 part in 1,000,000. In disturbed regions the differences of weight observed exceeded 1 part in 100,000. Preliminary experiments on the influence of magnetisation on the weight of a magnetisable material show an increase of the order of 1 part in 1,000,000 on magnetisation.

THE Transactions of the English Ceramic Society for the session 1906–7 show that a great deal of active experimental work is being done by members of the society, and that very considerable progress is being made, with the aid of scientific method, in elucidating obscure points in pottery work. A number of useful investigations are described in the Transactions, of which a few may be referred to as possessing more than a purely technical interest. Mr. Page contributes a paper on the properties of refractory clays, dealing principally with the connection between chemical composition and fusibility; Dr. J. W. Mellor and Mr. F. J. Austin have examined the changes in the microscopic character of various types of refractory substances when subjected to prolonged heating; and Dr. Mellor deals at length with the behaviour of pyritiferous clays on weathering and when heated. The members of the society are to be congratulated on the work they are doing in extending our knowledge of a very difficult subject.

AN eighth edition of "A Treatise on Qualitative Analysis and Practical Chemistry adapted for Use in the Laboratories of Colleges and Schools," by Dr. Frank Clowes, has been published by Messrs. J. and A. Churchill. The present edition has undergone revision mainly in the section on the preparation and detection of gases, and in sections dealing with the reactions and detection of organic substances.

IN Prof. D'Arcy Thompson's paper "On the Shapes of Eggs" in NATURE of June 4, the formula on p. 113 should be $p_n + \frac{T}{r} + \frac{T'}{r'} = P$, and in paragraph 13 the words "the egg is invariably spherical" should be "the yolk is invariably spherical." The first word on the penultimate line of this paragraph should also be *yolk* and not *egg*.

## OUR ASTRONOMICAL COLUMN.

ENCKE'S COMET, 1908*b*.—According to the ephemeris given by M. Kamensky in No. 4241 of the *Astronomische Nachrichten*, the southerly declination of Encke's comet is increasing, and the comet is apparently travelling rapidly through the southern constellations Sculptor and Grus towards Indus. Its position on June 21 will be

$$\text{R.A.} = 24\text{h. } 0\text{m., dec.} = -41^\circ\ 25'.$$

From an announcement in No. 4252 of the same journal (p. 71, June 3) we learn that the position determined by Mr. Woodgate, at the time of re-discovery on May 27, gave corrections of +5m. 22s. and −33′ to the ephemeris.

A FOURTH MINOR PLANET NEAR JUPITER.—Elements calculated by Dr. Ebell for the orbit of the minor planet 1908 C.S. indicate that this object belongs to the Achilles group of asteroids, which travel in orbits near to that of Jupiter. This makes the fourth member of this group to be discovered (the *Observatory*, June, p. 257, No. 397).

OBSERVATIONS OF JUPITER'S EIGHTH SATELLITE.—A note by Prof. E. C. Pickering, published in No. 4253 of the *Astronomische Nachrichten* (p. 87, June 5), states that, according to a telegram from Prof. Campbell, the eighth satellite of Jupiter was observed by Prof. Perrine, at the Lick Observatory, on April 1 and 29. The last observation at Greenwich was made on April 24, so that Prof. Perrine's second observation will serve to extend the path already observed, and will provide a useful check on the ephemeris calculated from the results of the Greenwich observations.

PHOTOGRAPHIC DETERMINATION OF STAR COLOURS.—In No. 3, vol. xxvii., of the *Astrophysical Journal* (April, p. 169) there is an interesting paper by Messrs. Parkhurst and Jordan, of the Yerkes Observatory, on the photographic determination of star colours and their relation to spectral types. The method employed is based on that suggested by Schwarzschild, in which it is assumed that a satisfactory measure of a star's colour may be obtained by comparing the visual magnitude of the star with the magnitude derived from photographs taken on ordinary plates, but the present workers have modified it by determining the "visual" magnitudes by photographic means. With this object in view, they regularly exposed pairs of ordinary ("Seed") and "Pan-iso" plates, the latter giving the "visual" magnitude. Their results show that this method furnishes a simultaneous comparison of the visual and photographic magnitudes of a star freed from most of the uncertainties of ordinary visual methods. As the colour intensities thus derived correspond, in general, to definite spectral types, this procedure furnishes a method of determining the spectra of stars which are too faint for the ordinary spectrographic method.

THE MAXIMUM OF MIRA IN OCTOBER, 1907.—During the period July 13, 1907, to March 9, 1908, Prof. A. A. Nijland made a series of observations of the magnitude of Mira, and in No. 4253 of the *Astronomische Nachrichten* (p. 79, June 5) he publishes the results obtained. These show that the maximum (mag. 3·25) was attained on October 30, 1907 = J.D. 2417879. The four last maxima observed are compared, as regards their dates, with the ephemeris published by Dr. Guthnick, and the differences (O–C) are thus shown to be +2, −19, −13, and −16 days respectively. The magnitudes at maximum range from 3·9 (J.D. 2417214) to 2·0 (J.D. 2417552), and the periods between the four most recently observed maxima, are shown to have been 310, 338, and 327 days respectively.

DETERMINATION OF LONGITUDE DIFFERENCE.—Bulletin No. 130 from the Lick Observatory describes the recent determination of the difference of longitude between the Lick and Mare Island Observatories, carried out by Messrs. Tucker and Sanford during April. The difference determined was 2m. 30·74s., with a probable error of ±0·01s., and, accepting that of the Lick Observatory as 8h. 6m. 34·81s. W., this gives the longitude of the Mare Island Naval Observatory as 8h. 9m. 5·55s. W.

CORONAL STREAMERS.—In No. 4, vol. xxvii., of the *Astrophysical Journal* (p. 286, May), Prof. J. A. Miller describes a method whereby it becomes possible to determine the heliocentric position of a certain class of coronal streamers. The streamers discussed are those which first curve away from, and then towards, the projection of the pole of the sun, or *vice versâ*. Applying his method to the discussion of such a streamer, shown on the photographs taken by Prof. Cogshall and himself in Spain in 1905, he finds the latitude and longitude of the point from which the streamer matter was projected, and also shows that the force of repulsion is so nearly equal to the attraction of the sun (the ratio being as 0·99 : 1·0) that the particle considered had probably been ejected some 251,860 seconds—or about seventy hours—before the eclipse occurred. At the time of the eclipse this particle was at the point of the streamer, where it reversed its direction of curvature, and was about 1·3 radii of the sun from its centre.

## LOW TEMPERATURE GALVANISING.

THE coating of iron with zinc in order to protect it from atmospheric corrosion is an industry which dates back to 1846, and is employed upon a very large scale. The original process, and still the chief one in vogue, was to dip the cleaned iron surface into a bath of molten zinc. The zinc forms an alloy upon the surface of the iron, and as zinc is very little acted upon by the atmosphere, whereas iron rapidly rusts and corrodes, a protective coating is obtained. Furthermore, in the case of tanks, buckets, &c., it is not necessary that the joints should be absolutely water-tight, because when dipped into the molten zinc any slight leaks are filled in with this metal.

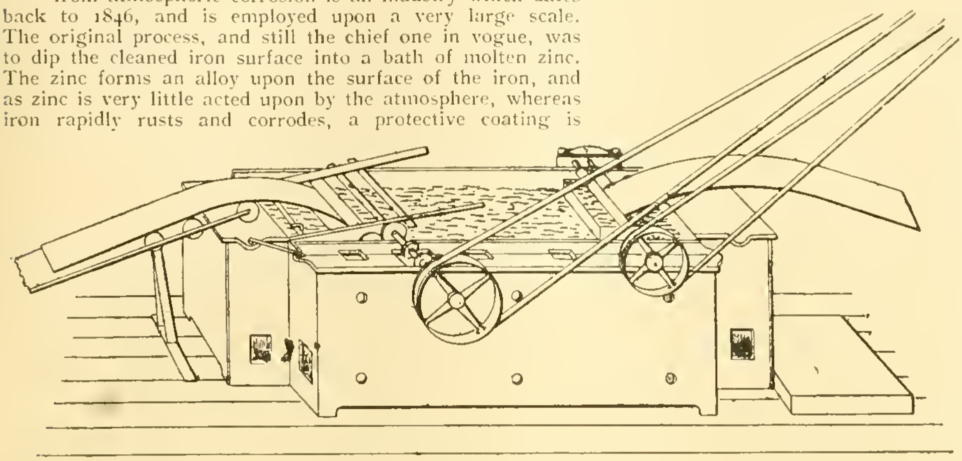


FIG. 1.

The great advantage of employing zinc as a coating for iron is that it is electropositive to this metal, and thus the tendency is for the zinc to go into solution and become oxidised, instead of the iron with which it is in contact being acted upon. The zinc, however, takes on a protective coating of oxide or oxycarbonate, and thus further corrosion is prevented, or at any rate will only take place very slowly.

There are, however, disadvantages in connection with hot galvanising. In the first place it is expensive to keep large quantities of zinc in the molten condition. Secondly, there is considerable loss of zinc through oxidation. Thirdly, the zinc tends to alloy with the iron and to form a difficultly fusible alloy. The higher the temperature of the bath the greater the tendency for alloy formation, but, on the other hand, the thinner the coating obtained upon the metal to be galvanised, and thus in this direction a saving in cost. The alloy of iron and zinc produced is extremely hard, and is sometimes used for making bearings, but as it is difficult to separate the iron from the zinc it is a distinct disadvantage to the galvaniser. Finally, the hot zinc is apt to destroy the temper of the iron, and sometimes to distort the shape of the article to be galvanised.

Consequently, it is necessary to keep the bath at as low a temperature as possible, the excess of zinc being removed by passing the sheets through rollers (Fig. 1).[1]

Cold galvanising or electrolytic galvanising has therefore been suggested, and is actually employed for specific purposes, but there are a good many reasons which have prevented it coming into general use. In the first place, the articles to be galvanised require a more thorough cleansing than is the case with hot galvanising, the least trace of grease being fatal to a good deposit. If there happen to be flaws or the joints are not quite tight, these are not filled in by the wet galvanising process. There are also difficulties in connection with the use of zinc anodes owing to disintegration. As a rule, therefore, lead or iron anodes are employed, and the strength of the electrolyte is maintained constant by circulating it through a filter bed consisting of coke and powdered zinc or coke and zinc oxide (Fig. 2). The disadvantage that flaws are not coated by electrolytic galvanising is in certain cases made use of.

For example, steam tubes employed for marine boilers may have slight flaws which are practically impossible to locate by mere inspection, but which, if the tubes were actually used in boiler construction, might lead to very serious accidents. If such tubes are electro-galvanised, the flaws are made apparent owing to the inequality of the galvanising, probably partially produced by local action.

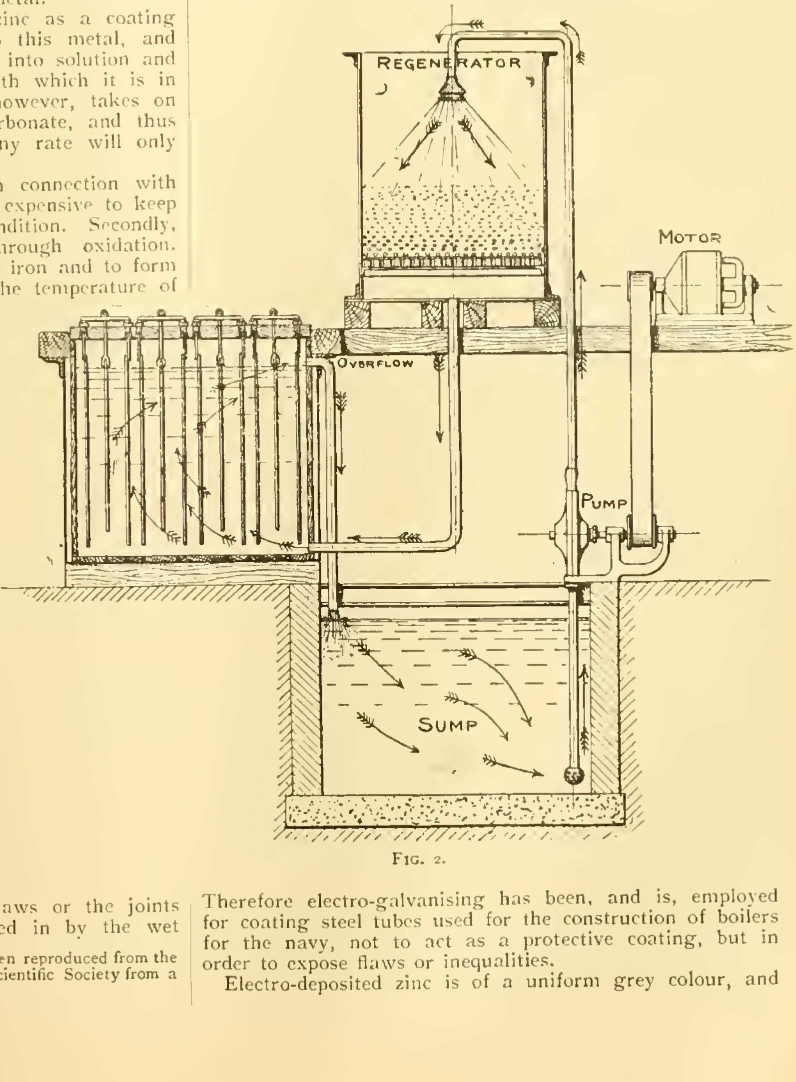

FIG. 2.

Therefore electro-galvanising has been, and is, employed for coating steel tubes used for the construction of boilers for the navy, not to act as a protective coating, but in order to expose flaws or inequalities.

Electro-deposited zinc is of a uniform grey colour, and

[1] The diagrams accompanying this article have been reproduced from the Transactions of the Glasgow Technical College Scientific Society from a paper read by Mr. S. Cowper-Coles.

does not exhibit the artistic crystalline structure produced in hot galvanising. It is very even, and takes on a beautiful polish, so that actually it can be made more artistic than zinc deposited by hot galvanising, which, owing to its crystalline structure, cannot very well be polished.

But beside the actual cold galvanising and the galvanising by means of molten metal, there is a low temperature dry process which was accidentally discovered by Mr. Sherard Cowper-Coles some little time ago. In order to temper certain articles, Mr. Cowper-Coles imbedded them in zinc powder, and they were then heated to a temperature which was considerably below the fusing temperature of zinc. After cooling the articles were taken out, and were, to the surprise of the operator, found to be homogeneously coated with metallic zinc. The zinc was firm and adherent, and on cutting a rod of metal through, it was found that the zinc had penetrated an appreciable depth into the other metal. Experiments were then undertaken to ascertain what was the lowest temperature which could be employed, and whether all metals would thus react with the zinc. It was found that metals could be evenly and completely coated with zinc by heating to a temperature of from 250° C. to 330° C. (zinc melts at 418° C.). The process is now called Sherardising, after the name of the inventor, and is worked essentially as follows:—

Zinc dust, which is obtained as a by-product in the metallurgy of zinc, is the raw product employed. This substance, which amounts to about 10 per cent. of the zinc produced, and can therefore readily be obtained in large quantities, consists of very finely divided zinc mixed with considerable quantities of oxide. Scale and oxide are removed from the articles to be coated; this, of course, is also necessary in all other galvanising processes. In other processes, however, it is also necessary to remove grease, but in this dry galvanising the removal of grease is not necessary, and its presence, at any rate in small quantities, appears to be a distinct advantage. After the scale has been removed the articles are placed in a closed iron receptacle, and the zinc dust charged in; the containing box may be arranged either to work stationarily or rotated. The temperature is then raised to 250° C. to 330° C. by means of gas firing, and maintained so for from half an hour to several hours, depending upon the coating required and the nature of the article to be coated. The drum is then allowed to cool, and discharged. Owing probably to the individual grains of zinc in zinc dust being coated with oxide, it is a very difficult matter to cause it to melt together even when the temperature is raised far above its melting point. This is one of the troubles met with in the metallurgy of zinc, that is, there is a tendency for the metal to condense as dust and not to run together and liquefy. But in the Sherardising process this is a distinct advantage, because, should the drum become overheated, there will be no danger in its melting together and spoiling the articles to be galvanised.

In order, so far as possible, to prevent increase in oxide during heating, the receptacle is preferably made air-tight, but when this is not possible about 3 per cent. of fine charcoal is added to the zinc. Otherwise, as the quantity of oxide increases, the deposit lacks in lustre. The fact that small quantities of grease do not prevent the production of a good deposit is of importance, because it enables machined work, such as bolts, screws, &c., to be placed directly into the galvanising drum without previous cleaning. For small articles, such as screws, rings, nuts, &c., a closed iron cylinder which can be rotated or oscillated is the most suitable form of furnace. For tubes, oblong or cylindrical work, it is most satisfactory to have the door at the end of the furnace, and oscillate it on its axis. A number of Bunsen burners are arranged below the drum, and the whole is enclosed in an iron shell lined with asbestos. For larger work, stationary iron boxes are employed, as illustrated in Fig. 3.

A plant has been erected near London containing four furnaces capable of taking drums 6 feet by 2 feet, with a cubic capacity of two tons of material at one charge. The furnaces are heated with Dowson gas. It is essential that the zinc dust be dry before being added to the furnace, otherwise the zinc is oxidised, and hydrogen is given off on heating.

It is stated that in practice dry galvanised or Sherardised steel and iron will withstand the ordinary corrosive agents to which galvanised ware is usually exposed to a remarkable degree. Even after the apparent removal of the zinc by abrasion, the iron will retain its resistivity.

This resistivity is probably due to the protective action of the zinc-iron alloy formed below the actual zinc coating. The temper of steel wire is not reduced by dry galvanising, owing to the low temperature at which the process is carried out. In Sherardising, the zinc does not form a more or less thick coating or skin, but actually sinks into the metal. As a consequence, the fine lines of screws and other articles which have been machined are not blurred. For example, the minute screws which are employed in making watches can be Sherardised, and fit the holes tapped to receive them quite as well as before being zinced.

In the ordinary method of galvanising it has not been

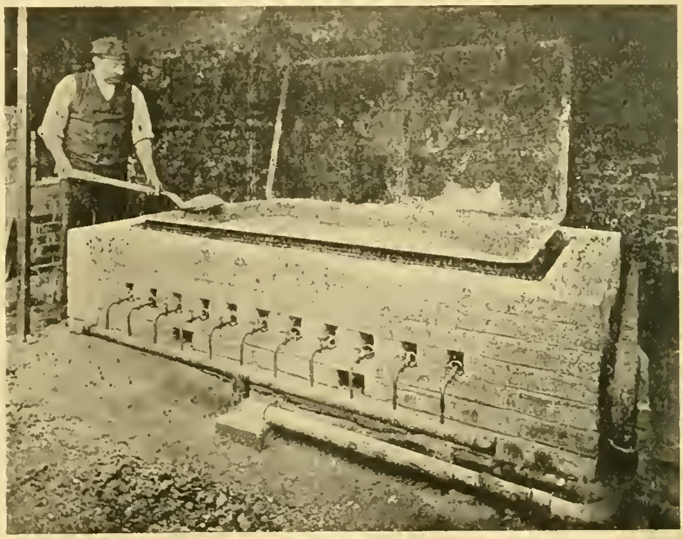

FIG. 3

found possible to produce patterns, because, of course, the whole article has to be dipped, and there are also difficulties in doing this with electrolytic galvanising owing to the electrolyte getting beneath the stopping material which may be used; but with the Sherardising process it has been found possible to produce some very artistic effects. In order to do this, the article is coated with a stopping-off composition. The composition is about the consistency of soap, so that it can be easily cut with a knife. The design is traced with an edged tool, and the portions to be removed are lifted away, so that a clean surface is exposed to the action of the zinc. The object so prepared is placed in an iron drum containing the metal which is to be inlaid in the powdered form, for example, the zinc dust. The galvanising is then carried out as already described.

The temperature and the time which the heating has to be continued are regulated according to the thickness which is required for the inlaying, and may vary from a few minutes to several hours. After inlaying it is found that the part inlaid is much harder than the brass or copper into which it is inlaid.

Furthermore, it is possible to obtain a variety of colours by means of the process. Suppose, for example, one wishes to inlay a copper vase, and convert some parts of it into brass; this can be done by variations in the thickness of the stopping-off composition and by heating to a higher temperature than is generally done. By proceeding in this manner some portions can be converted into yellow-coloured brass, and other parts remain pure copper.

The contrasts between copper and brass are very marked,

FIG. 4.—Copper and brass coal vase inlaid with zinc.

but softer effects can be obtained with zinc, aluminium, tin, and other metals. Fig. 4 shows such an inlaid copper vase.

One beauty about this process of inlaying metals which differentiates it from other processes is the soft transition which shades the inlaid metal from the surrounding metal. For instance, it will be observed that when inlaying zinc into copper, the zinc is surrounded by a halo of the brass-coloured alloy.

Mr. Cowper-Coles has also another process, which he calls Cowperising, and in which he uses vapour of zinc; the articles to be coated are *not* brought into contact with dry or molten zinc, but are placed in a chamber into which zinc vapour is passed. The chamber or drum is slowly rotated inside an outer cylinder in which the metallic zinc is heated by means of a gas or electric furnace. Hydrogen gas is also passed into the apparatus from a tube, and a pilot light is kept burning to make sure that air is not being sucked back.

The process has been found successful for decorating porcelain and metallic surfaces with a brilliant coating of zinc. The remarkable part about the action of zinc powder upon metals is the manner and speed with which it, at temperatures much below its melting point, sinks into and alloys with them. In this, Sherardising rather resembles Sir W. Roberts-Austen's experiment in which he placed pieces of gold and lead together, and showed that diffusion took place even at ordinary temperatures; in his case, however, the diffusion was very slow. But with the Sherardising process the zinc sinks in in a few minutes to an appreciable depth. Another peculiarity is that the zinc does not require to be pure, but is the commercial dust which is coated with oxide, and with this zinc dust I have found that it is practically impossible to get an electric current to pass through even a centimetre thickness, although 100 volts pressure was employed. Cadmium and a few other metals can also be employed, but they are not so satisfactory as zinc.

It looks as if the zinc has a very distinct vapour pressure even a very long way below its melting point, not to say its boiling point. The zinc vapour being immediately able to alloy with the iron or other metal in contact with it, equilibrium is destroyed, and a further portion of the zinc becomes vaporised. F. M. P.

## *STUDIES OF SOME AMERICAN METEORITES.*

THE large crater, three-quarters of a mile across and 500 feet in depth, near Canyon Diablo, in Arizona, which it is supposed was produced by the impact of an enormous meteorite, has already been described at some length in NATURE (1906, vol. lxxiv., p. 490). Since that date the locality has been visited by Dr. George P. Merrill, of the United States National Museum, and in a paper published in the Smithsonian Miscellaneous Collections (1908, vol. l, pp. 461–90, with fifteen plates) he gives the results of his observations, and reviews the evidence for and against the meteoric hypothesis. In the hope of finding a large mass of metallic nickel-iron, Messrs. D. M. Barringer and B. C. Tilghman have made a detailed examination of the crater, and have put down a number of bore-holes to the depth of 1100 feet in its floor. Beneath the surface débris from the sides of the crater there is a thick bed of lake deposits; this lies on a crushed and pulverised sandstone containing fused and pumiceous fragments and particles of nickel-iron, while at a depth of about 600 feet the undisturbed red sandstone of the district was met with. No large mass of meteoric iron was encountered; and with the exception of four small pieces, the numerous masses of Canyon Diablo meteoric iron have all been found outside the crater. All the evidence undoubtedly points to the crater having been formed by the impact of a meteorite.

Prof. O. C. Farrington, in his "Meteorite Studies, II.," published in the geological series of the Field Museum of Natural History (Chicago, 1907), gives a collection of miscellaneous notes respecting nine different meteoritic falls in the North and South American con-

Mass produced by joining the two individuals of the Chupaderos meteorite. × 1/20.

tinents, most of which have been previously described, though one, an iron from Lampa, in Chile, is now described for the first time. The paper is illustrated with fifteen excellent plates of photographic reproductions; special attention may be directed to those representing the large masses of meteoric iron mounted in the School of Mines in the city of Mexico, which, though long known, do not appear hitherto to have been figured. The two masses of the Chupaderos iron, found at a distance of about 800 feet apart, and known in Mexico since 1852, evidently formed part of the same mass, the total weight of which would have been about twenty-one tons. Particulars are also given respecting the fall of stones near Modoc, in Kansas, on September 2, 1905; fifteen stones with an aggregate weight of 35 lb. were found over an area of seven by two miles, the several masses gradually increasing in size from west to east, this being the direction in which the meteor fell. The same distribution of the stones according to size is noted in the fall at Weston, in Connecticut, in the year 1807.

## *THE SCIENCE COURT OF THE FRANCO-BRITISH EXHIBITION.*

All international exhibitions have contributed in some measure to the advancement of science. The assembling before the public of a great array of machinery has from time to time acted as a stimulus to inventions in which science was applied to promote safety, comfort, or luxury. The competition between manufacturers of scientific apparatus, encouraged by medals and other awards of excellence, doubtless resulted in improved workmanship and better design in the tools which the scientific investigator or teacher has to employ. The sporadic display of original or merely antique instruments (*e.g.* clocks) did little more than hint at an evolution of scientific knowledge, and fell far short of exhibiting in any adequately organised manner the actual progress of such evolution, full as it was—and is—alike of human and philosophical interest.

Happily, we need not discuss the causes which hitherto prevented the realisation of an exhibition dealing with all branches of research by scientific experiment; whether the managers of international exhibitions have been deterred by lack of faith in the popularity of a section devoted to purely scientific exploration of the boundaries of knowledge, or by a too vivid realisation of the difficulties attendant upon the formation of such a collection as would worthily represent British achievements in the past and activities in the present. There is no need to debate the matter; visitors to the Science Court of the Franco-British Exhibition can see for themselves the *fait accompli.* Thanks to the initiative of Sir Norman Lockyer, supported by Sir William Mather and the executive committee, and backed with equal heartiness and ability by members of the British Science Guild, for the first time in the history of international exhibitions there has been brought together a collection of exhibits devoted to the illustration of methods and results of scientific research.

As chairman of the Science Section, Sir Norman Lockyer expressed regret that it has not been found possible to organise a French section, and we shall all echo this sentiment the more fully from seeing what an instructive display is contributed by the limited area of Great Britain and Ireland. By its very nature scientific investigation subordinates national rivalry to national cooperation, and anyone may point to the fact that no department could have attained its present state of efficiency had its progress not been furthered by the genius of the *savants* of France.

The catalogue, a closely printed volume of one hundred and ninety pages, has a permanent value for purposes of reference, and is sold for the moderate price of sixpence. No individual critic can do justice to all the departments represented, which are compendiously described as including instruments and methods used in and results obtained from the exploration of (1) the land; (2) the sea; (3) the air; (4) the heavens. Visitors will be impressed with the richness of the collection in apparatus and documents of historic interest, and with the complete subordination of the trading element. To indicate the character of this unique exhibition we give short notes on a few of the interesting features.

*Heat.*—The Manchester Municipal School of Technology lend Joule's laboratory note-books and MS. of researches, and his apparatus used for observing the heat-effects of compression and rarefaction of air. Portraits of Joule and some models of apparatus and reprints of papers are also shown. The physical department of the Imperial College of Science and Technology, South Kensington, exhibits modern appliances used in recent calorimetric, thermometric, and barometric determinations, including sunshine receivers and recorders. One recorder shown registers electrically to 1 part in 10,000 the variations produced in a receiver distant a mile or more. With the platinum grid thermometer for determining the temperature of the air is shown a record obtained during the solar eclipse of August 30, 1905. The Cambridge Scientific Instrument Company show Boys's radiomicrometer, a Féry pyrometer, Callendar and Griffiths's bridge, &c.

It will be seen that we have, on the one hand, the historic apparatus and documents, on the other, the methods and means of up-to-date research. This is typical. All the numerous sections into which the Science Court is divided and subdivided show the same contrast of ancient and modern research. As a consequence, the serious student will everywhere find interesting material, and it may well happen that he will learn more and get fresher views of his subject from the early investigators.

*Magnetism and Electricity.*—This is a strong department, the evolution of telegraphy in all its branches being particularly well illustrated. From the Wheatstone Laboratory of King's College, London, come the original Daniell's batteries, the original resistance box, bridge and chronograph of Wheatstone, while Sir William Preece and H.M. Postmaster-General contribute numerous specimens dating from 1837 to 1908 which present a miniature of progress in the electric transmission of signals. Signor Marconi sends thirty-three items, including some of the apparatus used in Newfoundland for the first Transatlantic reception in 1901. Much of the evolution of the Ayrton-Perry instruments can be traced. The early and recent forms of lamp contributed by Sir J. W. Swan are particularly interesting. It is hardly necessary to say that Kelvin instruments find a place, as do the devices associated with the recent researches of H. A. Wilson, P. E. Shaw, Duddell, and Fleming. Dr. Shelford Bidwell shows his selenium cell, and attention will no doubt be attracted to his model of apparatus for transmitting pictures by telegraph, also dating from 1881.

*Chemistry.*—There is an excellent collection of preparations in connection with both physical and technical chemistry. Recent research is represented by contributions from the Davy-Faraday Research Laboratory, the Imperial College of Science, the University of Manchester, and many institutions and investigators too numerous to mention. Many will doubtless be interested in the apparatus used by Lord Rayleigh in the discovery of argon, and by Sir William Ramsay in his researches on helium and the new gases. The penetration of the physicist into the domain of the chemist is nicely illustrated by the inclusion of Sir Oliver Lodge's "ether machine" in the chemistry division. Magnificent specimens of salts of the platinum group were on view, lent by Messrs. Johnson, Matthey and Co. But of all the items in this division we were most attracted by (1) Black's original balance, dating from 1766—the foundation-stone of modern chemistry; (2) original mauvein preparations made by the late Sir William Perkin between 1868 and 1872. The general public may be expected to be interested in the "oldest lucifer matches," made by Walker, of Stockon-on-Tees, in 1827; also in the "chemistry of a bottle of eau de Cologne," contrasting natural and synthetic methods of production.

*Metallography.*—Micro-sections of metals prepared in 1863–4 by the late Dr. Sorby are shown; the remainder of the items illustrate modern developments of this branch of science, to further which a special institution was founded quite recently.

*Biology.*—The members of the biology subcommittee have secured an exhibit of profound interest from the Liverpool School of Tropical Medicine, which has sent specimens illustrating sleeping sickness, ngana, malaria, yellow fever, bubonic plague, and other terrible scourges. We were glad to see portraits of Major Ronald Ross and other leaders in the campaign which science is waging on behalf of humanity, and especially on behalf of the native races of the tropical regions of the Empire. The evolution of the microscope is excellently demonstrated by the instruments lent by the Royal Microscopical Society, ranging from the copy of the simple microscope of Leeuwenhoek (1675) to the 1848 pattern of Powell and Lealand. A full account of them may be found in Dr. Dallinger's editions of "Carpenter on the Microscope." Modern methods of mounting microscopical preparations are represented, also the processes for the preservation of anatomical structures on the larger scale.

*Anthropology.*—Anthropometric contrivances are numerous, and gain some additional interest from recent regulations with regard to the medical inspection of schools and from the efforts being made to secure an anthropological survey of Britain.

*Geography and Geodesy.*—The Government has given but little assistance to the science section as a whole, but in this division we find much instructive material lent by the War Office and the Board of Agriculture and Fisheries, the former through the topographical section of the General Staff and the latter through the Ordnance Survey. The production of the topographical map of the Orange River Colony is illustrated in all its stages, and there is a fine collection of Ordnance Survey maps of the United Kingdom. The Royal Geographical Society contributes photo reproductions of original MS. maps by British explorers in Africa, including Livingstone, Burton, and Speke. Surveying instruments used in famous pre-Victorian expeditions are to be seen, and also those of the latest 1908 pattern.

*Geology and Geodesy.*—The Geological Society shows facsimile reproductions of early tables and maps by William Smith, 1799 to 1801. Photographs of British scenery illustrative of geological features are contributed by the Geological Survey and the British Association Committee, of which Prof. Watts is secretary. We direct attention to a new small geological map of the United Kingdom, scale 1 inch to 25 miles, published by the survey to provide teachers with a cheap and accurate map. In the palæontological division *systematic* research is illustrated by the grouping, viz.:—(*a*) collecting of fossils; (*b*) preparation of fossils; (*c*) study of fossils; (*d*) literary aids to research; (*e*) presentation of results.

*Oceanography.*—The Admiralty has lent the gear used by H.M.S. *Challenger*, 1872–6, photographic reproductions of Captain's Cook's original charts, and various pieces of apparatus used in sounding, both antique and recent. Biological specimens brought by the *Scotia* from the Antarctic can be seen, while the submarine cable companies contribute an attractive exhibit.

*Meteorology.*—No fewer than twenty-five pages of the catalogue are required for the enumeration of the items in this remarkably complete division. Here one may study the equipments of stations of the first, second, and third orders, and the methods of dealing with observations and results. Applications of meteorological statistics to agriculture and public health are instructively set forth. Apparatus for investigating the upper air, for observations on board ship, and for such special purposes as dust-counting, are on view. The historical collection includes Merle's weather journal, kept from 1337–44, and the earliest treatise on the barometer, published in 1688. Photographs of lightning flashes and of cloud-forms are numerous and of high quality. In the subdivision devoted to terrestrial magnetism will be found the results of the *Discovery* Antarctic Expedition.

*Astronomy.*—Though placed last in the official classification, this section is second to none in extent and interest. The observatories of Greenwich, Cape of Good Hope, Edinburgh, Cambridge, Oxford, Stonyhurst, and the Solar Physics Observatory of South Kensington have all contributed to a wonderful display of instruments and photographs. The subcommittee has arranged a stand to show the more important instruments required to equip a modern astrophysical laboratory. The large variety of objects of historical interest include an equatorial by Abraham Sharp (*circa* 1674), an astrolabe constructed for Sir Francis Drake, a Newtonian telescope made by W. Herschel, an Arabian astrolabe dated 1224 A.D., and autograph letters of John Flamsteed relating to Greenwich Observatory in 1712. In an adjoining case we found a photograph of the new satellite of Jupiter, discovered by Mr. Melotte on February 28, 1908. We cannot imagine a better way to view the progress of astronomy during the last two centuries than by visiting this exhibition.

*The National Physical Laboratory* sends photographs and duplicates of apparatus used in standardising and research. Regarding such an exhibit as a gauge of the degree of advancement attained in the branches of knowledge for which the instruments are employed, and of the degree of skill reached by our manufacturing firms, we may feel legitimate pride in recent advances, particularly in electrotechnics.

In dealing with a new enterprise, it is, of course, easy to find details which are susceptible of improvement, but in this case the only faults we observed were minor ones, and will mostly disappear under the capable directors who have brought so large an undertaking to such a high pitch of attainment with commendable punctuality. We cheerfully omit minor criticisms, and express our strong feeling of indebtedness to the workers who have done so well. We also thank the executive of the exhibition for endowing the Science Section to the extent of about 7000*l.* The best return for this labour and generosity will be an attendance of visitors such as the merits of the exhibition deserve.

G. F. DANIELL.

## CONFERENCE OF TEACHERS IN TECHNICAL INSTITUTIONS.

THE second annual conference of the Association of Teachers in Technical Institutions was held in London last week. The following are among the matters of wide interest discussed at the conference:—

(1) The necessity for the provision of two types of schools for the continuance of the education of boys and girls from the ages of fourteen to seventeen years. The first of these types corresponds with the present existing first-class "secondary" school, the second with the "trade" or "preparatory trade" school, which should be a secondary school with a marked "technical" bias. This school should prepare definitely for the trades, crafts, or industries.

(2) As a small but distinct educational advance, the minimum age of exemption from obligatory school attendance should be fourteen years, without any exceptions, as provided in clause 2 of the Education (Continuation Schools) Bill promoted by Mr. Chiozza Money. This, however, is only one step forward. The leaving age for trades, industries, or crafts, where the conditions of the trade permit, should be sixteen or seventeen years. From fourteen to sixteen years, the boy or girl should attend a school provided in accordance with paragraph (1) above.

(3) The technical institution has to deal with students who have received their preliminary training in the primary and secondary schools, often in the primary schools only. The average quality of the material from the primary and secondary schools is far from satisfactory. There is too often a certain lack of intellectual "grip" and thoroughness. How far this is due to the widening of the school curricula in recent years it is impossible to say. Signs are not wanting that in many schools the old evils of stringent individual examinations are being replaced by an evil almost as great, namely, the cramming of a number of pupils for the valuable borough and county scholarships now offered in such profusion. Technical colleges and schools have still to devote much valuable time, space, and equipment to work which should have been done in the secondary schools.

(4) In the case of a large number of students attending evening classes in technical schools, their sole previous educational training has been in the primary school up to the age of thirteen or fourteen years. About sixteen or seventeen years of age, or later, they enter the technical schools, after a period of three or four years during which

they have failed to receive any systematic education. The remedy for this blank period lies in the continuation school. At present, however, the continuation schools, except in a few isolated cases like Manchester, Leeds, Bradford, and Birmingham, fail almost completely in this aspect of their work. This is particularly the case in London, where one of the many pressing questions is the improvement of the evening continuation schools and the correlation of the schools to the polytechnics.

(5) Technical institution teachers are, naturally, keenly interested in the Imperial College of Technology. They look forward to sending their best students (day and evening), by means of scholarships or bursaries, to this institution for the highest *technical* training and research. Judging by the present rate of progress, this will be impossible for a number of years. There is danger that, instead of the college being a "college of technology," it will merely be an organised group of institutions doing practically the same kind of work as that which is done in an ordinary university college. The governing body of the college needs to be brought more closely into touch with the main current of English technical education than it is, apparently, at present, in order that the work of the college may be properly coordinated with that of existing technical institutions. The "preliminary" work now being done in the college, which is done also by a considerable number of institutions all over the country, should cease at the earliest possible opportunity, and the whole energies of the college concentrated on the highest possible technical training and research. We need an institution which shall bear the same proportion to the Manchester Municipal School of Technology as the latter does to the technical institute of a small provincial town.

(6) There is a pressing need for the establishment of a common matriculation or school leaving examination for admission to all British universities, the professions, and the (day) technical colleges, in place of the multiplicity of examinations and examining bodies existing at present. Coupled with this is the need for a revision in the syllabus of some of the chief matriculation examinations as at present conducted.

(7) Reference was made during the conference to the scheme recently put forward by the King's College (London) authorities for instruction in "household economics," based upon a thorough introductory course of chemistry, physics, elementary bacteriology, physiology, &c. While this would be undoubtedly beneficial in many ways, for example, in raising the status of "domestic science" teaching, it is felt by many technical institution teachers engaged in similar teaching in polytechnics and technical schools that the promoters of the King's College scheme have hardly done justice, in their preliminary publications and notices in the Press, to those engaged in such work in technical institutions. The impression given in these publications is that, up to the present, domestic science teaching has been empirical, "rule of thumb," and not based upon a knowledge of scientific "first principles." This is scarcely correct. For the last fifteen years the training schools of domestic economy attached to the polytechnics and technical institutions have increasingly, year by year, laid stress upon attendance at compulsory courses of chemistry, elementary physics, theory of education, and in some cases elementary bacteriology.

J. WILSON.

## SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES.

THE thirteenth annual congress of the South-Eastern Union of Scientific Societies was held at Hastings on June 10–13.

Sir Archibald Geikie, K.C.B., F.R.S., who followed Prof. Silvanus P. Thompson, F.R.S., in the presidential chair, took as the subject of his address "The Weald." He chose the subject because research in the problems connected with the Wealden area was eminently suitable for that combined action which local societies and field clubs are well fitted to provide. He spoke against the natural predisposition of the mind, in re-constructing the geography of former geological periods, to be too much influenced by the present grouping of sea and land. He sketched the part played by Godwin-Austen in the discovery of coal at Dover in consequence of his brilliant generalisation, after his profound study of the geology of N. France, Belgium, and S.-E. England (work which recalls, too, the names of Prestwich, Etheridge, and Boyd Dawkins). Having sketched the problem of the Palæozoic rocks, and having passed on to the deposition of the Purbeck and Wealden strata, he said that it was not easy to find the place whence the remnants of the terrestrial life of the Wealden deposits were derived, but indicated his belief that the crystalline and Palæozoic rocks of Brittany seem to be the greatly denuded core of an ancient land; for the Wealden deposits thin out rapidly in northerly, easterly, and westerly directions, and the only quarter which seems to offer itself as possibly that in which some vestige of the Wealden land may still remain lies to the south. Since the resources of modern petrography have armed the geologist of to-day with far ampler and more effective means of conducting the inquiry than his predecessors possessed, it would be well for some member of the union to undertake research into the origin of the pebbles found in the Ashdown Sand, the Wadhurst Clay, the Tunbridge Wells Sand, and occasionally in the Weald Clay.

The president sketched the various divisions of the Cretaceous rocks above the Weald Clay, emphasised the break between the Secondary and Tertiary periods, and then proceeded to discuss the evidences of the Ice age afforded by the Wealden area. Prestwich was disposed to think that the uplands of the Weald may have been a separate source of snow and ice, but he (Sir Archibald Geikie) did not think the evidence on which Prestwich relied was, perhaps, strong enough to warrant that conclusion. The decaying nature of the various rocks made observation of glaciation of the Wealden area difficult. But Prestwich may be right, and there may be other indications yet discoverable of "the traces of the Ice age in the Weald."[1]

The president also directed attention to the problem of the Coombe rock, and Mr. Clement Reid's ingenious solution of its origin, but thought that more directly convincing proofs of the Ice age were to be found in the transported boulders—granite, syenite, and mica-schist—found in such numbers along the south coast from Worthing to Portsea, brought thither on floating ice, perhaps from the region of crystalline rocks in the N.W. of France. Before the Arctic conditions finally passed away, there appear to have been some alternations of milder seasons, and the time was further marked by oscillations in the relative levels of land and sea, indicated, on the one hand, by lines of raised beach, and, on the other, by submerged forests.

Mr. E. A. Martin read a paper on some considerations concerning dew-ponds, a subject on which he has been engaged some time, encouraged by a grant from the Royal Society. Mr. W. J. Lewis Abbott read a valuable paper on Pleistocene vertebrates of the S.E. of England, and conducted an excursion to all the salient geological features of the district, which, after eleven years' observation, he is well qualified to do. He considers the Hastings uplift the most important, and his paper will modify previous views on this important area. Mr. Edward Connold contributed a paper on local sponges, which was a valuable contribution to this somewhat neglected branch of inquiry, and the same remark refers to Butterfield and Bennett's paper on the spider fauna of the Hastings district. Mr. W. H. Mullens discoursed on Gilbert White's connection with Sussex, and Mr. John Ray on mediæval timbered houses of Sussex and Kent. Mr. Wilfred Mark Webb touched upon a lighter theme in Darwinism as applied to dress, tracing the origin of some peculiar survivals in male and female attire.

Next year the meeting place will be Winchester, at the invitation of the Mayor and Corporation, and the president is to be Dr. Dukinfield Scott, F.R.S., president of the Linnean Society.

R. A. B.

[1] Mr. Lewis Abbott supplied some in his paper on "Pleistocene Mammalia of S.E. England," subsequently read to the Congress.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The general board of studies will shortly proceed to make the following appointments:—(1) A reader in zoology, in succession to Mr. Bateson; stipend, 100*l*. a year. (2) A reader in metallurgy; the stipend is the net income arising from the benefaction of 10,000*l*. given for this purpose by the Goldsmiths' Company. (3) A lecturer in economics, in succession to Prof. Pigou; stipend, 100*l*. a year. (4) A lecturer in historical and economic geography; stipend, 150*l*. a year. (5) A Royal Geographical Society lecturer in regional and physical geography; stipend, 150*l*. a year. (6) A Royal Geographical Society lecturer in surveying and cartography; stipend, 50*l*. a year. Candidates are requested to send their applications to the Vice-Chancellor, with testimonials if they think fit, on or before July 28.

The electors to the Frank Smart studentship in botany give notice that they will shortly proceed to the election of a student. Any graduate of the University is eligible for the studentship provided that not more than fourteen complete terms have elapsed after his first term of residence. The successful candidate must devote himself to research in botany. The studentship is ordinarily tenable for two years. The value of the studentship is 100*l*. per annum, or such larger or smaller annual sum as the fund may produce. A candidate must send his name, with a statement of the course of research which he proposes to undertake, and such evidence of his qualifications as he thinks fit, to the Vice-Chancellor, Gonville and Caius College Lodge, on or before Tuesday, June 23.

The general board of studies has appointed Dr. Anderson university lecturer in physiology, Mr. F. H. A. Marshall university lecturer in agricultural physiology, Mr. C. G. Lamb university lecturer in electrical engineering, and Mr. C. E. Inglis university lecturer in mechanical engineering, all for five years.

The first examination for the diploma in mining engineering will be held in the Michaelmas term. The examiners nominated are Mr. E. H. Liveing, formerly professor of mining in the Yorkshire College, Leeds; Prof. H. Louis, Armstrong College of the University of Durham; and Mr. C. T. Heycock, of King's College.

Mr. R. C. Maclaurin, St. John's College, has been approved by the general board of studies for the degree of Doctor in Science.

LONDON.—The assembly of the faculties of University College has been fixed for Thursday, July 2, at 3 o'clock, when Prof. A. F. Pollard will read a report on the work of the session, and the results of the University, scholarship and class examinations will be announced. Scholars and medallists will be presented to Sir Edward Fry, F.R.S., who will deliver an address.

---

MR. A. D. HALL, director of the Rothamsted Experimental Station, will deliver a course of lectures on July 13–18 at the Graduate School of Agriculture, which the United States Department of Agriculture is holding this year at Cornell University. Mr. Hall will also deliver two lectures at the University of Illinois, Urbana, on July 7 and 8.

IN an address at the University of Wisconsin, Madison, on Sunday, Mr. Bryce is reported by the *Times* to have dwelt upon the useful relation which the State universities of western America bear to the States, commenting on the immense service rendered to scientific agriculture by the University of Wisconsin in increasing the product of the soil and the quality of the live-stock, making the farmer's life more interesting, and checking the influx of the people to the cities. It is wise, he remarked, not to allow practical subjects to oust theoretical physical science and human subjects. Theoretical science is the source and strength of progress in all industries and practical arts.

ONE of the departments of the Hungarian Exhibition at Earl's Court illustrates the progress and present position of education in Hungary. Starting with a section devoted to kindergartens and elementary schools, all the grades of education up to the universities, and colleges of university standing, are explained by suitable exhibits. A sketch of this part of the exhibition, which appeared in the *Times* of June 12, says that in every one of the grades photographs are on view illustrating the pupils and students at work in their classes. A very interesting feature is the model State farming school, in which all branches of farm work are taught to pupils between the ages of twelve and fifteen. Nursery-gardening instruction forms part of the curriculum at these schools also, and attention is paid to home and industrial work. The age at which education in Hungary is compulsory is in the kindergarten from three to six, and in the ordinary elementary school from six to twelve, while evening classes are given to pupils between the ages of twelve and fifteen. A *minimum* collection of implements used in all elementary schools is on view, embracing a wide selection of objects from chemical, mechanical, and electrical appliances to natural history specimens. The training college section contains excellent specimens of woodwork, and equally fine articles of lace and embroidery. Another feature is the attention paid to hygiene. So keen are the State authorities on securing a high standard of physical culture that every boy when he enters has his height measured and his strength tested. These details are entered in a register, which is kept as a record of his physical growth during his school years.

---

## SOCIETIES AND ACADEMIES.

### LONDON.

**Royal Society**, March 19.—"Secondary $\beta$ Rays." By Prof. J. A. **McClelland**. Communicated by Prof. J. Joly, F.R.S.

This paper deals with the secondary radiation of $\beta$ particles from a plate exposed to the $\beta$ rays from radium. It contains, in the first place, a detailed investigation of the intensity of this secondary radiation in different directions in the plane of incidence of the primary rays, and for different values of the angle of incidence.

The results show that the secondary $\beta$ particles may be divided into two parts. One portion of the radiation has a maximum value in the direction of ordinary reflection, and is referred to as the "reflected" rays. The reflected rays differ very little in intensity for different substances.

The author in previous papers has compared the intensity of the secondary $\beta$ rays from a large number of substances, and showed that it depends on the atomic weight of the substance. The secondary radiation increases with the atomic weight, and in such a way that the elements fall into divisions corresponding to the chemical periods. When the secondary radiation is analysed, as in the present paper, and the observations so taken as to exclude or reduce to a minimum the portion referred to above as the reflected rays, the connection with the atomic weight is brought out even more clearly than before.

The reflected rays are a more important fraction of the whole in the case of elements of low atomic weight, as for these substances the other portion of the radiation—the true secondary—is small.

The reflected rays are more marked when the angle of incidence is large.

Further evidence that there is a decided difference between the reflected rays and the other portion of the secondary rays, is given by measurements of the absorption in a direction in which the reflected rays are a maximum and in a direction where they are absent or a minimum. The reflected rays are similar in velocity to the primary rays, and vary little with the substance emitting them; the velocity of the true secondary rays is less than that of the primary rays, and depends on the substance emitting them.

The origin of the two parts of the secondary radiation is discussed in the paper, and the view taken that the reflected rays are some of the primary particles which in their path in the exposed plate have not entered into or caused change of energy in any atomic systems, thus retaining their original velocity and obeying approximately the law of reflection. The true secondary rays, on the other hand, are looked upon as $\beta$ particles expelled from the atoms of the exposed substance by the entry of the primary particles.

The paper further contains the results of measurements with a hemispherical ionisation vessel which give the sum of the secondary radiations in all directions from the exposed plate for different angles of incidence of the primary rays. A comparison of these results with those referring to the plane of incidence only, shows that the reflected rays are not strictly confined to the plane of incidence. Further work on this subject is in progress.

May 7.—"Helium and Radio-activity in Rare and Common Minerals." By the Hon. R. J. **Strutt**, F.R.S.

(1) Helium can be detected in almost all the minerals of the earth's crust.

(2) The quantity is in most cases about what might be anticipated from the traces of uranium and radium which the minerals contain. This is illustrated by the following selected results, which are given in round numbers only:—

| Mineral | Helium present, c. mm. per kilo. | Helium ratio, *i.e.* ratio of helium to uranium oxide |
|---|---|---|
| Samarskite | 1,500,000 | 14 |
| Hæmatite | 700 | 9 |
| Galena | 2 | 17 |
| Quartz | 2 | 10 |

(3) Where much higher helium ratios than the above have been observed, the excess of helium can always be connected with the presence of thorium, except in one outstanding case. Thus the experiments afford no evidence in favour of helium production by radio-activity of ordinary elements.

(4) The outstanding case is beryl, which contains abundance of helium, without anything approaching a sufficient radio-activity to explain its presence. This helium cannot be connected with any known constituent of beryl.

(5) Igneous rocks, and probably siliceous minerals generally, contain small quantities of argon. In other minerals its quantity is negligible, at all events in comparison with the helium present. Nor is there any indication that it increases with the amount of radio-active material.

May 21.—"A Further Note on the Nutrition of the Early Embryo: with Special Reference to the Chick." By E. **Emrys-Roberts**. Communicated by Prof. C. S. Sherrington, F.R.S.

(1) The secretion of the resting mammalian uterus contains protein, mucin, and salts; during the pro-œstral stage the proportion of mucin is decreased.

(2) The profuse mucinous secretion of mammalia during pro-œstrus is derived, not from the body of the uterus, but from the cervix and vagina.

(3) The nutrition of the embryonic chick is not dependent upon the yolk alone, but also upon the egg-white.

(4) Assimilation of the egg-white is divisible into three heads—the water, the salts, and the proteid.

(5) Of the three, the water is at first extracted at the most rapid rate, *i.e.* the percentage of water decreases as incubation proceeds.

(6) The percentage of salts in the egg-white remains more or less unchanged throughout incubation.

(7) The proteid of the egg-white is assimilated, not by a process of osmosis, but by a process of digestion performed by the chorionic cells.

(8) During this process the egg-white is considerably altered in composition and reaction, being converted, as incubation proceeds, into a more and more vitreous mass with a peculiar set of reactions, the outstanding reaction being that demonstrating the presence of albumoses and peptones.

**Physical Society**, May 22.—Dr. C. Chree, F.R.S., president, in the chair.—The spectrum top: F. P. **Sexton**. The coloured bands seen when a Benham top is rotated are explained. The effect depends upon the position of the sector lines and on a contrast. The rates of growth of the colour sensations are assumed to be in the order red, green, and blue, where red is the greatest, and the rates of decay are assumed to be in the inverse order. The colour in the inner ring with an anti-clockwise rotation, and also the second ring, are explained.—The coefficient of diffusion: B. W. **Clack**. The practicability of a new method for the determination of the coefficient of diffusion of salts through water, and to find how this coefficient varies with the concentration of the solutions, is discussed. The apparatus consists of a special kind of flask of about 450 c.c. capacity fitted with a vertical glass tube of known dimensions. The flask, filled with the salt solution, was suspended in cooled distilled water. The apparatus was so designed that one end of the vertical tube was maintained in contact with a salt solution of constant concentration, while the other end was kept in contact with distilled water. As the salt diffuses through the tube the weight of the flask varies, and an expression was deduced by which it is possible to find the value of the coefficient of diffusion from this rate of change in weight, which was automatically recorded. The salts experimented upon were NaCl, KCl, and $KNO_3$. The coefficient for NaCl and KCl decreases as the concentration of the solution decreases. For $KNO_3$ the opposite phenomenon is exhibited.—The production of small variable frequency alternating currents suitable for telephonic and other measurements: B. S. **Cohen**. A new method for producing these currents is described; this consists of a form of vibrating wire interrupter which operates a make-and-break contact. This is used to put a source of potential on and off a resonating circuit tuned to any desired frequency. The alternating current is taken from a small transformer in the resonating circuit. A series of damped wave-trains of any frequency can be produced by this means, the trains following each other with the frequency of the wire vibrations. The theory of action of the various circuits, and some applications of the waves to both telephonic and general electrical measurements, are given.

**Mathematical Society**, June 11.—Prof. W. Burnside, president, in the chair.—Relations between the divisors of the first *n* natural numbers: Dr. J. W. L. **Glaisher**.—Electrical resonance: Prof. H. M. **Macdonald**.—A form of the eliminant of two binary quantics: A. L. **Dixon**.—Perpetuant syzygies of the *n*th kind: H. **Piaggio**.

**Royal Astronomical Society**, June 12.—Mr. H. F. Newall, F.R.S., president, in the chair.—An example of Prof. Karl Pearson's calculation of correlation in the case of the periodic inequalities of long-period variables: H. H. **Turner**. After tabulating Chandler's periodic inequalities, the author worked out the correlation according to Prof. Pearson's method, and then made an examination of eight stars in detail for which special information was available.—Report of the expedition to Flint Island for the observation of the total solar eclipse of 1908 January 3: F. K. **McClean**. The author gave an account of his expedition, to undertake which he chartered a steamer to start from Auckland for Tahiti and Flint Island, being joined by a small party of astronomers from Australia and New Zealand. The difficulties of landing were overcome, and all preparations made, in spite of almost continual rains. Heavy rain came on upon the morning of the eclipse, and only ceased just as totality commenced. Very successful photographs of the corona and prominences were taken, which were shown to the meeting. Mr. McClean recommended the observation of the eclipse of 1910 in Tasmania, and Mr. Crommelin remarked that Halley's comet would come to perihelion about the time of the eclipse, and could be much better observed in the southern than in the northern hemisphere.—Observations of the sixth, seventh, and eighth satellites of Jupiter from photographs taken at the Royal Observatory, Greenwich: **Astronomer Royal**.—The orbit of Jupiter's eighth satellite: P. H. **Cowell** and A. C. D. **Crommelin**. Two hypotheses were considered, the one of direct and the other of retrograde motion; the question was not finally decided, but retrograde motion seemed much more probable. The orbit had 31° inclination from the ecliptic, and a period of about two years, but no definitive orbit could be obtained until the satellite had been again observed at the next opposition of the planet.—The mathematical theory of two star drifts, and on the systematic motions of zodiacal stars: A. S. **Eddington**.—The lunar bright rays: H. G. **Tomkins**. The author showed the different characteristics of the bright rays on the moon, and explained his theory that they are caused by salt efflorescence. Photographs were shown of saline regions in India and other countries, as well as specimens of saline deposits. He considered that there was evidence of a radial arrangement of terrestrial salt districts.

EDINBURGH.

**Royal Society,** May 4.—Prof. Crum Brown, vice-president, in the chair.—Sunset and twilight curves and related phenomena: D. M. Y. **Sommerville.** The objects of the paper were (1) to describe certain curves which approximate to the graphs of the time of sunset (or sunrise) and end of twilight (or daybreak) all the year round for various latitudes; (2) to tabulate the yearly phenomena of light and darkness for different latitudes under various conditions. The case of the earth was first discussed, and then the investigation was extended to cases in which the inclination to the ecliptic was given arbitrary values ranging from 0° to 90°, and in which also the same range was given to the limiting depression below the horizon of the sun's centre consistent with twilight conditions. The various possible combinations of daylight, twilight, and true night which make up any complete day were examined, and some interesting mathematical relationships obtained.—The electromotive force of iodine concentration cells in alcohol and water: Principal A. B. **Laurie.** The results show that if the E.M.F. is calculated from the mass equation constant determined by Jakowkin and the Nernst equation for osmotic pressure and E.M.F., the experimental results agree very closely where the potassium iodide is present in excess, but only approximately where the potassium iodide and iodine are present in sensibly the same proportions. In alcohol cells the E.M.F. results show a very close agreement with the Nernst equation for cells in which the potassium iodide is in excess, and also show that there is evidently a similar complex formed in the presence of alcohol as there is in the presence of water. The E.M.F. of cells in which mixtures of alcohol and water are used indicates that at 0° C. the dissociation of the potassium iodide is less for such mixtures than it is for alcohol or water, this effect disappearing at 25° C. Experiments with cells in which solutions of equal strength of iodine and potassium iodide were used, dissolved in water round the one electrode and dissolved in alcohol round the other electrode, show an E.M.F. of nearly two-tenths of a volt, the water solution being positive, and the action of the cell transferring iodine from water to alcohol and potassium iodide from alcohol to water. This alcohol-water cell has a considerable temperature coefficient, showing that heat is being absorbed during the passage of the current, but not so large as would be required by the Nernst equation if it was a purely gas-pressure cell. When connected to a galvanometer this cell gives a current for some hours.—Preliminary statement on the morphology of the cone of *Lycopodium cernuum* and its bearing on the affinities of Spencerites: Dr. W. H. **Lang.** The cone of *Lycopodium cernuum* is the most complex in the genus, but it was shown that in Spencerites certain of the most characteristic features were either distinctly visible or at any rate strongly suggested. Whatever view of their relationship be taken, there appeared to be a *prima facie* case for regarding the morphology of the cone as essentially the same in the two forms.—The origin of the adaxially curved leaf trace in the Filicales: D. T. Gwynne **Vaughan** and Dr. R. **Kidston.** As exhibited in *Thamnopteris Schlechtendali*, the leaf traces leave the stele in a thoroughly protostelic manner when free, at first appearing as an oval mass of xylem with a central protoxylem. While in this form an island of parenchyma appears adaxially to the protoxylem, which, gradually increasing, eventually displaces the centripetal xylem. By progressive stages the characteristic leaf trace becomes curved, and assumes the characteristic horse-shoe form so common to the Filicales.—A new species of Dineuron and of Botryopteris from Pettycur, Fife: Dr. R. **Kidston.**—The inca or inter-parietal bone, its homology and nomenclature: Dr. W. R. **Smith.**

May 18.—Prof. A. Gray, vice-president, in the chair.—The cohesion of steel, and on the relation between the yield points in tension and in compression: G. H. **Gulliver.** In a homogeneous isotropic solid the directions of maximum shearing stress are inclined at 45° to the directions of principal stress. Because of internal friction, the surfaces of sliding will be inclined to the direction of maximum tension at an angle which is greater than 45° by half the angle of friction. Experiments on steel bars lead to the value 0·176 for the coefficient of friction, a value which corresponds closely with the ordinary coefficient of friction for dry metallic surfaces. The shearing stress along a surface of sliding is always greater than the frictional resistance due to normal stress upon the same surface. Assuming this to be due to a cohesive force acting normally to the same surface, the author calculated the value of this cohesion for steel as being 3·384 times that which corresponds with the tension yield point, or 2·384 times that which corresponds with the pressure yield point. Experiment fully corroborated this conclusion. Experiments also confirmed the further conclusion that the fracture of a bar under tension begins in a direction normal to the axis.—The preparation of a glass to conduct electricity: C. E. S. **Phillips.** A mixture consisting of thirty-two parts of sodium silicate, eight parts of borax, and one part of Powell's glass is fused in a platinum crucible. The air bubbles are rapidly removed from the mass by means of a vacuum pump, and the resulting glass pressed into plates or cast in the usual way. The conductivity of this material is comparatively high, being about 1000 times greater at 20° C. than ordinary soda glass at 100° C. Its specific resistance is $5 \times 10^8$ ohms at 20° C. The index of refraction is 1·6, the density 2·6, and the softening point 551° C. On account of the high coefficient of expansion, viz. 0·00015, the conducting glass cannot be welded to ordinary tubing except by means of glasses with intermediate coefficients of expansion. The study of the surface changes was made by means of an electrical method depending upon the negative electrification of cadmium when in contact with a moist surface of the conducting glass. It was found in this way that the substance attracted less moisture with time, and therefore slowly improved. Some experiments were shown which proved that the glass conducts electricity through its mass, and that the effect is not merely a surface one.

PARIS.

**Academy of Sciences,** June 9.—M. H. Becquerel in the chair.—An apparatus designed for micrometric levellings: M. **Gouy.** A microscope furnished with a wire micrometer, and standing upon a tripod the feet of which are ivory points, slides on a plane horizontal disc of polished glass. The micrometer wire being first set on the object the position of which is to be measured, its position on the standard scale is found by sliding the tripod over the disc until the divisions of the scale are in focus. As showing the accuracy obtainable by this simple method, the probable error of a setting of the micrometer, the microscope remaining fixed, was found to be 0·043 $\mu$, whilst when the microscope was moved over the disc between each setting the probable error of a setting was 0·042 $\mu$.—The direct addition of hydrogen to the polyphenols: Paul **Sabatier** and A. **Mailhe.** Previous attempts to apply the Sabatier and Senderens reaction to the diphenols and triphenols have failed, due, as is now found, to the employment of too high a temperature in the reaction. At a temperature of about 130° C., in a rapid current of hydrogen, hydroquinol, pyrocatechol, resorcinol, and pyrogallol give good yields of the corresponding *cyclo*hexadiols and triols respectively. Hydroquinol gave the *cis*-quinite exclusively, and pyrocatechol and resorcinol also appeared to give the *cis*-compounds, although this point has not yet been completely proved. Since this method yields these compounds easily, and in a very pure state, a special study is being made of the properties of these derivatives.—Magnetic observations at Tananarive: E. E. **Colin.** Three tables are given showing the results of the absolute measures of declination, of inclination, and of the horizontal intensity, from May, 1907, to April, 1908.—The exact analysis of marsh gas. The dissociation of several hydrocarbons obtained in the grisoumeter and eudiometer: Nestor **Gréhant.**—The regulation of electrogenic groups: J. L. **Routin.**—The development in a continued fraction of an algebraical number: M. **Auric.**—The true cause of the doubling of the curve of loss of activity of conductors covered with a dielectric layer, rendered radio-active, and with an electric charge: Ed. **Sarasin** and Th. **Tommasina.**—The sign of electric dichroism and of magnetic dichroism: Georges **Meslin.**—The self-induction spark: André **Léauté.** The essential cause of the striæ observed for the first time in the photographs of M. Hemsalech is the existence of two circuits in parallel.—Catalytic dehydrations of organic compounds: J. B. **Senderens.** Several inorganic substances have been found by the author to possess catalytic properties, the most active being precipitated alumina dried at a temperature below a red heat. This substance at about 300° C. splits up ethyl ether into ethylene and water, acetic acid (at 350°) into acetone, water and carbon dioxide, propionic acid into diethylketone, water and carbon dioxide, ethyl acetate into water, ethylene, carbon dioxide and acetone, and ethyl oxalate into water, carbon monoxide and dioxide, and ethylene.—The action of silver nitrate upon chloroauric acid, and the preparation of fulminating gold: Jules **Jacobsen.** Pure chloroauric acid, prepared by the action of chlorine upon pure gold in suspension in hydrochloric acid, is precipitated by silver nitrate, the precipitate having the composition $Au(OH)_3.4AgCl$. A solution of ammonia removes the silver chloride from this substance, leaving a yellow, flocculent precipitate of fulminating gold. Analyses of this latter gave figures corresponding to the formula $Au(OH)_2NH_2$.—The separation of ammonia and the amines by means of boiling absolute alcohol: Jean **Bertheaume.** It is shown that this commonly used method of separation is imperfect, a determination of the solubilities of ammonium chloride and methylamine hydrochloride proving that at least 8·5 per cent. of ammonium chloride is always present in methylamine hydrochloride purified in this manner.—Contribution to the study of the artificial peroxydiastases: J. **Wolff.** A study of the oxidation of pyrogallol by hydrogen peroxide in presence of colloidal ferrocyanide of iron. The effects of the latter are shown to be in all respects comparable with those of the natural peroxydases.—A new mica of the paragonite group: Ph. **Barbier.** This mica is characterised by its proportions of soda (7·6 per cent.) and lithia (1·2 per cent. to 2·0 per cent.), the association of these two elements, sodium and lithium, being unusual. The name hallerite is proposed for the new mineral.—A certain function of hepatic replacement exercised by the feather in birds: Jean **de La Riboisière.** For any species of bird the amount of liver and feathers, referred to 100 grams of the total weight, may undergo extensive variations. But it would appear that in each species those individuals having more liver have less feathers, and reciprocally.—The *rôle* of the yeasts and the nature of the vine in the formation of bouquet in wine: A. **Rosenstiehl.**—The iron deposits of Coatquidan: F. **Kerforne.** This deposit was worked for iron ore in 1825, but after some time was abandoned. The ore is a red hæmatite, containing a considerable proportion of fine quartz grains. Its geological level is at the base of the Armorican grit.—The principles to be applied to render buildings aseismic: Montessus **de Ballore.** Armoured concrete is the best material for building purposes in countries liable to earthquakes.

## METEOROLOGY OF INDIAN SEAS.

*Meteorological Atlas of the Indian Seas and the North Indian Ocean.* Prepared chiefly by W. L. Dallas, under the direction of Dr. Gilbert T. Walker. Pp. viii+36 charts. (Simla: Published by the Meteorological Department of the Government of India, 1908.) Price 17s. 6d. net.

ALTHOUGH steam has almost entirely superseded sail for the propelling of ships, there nevertheless appears to be a steadily increasing desire on the part of sailors for accurate information relating to marine meteorology, and recognition of its importance in the interests of navigation.

A meteorological atlas, recently published by the Meteorological Department of the Government of India, should therefore be welcomed by seamen who navigate the ocean areas of which it treats.

This atlas is composed of thirty-six charts, printed in colours, beautifully finished, and accompanied with descriptive remarks. Twelve of these are designed to show the average conditions of atmospheric pressure, wind, and sea-surface currents, or "sea currents," as they are termed in this volume. The value of the charts would have been enhanced if results of air-temperature observations had been added. The effect of a prevailing wind upon mean temperature, and the relation between temperature and pressure are problems of interest to students of meteorology.

Nine charts show the monthly tracks of important cyclones, and cyclonic storms, over the Arabian Sea and Bay of Bengal; and fifteen charts the conditions prevailing, and the changes taking place, during the existence of typical storms in those areas.

The charts refer to an area embraced by the parallels of 30° N. and 12° S. lat., and the meridians of 40° E. and 100° E. long. The monthly charts of barometric pressure, wind direction, and force exhibit mean results of 8 a.m. observations (local time) for areas of 4° of latitude and 4° of longitude.

Pressure is shown in red by isobars, but is also given in tenths and hundredths of an inch, in the left-hand upper corner of each 4° square. Wind direction is indicated by an arrow in black, and wind force (by Beaufort scale) by figures at the tail of each arrow, which denote the mean force for the whole of the 4° square to which the arrow refers. The flow of the currents is shown, in blue, by wavy arrows, and the velocity in nautical miles per 24 hours is given, in most cases by figures attached.

In the directions for using the pressure data a table is given for the purpose of reducing readings of the barometer, at any hour of the day, to that of 8 a.m. For the sailor this is a useful table.

A defect in this volume is the absence of any information with respect to the number of observations upon which the results for each meteorological element is based. Wind direction, for instance, may be based on 2, 200, or more observations; they may be all for one year, or may be spread over a number of years; they may be recorded by one ship, or by many ships.

The wind arrows shown on the first twelve charts are said to represent the mean direction of the wind, but the exact meaning of the term "mean direction" is not stated. It may be the prevailing direction that is meant, or it may be the resultant wind. In any case a single wind direction in each square, either for the purposes of scientific investigation or for the uses of the navigator, is inadequate for the representation of wind distribution, even where the wind's direction is most constant. Information relating to wind frequency, in order to be of value to the sailor, should deal with the percentage of frequency of all winds within definite areas; and for the Indian Ocean, Bay of Bengal, and Arabian Sea this is essential. In order to show the march of the south-west monsoon from east to west at its commencement, the gradual changes from north-east and north-west monsoons to south-west monsoon, and the reverse, and to exhibit clearly the northern limit of the south-east trade wind, month by month, nothing short of a complete wind rose will suffice.

The wind directions and forces have been, it is stated, extracted as they stood in the ships' log-books. This may be regarded as sufficiently accurate in connection with wind direction, as the magnetic variation over the area treated is small, and the deviation of ships' compasses is now usually kept within negligible limits; but as regards wind forces it is otherwise. The objections in this respect to the method adopted are, however, recognised, and are alluded to as follows:—

"They may represent the ordinary force of the wind, over the square to which they refer, or they may arise as the average of winds of widely varying velocities."

To meet this difficulty the sailor is referred to the remarks for the month, given in the pages opposite the charts; but it seems doubtful whether these remarks will help the sailor much in all cases, as only the most general information is given in this connection. Owing to the absence of information as to the number of observations on which each wind arrow is based, it is not possible to compare the direction and force of the wind in one square with those of another, or to estimate the chances of experiencing any wind other than the mean wind in any particular square.

The information relating to surface currents has been copied, it is stated, from the "Monthly Current Charts for the Indian Ocean," issued by the Hydrographic Department of the Admiralty. The charts dealing with the track of storms, and those illustrating typical storms in the Arabian Sea and Bay of Bengal, in different seasons of the year, should prove exceedingly valuable to the sailor, especially the former.

It is to be regretted that in this work the term "cyclone," used by most meteorologists to define a characteristic distribution of pressure and wind, has been employed instead to express the force of the wind in a tropical revolving storm. The term was originally adopted by Piddington in his "Sailors' Horn Book"

(1848), when, in reference to the classification of winds, he says:—

"I suggest that we might for this last class of circular, or highly curved winds, adopt the term 'cyclone,' from the Greek κυκλος (which signifies, amongst other things, the coil of a snake), as neither affirming the circle to be a true one, though the circuit may be complete, yet expressing sufficiently the *tendency* to circular motion in these meteors."

In the volume under notice the definitions given in this connection are as follow:—

"A cyclonic circulation in which the winds do not exceed force 10 is termed a 'cyclonic storm,' while a circulation in which the winds are of hurricane force, 11 to 12, is called a 'cyclone.'"

According to the Beaufort scale, storm force is expressed by the number 11; while employing this scale, is it not illogical to define a circulation, in which the winds do not exceed 10, as a "cyclonic storm"?

The copious remarks which accompany the charts are interesting and instructive, and add greatly to the worth of the volume. M. W. C. H.

## A TEXT-BOOK OF TROPICAL MEDICINE.

*Tropical Medicine, Hygiene, and Parasitology.* A Handbook for Practitioners and Students. By Gilbert E. Brooke. Pp. xvi+498. (London: Charles Griffin and Co., Ltd., 1908.) Price 12s. 6d. net.

THIS is a volume of the well-known medical pocket-book series, and corresponds in size and binding to Davies's "Handbook of Hygiene." It is a book of five hundred pages, and is divided into four sections.

The first section deals with the hygiene of the tropics, and discusses climate, food, exercise, clothing, hygiene of the mouth, pregnancy, and infant feeding in the tropics. The information and advice given in this section are useful and practical. For example, in regard to alcohol the author is of opinion that while it is not absolutely necessary for a man in any climate, a small quantity well diluted is often beneficial in the tropics. Most experienced travellers will agree with this, since the debility and consequent want of appetite brought about by tropical heat renders the stimulating effect of alcohol more necessary in warm than in temperate climates. Three ounces of whisky in the twenty-four hours is stated by the author to be the maximum which should be taken by a man in health. This will be thought by many dwellers in the tropics to be a counsel of perfection, but certainly the advice is sound, practical, and necessary. In regard to mosquito-bite prophylaxis, Dr. Brooke recommends various external applications; but surely experience teaches that these are of little or no practical use. The best protection is a good mosquito net. The author, speaking of mosquito nets, rightly says that the net in common use is a snare and a delusion. The best plan certainly is to have a permanent mosquito-proof room, which can, if necessary, be rigged up with ordinary mosquito-netting at the cost of a few shillings. In this room, or part of a room, there should only be a bed, a table, and a lamp. If one has to dine out where mosquitoes are numerous, a pair of Wellington boots may be found more productive of a calm, equable mind than the ordinary silk socks and pumps of fashion. Dr. Brooke seems to be of opinion that tropical medicine is something quite different from the medicine taught in the schools, and that no one can pretend to treat these diseases unless he has had special training. There seems to be too much made of this nowadays. Surely with a five years' curriculum it should be possible to teach a student the art of medicine sufficiently thoroughly to enable him to recognise a new disease when he comes in contact with it for the first time! A carpenter is not supposed to have made everything during his apprenticeship. He is taught the principles of his trade, and afterwards applies them to his daily work, whatever it may be.

The second section deals with medico-biology, and includes the classification of animal and vegetable parasites, notes on tapeworms, nematodes, mosquitoes, fleas, ticks, and snakes. Here also a great deal of useful information is compressed into some eighty pages; and there are several plates giving figures of the ova, larvae, and worms most commonly met with. Of course, as is unavoidable in the compilation of a text-book, more or less trivial errors are apt to creep in, such as the name *Streptococcus pyogenes aureus*, or the assertion that *S. scarlatinae* is the cause of scarlet fever, or that the tsetse-flies act as hosts in the spread of *Piroplasma bigeminum*, and such-like slips of the pen; but these do not really take away from the general usefulness of the section.

The third section is devoted to the description of the etiology, symptoms, and treatment of tropical diseases. These are arranged alphabetically, which arrangement has little to commend it, especially as the author has tried his hand at nomenclature and evolved two new names for sun-stroke, Phœbism and Diathermasia! On the whole, the descriptions of the various diseases are clearly given and well illustrated. In a rapidly progressing subject such as that of tropical diseases is at present, it is scarcely possible for a text-book to be quite up-to-date. In the description of dengue, for example, there is no notice of the recent important work which has been done in the etiology of this disease. In Malta fever it is stated that the method of transmission of the disease is uncertain. That is not so. This was clearly established two years ago, when it was shown that Malta fever is carried from infected goats to man through the medium of milk. Since goats' milk was banished from the dietary this fever has practically disappeared from the English garrison in Malta. This fact should be placed in the forefront of the description, and everything else made subsidiary to it. Again, what is the use at the present day of writing that Manson considers the weight of evidence to point to its diffusion by air-currents rather than by food and water? This is an old speculation which ought to be decently buried and forgotten. Further, more than half a page, in the account of the same fever, is devoted to describing some experiments carried out by two naval surgeons. These experiments ought not to have been made, for several reasons. These gentlemen had no right to risk their lives or health without sufficient reason while in the public service. It was unnecessary to carry out the experiments on man, as lower animals were available. Even if one or both had taken the disease, the experiments would have been useless, as they were living in the endemic zone and liable to take the disease naturally. What was the use, for example, of two non-immunes drinking urine from a case of Malta fever if they neglected in the first place to demonstrate that the urine contained the *Micrococcus melitensis?* As only one sample of urine in ten contains the cocci, it was ten to one against their taking the disease. Such thoughtless experiments ought not to be encouraged by being recorded in text-books as praiseworthy actions or serious attempts in the investigation of disease. With the exception of slight blemishes such as these, which, indeed, are inseparable from text-books, the descriptions of the various tropical diseases are good, and some are excellent. Especially is the description of the symptoms and treatment of these tropical maladies quite practical and useful.

The fourth section is taken up with practical hints in microscopy, photography, disinfection, examination of blood, &c. This part of the book contains much sound advice on the best microscopes and cameras for tropical work, on stains, staining methods, modes of preparing blood and tissues for examination, and should prove very useful to medical men in out-of-the-way places out of touch with books and laboratories.

The book concludes with several appendices on sanitary conventions, vegetable poisons of the tropics, how to collect flies, ticks, &c.

This text-book on tropical medicine can be confidently recommended to colonial surgeons and medical officers of the British and Indian Services as containing a vast amount of data from various sources, with practical hints from the author's personal experience and observation, which makes it an admirable *vade mecum* when the exigencies of travel render the carriage of several books impossible.

DAVID BRUCE.

## A MONOGRAPH OF BRISTLE-WORMS.

*A Monograph of the British Annelids.* Vol. ii., part 1. Polychæta, Nephthydidæ to Syllidæ. By Prof. W. C. McIntosh, F.R.S. Pp. viii+232+lxx plates. (London: Dulau and Co., 1908.) Price 25*s*. net.

WHEN Huxley was appointed professor in the Jermyn Street School of Mines, his first great scheme was the publication by Government of a zoological coast survey of Great Britain, and one of the first groups to be selected was this one of the Annelids. Unfortunately for biology that scheme was never carried out, and the opportunity that presented itself some fifty years ago of obtaining State assistance for what was truly a State work has not recurred. Not only has the publication of systematic coastal work been left to isolated ventures, but many groups, and the Annelids among them, have been so little studied on our own coasts that the work of naming any of the most common littoral species (except perhaps the lugworm) is out of all proportion to the value of its determination. Yet these Annelids are not only of great interest to the zoologist, but, as forming one of the chief foods for fish, they are among the most important factors in the welfare of our fisheries. The Ray Society and the Carnegie Trust are therefore to be congratulated on the issue of another section of this great monograph, which they have subsidised. Prof. McIntosh is known and read of all students of biology, and his unwearied devotion to this work, his wide knowledge, and long experience of these Annelids constitute him a master. He, perhaps of all men, was the only one who could write this work, and the completion of his monograph begun so many years ago is indeed a consummation devoutly to be wished. May he have the health and assistance necessary to that end.

The present instalment contains a systematic account of six families. Its most striking feature lies in the coloured plates drawn by the author's sister, the late Mrs. Günther, and the artist Miss A. H. Walker. These presentations of Phyllodocids, Hesionids, Nephthyds, and Syllids are most beautiful, and suggest many problems of coloration and of movement that are not referred to in the text. The fine green colour of many Phyllodocids tingeing even their egg-masses, the prevalence of segmental spots in most families, and the significance of varietal colorations, are subjects on which we possess very little organised knowledge, for if the systematic study of Polychæt Annelids has been neglected in this country, the bionomics and physiology of the groups have been left to a few Continental observers. It is to be hoped that the issue of this work will stimulate the study of the group in these directions.

There are two serious drawbacks to the value of this work which a little trouble could easily have obviated. If one wishes to find out what families, genera, and species are described in this part, there is no means of doing so except by wading through the text. A table of contents is not much to ask for, but it has been omitted, and as there is no index the labour of finding out what there is in the work is quite needlessly enhanced. The headings of the left-hand pages might well have given the family name under consideration instead of the species as at present. The second drawback is the binding of six extraneous plates right in amongst those proper to the part, sandwiched in between those illustrating two other families. These intrusive plates evidently belong to a later section of the work; yet we find no reference to their presence, and the confusion that is likely to arise ought to induce the council of the Ray Society to take some steps in order to avoid the repetition of, and if possible rectify, what we presume must be an oversight.

To turn from matters of editorial criticism, we are glad to see that Mr. Goodrich has given his skilled assistance and expert knowledge of the nephridia of these animals, so that these organs are adequately referred to and figured in the text. The references to other recent work on this subject show that not only the merely diagnostic literature, but all that bears upon the subject, has been exhaustively studied.

Among the most interesting sections is the one bearing on the Syllids. It has long been known that these Annelids are capable of asexual reproduction, and that the buds so formed, on assuming maturity, carry their eggs attached to their feet. Prof. McIntosh refers to several interesting cases of bud-formation. Certain American species of Trypanosyllids, for example, give rise to lateral buds, the stock assuming a frond-like appearance. Mr. Crossland has found an East African Syllid which has a crown of buds at its hinder end, and other species which are parasitic on Nemertines, Polychæts, and other hosts. There are some thirty representatives of this family already known from British waters, and their description and changes of form on assuming maturity are fully dealt with.

The distribution of these Polychæt Annelids will undoubtedly form a most interesting mass of evidence when it is collated. In its present form no conclusions can be safely drawn. We can only say that many species have a very wide range, extending to both sides of the Atlantic, and occurring as far north as Greenland and as far south as the Falkland Islands, whilst in some cases the same species is found both in the Atlantic and in the Indian Oceans. It is also clear that the British Polychæt fauna is probably as rich in specific variety as that of any other coasts so far explored. The coasts of Ireland, though not so thoroughly worked as those of the Channel or of the east of Scotland, have yielded many interesting forms, and the careful comparison which the author has instituted between specimens from different localities and between those of our own and of other coasts is but one instance of the careful discrimination and comparison which distinguish the work. We are glad to see that another part is ready for press, and we hope that financial aid will be forthcoming to complete this monograph.

## DIRECT-CURRENT ELECTRICAL ENGINEERING.

*Principles of Direct-current Electrical Engineering.* By J. R. Barr. Pp. viii+454. (London: Whittaker and Co., 1908.) Price 10s. net.

As the author states in the preface, this treatise was primarily written for the use of intermediate classes in universities and technical colleges, and is based on his lectures to second-year students. It is intended to bridge the gap between the several elementary manuals and the many works on special branches, and in this object the author has succeeded admirably. During the last few years innumerable books dealing with direct-current electrical engineering have appeared, but they are either too elementary or else too highly specialised. This book deals chiefly with principles, but the author has kept not only the theoretical, but also the practical side of the question well in view.

The first two chapters are devoted to the units employed in electrical engineering and the fundamental principles, such as Ohm's law, the heating effect of currents, &c., while the third chapter deals with electromagnetism and the magnetisation of iron. The latter chapter gives the student a clear insight into the magnetic quantities underlying the design of dynamos and motors. A short description is given of Ewing's hysteresis tester and permeability bridge, and the method of using it.

About sixty pages are occupied with a discussion of electrical measuring instruments. The principles governing the construction of ammeters, voltmeters, wattmeters, and electric-supply meters are set out in a clear and practical manner, and even maximum-demand indicators are briefly touched upon.

Two chapters treat of storage batteries and electric lighting, but these are rather disappointing. Surely the short section dealing with metallic filament lamps might have been amplified with some advantage, especially considering the enormous progress made in illuminating engineering. It is, further, somewhat out of date to take up a section with a discussion of 37-volt osmium lamps. Practically speaking, these lamps are not used at all, and in all probability their manufacture has been abandoned for some time. It would have been better to have given us particulars about the osram, wolfram, tungsten, and zircon-wolfram lamps, which are now made for 250-volt circuits, and are of great practical importance. Open, enclosed, and flame-arc lamps are briefly touched upon, as well as illumination and photometry, but on the whole this chapter is, as already said, rather unsatisfactory.

Overhead and underground conductors, and the principal methods of laying cables, as well as the calculation of voltage drop in conductors, are next described in about forty pages.

The last six chapters of the book are devoted to dynamo-electric machinery, its construction, design, and operation, and these chapters are undoubtedly the best in the book. The construction of armatures, commutators, and brushes is very fully dealt with, and the use of coloured diagrams used for illustrating the various methods of armature windings should be extremely useful to students. The theory of the magnetic circuit is gone into very carefully, and it will give the student a clear insight into the calculations required for the design of dynamo-electric machinery.

The methods of determining characteristic curves, parallel operation, and methods of voltage control are also considered, while one chapter deals with motors and controllers. The section on testing is very brief, and it is hoped that in a next edition this may be somewhat enlarged.

In the last chapter we come to the subject of electricity control, and the author enters fully into the points connected with switchboards. The section dealing with fuses, circuit-breakers, lightning arresters, and switches is excellent, and contains a large amount of practical information. Various examples of switchboard designs, illustrated by working drawings, complete a very interesting chapter. At the end of the book there is an appendix containing practical problems to be worked by the students.

The author is to be congratulated upon the work which he has produced. It is not too practical or too theoretical, but contains just the information which a second-year student wants. The book is well printed, and contains a great many working drawings and diagrams. It is hoped that the author may find time some day to write a companion volume on alternating-current electrical engineering.

L. C.

## EDUCATION AND EMPLOYMENT.

*A Handbook of Employments.* Specially Prepared for the Use of Boys and Girls on Entering the Trades, Industries, and Professions. By Mrs. Ogilvie Gordon. Pp. 444. (Aberdeen: Rosemount Press, 1908.) Price 1s. net.

THE system of apprenticeship, which has been so largely instrumental in producing and maintaining the highly skilled workmen for which English industry has always been famed, is slowly but surely dying out. Especially in the large towns, it is more and more difficult to find employers who are willing to take bound apprentices; they complain that such apprentices take little interest in their work, are not so willing or anxious to please as boy labourers, and that the high rents they have to pay in towns make their bench room so expensive that in these days of keen competition they cannot afford to take apprentices.

On the other hand, there are so many ways in which boys from fourteen to eighteen can earn comparatively high wages in unskilled employments, that the temptation to their parents to abandon any attempt to apprentice them and to make them immediate wage-earners is very strong.

To endeavour to counteract these tendencies, several local authorities have started some form of industrial or trade school, and although these will never probably take the place of apprenticeship, as the conditions in a school can never be the same as in the shops, they will help to stimulate the interest of the boys in manual pursuits, and so form a strong incentive to learn some trade; and they will also make the trade easier to acquire by the training of eye and hand they have received in the school, as well as by the knowledge they have acquired.

These schools may therefore be expected further to increase and develop, and may become gradually a necessity of our industrial system. But whereas the old apprenticeship system automatically regulated the supply to the demand, any artificial system of drafting boys into given trades will need careful control.

The introduction to Mrs. Gordon's book is most interesting and suggestive; the twenty pages show that the writer has not only given great attention to the problems of employment, but has also been in close touch with them in their most important aspects. Mrs. Gordon strongly urges the formation of employment bureaux to give information as to the local prospects of employment, the remuneration offered and prospects of advancement, the qualifications required for the various occupations, and the facilities offered in technical and continuation classes. It is suggested that these bureaux should be managed by committees, on which the education committee, the town or borough council, chamber of commerce, and association of social workers should be represented. We would suggest the addition of employers of labour. A scheme for such a committee is given, from which it appears that the probable cost of a bureau would be between 150*l.* and 250*l.* per annum. For the reasons given above, in addition to those Mrs. Gordon puts forward, we believe that bureaux on some such lines as these will gradually become a necessary part of our educational system.

The remainder and greater part of the book (some 400 pages) is the result of inquiries undertaken in four of the large cities of Scotland as to the conditions of employment in some seventy-six industrial occupations requiring short periods of training, and more than 100 industrial and professional occupations requiring long periods of training. The inquiries were made voluntarily in Glasgow by Mr. R. H. Tawney, an assistant in the Glasgow University, in Edinburgh by Miss Chrystal Macmillan, in Dundee by Mrs. Carlaw Martin, and in Aberdeen by Mrs. Elliot Ogston Clark; and although, necessarily, some of the results are chiefly of local interest, the greater part, with slight modifications of hours and wages, remain true of any district, and the whole forms a most valuable handbook, giving in an easily accessible form the main features of almost every trade and profession.

## OUR BOOK SHELF.

*Self-Instruction in the Practice and Theory of Navigation.* By the Earl of Dunraven, Extra Master. Revised and enlarged edition in three vols. Vol. i., pp. xxvii+272; vol. ii., pp. ix+337; vol. iii., pp. ix+340. (London: Macmillan and Co., Ltd., 1908.) Vols. i. and ii., 17*s.* net; vol. iii., 8*s.* 6*d.* net.

EIGHT years ago the Earl of Dunraven wrote a work in two volumes on the theory and practice of navigation. It was an extraordinary, but in some respects an excellent book. It was extraordinary in the sense that the author had, as he frankly admitted, no great store of information beyond that necessary to satisfy the nautical examiners of the Board of Trade for an extra master's certificate. But if he made little attempt to probe the theoretical principles upon which the practice of navigation rests, he had mastered very thoroughly that portion of the science into which an examiner might inquire. It was an excellent book, because the author knew how to teach; he had the art of successfully conveying to the pupil just that amount of information which would carry him through the ordeal of examination, and we have no doubt that many who write themselves "Extra Masters" are indebted to Lord Dunraven for this qualification. When the choice of a teacher lies between the man of acknowledged mathematical capacity who cannot teach and the indifferently equipped man who can, it is, for the purposes of examination, better to fall into the hands of the man of moderate acquirements.

But there came a time when the Board of Trade raised their standard. As Lord Dunraven puts it, "the Board of Trade in their infinite wisdom decreed that a master mariner . . . must not only be a past-master in the art of navigation, but must also qualify as a naval architect and shipbuilder, be an accurate cartographer, and well advanced in mensuration and mathematics." What was to be done? Lord Dunraven tells us that he does not pretend to be a master of any of these subjects, but he was determined that his book should do for the extra masters of the future what it had done for those in the past, so he heroically mastered the necessary amount of information, increased his book to three volumes, and brought it up to date.

We have no hesitation in saying that the same capacity for imparting the precise information which characterised the earlier edition is equally noticeable in this. The arrangement of the contents is not materially different. In the first volume we have a good deal of elementary preparation that ought to have been acquired in school, and some technical problems, including the use of the compass under various conditions and a review of the law of storms. The second volume is more particularly devoted to the problems of nautical astronomy, which are necessary in order to obtain a master's certificate. In the third volume we climb to that dazzling height the attainment of which entitles the ambitious plodder to the coveted "blue ticket" of an extra master. There are not only a great many examples given the working of which would be advantageous, but many useful hints that it would be unwise for the intending candidate to neglect.

*The London Catalogue of British Plants.* Tenth edition. By F. J. Hanbury. Pp. 48. (London: George Bell and Sons, 1908.) Price 9*d*.

Since the ninth edition of the "London Catalogue" was published in 1895, important events in connection with the nomenclature of British plants have occurred. At the Vienna congress, rules with regard to priority and other matters were framed, and hardly less important for the "London Catalogue" was the publication of the ninth edition of Babington's manual and other special works on British plants. The chief credit for the present revision is assigned to Mr. W. A. Clarke and the Rev. E. S. Marshall, but various specialists have contributed revisions of genera or sections. The number of plants enumerated in the "Catalogue" is appreciably greater than the list issued from the Natural History Museum, since, according to the preface, it aims at providing a useful working list. Although both lists are compiled on similar lines, it will be found that the species under critical genera, such as Ranunculus, do not coincide, whence it need only be concluded that experts still agree to differ.

*Jahrbuch der Naturwissenschaften*, 1907–1908. Edited by Dr. Max Wildermann. Pp. xii+509. (Freiburg: Herdersche Verlagshandlung, 1908.) Price 7·50 marks.

This is the twenty-third issue of a year-book in which progress in various branches of science is described in a series of articles by different authors, with references to the original publications abstracted. The subjects are dealt with under (1) physics; (2) chemistry; (3) astronomy; (4) meteorology; (5) anthropology, ethnology, and archæology; (6) mineralogy and geology; (7) zoology; (8) botany; (9) forestry and agriculture; (10) geography; (11) hygiene and medicine; (12) applied mechanics; (13) technology; (14) miscellaneous reports. In addition, the volume contains summaries of celestial phenomena observable from May 1, 1908, to May 1, 1909, short obituary notices of men of science deceased in the year surveyed, and an author-and-subject index.

The volume should be of service as a general record of scientific work of which accounts have appeared in periodicals and the publications of societies.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

### Prominence and Coronal Structure.

In a paper communicated to the Royal Society in December last (Roy. Soc. Proc., A, vol. lxxx., p. 178), an abstract of which appeared in this journal (vol. lxxvii., p. 314, April 2), I directed attention to a peculiar form of prominence which had been photographed with the spectroheliograph of the Solar Physics Observatory in the "K" light of calcium. This prominence, situated towards the south pole of the sun in the *eastern* quadrant, about position-angle 137°, was recorded on two separate negatives taken at the times 3h. 14m. p.m. and 3h. 50m. p.m. G.M.T. on July 17, 1907. Although on each photograph images of other prominences were recorded, no particular attention was directed to them, as they did not present any unusual features. It may, however, be incidentally remarked that the most intense prominence recorded on both the photographs, and situated near the south pole in the *western* quadrant about position-angle 218°, was reproduced in the paper in Plate iii., Fig. 5. I did not

Fig. 1.—The prominences on the Sun's limb photographed in calcium light on July 17, 1907, 3h. 14m. p.m. G.M.T., at South Kensington.

think it necessary for the purpose of that communication to reproduce the whole limb of the sun, but confined myself to the disturbed area in the south-eastern quadrant. The presence of a large prominence in the south-western quadrant has raised questions of identity, so the complete limb is now here reproduced (Fig. 1) to show the relationship between the two prominences and the sun's south pole.

In April last I received from Mr. Philip Fox, of the Yerkes Observatory, U.S.A., a communication in which he wrote:—

"The large prominence which you discuss certainly has curious form. I have examined my plates for July 17, 1907, and find no prominence of unusual form near the south pole in the eastern quadrant, but there is a beautiful one near the pole in the western quadrant at position-angle 215°. I am wondering if by chance you have given the wrong quadrant and if our prominences are identical. I made my exposure at 5h. 56m. p.m. G.M.T."

On both the Kensington negatives there is a large prominence in the south-western quadrant at about position-angle 218°, and it is intense and shows little indication of diminution in brightness. This is, no doubt, the prominence referred to by Mr. Fox, who gives 215°

as its position-angle; its form has, however, considerably changed in the interval of time between the exposures. Mr. Fox kindly forwarded me a photograph of this prominence, which is here reproduced (Fig. 2), and he oriented it in the corner on rather a small scale. This orientation is reproduced by me on a larger scale in white

FIG. 2.—The large prominence in the south-west quadrant, photographed in calcium light by Mr. Philip Fox on July 17, 1907, at 5h. 56m. G.M.T., at the Yerkes Observatory, U.S.A.

on the photograph. It will be noticed that the upper portion of the prominence is directed from the south towards the west, but in the Kensington photograph (Fig. 1), and also in Prof. Hale's (Fig. 3), the material is directed from the west towards the south. The question arises, is Mr. Fox's orientation right (his position-angle is correct), or has the material altered its position between the times

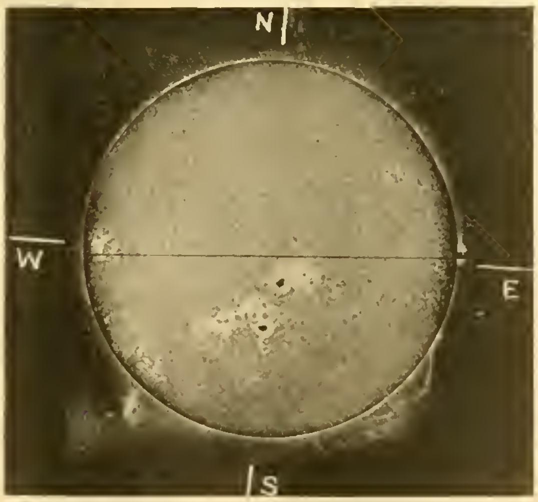

FIG. 3.—The Sun's disc and prominences on the limb, photographed in calcium light by Prof. Hale on July 17, 1907, at 2h. 46m. p.m. G.M.T., at Mount Wilson, U.S.A.

the photographs were taken? I am rather inclined to question the orientation.

Directing attention now to the triple arch prominence about position-angle 137°, which was shown in the first of the Kensington negatives (Fig. 1), I pointed out that in the second photograph, taken thirty-six minutes later, only remnants of the system remained. So rapidly did the whole of this disturbed region wane in intensity that it is not astonishing to hear that two hours later Mr. Fox reported that no prominence of unusual form was there.

The recent communication to this Journal (vol. lxxviii., p. 151, June 18) by Mr. A. A. Buss is of great interest to me, because it made me acquainted with a photograph, secured by Prof. Hale, of the same prominence taken half an hour previous to the first Kensington picture. Through the courtesy of Mr. Newbegin, jun., I received a copy of this very interesting photograph, and one is now able to follow more accurately the sequence of events in the disturbed area. I hope Prof. Hale will forgive me for reproducing his photograph here (Fig. 3), but it is only by showing the two photographs together that a satisfactory comparison can be made. I have ventured to insert the orientation on Prof. Hale's photograph in order to render the identification of the prominences more easy.

The most striking difference between the two photographs is, apart from their form, the great intensity of the large prominence in the south-east quadrant in Prof. Hale's picture (2h. 46m. p.m. G.M.T.) and its comparative faintness in that obtained at Kensington (3h. 14m. p.m. G.M.T.); other prominences are of about the same intensity in each. This diminution of brightness indicates how rapidly the prominence must have waned during the twenty-eight minutes' interval between the exposures. The second photograph taken at Kensington (3h. 50m. p.m. G.M.T.) showed that this rapid waning had continued.

According to Mr. Buss's visual observations, made between 1h. 30m. and 2h. 20m. p.m. G.M.T., *i.e.* before Prof. Hale's photograph was taken, the disturbance as a whole commenced at about position-angle 112°, where an eruptive prominence was situated. The material from this prominence was ejected towards the south pole, dissolving, as he describes, "from a stout, dense and bright stem into a number of bright, more or less parallel layers of striæ." This appearance is shown in Prof. Hale's photograph, but when the Kensington photograph was taken it had assumed the form of concentric arches. These additional facts make me endorse Mr. Buss's opinion, that is, that it is unnecessary to assume that the *material* forming the arch system *originated* from a disturbance below it, or, as I stated in my paper, that "their concentric nature seems to suggest that they were produced at one point of initial disturbance and then moved radially outwards."

It may be added that these new facts in no way invalidate the conclusion drawn in my paper, which was that envelopes, similar in form to those photographed during eclipses, had been recorded in calcium light, thus strengthening the view that they were composed of prominence and not coronal matter.

WILLIAM J. S. LOCKYER.

## Mendelism: a Personal Explanation.

I SHOULD be glad if room could be found for this small matter of personal explanation. I fear I may have misled one or two of your readers on a minor point. Those of them who are interested in the interpretation of hereditary phenomena may remember that in the number of this Journal for September 12, 1907, Mr. Punnett took a reviewer to task for saying that "No one has repeated Mendel's experiments with the deliberate intention of testing the Mendelian interpretation" (of the phenomena of inheritance). In my reply I was not content with defending my original position by justifying that statement; but I must needs carry the war into the enemy's country by taking Mr. Punnett to task for not including de Vries's papers in his list of memoirs dealing with repetitions of Mendel's actual experiments, in order to show how familiar I was with the literature of the subject.

I wish to say that if I had been as familiar with the literature of the subject as Mr. Punnett was, I should not have taken the offensive. Mr. Punnett was quite right in not including a reference to de Vries's papers, because Prof. de Vries, though he has watched the results of crossing in other plants, has not worked with peas. I was misled by the commonly repeated statement that

Mendel's papers were re-discovered, and his results confirmed, at the beginning of this century, by Tschermak, Correns, and de Vries, into believing that de Vries had repeated Mendel's experiments on peas; and I rashly assailed Mr. Punnett for not making any reference to papers which I had not read. Mr. Punnett was therefore entirely in the right, and I was in the wrong.

Mr. Lock has also pointed out to me that an experiment, almost identical with the kind of crucial one which I said ought to be performed, has already been done. I am familiar with the experiment to which Mr. Lock refers (one of his own with maize), and though I regard it as very strong evidence in favour of the Mendelian interpretation of hereditary phenomena, I am sure that Mr. Lock will agree with me that an experiment the results of which will be obtained in September, 1909, is an even more crucial one. A. D. Darbishire.

## THE RESEARCH DEFENCE SOCIETY.

THERE is evidence of a growing feeling among members of the medical profession that the time has come to disperse the atmosphere of mystery which has hitherto attended their ministrations, and to take the public more into their confidence as to the principles on which health may be preserved or regained. They have every reason to believe that the popular ignorance of medical science not only hinders the progress of hygiene and therapeutics, but also is the soil on which quackeries of all kinds grow and flourish, and that the education of the laity in the elementary principles of medicine would conduce to the public health, and at the same time benefit the physician by freeing him from the competition of the incompetent and unscrupulous.

One of the noisiest sections of the opponents of scientific progress is formed by the numerous small societies the object of which is stated to be the further limitation or the complete prohibition of experiments on animals. It might seem that the evidence given before the Royal Commission on Vivisection would suffice to demonstrate the benefits accruing to humanity from the use of this experimental method in the past, as well as to indicate that its prohibition would relegate medicine to the slow advance it made in the Middle Ages. But it is felt that only a small fraction of the public has the courage to seek knowledge in a Blue-book, and that to reach the multitude information must be conveyed in a less unprepossessing guise.

With this object in view, the Research Defence Society has been formed, with Lord Cromer as president, "to make known the facts as to experiments on animals in this country, the immense importance to the welfare of mankind of such experiments, and the great saving of human life and health directly attributable to them." In his letter to the Press announcing the formation of the society, Lord Cromer directs attention to the evidence given before the Royal Commission that "these experiments are conducted with proper care, and that the small amount of pain or discomfort inflicted is insignificant compared with the great gain to knowledge," and states that the society will "endeavour to make it clear that medical and other scientific men who employ these methods are not less humane than the rest of their countrymen, who daily, though perhaps unconsciously, profit by them." With this object the society proposes to publish articles, to give information to all inquirers, and assist all who desire to examine the arguments on behalf of experiments on animals.

The founders of the society ought to be gratified by the success which has already attended their efforts, for it numbers more than 1200 members, of whom 100 are ladies, and this membership has been drawn from all departments of public life, and includes representatives of every class, including many who have taken an active part in the prevention of cruelty to animals. The medical profession is naturally largely represented, but the great number of members who appear to have no direct connection with either medicine or science indicates that there is a wide-felt impression that the methods adopted by the opponents of vivisection are objectionable, and that they have failed to justify their criticisms of this method of investigation.

The society has lost no time in opening its crusade, for we have already received two pamphlets published under its auspices. The first of these comprises "The Evidence of Lord Justice Fletcher Moulton before the Royal Commission on Vivisection" (Macmillan and Co., Ltd.), and the society is to be congratulated on having had this extremely valuable presentation of the principles of the question available as an introduction to its promised series. For, while the other witnesses on the scientific side were by the nature of things compelled to limit their evidence to a detailed account of the methods adopted in their special branches and the results accruing from them, Lord Justice Fletcher Moulton was able to take a wider view, and pointed out with indisputable logic that the experimental method offers the only way to advance in medical as in other scientific subjects. Far from questioning the justification of using animals for experimental purposes, he holds that it is actually immoral to test any method of treatment in man until it has been ascertained as far as possible by investigations on animals that it may be used without injury. As for the suggestion that investigators should experiment upon themselves, he considers that this is to be deprecated except after full investigation by means of animal experiments, not only on account of the danger to the individual subject of the experiment, but because such a procedure tends to lessen the feeling of the sanctity of human life.

The great value of Lord Justice Fletcher Moulton's evidence has been recognised by all who are interested in the subject. He was the only layman who appeared before the Commission in defence of scientific method, and he has presented his views with a cogency which must convince anyone who is capable of following a simple line of argument, and has not abandoned common sense and ordinary logic.

The second pamphlet is by Colonel David Bruce, and is entitled "The Extinction of Malta Fever (a Lesson in the Use of Animal Experiment)" (Macmillan and Co., Ltd.). It forms an admirable complement to the first, for while Lord Justice Fletcher Moulton is largely concerned with the ethical considerations involved in vivisection and the general principles of scientific investigation, Colonel Bruce gives a concise account of one case in which these principles were applied with remarkable and indisputable benefit. Malta fever formerly accounted for about 75,000 days of illness each year in the garrison at Malta, and hundreds of officers and soldiers had to be invalided to England as the result of its ravages. The old statistical methods had been applied for many years, but had failed to give any clue to the cause of the fever, and no improvement resulted from improved sanitation. Finally, the Government induced the Royal Society to send out a commission under Colonel Bruce to investigate the subject, and they soon satisfied themselves by experiments on animals that the cause of the fever is a micrococcus which gains entrance to the human body by means of the goat's milk, which is largely consumed in the island. About half the goats in Malta harboured the microbe, and 10 per cent. of them secreted it in their milk. Measures were at once taken to prevent further infection of the garrison by this vehicle, and the results are strikingly displayed in two charts. In 1905 the number of cases was 643; in 1907, after the preventive measures came into force, seven cases were admitted from Malta fever. Surely further argument is unnecessary to prove the value of the method which can adduce such results.

On June 19 the Research Defence Society held its inaugural meeting in the hall of the Royal Society of Medicine, 20 Hanover Square. There was a very gratifying attendance of members, nearly half those present being ladies. The honorary secretary of the society, Mr. Stephen Paget, read the report of the committee, and stated that he had received a number of letters from members regretting their inability to attend the meeting. The Earl of Cromer, the president of the society, was in the chair, and delivered a very telling speech, which has appeared in the daily Press, and which was directed to show that there is little or no pain inflicted in the methods used in experiments on animals in this country, and that in this way alone is there any prospect of further advance in medicine. The first motion approving of the aims of the society was moved by Sir Thomas Barlow and seconded by Lord Robert Cecil; the second one, approving of the formation of branches, was moved by Mr. Walter Long, who, referring to his experiences in stamping out rabies, stated that he was inspired to do so only by his faith in Pasteur's results, and was seconded by Prof. C. J. Martin. The very successful meeting was closed by a vote of thanks to the president for his speech, and for the keen interest he took in the society, which was moved by Mr. Butlin and seconded by the Hon. Sydney Holland.

## *ARTIFICIAL DIAMONDS.*

FOR some time past the daily Press has been interested in the production of diamonds artificially. Long articles have been written upon the subject, and various persons, scientific and otherwise, interviewed, owing to the prosecution of M. Lemoine by Sir Julius Wernher on account of his failure to produce diamonds by chemical means after he had stated he was able to do so, and, in fact, had promised to produce diamonds of very large size at a price which would compete readily with the natural product. However, after obtaining large sums of money to build a factory, and apparently carrying out experiments in which small diamonds were supposed to be obtained, M. Lemoine entirely failed to produce large ones. When diamonds said to have been produced in the crucibles were critically examined, experts were able, not only to assure the magistrate that these diamonds were not artificial, but were also able in several cases to identify them as stones which had been bought from known sources. The whole case hinged upon a certain envelope which was originally lodged in an English bank, and in which it was stated a formula was contained by means of which diamonds could be produced artificially. On Tuesday, June 16, this envelope was to be opened before the magistrate, but in the meantime the modern alchemist had vanished. When the letter was opened, according to the *Times* of June 18, the following particulars were found:—

"I, the undersigned Henri Lemoine, declare that to make artificial diamonds, it is sufficient to employ the following process:—(1) take a furnace; (2) take some powdered sugar carbon; (3) place the carbon in a crucible; (4) place the crucible in the furnace and raise the temperature to from 1700° C. to 1800° C. in order to obtain crystallisation; (5) when this high temperature has been obtained apply pressure to the cover of the crucible. The diamonds will then be made, and it remains only to take them out."

From this it will be noticed that the formula contains absolutely nothing new; sugar carbon, being the purest form of amorphous carbon, has always been the starting product when any successful attempts to prepare diamonds have been made. Consequently those daily papers which ridiculed the process because of the fact that sugar carbon was one of the ingredients, showed want of knowledge of the subject. However, now that the whole formula is made public, it is, to say the least of it, absurd.

It will be noticed that the carbon is to be placed in a crucible and heated to from 1700° C. to 1800° C., and then pressure is to be applied to the cover of the crucible. When, in 1896, Moissan succeeded in obtaining diamonds artificially, he did subject sugar carbon, when at a very high temperature, to a very great pressure. It will be remembered that sugar carbon was dissolved in molten iron, and the crucible containing this was heated to a temperature of 3000° C. to 4000° C. While at this high temperature the crucible and its contents were plunged into cold water or mercury in order to cause rapid solidification. When carboniferous iron is cooled, it expands in the act of solidifying. By suddenly quenching the iron, a solid layer or crust is obtained outside the molten metal; consequently when the inside layer commences to solidify it expands, and thus, as it is encompassed with a solid crust, enormous pressure is exerted. On dissolving away the iron by means of acids, minute crystals of diamond were produced.

About the same time Marjorana, by heating a small piece of carbon in an electric arc and then suddenly compressing it by driving a piston down upon it with enormous force, the force being produced by firing a charge of powder in the piston chamber (NATURE, June 7, 1900), also obtained minute diamonds.

In 1905 Sir Andrew Noble exploded cordite in closed steel cylinders, when it was calculated that a temperature of 5100° C. was obtained and a pressure of 50 tons per square inch. Sir William Crookes examined some of the carbon deposited, and found it to contain minute diamonds. It would appear, therefore, that M. Lemoine exploited results well known in the scientific world in order to deceive people engaged in the diamond industry.

It is a rather remarkable fact that although amorphous carbon can be converted into graphite, and diamond may also be converted into graphite, as was recently shown by Parsons and Swinton, who obtained graphite from diamond by rapid bombardment with kathode rays, it does not appear possible to convert graphite into diamond. It has been found that when amorphous carbon and graphite are heated to a temperature of 3600° C. in the electric arc in an atmosphere incapable of acting chemically upon carbon, they vapourise without first liquefying, and on cooling condense to form crystals of graphite. Diamond, on the other hand, is first converted into graphite, then vapourises, and on condensation forms graphite. It thus appears that carbon must be in a dissolved condition, and must be cooled under pressure in order for a diamond to crystallise out. Possibly, therefore, we shall never be able to obtain the conditions necessary for producing large diamonds in the laboratory. Low down in the earth's crust carbon may be dissolved in iron or other substances, and may at high temperature be subjected to enormous pressure, such as we, even with the wonderful machinery at our command, and capable of exerting pressures of thousands of tons, have not contemplated. In the earth also the cooling while under this pressure will be slow, and therefore there are the conditions necessary for the growth of large crystals.

Although in nature diamonds are found in pipes of blue clay, this is apparently not the magma in which crystallisation originally took place, for the diamonds may have been forced into the clay by volcanic agencies. Actual blocks of one of the original rocks in which crystallisation took place have been found in blue clay. These blocks consisted of an eclogite containing large quantities of iron, and small diamonds were found, thus suggesting that such was the original mode of formation of the diamond. F. M. P.

## *PICTOGRAPHS OF ARROWS IN FRENCH CAVES.*

THE mural paintings and engravings of the Pyrenean caves is the subject of a series of memoirs by Prof. E. Cartailhac and l'Abbé H. Breuil, now appearing in *l'Anthropologie.* In the current number is an account of the "Grotte des Forges" at Niaux, Ariège. The cave is a narrow gallery more than 1400 m. in length, with several short branches; at 611 m. from the entrance a broad lateral gallery runs due south for a distance of 160 m., and terminates in a rotunda, the walls of which are decorated with bisons, horses, deer, wild goats, and groups of signs. There are no designs of animals in the first half of the main gallery, and only five at long intervals in the second. The authors write with enthusiasm concerning the rotunda. The paintings possess to a supreme degree the style of the period, and represent the same animals that were familiar to the Palæolithic artists of the Pyrenees, the bisons being in the great majority. The drawings, which represent animals in profile, are drawn with a brush in black pigment with a sure and exact touch, and the characteristic traits of the animals are conscientiously delineated. The best polychrome frescoes are to be seen in the caves at Altamira, in Spain, but Niaux is unexcelled in its line work. The black pigment consisted of a mixture of charcoal and oxide of manganese worked up with grease.

Bison in the Salon noir of Niaux transfixed by three arrows.

Perhaps the most important new feature of the Niaux pictographs is the representation of arrows sticking into many of the animals, thus conclusively proving the existence of the bow and arrow at this early period. The accompanying figure represents a large bison with four arrows, the two lateral being red in colour. Some of the animals are marked by a spot, which may be intended to represent a wound.

A lamp placed on the ground in a corner of the rotunda or "salon noir" revealed, by chance, a series of engravings on the firm clay soil of the cave. The same animals that were painted on the walls were also engraved on the ground. The drawings were of the same style, and some of the animals were pierced with arrows. But it was only on the ground that designs of fish occurred, one of which, 30 cm. in length, is readily recognised as a trout. Even some impressions of the naked feet of the artists were still visible. Of definite objects very little has as yet been discovered, only one small flint scraper of characteristic Palæolithic type, and fragments of bones, pieces of yellow ochre, and ashes. To execute the painting the Cave-men must have had artificial light of some sort.

The sign-pictographs are obscure in their significance. Some look like feathers with long quills; possibly they are arrows, in which case the arrows were feathered. There are several straight or slightly curved broad lines, from near the end of which a prominence is depicted; these appear to represent stone implements let into a thick stick. Other sticks or clubs are straight or slightly curved; these the authors regard as boomerangs. Other markings consist of lines or groups of spots, some of a red colour arranged in a circle surrounding a central spot. These recall the markings on the coloured pebbles of the famous cave of Mas d'Azil.

These discoveries by our French colleagues are shedding welcome light upon the life of the Palæolithic cave-dwellers of western Europe, but doubtless more information will come to hand when the investigation of the wonderful French caves is completed.

A. C. H.

## *NOTES.*

SIR GEORGE DARWIN, K.C.B., F.R.S., has been elected a foreign member of the Amsterdam Academy of Sciences.

THE "Società italiana delle Scienze (detta dei XL.)," of which Prof. Cannizzaro is president, has elected Sir William Ramsay as a foreign fellow (Socio straniero).

THE annual conversazione of the Royal Society of Arts will be held at the Natural History Museum, South Kensington, on Thursday next, July 2.

WE learn from the *British Medical Journal* that Prof. Grassi, whose name is well known in the scientific world in connection with research on malaria and other subjects, has been created a Senator of the kingdom of Italy.

THE annual meeting of the Victoria Institute will be held at Burlington House on Wednesday, July 15. The chair will be taken by the president, the Earl of Halsbury, F.R.S., and an address will be given by Mr. E. Walter Maunder.

THE council of the Royal Society has awarded the Mackinnon studentships for the year 1908 as follows:—one in physics to Mr. J. A. Crowther, of St. John's College, Cambridge, for an investigation of the passage through matter of the $\beta$ rays from radio-active substances; one in biology to Mr. D. Thoday, of Trinity College, Cambridge, for a research into the physiological condition of starvation in plants and its relation to the responsiveness of protoplasm to stimulation, especially to stimuli affecting respiration.

MR. A. G. BAGSHAWE, the director of the Sleeping Sickness Bureau, who can be addressed care of the Royal Society, Burlington House, London, W., desires it to be known that he will be glad to receive reprints of any papers dealing with sleeping sickness, trypanosomiasis, and cognate subjects, and, indeed, any information relating to the work of the bureau.

REUTER'S Agency learns that a fresh commission is being organised to proceed to East Africa to study sleeping sickness, its object being to continue the work carried on from 1902 until it was temporarily suspended in 1905, owing to the death in England of Lieut. Tulloch, who contracted sleeping sickness during his researches in Uganda. The new commission will be in charge of Colonel David Bruce, C.B., F.R.S., and, on September 25, will proceed from England, *via* Mombasa, to Lake Victoria, on the northern shores of which the Uganda Protectorate is preparing a laboratory in the province of Chagwe, two miles from the lake, for the purposes of the investigation. The spot chosen will be within five or six miles of one of the concentration camps organised by the Government, where sleeping sickness patients are under treatment. The work of research will include the study of the natural history of the fly, and also of Dr. Koch's theory that crocodiles provide foodstuffs for the *Glossina palpalis*. The commission will also investigate the question whether the lower animals harbour the parasites, and the exact method by which the fly transfers the parasite.

WE regret to announce that Prof. W. R. Cassie, professor of physics at the Royal Holloway College for Women, Egham, and honorary secretary of the Physical Society, died suddenly on June 22. Prof. Cassie, who was born at Fraserburgh in 1861, was educated at Aberdeen University and Trinity College, Cambridge. He was Clerk-Maxwell student of experimental physics at the Cavendish Laboratory from 1891–3; a Cambridge University extension lecturer from 1888–93; Thompson lecturer on natural science, Free Church College, Aberdeen, 1893–4; and in 1893 was appointed to the chair of physics occupied by him at the time of his death.

MR. GEORGE SIM, author of "The Vertebrate Fauna of Dee," died at Aberdeen on June 15 at the age of seventy-three. He was a fine type of the self-trained naturalist, and made many interesting contributions to faunistic zoology. His knowledge of British birds, fishes, and crustaceans was very wide and accurate, and he was remarkably disinterested and generous in placing both specimens and information at the disposal of serious workers. He pursued several lines of inquiry into great detail, having, for instance, a quite extraordinary knowledge of the specific characters of fish-scales. He gave some of his collections to the University of Aberdeen.

THE committee of the Lawes Agricultural Trust held its annual meeting for the inspection of the Rothamsted Experimental Station on June 19. A vote of condolence was addressed to Lady Evans expressing the sympathy of the committee in the loss she had sustained through the death of Sir John Evans, who had been chairman of the committee since the foundation of the trust, and to whose endeavours the organisation and extension of its work had been so largely due. In the afternoon the laboratory and field experiments were inspected.

THE council of the Royal College of Surgeons has given permission to Dr. Elliot Smith and Dr. Wood Jones, of the Cairo Medical School, to carry out, in the museum of the college, an examination of a collection of material found during excavations in the Nile Valley. The material is representative of peoples inhabiting Nubia in ancient times, and is expected to throw light on their pathology and the results of their surgery. The Egyptian Government has expressed its willingness to present the collection of specimens to the museum of the Royal College of Surgeons, and the council has accepted the offer.

QUEEN'S UNIVERSITY, Ontario, has received as a gift from Dr. J. P. Thomson, hon. secretary and treasurer of the Royal Geographical Society of Australasia, Brisbane, a large and valuable collection of specimens for its museum. The collection, which is typical and widely representative, consists of no fewer than 457 ethnological specimens and 140 shells of different kinds from Polynesia, New Guinea, and Australia, many of the specimens being very rare. Dr. Thomson is also sending to the University a large collection of economic minerals, a great number of additional ethnological specimens, some rare birds' skins from New Guinea, and many Queensland butterflies and moths. The thanks of the University have been conveyed to Dr. Thomson, whose valuable gifts are deeply appreciated.

THE Society of Mineral Industry, the most important mining and metallurgical institution in France, celebrated at St. Etienne on June 14–20 its jubilee by a very successful congress, which was attended by 436 engineers from the various mining and metallurgical districts of France. Mr. L. Tauzin, inspector-general of mines, presided; and papers were read by Messrs. Siegler, Vicaire, Bureau, Marsaut, Laur, Fayol, Rateau, de Renéville, and Lemière. Visits were paid to the principal collieries and steelworks in the district. At the banquet on June 17 gold medals were presented to Messrs. Marsaut, Rateau, Fayol, Pourcel, and other distinguished members of the society who had done most for mining and metallurgy during the past fifty years, and congratulatory addresses were presented by Mr. Bennett H. Brough on behalf of the Iron and Steel Institute, and by Mr. Hedley on behalf of the North of England Institute of Mining Engineers.

AT the annual general meeting of the Linnean Society of New South Wales, held in March last, Mr. A. H. S. Lucas delivered his presidential address, taking as his special subject the relations of science and government. Having advanced to his present position in the provinces of nature, man must, he said, fortify the position he has won, and must advance by utilising the knowledge which workers in science alone can provide. This essential fact, he maintained, is not sufficiently recognised by the public or by politicians. The appreciation by Australia of the modern point of view is, he urged, of great importance, because she has begun to learn through the pocket the costliness of ignorance. The Government alone can watch over the permanent interests of the State and see that resources are not impoverished. The scientific method, the method of accurately informed common sense, is the only efficient method in government as in everything else. Science is the natural ally of government. In regard to material questions, the man of science of the twentieth century occupies the position of the prophets of old. Without science no nation can keep its place in the van, for "science is the golden guiding star of practice; without science there can only be a blind groping in the region of undefined possibilities."

WE have to acknowledge the receipt of three papers issued by the University of California, the first of which, by Mr. J. C. Bradley, is devoted to two species of amphipod crustaceans of the genus Corophium from the Pacific coast. The other two, by Mr. C. A. Kofoid, deal with the pelagic unicellular organism Ceratium, more especially from the point of view of exuviation and regeneration.

ACCORDING to the "Aarsberetning" for 1907, the authorities of the Bergen Museum are devoting special attention to the exhibition series, which is being developed much on the lines of our own Natural History Museum. Several of these new exhibits are illustrated by reproductions from photographs, and among them, judging from these illustrations, may be specially commended a pair of bar-tailed godwits with their young, and the head of a rorqual.

The history of the Hancock Museum at Newcastle-on-Tyne forms the subject of an article by the curator, issued as an appendix to the Transactions of the well-known northern natural history society. A feature of this institution is that it is owned and maintained by the society, and therefore costs nothing to the ratepayers. The maintenance of such a large institution naturally imposes a heavy burden on the society, the efforts of which in other directions are in consequence somewhat crippled. On the other hand, the society enjoys the advantage of complete and unfettered control of a number of valuable collections which have from time to time been consigned to its custody. The article is illustrated with two views of the museum, together with portraits of Joshua Alder, Albany and John Hancock, and Thomas Atthey.

We have been favoured with a copy of the first number of the Annals of the Transvaal Museum, at Pretoria, which contains an illustrated account of the origin, progress, and present condition of that institution, together with several papers on the zoology and botany of the Transvaal. The fauna of South Africa is illustrated in a series of saloons specially devoted to that purpose, while other saloons contain the mammals, birds, fishes, &c., of other parts of Africa and the world generally. So far as can be gleaned from the photographs, many of the larger mammals appear to be well mounted, and it is satisfactory to learn that the collection includes a fine example of the white rhinoceros. The museum was founded in 1892, on the initiative of Dr. W. J. Leyds, and since that date appears to have made remarkable progress, although its development is hindered by lack of sufficient funds and space.

In the course of his presidential address to the South London Entomological and Natural History Society, as reported in the Proceedings of that body for 1907–8, Mr. Robert Adkin directed attention to the advantage accruing from federation among local scientific bodies. The Yorkshire Naturalists' Union set the example of such federation so long ago as 1862, with the result that while numerous advantages were found to follow, no harm was done to the local work of the various bodies which constitute the union. In 1896, at the invitation of the Tunbridge Wells society, the South-eastern Union of Scientific Societies was established, as the result of which it has been found practicable to hold an annual congress at one of the towns within the area covered by the union, to the great advantage of the members. Nor was this all, for in the shape of the *South-Eastern Naturalist* the union publishes a journal which deservedly occupies a high position among literature of this class. The success of this southern federation is indicated by a proposal that the local societies of Essex and Hertfordshire should be eligible for admission to the union.

The eighth part of vol. iv. of the Annals of the South African Museum contains no less than five papers by Dr. R. Broom on the Permo-Triassic tetrapodous vertebrates of the country. In the first the genus Propappus, originally named from a single limb bone, is stated to be distinct from Pariasaurus, having, among other peculiarities, a dermal armour on the spinal region. New generic types of the carnivorous groups are also described, and it is pointed out that the difference in the structure of the palate between the Permian and the Triassic representatives of these reptiles amply justifies their separation into distinct groups. While the latter, as typified by Galesaurus, have a typically mammalian secondary palate, that region in the former is a modification of the type obtaining in rhynchocephalian reptiles. For these two groups Dr. Broom employs the names Cynodontia (=Theriodontia) and Therocephalia. In the last of the series the author assigns certain Cape labyrinthodonts (one of which had been referred to the American Eryops) to the new genus Rhinesuchus, of which, however, the type is a German species.

Mr. T. Sheppard, curator of the Hull Museum, has issued another of his useful penny booklets, in which he discusses prehistoric remains from Lincolnshire, and fish and other remains from the Chalk of Lincolnshire and Yorkshire. These relics are mostly of the Bronze age; a few are Neolithic, but Palæolithic man is apparently not represented in this part of the country. They include some fine cinerary urns and an "incense cup" from a tumulus at Kirton Lindsey; and some stone implements, such as a perforated adze axe-hammer, from the Drift. One remarkable perforated adze is suspected to be the handicraft of the notorious Flint Jack. From Burton-on-Humber come a fine bronze palstave and two imperfect axes, probably rejected failures from a founder's horde. The fossils include those of ganoid and teleostean fishes, as well as selachians from the well-known chalk quarries at Barton and South Ferriby. Mr. Sheppard's careful examination of these relics, of which his pamphlet contains good illustrations, supplies an excellent example of the class of work which a local museum under competent management can usefully prosecute.

Dr. R. Semon contributes to the *Biologisches Centralblatt* (April 1) an article on the effects induced in plants by alternations of light and darkness, and the question originally investigated by him whether these effects are transmitted to plants of a subsequent generation. He directs particular attention to the facts that he experimented with seedlings of *Albizzia lophantha*, and used a very weak stimulus.

Attention is directed in the report for 1906–7 on the botanical and agricultural establishments of Antigua to the advantages derived by the presidency from the working of the Imperial Department of Agriculture for the West Indies. In addition to the re-establishment of an efficient botanic station and a revival of the decadent sugar industry, the Department has fostered agricultural education and has developed an appreciable cotton trade. In connection with sugar, it is noteworthy that two central factories are in operation. Reference is made in the report to the celebration of arbor day, when two hundred trees, largely mahogany, were planted. It is noted that for hedges *Malpighia glabra* and logwood, *Haematoxylon campechianum*, have been found useful.

It will probably be unknown, even to some bamboo fanciers, that certain bamboos in Japan have a special value because they are flecked or coloured. Where the effect is a natural one, it is generally due to lines or stripes of a colour differing from the general ground colour; in other cases the figuring is produced by fungi. Instances of the latter are furnished by a Chinese undetermined species of Phyllostachys and the Japanese plant, *Arundinaria Narahira*. An account of the latter and the parasitic fungus *Miyoshia fusipora* is contributed by Mr. S. Kawamura to the Journal (vol. xxiii., art. 2) of the Royal College of Science in Tokio. Artificial sowings on the bamboos were not very successful, but conidia, perithecia, and ascospores were obtained in cultures, as a result of which the fungus is made the type of a new genus, allied to Trichosphæria, of the order Sphæriaceæ. The bamboos are converted into walking-sticks, flutes, and small articles.

In connection with an article on the "Pigmentation Survey of Scotland," which appeared in Nature of May 21 (p. 68), Mr. J. F. Tocher requests us to state that the survey, which was carried out under the supervision of a committee consisting of Sir W. Turner, Prof. R. W. Reid, Mr. J. Gray, and himself, has up to the present extended only to school children—one-eighth of the total population; that his share in Mr. Gray's report, published in the Journal of the Royal Anthropological Institute, and noticed in Nature, was confined to supplying a key map and some statistical tables; that he is not responsible for the views expressed in Mr. Gray's article; and that a complete account of the results, with the conclusions which he has drawn from them, is in the press, and will be published at an early date.

The methods of manufacture of the remarkable Malaita shell bead money current in the Solomon group are described by Mr. C. M. Woodford in the June number of *Man*. Of this there are three varieties:—white, made from the shell of *Arca granosa*; red, from that of *Chama pacifica*; black, from a large black mussel or pinna. The shells are first broken into irregular fragments about the size of a threepenny piece. They are next chipped into the form of a roughly circular disc, in diameter about as large as a pea. Finally, these are ground into shape on a stone, the fragments being fixed on the flat surface of a piece of soft wood of semicircular section. This stone is so rare and valuable that Mr. Woodford was able to secure only a few pieces. After being pierced by means of a pump drill, the beads are threaded on strings, each a fathom or about 5 feet long, the character and colour of the beads determining their values as currency.

An admirably illustrated description of the Federal Fuel Testing Laboratory at Zurich is given by Prof. E. J. Constam in the *Engineer* (vol. cv., p. 618). The laboratory was started in 1906, and has already done much to ensure that Switzerland receives the proper equivalent for the 3,000,000*l*. annually expended on imported fuel. In the first year of its existence, besides research work, more than 3300 samples of coal and briquettes were examined. Most came from Germany, and the rest from Belgium, France, and England. This extensive examination of imported fuels has tended to enlighten the consumers as to the qualities and economic value of the fuels from the various countries and collieries, and has contributed towards their classification according to heating power. It is to be hoped that before long this latter will be universally adopted for the basis of coal contracts, instead of the vaguely defined evaporation power, or the percentage of combustible matter.

From the Pulsometer Engineering Co., Ltd., we have received a catalogue of pulsometers which, in that it contains a detailed description of the working and of the various applications of this useful form of steam pump, is of greater interest than the usual type of manufacturers' price-list. The pulsometer will pump dirty water, it has no moving parts except the valves, it disposes of its own exhaust steam, it can be supported on its suction pipe or slung from a chain. In short, it is essentially a pump that will stand rough usage, and requires no skilled attention. In these circumstances the useful services it is capable of rendering are evident, and the variety of applications of the pulsometer are well shown in the excellent illustrations given in the catalogue.

We are indebted to Prof. G. Platania for an interesting pamphlet (reprinted from the *Annuario* of the R. Nautical Institute of Catania, 1908) on the determination of wind direction and force at sea, and on the Beaufort scale. The author quotes the results of various comparisons of wind-force estimated by the latter method with the records of anemometers both in this country and abroad, and especially the recent elaborate discussion by Dr. Shaw and Dr. Simpson (Meteorological Office Publication, No. 180, 1906). The author also quotes a useful modification of the scale, suggested by Commander Hepworth, in view of the changed conditions due to the use of steam and to the rig of modern sailing vessels since it was devised by Sir F. Beaufort in 1806. Prof. L. Marini proposed an elegant method of finding the true direction and velocity of the wind from the speed of the ship and the direction of the apparent wind, without reference to its velocity (*Rivista Geogr. Ital.*, 1907), which, although worthy of being known, is not very easy of practical application. Prof. L. Rotch's ingenious instrument, made by Casella, of London (Quart. Journ. R. Meteor. Soc., 1904), is admitted to be more useful in practice.

The values which have been obtained for the molecular weight of the radium emanation have been based on observations of the rates of diffusion of the emanation and of various gases in the same circumstances. According to Graham's law, the molecular weights should be inversely proportional to the squares of the rates of diffusion, but the values of the molecular weight of the emanation calculated on the assumption of the truth of this law have differed widely from each other. Rutherford and Brooks obtained a number between 44 and 74, while Bumstead and Wheeler more recently found a value about 180. Mr. P. B. Perkins, of Yale, has just completed a comparison of the rates of diffusion of the emanation and of mercury vapour through a porous plug, and publishes his results in the June number of the *American Journal of Science*. He concludes that the molecular weight of the emanation exceeds that of mercury, and probably differs little from that of radium, 227.

Although much has been written on the theory of the Ruhmkorff coil, the simpler single circuit induction coil, so much used in these days to ignite the explosive mixture in gas and petrol engines, has received little attention, and no accurate measurements of its efficiency have been made. The *Physical Review* for May contains an article on the subject which is probably the first ever published. It is from the pen of Mr. B. F. Bailey, and includes both a theoretical treatment and a comparison of theory with experiment. In the case of one of the coils tested the efficiency, that is, the ratio of the energy of the spark to that supplied to the coil, was 54 per cent., while the calculated value was 56 per cent., and the author shows how, by cutting down the time of contact, the efficiency of the coil was raised to 85 per cent.

The Philosophical Institute of Canterbury is one of the district institutes affiliated to the New Zealand Institute, and is devoted, among other works, to the encouragement of science. It was founded in 1862, and though undergoing many vicissitudes since that date, it has had a continuous existence, and has numbered among its members most of the residents of Canterbury interested in science. The institute holds regular monthly meetings from May to

December, and a syllabus for the present year has been received. Among subjects to be dealt with this session we notice Mendel's law of heredity, physical and geological problems suggested by the construction of the Arthur's Pass Tunnel, bird life in New Zealand, and Antarctic exploration. The council of the institute has in hand the publication of reports that will be made on the collections secured during the recent sub-Antarctic expedition to the Auckland and Campbell Islands, and has taken steps to secure the proper investigation of scientific questions which will be raised by the boring of the Arthur's Pass Tunnel. Mr. E. G. Hogg, of Christ's College, is the president of the institute; Mr. R. Speight, of Canterbury College, the honorary secretary; and Dr. Chas. Chilton, of Canterbury College, the honorary treasurer.

The issue of *Science* for June 5 contains an interesting symposium at the Illinois State Academy of Science on the opportunities for American young men in science. Prof. J. G. Coulter deals with the opportunities available in botany, Prof. W. A. Noyes with openings for chemists, Dr. H. Foster Bain with the outlook in geology, Prof. H. Crew that in physics, and Dr. H. V. Neal that in zoology. There is a fair unanimity among the contributors that the young man whose primary object is to make money should not select as his life's work the pursuit of pure science. It is curious to remark that Prof. Coulter referred to the lack of interest in science on the part of the American public, and traced it to the same cause as was suggested in the *Times* correspondence arising out of the speeches at last year's Royal Society dinner to account for the similar apathy in this country, that American men of science rarely make it their duty properly to popularise the problems on which they are at work. Prof. Coulter stated that in America the demand for trained botanists continues to exceed the supply. Prof. Noyes estimated that there are about 8000 chemists in the United States, and concluded by saying that the demand for chemists to fill positions in connection with the bureau of chemistry has largely exceeded the supply of suitable men. Dr. Bain made it clear that it may be taken for granted that properly equipped and willing workers in geology may rest assured of positions being open to them. Prof. Crew summarised the opportunities for young men in physics under the headings of research, applied physics, engineering, and teaching, and spoke very hopefully of the outlook in each of these directions. Dr. Neal said, so far as zoology is concerned, that the chances for getting good zoological positions have much improved during the last ten years. Though there is this increased demand, there has been no increase in the supply of men to fill the posts. New fields for employment are being opened, and there is every possibility that the present demand for zoologists will be maintained.

Prof. E. B. Poulton's "Essays on Evolution" are to be published by the Oxford University Press on July 1, the fiftieth anniversary of the meeting of the Linnean Society at which was read the joint essay on natural selection by Darwin and Wallace. The ten essays cover the period 1889–1907.

Messrs. E. and F. N. Spon, Ltd., have published, at 4*d*. net, tables of logarithms, antilogarithms, useful constants and the functions of angles, taken from the examination tables of the Board of Education. The tables are mounted on linen, and so folded that they will go into the pocket easily; they can be opened out in such a way that the logarithms and antilogarithms can be examined side by side.

The first part of the "International Geography" by seventy authors, edited by Dr. H. R. Mill, has now been published separately by Messrs. Macmillan and Co., Ltd., at 1*s*. 6*d*. This section, which deals with the principles of geography, is the eighth portion of this standard book to be issued in a convenient separate form, and at a price which makes it available as a class-book in schools. These parts of the "International Geography" deserve to be widely used in schools where the study of geography is taken seriously.

We have on previous occasions directed attention to the medical and scientific circulating library conducted by Mr. H. K. Lewis, of Gower Street, London, W.C. The new edition of the library catalogue, revised to the end of 1907, has been published recently at a price of 2*s*. net to subscribers and 5*s*. net to non-subscribers. The catalogue shows that the student and man of science may here obtain the advantage of a very large collection of modern medical and scientific text-books and special monographs. In addition to books on pure and medical science, works on different branches of engineering science and general technology are included. Not only are the books classified under their authors' names, but they are also conveniently arranged in a second section according to subjects.

## OUR ASTRONOMICAL COLUMN.

The Rings of Saturn.—In a note published as Bulletin No. 32 of the Lowell Observatory, Prof. Lowell develops rather more fully the idea that the appendages B and C of Saturn are not flat rings, but tores. He arrives at this conclusion, by two independent methods, from a discussion of the phenomena observed at Arizona during November and December last. In the first place, a black core was observed running medially through the length of the shadowy band which then encircled the planet. This core was seen by all the observers at Flagstaff, although not caught by Prof. Barnard at Yerkes nor reported in the Lick observations, and is presumed to be the black shadow of the plane ring A bordered by the particles of the rings B and C scattered above and below the plane of A. That is to say, the rings B and C differ from A in being tores and not flat rings. Then the agglomerations, seen at many different observatories, are shown to be better accounted for by Prof. Lowell's theory of the form of the rings than by the several other theories which have been proposed. An analytical discussion of the perturbing effects to which the ring matter is subjected by the satellites, &c., shows that the assumed heaping up of the particles, as indicated by the agglomerations, is in accordance with gravitational laws. Furthermore, it is shown from the observational results that the inevitable disintegration of the rings is in the process of taking place.

The Forty-inch Objective of the Yerkes Observatory.—An interesting paper by Mr. Philip Fox, giving the results of an investigation of the 40-inch objective of the Yerkes Observatory, appears in the May number of the *Astrophysical Journal* (vol. xxvii., No. 4, p. 237). The tests, in the first instance, were carried out at the suggestion of Prof. Hartmann, who is desirous that the data might be published for every objective in active use, but they have been extended and comprehensively discussed by Mr. Fox. The method employed was that of the "zonal test," using a perforated diaphragm having sixty holes, each of 2 cm. diameter, located at the corners of squares on fifteen different zones. Briefly, the results indicate, *inter alia*, that the centre of the Yerkes objective is of appreciably shorter focal length than the edge. The variations come, however, well within the limits for which Prof. Hartmann classifies an objective as "preeminently good." Plates taken at varying zenith distances appear to indicate that the performance of the objective varies with the zenith distance, and, should this be confirmed, it appears certain that, even could the mechanical difficulties of construction be overcome, refractors of greater dimensions than the 40-inch cannot be constructed with the hope of uniform performance at all altitudes.

The same journal contains a discussion by Prof. Hartmann of an improvement of the Foucault knife-edge test in the investigation of telescope objectives.

THE TEMPERATURE OF THE SUN.—In a preliminary note, now published as an abstract from the *Annalen der Physik* (vol. xxv., pp. 905–20, 1908), Dr. Goldhammer discusses anew several sets of results obtained in the determination of the temperature of the sun. From the discussion of Langley's various observational data he arrives at the conclusion that the probable actual temperature of the sun is not less than 10,000° absolute.

THE VARIATION OF THE POLE.—Prof. Albrecht's annual summary, for 1907, of the provisional results derived from the observations made at the various international latitude stations appears in No. 4253 of the *Astronomische Nachrichten* (p. 73, June 5). The extrapolated values for the variation, in the several coordinates, for 1908·0 are:— $x = -0''\cdot097$, $y = +0''\cdot185$, and $z = +0''\cdot012$. The curve showing the departure of the pole from the mean position between 1899·0 and 1908·0 shows that the value of the $y$ variation at the commencement of the current year was approaching the maximum observed during that period.

OBSERVATIONS OF THE PERSEID SHOWER IN 1907.—No. 4253 of the *Astronomische Nachrichten* (p. 83, June 5) contains a note by Prof. J. Sykora in which are given the results of the meteor observations made at Tashkent and Iskander during the nights of August 10–12, 1907; Iskander lies about 44 kilometres to the north-east of Tashkent. From the recorded paths of 178 Perseids the centre of the radiant of the shower, for 1907, was found to be $\alpha = 42°\cdot7$, $\delta = +53°\cdot8$, and the area covered by the radiants lay between 31° and 55° in R.A. and +49° and +59° in declination. The calculation of the altitudes showed that the mean heights of appearance and disappearance were 167 and 96 kilometres respectively. The trails of nine meteors were photographed, and brief descriptions of trails are given in the paper; several of them indicate marked variations of brightness during the meteor's flight.

## *RECENT DEVELOPMENTS IN ELECTRIC LAMPS.*

IN an article which appeared in NATURE last June the present writer reviewed briefly some of the improvements which had been made and promised in incandescent electric lamps. At the time that article was written, matters were in a condition of considerable uncertainty on account of the great number of new developments which had been announced, the value of which was, to a very large extent, uncertain. The frequent announcements of these improvements, which were appearing almost weekly, led electrical engineers to feel considerable hesitation in adopting any new lamp for fear that it should be superseded almost immediately after its adoption. Since that time the position has become much quieter, and during the past six months the solid progress which has been made in the introduction of these lamps on the market has been remarkable. Now that considerable experience has been obtained of the practical working value of the different types of lamp, a favourable opportunity is afforded of taking a general survey of the present position and prospects for the future. At the same time, a similar survey may be taken of the conditions existing in the field of arc lighting, in which the developments during the past two or three years have been almost equally noteworthy.

### *Incandescent Lamps.*

As was pointed out in the article referred to above, the only two lamps which appeared to merit particular attention were the tungsten and the tantalum lamp. The tantalum lamp has now been in practical use for about two years, and has not undergone any appreciable modification since the time of its first introduction. Difficulties of producing a satisfactory lamp for use with alternating current are still not overcome, and the difficulties of drawing tantalum wire sufficiently fine to enable either low candle-power low-voltage, or medium candle-power high-voltage lamps to be produced still await practical solution. It is true that the range of candle-power with low-voltage lamps has been extended by the introduction of a 16-candle-power lamp, and that announcements have been made from time to time that a satisfactory solution has been found for the manufacture of high-voltage lamps. The fact remains, however, that high-voltage lamps are not yet produced commercially. The tantalum lamp has satisfactorily proved its value for electric lighting. Although the general results obtained seem to show a comparatively short average life of about 700 hours, and though the efficiency is approximately only half that of the newer tungsten lamp, it is apparent that this lamp will have to be reckoned with for some time to come as a very important factor in the field of incandescent electric lighting. Though it may not be able to compete on the score of efficiency with the tungsten filament, yet the greater strength of the filament must always operate to counterbalance these disadvantages.

The tungsten lamp, ever since its commercial introduction into this country under the name of the "Osram" lamp by the General Electric Company, has made rapid strides in popularity. Considering that the lamp has only been on the market for a matter of about nine months, its very widespread use at the present time must mark almost a record in the development of electric lighting. In its practical performance, also, this lamp has fulfilled, or more than fulfilled, the hopes which were raised for it before its introduction. Beyond the blackening which occurs with a small percentage of these lamps, the general experience is that a life of 1000 to 1500 hours is obtained almost without any decrease in the initial efficiency of about $1\frac{1}{4}$ watts per candle. This blackening appears to be a defect in manufacture which will doubtless be soon overcome, since it is not a characteristic of all lamps, but is only observed in a very small percentage, which generally show this defect almost immediately they are put into use. The tungsten lamp has hitherto possessed the disadvantage, when compared with its tantalum rival, that it could only be used in a vertical position, but a modified type has just been introduced which can be burnt at any angle. On the other hand, the tungsten lamp has the advantage that it is suitable for use on either direct- or alternating-current circuits. Up to the present, the range of voltage for which the lamps can be made is practically the same as that for the tantalum lamps, viz. voltages up to 130, but the tungsten lamp has not yet been made for voltages of 100 in such low light units as the tantalum lamps, the lowest at present obtainable being approximately thirty candles. Tungsten lamps have also been made, but not yet commercially introduced, for high voltages (200 and above), and the introduction of a 40-candle-power lamp for 200 volts is promised very shortly.

It is yet too early to say precisely what will be the effect of the introduction of these two lamps on electric lighting in general. At present, for the most part probably, the lamps have been used for the lighting of factories, shop windows, and public or semi-public places where costs of lighting are very closely considered and artistic effects are of secondary importance. It is perhaps not safe to argue from the success which the lamps have attained in the past year for these purposes that they will meet with corresponding success in private house lighting, especially as in that case the size of the light unit becomes of much greater importance. It is more than probable, however, that the general public will welcome the higher light units if they provide them, as these lamps do, with a means at the same time of actually reducing their lighting bills. The present writer, for example, has substituted two 32-candle-power Osram lamps for a single 16-candle-power carbon filament lamp, and finds that it has resulted in actual saving in money in spite of the fact that four times as much light is obtained. It is noteworthy that the fears which were expressed that the difficulties in running lamps in series would very seriously affect the introduction of metal filament lamps do not appear to have been well founded.

Beyond these two types of lamp the development in incandescent lighting has been slight. The exceedingly interesting discovery (from a scientific point of view) by the General Electric Company in America of a method for radically altering the nature of the carbon filament unfortunately came too late to have any practical effect. These so-called "metallised" filament lamps, had they come four or five years ago, would have been welcomed as a great step in advance, but coming as they have at the same time as the metallic filaments, are practically doomed to failure, since they possess the same disadvantages, and, in addition, can only be worked at an efficiency of $2\frac{1}{2}$ watts per candle. The same may be said of the Nernst lamp, which is almost bound to give way in the sphere of incandescent lighting to metal filament lamps. It is possible that the Nernst lamp will find a sphere of its own for intermediate lighting where light units of 100- to 200-candle-power are required, but it is much more probable that it will be ousted also from this field by the high candle-power metal filament lamps.

*Arc Lamps.*

The remarkable change in the prospect of incandescent lighting which has been effected by the introduction of the metal filament lamp has been paralleled by a similar change in arc lighting by the introduction of flame lamps. The gain in efficiency in a metal filament lamp over a carbon filament lamp is approximately three times, and an almost similar gain is obtained in a flame lamp over an ordinary open type arc lamp. The idea of introducing chemicals into the arc in order to colour the flame is an exceedingly old one, but the practical solution was not obtained until Bremer brought out his mineralised flame carbons. The carbons introduced by Bremer were mineralised carbons in which the flame-producing material was intimately mixed with the material of the carbon rod itself. Alterations were later effected by the various carbon manufacturers by which the flame-producing material, instead of being introduced into the main body of the carbon, was only introduced into the core. This latter type of carbon is by far the most common, but carbons of the Bremer type are still in use, and have been considerably improved recently by M. Blondel, who claims to have succeeded by their employment in producing a far more efficient lamp than the ordinary flame lamp.

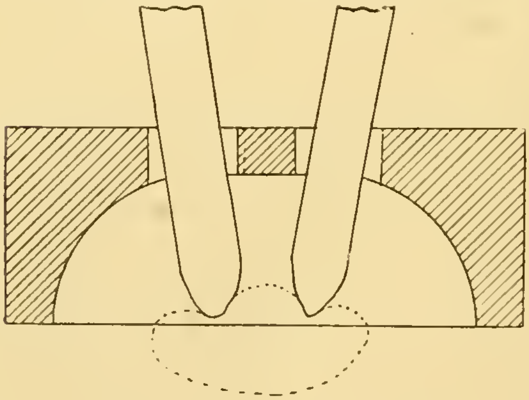

FIG. 1.—Arrangement of Carbons in Flame Arc.

Flame carbons are constructed to burn with the carbons arranged vertically above one another, as in ordinary lamps, but the more general construction is to arrange the carbons side by side inclined to one another at an angle of about 15°, as shown in Fig. 1. The arc, which balances between the tips of the carbons, as shown in the figure, is spread out into a fan shape, and kept down at the tips by the use of a magnetic controlling field. Immediately above the arc, both in the lamps for vertical and inclined carbons, is placed an inverted cup, the object of which is to prevent the free upward currents of air and maintain the carbons always in an atmosphere of inert gases, thus considerably lengthening their burning hours. This cup is consequently given the name of an economiser.

The arrangement of the carbons in the inclined lamps causes a very large proportion of the light to be thrown vertically downwards, which is certainly not a desirable condition for the lighting of open spaces, involving as it does hanging the lamps very high if even illumination is to be obtained. The rich golden-yellow colour of the light though useful for the purpose of display, is also to be reckoned as a disadvantage of these lamps. The colour is, however, not so very far different from that given by the incandescent lamp, and has not been found a very serious drawback. Flame arcs of other colours, for example, white and pink, can be produced, but the volume of light in these cases is greatly below that of the yellow arc. The flame arc lamp has an efficiency of approximately 0·4–0·5 watt per mean spherical candle, which is two or three times as good as that of the ordinary open-type arc. The high cost of maintenance in carbons, which are expensive to make and burn rapidly, is very much more than compensated by the low cost of power for a given amount of light. In the Blondel lamp the carbons which are used are of larger diameters, and are arranged vertically one above the other. This has the advantage of giving a better light distribution, and it is claimed that the mean spherical candle-power is nearly double that of the ordinary flame arc.

Whilst the flame arc has been rapidly developed in Europe, it has met with but little success in America on account of the fact that in America the cost of labour for frequent trimming counts much more than it does in this country. For this reason the use of enclosed arcs in America has become almost universal in spite of the fact that they only have about half the efficiency of the ordinary open arc. To meet these somewhat special conditions, experimental work has been carried on during the past two or three years by Messrs. Steinmetz and the General Electric Company of America on the production of a long burning flame lamp. The "magnetite" arc, as it is called, which is the result of this work, utilises electrodes composed chiefly of magnetic oxide of iron. In the latest electrodes titanium oxide, which produces a more intense light in the arc than iron oxide, is used, but iron oxide is still employed to give the electrode conductivity when cold. The actual mixture contains also oxide of chromium, but this plays a purely secondary part in steadying the rate at which the other oxides are evaporated.

The lamp is constructed with the magnetite electrode as the negative, and a solid copper electrode as the positive. In place of copper a special alloy is being introduced. The arc has all the characteristics of a flame arc, but possesses some peculiarities due to the fact that the flame-producing material is contained only in the negative electrode. Its efficiency, from figures which have been published, appears to be in the neighbourhood of 0·8 to 1·0 watt per candle, from which it will be seen that it is a little more efficient than the ordinary open-type arc and twice as efficient as the ordinary enclosed arc, which will be its greatest competitor in America. The electrodes, when 12 inches long, are stated to have a life of 150 hours, which is as much or more than similar sized electrodes in enclosed lamps. It will therefore be seen that the magnetite arc is likely to prove a valuable advance on the enclosed arc, and where economical conditions have determined the use of this lamp it is likely to be superseded by the magnetite arc. It cannot, however, at present compete against the ordinary flame lamp, where the cost of trimming is not so important a factor.

*Vapour Lamps.*

A word may be said in relation to the development of the mercury vapour lamp. This type of lamp, which has been developed by Mr. Cooper-Hewitt in America, has not met with any extended use on account of the exceedingly unpleasant colour of the light which it gives. Though in some circumstances this may not prevent the adoption of this lamp, there is no doubt that it will always seriously hamper its use in competition with pleasanter coloured illuminants. Attempts have been made to improve the colour by introducing other metals, such as metals of the alkali group, into the tube, but these have not hitherto proved successful. It is stated, however, that a very marked improvement has been effected by the firm of Heraeus, in Germany, by adopting quartz tubes instead of glass tubes, and pushing the temperature at which the arc is run up to very much higher limits. By working the lamp at such a current density that the internal pressure in the tube is approximately one atmosphere, it is stated that the efficiency of the lamp is more than doubled, and that a continuous spectrum is added to the line spectrum of the mercury, thus giving the light a quite pleasant and almost normal colour. These quartz-tube lamps have the additional advantage that under the conditions of working the length of tube for a given voltage is very much less than when glass tubes are used. The commercial introduction of these lamps is promised for this year.

Reference might also be made to one other type of electric lamp which has during the past year come into commercial use, namely, the Moore tube lamp. This lamp is simply an ordinary vacuum tube of great length, and operated at a very high voltage. The tubes, which are $1\frac{3}{4}$ inches diameter, can be made up to 200 feet in length, and are fixed up in position by welding together short lengths of tube, high-voltage supply being obtained by means of a transformer the secondary terminals of which are connected to graphite electrodes in the tube. The essential feature of this lamp is the method which has been adopted to overcome the difficulty that the vacuum decreases as the lamp burns, owing to the absorption of gas by the glass tube. In order to maintain the vacuum constant a most ingenious valve is employed. The main tube communicates by means of a branch with the outer air, this branch tube being sealed by a porous carbon plug covered with mercury. The level of the mercury can be altered by the rising or falling of a float; in one position of the float the carbon plug is completely covered, in the other it is partly uncovered. The movements of the float are controlled by a solenoid connected in series with the primary of the transformer supplying the tube. When the vacuum falls the conductivity of the tube increases and the primary transformer current rises; this lifts the mercury float and causes the mercury level to fall, uncovering the point of the carbon plug and allowing a little air to filter into the tube. The conductivity of the tube is thereby decreased, the primary current falls again, and the porous plug is again completely covered with mercury. It is stated that this valve, which operates normally about once a minute, maintains the vacuum in the tube, which is in the neighbourhood of 0·1 mm. of mercury, constant within 10 per cent.

The only installation of this lamp in this country is that in the courtyard of the Savoy Hotel, and those who have seen this will probably agree that the light represents in many respects the ideal form of artificial lighting. The colour of the light given by the tube depends upon the gas which it contains, and is pure white for carbon dioxide, slightly pink for nitrogen or air. Nitrogen is stated to be twice as efficient as carbon dioxide, and slightly more efficient than air. When it is desired to operate the tube with either of these gases the open end of the valve is connected to either a phosphorus tube (to extract the oxygen from the air drawn in) or to a gas apparatus generating carbon dioxide by the action of acid on marble. The efficiency of these lamps is difficult to determine, but appears to be in the neighbourhood of 1·6 to 1·8 watts per candle.

It is interesting to note that the improvements described above in incandescent and arc lamps have once again brought electric lighting on practically the same level for cheapness as gas lighting. The introduction of the gas mantle gave gas lighting so great a superiority on the score of cheapness that for a great many years it has only been possible for electricity to hold its own on account of its many other advantages. Just as the ordinary gas mantle beat the carbon filament lamp, the high-pressure gas-mantle systems competed on an equal, or even on a slightly better, basis with arc lighting. The whole complexion which appears is now changed, since the 1 to 1·5 watt metal filament lamps can compete with the ordinary mantle for small lighting, and flame lamps are superior to the high-pressure gas lamps. It must be remembered that, from a scientific point of view, the efficiency of electric lamps is vastly superior to any type of gas lamp, the main cheapness of gas lighting being entirely due to the difference between the cost of power delivered to the lamp in the form of gas and in the form of electric energy. It is interesting to remark that whereas the improvements in gas lighting have been effected by departing from an incandescent flame to an incandescent solid, the improvements in arc lighting have been obtained by a move in exactly the opposite direction.

In conclusion, attention may be directed to the honourable position occupied by this country in the developments of electric lamps. A little more than a century ago an English philosopher, Sir Humphry Davy, discovered the electric arc. Thirty years ago an English inventor, Sir Joseph Swan, shared with an American, Edison, the distinction of overcoming the difficulties attendant upon the production of an incandescent electric lamp of small candle-power. With these two names England's connection with the development of electric lighting begins and ends. The first satisfactory arc-lamp carbons were made by Carré (France). The invention of the cored carbon is due to Siemens (Germany), the practical realisation of flame carbons to Bremer (Germany), and their further development to the Continental manufacturers and to Blondel (France). The magnetite arc has been developed by Steinmetz and the General Electric Company of America. The mercury arc was shown to be practical by Arons (Germany), and was perfected by Cooper-Hewitt (America). Its latest development is due to the firm of Heraeus (Germany). The vacuum-tube lamp we owe to McFarlane-Moore (America). In incandescent lighting the only radical improvement which has been effected in the carbon filament is the metallised filament of the General Electric Company of America. The Nernst lamp is due to Prof. Nernst and the A.E.G. of Germany. The first metal filament lamp was the "Osmin" lamp of Welsbach (Germany), which was followed by the tantalum lamps of Siemens (Germany) and the tungsten lamps which were perfected by Welsbach (Germany), Just and Hannaman (Austria), and Kuzel (Austria).

One may well ask what is the reason for this unsatisfactory state of affairs. The actual reason is not far to seek. In the field of scientific discovery England has always been, and still is, in the front rank, but not any of the improvements enumerated above are in the nature of discoveries, but are all inventions of a type which have been, and can only be, developed by years of costly experiments carried out always with a commercial end in view, a form of research which is for the most part carried out in the laboratories which are to be found attached to the more important Continental and American factories. The question therefore reduces to asking why it is that these laboratories are not to be found in connection with English works. If you ask the manufacturer, he will probably answer that with unprotected markets, unrestricted competition, and the uncertainty of being allowed to enjoy the fruits of his labour, he cannot afford to spend a share of his money in the prosecution of costly research which may only after many years, and possibly never, yield results. If you ask the man of science, he will probably tell you that it is due to the complicated set of facts which were summed up by Prof. Perry in the words "England's neglect of science," of which the most striking examples are afforded by the position which science takes in all our systems of education, and by the attitude of indifference, amounting almost to contempt, which is directed towards it by all our Governments, our men of means, our manufacturers, and almost all classes of the community. Each answer probably comprises part of the truth, and the two together possibly comprise the whole, and whilst everyone is agreed that something ought to be done, we are all too busy arguing which is the best specific to take any steps towards a remedy. In the meantime, further developments are being worked out abroad, and every year is making it harder for this country to make up the leeway which it has lost and is losing.

Maurice Solomon.

## RUSSIAN SCIENTIFIC WORKS.

THREE volumes of the Bulletin of the Academy of Sciences, containing the proceedings of the physico-mathematical section, have been received recently. In vol. xxii. Mr. Wyragevitch describes certain Actinozoa of the Black Sea in the neighbourhood of Balaclava, and Mr. A. Borissiak contributes notes on the Black Sea plankton. Mr. K. N. Davidoff's article on the islands of the Indo-Australian archipelago deserves mention. The confusion of European and Malay races in Amboina has produced a curious type, and the Malay tongue has absorbed, it is shown, Dutch and Portuguese words. The barbarous custom of wooing with the head of an enemy still prevails. The Solifugæ of Persia are discussed by Mr. A. Birula. In vol. xxiii. Mr. V. Bianchi writes on Passeriformes and Palæarctic larks, basing his remarks on studies in the museums of London, Tring, and Paris. Mr. N. Donitch contributes observations of the annular solar eclipse in March, 1904, made at Cambogia, and of the total solar eclipse in August, 1905. The latter was observed from Alcala and Assouan. Notes on inundations at St. Petersburg are contributed by Mr. S. Griboyedoff, and studies of rainfall in that capital, with diagrams and tables, are given by Mr. E. Rosenthal. Vol. xxiv. contains the results of lengthy investigations, by Mr. A. Bielopolsky, of the radial velocity of the variable star Algol, and another astronomical paper, by Mme. Zhiloff, on the orbit of the minor planet Doris (48). A new species of pheasant from the mountain regions of western China is described by Mr. V. Bianchi. Details of balloon experiments at the aërodynamic institute at Kutshino are furnished by Mr. V. Kuznetsoff. From fossils collected by the Polar expedition of the late Baron Toll in 1900–3, Mme. M. Pavloff is able to draw deductions as to the changes of climate in east Siberia since the Tertiary period. Several papers on aërial mechanics are contributed by Mr. D. P. Riabushinsky. Mr. M. Golenkin writes on a botanical visit to Java, and the report of the geological museum of Peter the Great concludes the volume.

In series vi., part i., of the Bulletin of the Imperial Academy of Sciences, Prince B. Galitzin describes the seismic station at Pulkovo. Mr. P. Vannari writes on the duration of sunshine in Russia. Part ii. opens with suggestions, by Mr. M. A. Nikatshev, for the establishment of a commission to arrange atmospheric observations in different parts of Russia. A memoir of Prof. D. I. Mendeléeff appears in part iii. Memoirs of the geologist N. A. Sokoloff, the chemist H. Moissan, the German meteorologist W. von Bezold, and Signor G. I. Ascoli, philologist, appear in part iv. Among short abstracts of papers is one by Mr. A. Kuljabko on the application of artificial circulation to heads of fishes after cutting them off, and one by Mr. V. Bianchi on Muscicapidæ. In a note on the temperature of lakes, Mr. V. B. Shostakovitch confirms the opinion of Middendorf that a mass of water heated in summer will retain this heat for a long time in spite of heavy frost and snow on the surface. Part v. contains memoirs of the geologist Bertrand and the chemist Berthelot. Mr. A. S. Skorikoff has made elaborate investigations of the plankton of the Taurida pond, St. Petersburg. Mr. S. P. Popoff has studied crystalline phosphates from the shores of the Gulf of Kertch. Prince B. Galitzin writes in part vi. on lines in the spectrum of mercury vapour. Mr. N. Korostelev reports on actinometrical observations at Tashkent in February of last year. Of geological interest are the papers by Mr. A. Fersmann on stolpenite from the Rhone and pyrargyrite from the Pervoblagodatsk ore in the Urals. In part vii. Mr. V. Bianchi describes forms of Pyrrhospiza.

Papers by Mr. A. Karpinsky on the results of soundings in the Pripet basin, and by Mr. A. Fersmann on the mineralogy of the Simferopol district, will be found in part ix. In part x. Mr. F. N. Tshernisheff writes on the discovery of Upper Trias in the northern Caucasus, based on the researches of Mr. V. I. Vorobieff. Mr. Y. S. Edelstein writes on the discovery of Upper Silurian layers in the neighbourhood of Samarkand. The longest paper is that of Mr. V. I. Vernadsky, on striation in crystalline surfaces, with mathematical illustrations. In No. 11 brief notices are given of papers on different investigations, which are to appear *in extenso* either in the Annals of the Zoological Museum or the Transactions of the Academy. One of the most interesting of these is the abstract of Mr. L. S. Berg's paper on the fish of the Amur basin, where the fish consist of a mixture of Palæarctic and tropical forms. Two articles are devoted to crystallography; Mr. V. V. Karandeieff writes on rotatory power and symmetry, and Mr. V. I. Vernadsky discusses the physical theory of twin formation and crystalline groups. Some critical forms of Centaurea, L., are described by Mr. A. Petunnikoff. A controversial article, "In Defence of Natural Genera," written in English, is contributed by Mr. V. Bianchi, who differs from Dr. E. Hartert over what he calls "genus-lumping."

In No. 12 Mr. V. Lubimenko gives a paper on the influence of light on the absorption of organic substances by green plants. Investigations were directed to (i) has light any influence on the assimilation of organic combinations, where photo-synthesis is entirely absent? (ii) what is the influence of light of different intensities? (iii) is the influence of light dependent on the absorption of different wave-lengths? Experiments connected with light and the absorption of saccharose, glucose, and maltose are described, and Mr. Lubimenko hints that further experiment will provide interesting results. Mr. P. K. Kokovtsov's paper on some Central Asian tombstone inscriptions of Syrian-Christian character belongs to literary archæology. Astronomers will be interested in the calculations (in French) of the elements of Encke's comet, by Mr. Kamensky and Mdlle. E. Korolikov. There are short communications by Mr. O. Backlund upon the rhombic pyroxene of a hypersthenic gneiss, and by Mr. P. Stepanov on the Upper Silurian fauna of the Lake Balkhash district. Prof. G. D. Romanovsky studied the palæontological materials of Turkestan gathered by different investigators, and sedimentary formations belonging to all periods from the Silurian, with the exception of the Permian period, have been identified in that province.

Much research is recorded in vol. iii. of Mr. G. E. Grum-Grzhimailo's description of a journey in western China, round Kuku-nor, through Nan-shan, Bei-shan, and along eastern Tian-shan to Russia. There are handsome maps of Nan-shan, Bei-shan, and Tian-shan, showing the route of the expedition, twenty-five phototypes, and twenty-nine zincographs. The earlier chapters describe the route and adventures; the later chapters and appendices deal with natural history. The women of the Panaks (Kuku-nor Tanguts), who are in a position of humility, maintain an immemorial custom of veiling their faces in their plaited hair before strangers. There are two chapters on the ethnology of Amdo and the Kuku-nor region, the native names of localities being given with explanations and comparisons. One conclusion is that there is a strong white admixture among the Tibetans, who have a legend that their first king came from India. Butterflies (*e.g. Agrotis xanthographa*, F., and *Pseudohadena pexa*) approached the encampment when the temperature was surprisingly low. The Mongols and Tibetans consider the bear as king of beasts, and in the nature of a missing link between man and beast. It is thought that tales of "dumb, hairy savages" may sometimes be traced to inexperienced travellers who have seen bears. A rock was seen bearing an inscription in Mongolian and Tibetan, the Buddhist prayer "Hail, Pearl hidden in the Lotus," probably referring to *nirvana*, the translation and interpretation of which are a mystery. There are explanatory notes by Gabet and Waddell. Two legends with regard to the origin of kite-flying among the Chinese are recorded. When the expedition refused the offer of a convoy, the Chinese commander remarked, "Your men are a hundred times braver than our soldiers." A chapter is devoted to the climate of Tibet. Extensive study of the fauna shows that many examples of Siberian forms occur in Tian-shan, Han-su, and Pamir fauna, and our author traces the probable route of these forms by way of the Caucasus and Hindu-kush. As regards Lepidoptera, the interior regions of Tibet are a *terra incognita*. Several pages are occupied with the distribution and classification of Parnassius and Colias. The wanderings of the Old Believers, mentioned by Prjevalsky and Kozlow, are the subject of a separate chapter.

A rich and interesting ornithological collection of 1500 skins, twenty-two eggs, five nests, and three skeletons, made by Mr. Kozlow, has been entrusted to the experienced hands of Mr. V. Bianchi, and its description is contained in "Mongolia and Cham," vol. v., "Aves expeditionis Kozlowi." Eight new endemic forms were discovered. The name Cham or Kham relates broadly to the whole Alpine country of south-eastern Tibet, and in a narrower sense it refers to the area upon which agriculture is possible at a certain height. In the latter sense the boundaries of Cham are still uncertain. The volume opens with a physicogeographical sketch of the regions traversed by the expedition, passing to tables of distribution and analyses of the different species. The chief interest of the collection is that it was made in localities previously unvisited by European naturalists. Four plates of birds appear at the end, with a map indicating the routes of Mr. Kozlow and his colleagues. The longitude is reckoned from Pulkova, 50°–80°, the difference of longitude between Greenwich and Pulkova being 30° 19′ 40″·10. The classification of diatoms was entrusted to Mr. K. S. Merezhkovsky, and Mr. N. A. Tatshaloff recorded the astronomical results of this important expedition, their work being contained in two shorter volumes.

## THE AMERICAN PHILOSOPHICAL SOCIETY.

THE general meeting of the American Philosophical Society was held at Philadelphia on April 23–25. The opening session was on April 23, and morning and afternoon sessions were held on the following days, with an evening lecture by Prof. H. F. Osborn on April 24 at the hall of the Historical Society of Pennsylvania, which was followed by a reception to the visiting members and friends of the society. The sessions were largely attended. The meeting closed with a dinner at the Bellevue-Stratford on the evening of April 25.

Forty-two papers were presented, covering a wide range of subjects, but we are only able to find space for summaries of a few of them.

"Determination of Dominance in Mendelian Inheritance," Dr. C. B. Davenport. In studying heredity, where a single character is considered which one parent possesses and the other lacks, or a character that is contrasted in the parents, it is generally found that the offspring are alike, and like one parent only. From examples of poultry, of insects, of certain mammals, including man, and certain plants, in regard to inheritance that may be described as Mendelian, it is concluded that where a stronger determiner meets a weaker determiner in the germ, dominance is the result. When the character is present in one parent only we have the extreme case and typical Mendelian inheritance, but when the determiners are of nearly equal potency the Mendelian law is obscured.

"A Preliminary Report upon a Crystallographic Study of Hæmoglobins: a Contribution to the Specificity of Vital Substances in Different Vertebrates," Profs. E. T. Reichert and A. P. Brown. The primary object of this research was to determine whether or not corresponding albuminous substances are identical in different species. The results of the investigation, which has covered more than one hundred species of vertebrates, show:—(a) the crystals of oxyhæmoglobin obtained from any single genus are isomorphous, but unlike those obtained from other genera unless these genera are closely related or in the same family; (b) specific differences in angle and habit are obtained between crystals obtained from species of the same genus, so that it is generally possible to re-organise the species by the crystals; (c) the occurrence of several types of crystals of oxyhæmoglobin in the same species; (d) indications are found in the crystal angles of a substance in the molecule common to all hæmoglobins, no matter what the system of crystallisation. The application of this method of research to problems in zoological classification and in heredity was pointed out.

"The Effect of Certain Preservatives upon Metabolism," Dr. H. W. Wiley. Details were given of the work that Dr. Wiley is carrying on in the study of the effect upon the human organism of a number of preservatives commonly used in the preparation of foods, such as borax, boric acid, salicylic acid and salicylates, sulphurous acid, sulphites, benzoic acid and benzoates, formaldehyde, copper sulphate, and potassium nitrate. Experiments with the first five of these preservatives show conclusively that their continued use, in quantities such as are used in food preservatives, hinders or prevents metabolism, and may seriously derange the functions of the organism. The other substances enumerated are still under investigation, but the results thus far obtained seem to indicate that they are equally injurious.

"Observations Regarding the Infliction of the Death Penalty by Electricity," Prof. E. A. Spitzka. This paper sets forth the history of "electrocution," the methods employed, and the phenomena observed in this mode of death, together with the *post mortem* findings, detailing the observations of the author, based upon thirty-one electrocutions at Sing Sing, Auburn, Dannemora, and Trenton prisons. Compared with other methods, "electrocution" is the most humane method of inflicting the death penalty, because of its efficiency, quickness, and painlessness, and it should be adopted in every State in the Union.

"A Comparison of the Albino Rat with Man in Respect to the Growth of the Brain and the Spinal Cord," Prof. H. H. Donaldson. A statistical study of the growth of the brain and the spinal cord in the white rat, in which the weight of the brain and of the spinal cord is recorded and compared with the body weight at various stages of the development of the animal. The results are plotted, and from these records logarithmic curves are drawn. When compared with the curves derived from the same data in the case of man, and plotted to a corresponding scale, a close similarity in the curves is noted.

"The Classification of the Cetacea," Dr. F. W. True. The opinion is expressed that the Cetacea are not directly derived from Zeuglodonts, and that their origin is not at present known; also that the white whale and the narwhal should not be removed from the family Delphinidæ, and that the river dolphin, Stenodelphis, should, for the present at least, be placed in that family.

"Results of the American Museum Exploration in the Fayûm Desert of Northern Egypt," Prof. H. F. Osborn. The camp of the American Museum Expedition was located to the west of Qasr el Sagra, near the bone quarries opened by Beadnell. Remains of Arsinoïtherium, Palæomastodon, and Mœritherium were obtained from these quarries. A reconnaissance into the Zeuglodon valley, near Gar el Gehannem, was described. The restorations of Mœritherium and Palæomastodon, made by Mr. Charles R. Knight under the direction of Prof. Osborn, were exhibited. From northern Africa the elephant stock migrated south through Africa, north into Europe, and north-east and east through Asia into the Americas. From a comparison of the ancestral elephant Mœritherium with the Sirenian Eotherium, it is believed that the sea-cows and elephants are derived from the same stock.

"Additional Notes on the Santa Cruz Typotheria," Dr. W. J. Sinclair. A presentation of the general conclusions reached as a result of two years' study of the Typotheria from the Santa Cruz formation of Patagonia. They appear first in the Notostylops beds (uppermost Cretaceous or basal Eocene), and become extinct in the Pampean (Pleistocene). It is generally assumed that the rodents and conies are related to Typotheria, but this does not appear to be the case; the resemblances are probably due to convergence. The Toxodontia and the Typotheria probably had a common origin. The Typotheria do not lend much support to the idea of a former land connection with Africa, showing no relationship with the recently discovered Eocene mammals from the Fayum province of Egypt.

"Progress in the Demarcation of the Boundary between Alaska and Canada," Prof. O. H. Tittmann. Details are given of the methods employed in determining the Alaskan boundary. The length of the boundary is about twelve hundred miles, extending from the Arctic Ocean south along the 141st meridian to near Mt. St. Elias, and thence along the coast strip of south-eastern Alaska. In south-eastern Alaska aluminium-bronze monuments are placed wherever it is practicable to do so, but, as most of the turning points in the line are inaccessible snow-clad peaks, they will be defined by triangulation connection with the work of the Coast and Geodetic Survey. The initial point on the 141st meridian, which is also being marked by monuments, was determined by a telegraphic longitude circuit extending overland from Vancouver through Canadian territory, and by way of Seattle and the United States Government cables to Valdez, and thence overland to the boundary.

"A Living Representative of the most Primitive Ancestors of the Plant Kingdom," Dr. G. T. Moore. Chodat has derived the green algæ from the Palmellaceæ. In this family he points out that there exist three principal stages or conditions:—(1) the zoospore condition; (2) the sporangium condition; and (3) the tetraspora condition. The author thinks that a better starting point is found in Chlamydomonas, which also shows three corresponding conditions in addition to the zoospore type, namely, the volvex type, the tetraspora type, and the endosphæra type. The tetraspora type of Chlamydomonas has developed into the Palmellaceæ, and thence into the algæ and higher green plants. Even as high as the mosses and ferns a Chlamydomonas stage is to be seen in the male gamete.

"The Explosion of the Saratoga Septic Tank," W. P. Mason. The explosion of a tank used for the storage of sewage, and supposed to be due to the ignition of an explosive mixture of marsh gas and air, is discussed. The marsh gas is derived from the fermentation of the sewage, and the ignition is assigned to the generation of phosphine, which is supposed to have ignited spontaneously.

"Some Chilean Copper Minerals," Prof. H. F. Keller. The author describes a number of rare minerals containing copper from the mines in the province of Tarapaca, Chile. Among them the most interesting are peloconite, a manganese ore containing a considerable proportion of copper; a new double sulphate of copper and magnesium isomorphous with chalcanthite; and a beautifully crystallised sulphate and arsenate of copper, which could not be identified with known species.

"Absorption Spectra of Solutions," Prof. H. C. Jones. The object of the present investigation was to ascertain whether combinations between the solvent and dissolved substance had any effect upon its power to absorb light. Certain salts in the anhydrous state have very different absorption than when combined with water. A solution of anhydrous neodymium chloride in absolute alcohol gives absorption bands differing from those obtained when a few per cent. of water is added. The application of this observation to the author's theory of hydration is discussed.

"Effect of an Angle in a Wire Conductor on Spark Discharge," Prof. F. E. Nipher. The problem to be solved is to determine the real current direction in a wire through which a spark discharge is passing. The spark discharge was that of a long eight-plate machine. One terminal was grounded on a water pipe, the other was grounded in the air. A small wire bent at a sharp right-angle was placed vertically in the lines of the earth's magnetic field, and so connected that the negative discharge could be sent either up or down around the angle, and its effect recorded on a photographic plate placed under the angle. Very interesting photographic results were obtained, but the author does not consider that the main question was conclusively answered.

"Some Results of the Ocean Magnetic Work of the Carnegie Institution of Washington," Dr. L. A. Bauer. Dr. Bauer described the work of the *Galilee* expedition in the Pacific since August, 1905. The work accomplished, briefly stated, is as follows:—(*a*) magnetic observations have been made on the ocean areas which closely approach land observations in accuracy; (*b*) errors found in magnetic charts of the Pacific Ocean amount to 1° to 5° in declination (or variation of the compass) and in dip, and about 0·04 in the horizontal magnetic force. The correction of such errors, especially the error in declination, is of great importance for the safe and rapid navigation of vessels.

"The Investigation of the Personal Error in Double-star Measures which Depend on the Position of the Angle," Eric Doolittle. This paper gives the result of the determination of the constant personal errors, and also of the probable uncertainty of the measures of double stars made during the past ten years at the Flower Astronomical Observatory of the University of Pennsylvania.

"Relative Advantages of Various Forms of Telescopes for Solar Research," Prof. G. E. Hale. Prof. Hale discussed different types of telescopes for solar research, describing particularly the equipment at the solar observatory of the Carnegie Institution at Mount Wilson, California. The advantages of the fixed horizontal telescope with heliostat were pointed out. The author also described the large spectroheliograph of this observatory, and exhibited a number of examples of photographs taken by means of this instrument, including solar prominences, faculæ, and sun-spots.

"Photographs of Daniel's Comet," Prof. E. C. Barnard. The comet was photographed on thirty-eight nights with the Bruce photographic telescope of the Yerkes Observatory. The photographs showed that the most active period in the comet's history occurred nearly a month before perihelion, at which time changes occurred so rapidly that the appearance of the comet changed from night to night. Indeed, on comparing the Yerkes Observatory photographs with photographs made at M. Flammarion's observatory in France and at the Lick Observatory on the same night, marked differences in the photographs could be seen.

## *SOME RECENT AGRICULTURAL PUBLICATIONS.*[1]

(1) A CONSIDERABLE change has come over the Journal of the Royal Agricultural Society during the last few years. Founded in 1839, its earlier numbers contained many papers of great scientific and practical interest, and the student of agricultural science frequently has occasion to refer back to them for the writings of Daubeny, Pusey, Way, Lawes and Gilbert, A. Voelcker, and others of the great masters who contributed some of their best work to its pages. It cannot be said that recent numbers are up to the high standard of the older ones. Several causes have contributed to bring about this result. The journal only appears once a year, and men are often unwilling to hold back their papers from publication for so long a period. Much of the work done at the various colleges is directly or indirectly financed by county councils, who like to see something for their money; the results are therefore issued as separate bulletins by the councils or colleges concerned, and distributed among the farming community. Recently, too, some very vigorous competitors, including the Journal of the Board of Agriculture and the Journal of Agricultural Science, have arisen, and these publish much of what would, in the past, have found its way to the Royal Agricultural Society's Journal. The present volume is smaller in size even than the first one issued nearly seventy years ago! There has been a considerable change in the character of the papers. The original paper has almost disappeared; there is, for instance, in this volume not a single contribution from the various teaching centres, if we exclude the report of the zoologist and Mr. Archibald's notes on certain birds, while Rothamsted only contributes a short note. Instead, the papers are of a "practical" or a text-book nature; they describe accepted good practice on certain matters, or give information which could be found elsewhere if the reader knew where to look for it. There is much to be said for this, and the utility of some of the papers in the present volume is beyond question, but it is doubtful whether this is quite the best line to take up. The journal would almost certainly be more valuable to the practical man if it aimed at furnishing him with a record of the progress of agricultural knowledge in its various branches so that he could apply the newly discovered facts to his own methods, if he thought he would gain thereby, and be in possession of definitely established principles to guide him whenever it became necessary profoundly to modify his practice, as happened to many of the wheat-growers a generation ago, and is happening to the hop-growers now. Such a record would include a critical survey of the numerous county council feeding and

[1] (1) The Journal of the Royal Agricultural Society of England, vol. lxviii. (1907.)
(2) Bulletins 1 to 8 of the Midland Agricultural and Dairy College (Field trials in 1907).
(3) Results of Experiments at the College Farm, 1907, University College, Reading.
(4) Bulletin No. 7 Armstrong College, Newcastle-upon-Tyne.
(5) Field Experiments in Staffordshire and Shropshire for 1907.

manurial trials, of progress in soil management, plant breeding, in bacteriology, in our knowledge of plant and animal requirements, so far as practical agriculture is concerned, besides dealing with questions of cost and with practical methods ascertained to give good results and worthy of wider trial.

To come, however, to the actual papers. Two on pigs deal respectively with the general problem and with the bacon-curer's requirements in a way that will appeal to the practical man. Mr. Archibald completes a series of notes on wild birds begun in the journal for 1892 and continued in the 1894 number; if these could be bound up into a separate booklet they would doubtless prove very attractive to the agricultural community. The report on the prize farms in Lincoln is a valuable revival of a practice discontinued since 1892; some of the best things in the literature of practical agriculture are found in the old reports. Mr. Güssow's article on poisonous plants is of interest both to botanists and to practical men.

Dr. Voelcker's report on the work carried out at Woburn is as interesting and suggestive as usual. In the pot-culture station, lithium salts have been found to be very poisonous to wheat, as little as 0·05 per cent. reducing the yield to one-quarter, whilst manganese and iron salts increased the yield. A connected account of the work is promised, and will be awaited with interest. In the field experiments it has been thought desirable to alter the scheme of manuring consistently adhered to since 1876, and we cannot help thinking that this is a great mistake. Stackyard field is one of the best experimental fields in the kingdom, and would prove an almost ideal place for solving problems in soil physics and in soil bacteriology when the methods of working are sufficiently developed. Manures take so long to act on the soil, and we know so little about the action, that it would surely have been better not to break the continuity of treatment, but to leave the fields as material for future workers just as is being done at Rothamsted.

(2) to (5) These bulletins are typical of much of the work executed under the auspices of county councils. The field trials fall under two heads, variety and manurial trials; in the former a number of the varieties of a plant are grown to see which gives the biggest yield, in the latter a scheme of manuring is designed to test the effect of the various fertilisers. Properly executed with duplicate plots and accompanied by adequate chemical analyses, the manurial trials are capable of furnishing results both of practical and scientific interest. Without soil analyses the results have only a temporary value, and are, indeed, often useless to those who do not know the actual field on which the trial was made. Although no analyses are recorded in the bulletins, it is to be hoped they exist. The Midland College bulletins speak well for the energy and enterprise of the staff. Some refreshing departures from the conventional *motif* are found in the Reading report, the experiments on weeding and on cultivation being particularly interesting. E. J. R.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The Public Orator, Dr. Sandys, spoke as follows in presenting to the Chancellor the five representatives of mathematics and natural science who received the degree of Doctor in Science *honoris causa* on June 17:—

The Hon. Charles Algernon Parsons, C.B., F.R.S., Honorary Fellow of St. John's.

Regiae Societatis praesidis, Astronomiae fautoris maximi filius, quem hodie decoramus, etiam in ipsa pueritia machinarum novarum inventor felix fuisse dicitur. Postea Dominae Margaretae Collegii alterius scholaribus adscriptus, honorum mathematicorum in classe prima, Dominae Margaretae in nave prima, locum insignem est adeptus. Deinde Archimedis aemulis hodiernis additus, non grammophoni tantum tubam terribilem sonitus suaviores edere docuit, sed etiam navium vi vaporis impulsarum more novo movendarum opus difficillimum exitu prospero est aggressus. Machinae genus illud novum, a Societate Regia numismatis aurei honore approbatum, etiam navibus maximis oceanum transeuntibus postea est accommodatum. Quod si Neptunum ipsum alumni nostri de meritis interrogare volueritis, sine dubio Neptunus ipse protinus respondebit:—

Experto credite quantus
Per pontum properet, quo turbine torqueat undas.

Sir Andrew Noble, Bart., K.C.B., F.R.S.

Ballistarum scientiam hodiernam baronetti huius ingenio plurimum debere inter omnes constat. Milites nostri, machinarum bellicarum in apparatu neque terra neque mari rerum novarum cupidi, viri huius praesertim consiliis admoniti, meliora didicerunt. In ballistis vero nostris in melius mutandis, atque etiam imperii Iaponici in navibus aedificandis, nemo Archimede nostro venerabili plus effecit. Nemo operariis nostris cessantibus et mercedem maiorem flagitantibus potiora suasit. Quid autem est praeclarius quam honoribus perfunctum senem posse dicere idem quod apud Ennium dicat ille Pythius Apollo, se esse eum unde sibi et populi et reges et omnes sui cives, summarum rerum incerti, consilium expetant?[1]

Sir William Crookes, F.R.S.

Cancellarii nostri auspiciis nunc demum eum ipsum praesentem videmus quem diu desideravimus, quem alia ex alia scientiarum in studiis occupata Societas praesidem suum olim suspexit. De scientia chemica et physica explorenda per annos plus quam quinquaginta praeclare meritus, in rerum primordiis primis spectri (ut aiunt) auxilio examinandis eam ipsam provinciam feliciter exploravit, quae etiam scientiae physicae in officina nostra maximo cum fructu indagata est. In observando quam acutus est, in experiendo quam peritus, in rebus difficillimis investigandis quam pertinax! Viri tanti exemplo Vergili dictum denuo praeclare confirmatum est:—"Labor omnia vicit improbus."

Prof. Horace Lamb, F.R.S., Late Fellow of Trinity, Professor of Mathematics in the Victoria University, Manchester.

Abhinc annos septem et triginta Newtoni in Collegio alumnum nostrum Newtoni disciplinam perquam feliciter coluisse constat. Postea in Australia professor nominatus, in colonia nostra remotissima studiorum mathematicorum, studiorum physicorum, diu duratura posuit fundamenta. Deinde scriptorum eius propter merita insignia a Mancuniensibus domum revocatus, ea quae ipse de vi electrica disputationum suarum in regione pura invenerat, ab aliis in machinis fabricandis vita nova donata vidit. Peritis nota sunt "Hydrodynamica" eius, in editione nova in maius exaucta. Etiam aliis innotuit oratio Societatis Britannicae in conventu Cantabrigiensi haud ita pridem pronuntiata, in qua primum studiorum mathematicorum historiam recentiorem dilucide delineavit; deinde etiam in studiis illis severis aliquid audendum, aliquid periclitandum esse dixit; denique rerum naturam nondum omnem esse exhaustam, sed miraculis etiam nunc esse plenam, quae scientiarum cultores per plurima in posterum saecula sint exercitura.

Prof. George Downing Liveing, F.R.S., Fellow of St. John's.

Abhinc annos duo et sexaginta Cantabrigiam primum petivit vir intra proximum quinquennium in disciplina mathematica et in rerum naturae studiis honores summos adeptus, qui, post itinera sua Berolinensia, scientiae chemicae inter nosmet ipsos docendae sese strenue dedicavit, et Divi Ioannis in Collegio primam scientiae illius officinam Cantabrigiensem aedificandam curavit. Postea Universitatis professor nominatus, horum studiorum officinae amplissimae publice condendae summam diligentiam, summam operum exterorum experientiam, feliciter adhibuit. Lucis vero radiis spectri (ut aiunt) ope retexendis, et rerum naturae penetralibus examinandis, quot annorum labores dedicavit! quot discipulis studiorum uno tenore assidue peractorum exemplar quam pulchrum praebuit! In operibus bonis adiuvandis liberalissimus, in negotiis academicis partium liberalium defensor indefessus, per tot annos inter tantas rerum vicissitudines animum serenum, aequum, prudentem, modestum conservavit.

[1] Cicero, "De Or.," i. 199.

Virum talem preconio eodem dignum esse crediderim, quo populi Americani praeses quidam magnus, professoris nostri in anno primo munus suum ingressus, populi sui a poeta eximio postea est laudatus :—

En vir benigne intentus, fortis, providus,
Sagax patiensque, laudem non culpam timens.[1]

On June 17, Lord Rayleigh was formally installed as Chancellor of the University in succession to the late Duke of Devonshire. At a luncheon given by the master and fellows of Gonville and Caius College to the Chancellor, the recipients of honorary degrees, and a large party of guests, Sir Andrew Noble announced that several of Lord Rayleigh's friends, non-resident members of the University, proposed, in order to express the gratification of the scientific world at his election, to offer to the University a fund large enough to provide an annual award to be associated with the name of the Chancellor.

The Harkness scholarship for 1908 has been awarded to T. O. Bosworth, and the Wiltshire prize to W. C. Smith. The John Winbolt prize has been awarded to L. B. Turner, for his essay on "The Elastic Breakdown of Materials submitted to Compound Stress." The examiners were also of opinion that the essay sent in by E. T. Busk was deserving of honourable mention.

The special board for biology and geology has approved a grant of 200*l.* from the Balfour fund made by the Balfour managers to J. Stanley Gardiner, in aid of researches in the Seychelles, Aldabra, and the neighbouring islands.

The professorship of chemistry is vacant by the resignation of Prof. Liveing. The electors will meet for the purpose of electing a professor on Saturday, July 25. Candidates are requested to communicate with the Vice-Chancellor on or before July 13.

OXFORD.—The Drapers' Company has offered to make a grant of 22,000*l.* for a new electrical laboratory at the University, and to contribute 1000*l.* toward its equipment. This generous offer will be brought before Convocation in October.

LIVERPOOL.—The council of the University has instituted two new chairs, one of Celtic studies and the other of mediæval archæology. Prof. Kuno Meyer, who already holds the endowed chair of German in the University, has been appointed to the first of these new chairs, and Mr. F. P. Barnard to the second.

A COURSE of lectures and demonstrations on the scientific study of fisheries has been started this summer session in the University of Aberdeen. It is being conducted by Dr. T. Wemyss Fulton, scientific adviser to the Scottish Fishery Board.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Royal Society**, April 30.—"A Photographic Determination of the Elements of the Orbits of Jupiter's Satellites." By Bryan **Cookson**. Communicated by H. F. Newall, F.R.S.

During the opposition of Jupiter in 1902, the author was engaged in making a series of measurements of the relative positions of the four Galilean satellites with the 7-inch heliometer at the Cape Observatory. Simultaneously with these visual observations, photographs were taken with the astrographic telescope. This paper contains a short account of the work done in connection with the photographs; a detailed account has appeared as vol. xii., part iv., of the "Annals of the Cape Observatory."

The investigation with the heliometer was undertaken with the object of determining the mass of Jupiter and correcting the best available elements of the orbits of the satellites, which observation showed were considerably in error.

The mass of the system of Jupiter, in terms of the sun's mass, was determined with great care from the heliometer observations. The value finally deduced is

$$1 : 1047{\cdot}30 \pm 0{\cdot}06.$$

[1] (Abraham Lincoln).
"The kindly-earnest, brave, foreseeing man,
Sagacious, patient, dreading praise, not blame."
Lowell's "Commemoration Ode," vi. *ad finem.*

In the case of the second satellite, which has an orbit at an inclination of 0°·48 to Jupiter's equator, the node retrogrades 12° per annum, and of this motion 82 per cent. is due to the compression of Jupiter, 4 per cent. to the influence of satellite I., 13 per cent. to that of III., and 1 per cent. to that of IV.

The fifth satellite discovered by Barnard is so near to the primary that the node of its orbit revolves through about 912° per annum, and second-order terms begin to make themselves felt. A careful measurement of this motion would be of much value, for a comparison of the compression of Jupiter, deduced from the motion of the node of V. with that deduced from the motion of the node of II., might provide information concerning the distribution of mass in Jupiter.

June 4.—"On the Decay of the Radium Emanation when dissolved in Water." By R. B. **Moore**. Communicated by Sir William Ramsay, K.C.B., F.R.S.

The results obtained by Ramsay and Cameron on dissolving radium emanation in water and in copper sulphate solution have made it advisable to investigate the behaviour of the emanation, when dissolved in such solvents, from a radio-active standpoint. The present note deals with the rate of decay of the radium emanation when dissolved in water. The emanation accumulated by 110 milligrams of radium bromide in two days, with the accompanying oxygen and hydrogen, was collected in a gas burette over mercury. After exploding, a small amount of water was run into the burette, and the solution of the emanation thus obtained, together with the slight excess of hydrogen, was transferred to a glass tube 2 inches long and 5 mm. in diameter, which had previously been exhausted. The solution filled about five-sixths the volume of the tube. The latter was sealed, and the decay curve of the emanation was obtained by means of the $\gamma$ rays, sheet lead being used to cut down the rays to the required amount. The half-time period found was 3·8 days. It may, therefore, be assumed that the emanation decays at the same rate when dissolved in water as it does in air.

**Geological Society**, June 3.—Prof. W. J. Sollas, F.R.S., president, in the chair.—The fossiliferous rocks of the southern half of the Tortworth inlier: F. R. **Cowper Reed** and Prof. S. H. **Reynolds**. This paper is a continuation of that on the igneous rocks of this area published in 1901 (Quart. Journ. Geol. Soc., vol. lvii., p. 267). The rocks are affected by the Hercynian flexures which produced the Bristol coal-basin, and the outcrop of the beds in the main follows the horseshoe-shaped outcrop of the Old Red Sandstone. This regularity is lost at Daniel's Wood and Middlemill. Two important transverse faults traverse the outcrops, which are further obscured by the overlap of unconformable Trias. The trap-bands are found to be confined to the Llandovery, the number of recorded fossils has been largely added to, and previous statements as to the thinness and imperfect development of the Ludlow rocks and as to the probable exposure of the district to erosion in Ludlow and Lower Old-Red-Sandstone times are confirmed.

**Chemical Society**, June 4.—Sir W. Ramsay, K.C.B., F.R.S., president, in the chair.—The interaction of copper and nitric acid in presence of metallic nitrates considered with reference to the existence of hydrates in solution: E. H. **Rennie**, A. J. **Higgin**, and W. T. **Cooke**. The authors consider that the acceleration caused by some nitrates and the retardation induced by others on the dissolution of copper in nitric acid are due to the withdrawal by the salts of water or nitric acid from the solution, and the consequent concentration or dilution of the acid.—The triazo group, part iv., allylazoimide: M. O. **Forster** and H. E. **Fierz**. Allylazoimide prepared in small yield and with some difficulty from allyl chloride and sodium azide is a mobile refractive liquid which boils at 76°·5 under 760 mm. pressure.—Aromatic arsonic and arsinic acids: F. L. **Pyman** and W. C. **Reynolds**. The following new substances are characterised:—bis-2-aminotolyl-5-arsinic acid, bis-2-acetylaminotolyl-5-arsinic acid, bis-*p*-aminophenylarsinic acid, and bis-*p*-acetylaminophenylarsinic acid.—Condensation products from aminopinenedicarboxylic acid: W. **Godden**.—A delicate test for bromides alone or in solution with chlorides: J. S.

**Jamieson.** The solution is heated with dilute sulphuric acid and potassium dichromate, shaken with chloroform, and the chloroform layer washed with water two or three times, and finally shaken with dilute potassium iodide. In the presence of a bromide the chloroform is coloured violet.—Experiments on the synthesis of *l*-methyl*cyclo*hexylidene-4-acetic acid,

$$CHMe\left\langle\begin{array}{l}CH_2.CH_2\\ CH_2.CH_2\end{array}\right\rangle C{:}CH.CO_2H,$$

part i.: W. H. **Perkin,** jun., and W. J. **Pope.**—A method for the measurement of rate of change in solid alloys. Preliminary note: G. D. **Bengough.**—Viscosity determinations at high temperatures: C. E. **Fawsitt.**—Dinitrodiphenylamine-*o*-sulphonic acid. Preliminary note: S. **Smiles.**—The study of the absorption spectra of the hydrocarbons isolated from the products of the action of aluminium chloride on naphthalene: Miss A. **Homer** and J. E. **Purvis.** These hydrocarbons (Trans. Chem. Soc., 1907, xci., 1103) have absorption curves which agree with the view that $C_{14}H_{16}$ is a naphthalene derivative, whilst $C_{10}H_{26}$ has a constitution similar to that of $\beta\beta$-dinaphthyl, and $C_{26}H_{22}$ that of an alkyl derivative of picene, and not of dinaphthanthracene, as had been previously suggested.—The synthesis and constitution of certain pyranol salts related to brazilein and hæmatein: W. H. **Perkin,** jun., R. **Robinson,** and (in part) M. R. **Turner.**—Brazilin, hæmatoxylin, and their derivatives, part ix., on brazilin, hæmatin, and their derivatives: P. **Engels,** W. H. **Perkin,** jun., and R. **Robinson.**—The effect of constitution on the optical activity of nitrogen compounds: R. W. **Everatt.**—The electrolytic oxidation of some hydroxybenzoic acids: A. G. **Perkin** and F. M. **Perkin.**—Note on morindin: A. G. **Perkin.** It is suggested that the morindin of *Morinda citrifolia* obtained by Oesterle and Tisza is different from that of *M. umbellata*, since it appears to be different in composition and to yield a different sugar on hydrolysis.—Some esters of arsenious acid: W. R. **Lang,** J. F. **Mackey,** and R. A. **Gortner.** Descriptions of a number of alkyl esters prepared by heating alcohols and phenols in contact with arsenious oxide, using a reflux condenser with a Soxhlet attachment containing anhydrous copper sulphate to remove water formed, are given.—α-Methylcamphor and fenchone: W. H. **Glover.** It is shown that α-methylcamphor and fenchone are essentially different in type, and on this ground exception is taken to Wallach and Semmler's formula for fenchone, which it is proposed should be represented as follows:—

$$\begin{array}{l|l}CH_2.CH_2.CMe & \\ & \quad CMe_2 \\ CH_2.CH\text{–}CO & \end{array}$$

.—Ester hydrolysis and theories of esterification: A. **Lapworth.**—Experiments on the formation and hydrolysis of esters, acetals, and allied compounds. Preliminary note: E. **Fitzgerald** and A. **Lapworth.**

**Linnean Society,** June 4.—Dr. D. H. Scott, F.R.S., president, in the chair.—Note on the spicules of *Chirodota geminifera*, Dendy and Hindle: Prof. A. **Dendy.** A correction to the paper recently published in the society's journal, Zoology, xxx. (1907), pp. 95–124.—The Caryophyllaceæ of Tibet: F. N. **Williams.** The collection was made during the recent military expedition to Lhassa, and it raised the known species to forty-three, from the eleven reported by Messrs. Hemsley and Pearson in the society's journal, Botany, xxxv. (1902), pp. 169–170. The route taken by the marching column was virtually unexplored previously, hence the number of novelties, namely, nineteen new species.—*Koonunga cursor*, a remarkable new type of malacostracous Crustacea: O. A. **Sayce.**—The Polychæta of the Indian Ocean: F. A. **Potts**; and the Stylasterina, from the same, elaborated by Dr. S. J. **Hickson** and Miss Helen M. **England.**—A contribution to the mycology of South Africa: W. N. **Cheesman**; with a supplement by T. **Gibbs.**

EDINBURGH.

**Royal Society,** June 1.—Dr. John Horne, vice-president, in the chair.—Note on some points in the anatomy of a Trilobite, *Calymene blumenbachii*: Dr. Malcolm **Laurie.** The "hypostome" in Calymene does not articulate with the doublure of the carapace. The margins turn back and articulate about one-third of their length from the front with the inside of the glabella. Movement on this joint draws the front of the hypostome away from the doublure, with which it is connected only by a membrane. There is also a plate articulated by a round joint behind the rostral plate which seems capable of turning into a horizontal position. It becomes a question whether the mouth in this form was in front of or behind the "hypostome."—Experiments with Heusler's magnetic alloy: J. G. **Gray.** The points mainly investigated were the magnetic properties of the alloy between 0° C. and 400° C., and the effects of quenching after heating to high temperatures, and of cooling in liquid air. The effect of the low temperature was to increase the susceptibility. In this respect it resembled Hopkinson's nickel-iron alloy, which begins by being non-magnetic at ordinary temperatures, but becomes magnetic after having been cooled to about −50° C. This result is the more curious inasmuch as Hopkinson's alloy is composed of magnetic materials, but is non-magnetic at the start, whereas Heusler's alloy is magnetic, but is composed of non-magnetic metals.—Note on the electrical resistance of spark gaps: Dr. R. A. **Houston.** The method employed was by use of the resonance curve after the manner introduced by Bjerknes. The resonator was adjustable, and the maximum resonance was detected by means of a galvanometer deflection produced by a thermo-couple, which was heated by the discharge. A deflection was also taken when the resonator had its self-induction slightly altered on each side of the adjustment for the maximum effect. From these and other data the logarithmic decrement of the oscillator can be calculated by means of a formula due to Drude, and thence, knowing the capacity and self-inductance, we can estimate the resistance of the spark gap. Results were obtained for different materials of the electrodes (zinc, aluminium, cadmium, tin, iron, &c.), and for various lengths of spark gap. These were somewhat irregular, but in the case of nickel and aluminium increase in length of spark caused a striking decrease in the decrement.—Treatment of aneurism by electrolysis: Dr. Dawson **Turner.** The many attempts to utilise electrolysis in aneurisms have been made in the hope that clotting might occur round the pole and thus serve as a nucleus for further coagulation and deposits of fibrin, with partial filling of the aneurism cavity. The experiments showed that silver and platinum, which have been mostly used by surgeons, had no action of the kind desired, and, besides, gave off gas bubbles in quantity. There is similarly no advantage in using iron or nickel, for no precipitates are formed. Lead, copper, and zinc, however, all produce precipitates, and of these zinc is to be preferred, both because of the character of the precipitate and because of the complete absence of gas bubbles.—Dr. Dawson **Turner** also exhibited some of Prof. Leduc's photographs of growth due to osmosis, and the microscopic structure of such growth.—The "negative viscosity" of aqueous solutions: Dr. W. W. **Taylor** and T. W. **Moore.** The results brought forward in this paper proved the insufficiency of any of the recognised explanations of this phenomenon.

PARIS.

**Academy of Sciences,** June 16.—M. H. Becquerel in the chair.—A partial differential equation relating to a closed surface: Emile **Picard.**—Researches on the rotation and lustre of the various atmospheric layers of the sun: H. **Deslandres.** A description of a modification of the method given in 1902 for the study of the rotation of the planets, and now applied to the sun. Instead of rotating the spectroscope, which becomes inconvenient with the large dispersion possible for the solar rays, the image of the sun upon the slit is inverted by a suitably mounted prism. The results of comparisons of the iron and cobalt lines (λ 3935·96 and λ 3936·12) and the calcium line $K_3$ lead to the conclusion that the upper layers of the solar atmosphere vary considerably in the velocity of rotation, and these may be different in the two hemispheres.—The organs and mode of vegetation of the Neuropterideæ and other Pteridosperms: M. **Grand'Eury.**—The ninth campaign of the *Princesse Alice*: the **Prince of Monaco.** This voyage in the Arctic regions lasted from June 16 to September 12, 1907, and was much hindered by unusual quantities of ice and by fog. Work was done in the fields of meteorology, oceanography, geography, zoology, and physics. A curious fact with regard to Lumière autochrome plates is noted. Commencing at about latitude 60° 40′ N., a blue veil appeared on the plates, increasing in intensity with the progress north up to the highest point reached, 79° N. The inverse effect was noted on the return south.—Bilinear forms: M. **de Séguier.**—The partial differential equation of vibrating membranes: S. **Sanielevici.**—The flocculi of hydrogen photographed with the rays $H\alpha$ and $H\delta$: G. A. **Hale.** The flocculi appear to move less rapidly than the gaseous atmosphere in which they float.—The apparent dispersion of light in interstellar space: Pierre **Lebedew.** The experimental results on variable stars obtained by Ch. Nordmann, and confirmed by G. Tikhoff, have been explained by these authors by the hypothesis that light undergoes a dispersion in interstellar space comparable with the dispersion in air at a pressure of 7mm. at 0° C. In the present paper this hypothesis is shown to be improbable and unnecessary.—An arrangement for the study of the sensitiveness of electrolytic detectors: P. **Jégou.** The method described does not require the mental comparison of the loudness of a sound heard in the telephone with a sound previously heard under another set of conditions. The instrument figured gives readings on an arbitrary scale corresponding to no sound in the telephone. The apparatus has been applied to study the effect of temperature on the sensitiveness of the electrolytic detector.—The photography of speech: M. **Devaux-Charbonnel.** A microphone is placed in series with a battery and an oscillograph, and the movements of the latter photographed. A study of the vowels showed that the curves are always the same for each, provided that care be taken to pronounce them in the same manner. This condition was easy to fulfil for I and U, more difficult for A, O, E′, and most difficult for the mute E.—The ultimate rays of the metalloids: tellurium, phosphorus, carbon, silicon, and boron: A. **de Gramont.**—Researches on the solubility of silver iodide in ammonia: H. **Baubigny.** In previous determinations of this constant sufficient care has not been taken to define the temperature and the strength of the ammonia. At 16°, in ammonia of density 0·926, the solubility is of the order of 1/6000, or less than half the solubility usually accepted.—Ammoniacal chloride of arsenic: MM. **Besson** and **Rosset.** The composition of the compound formed by the action of ammonia on $AsCl_3$ is held to be $AsCl_3.4NH_3$. The products separated by M. Hugo by the action of liquid ammonia do not correspond to the original compound, the liquid ammonia behaving rather as a reagent than as a solvent.—The alkaline chloroiridates and chloroiridites: Marcel **Delépine.**—The hydrates of the phosphoric acids: H. **Giran.**—The hydrates of the fatty acids: D. E. **Tsakalotos.**—Colloidal barium sulphate: A. **Recoura.** A solution of sulphuric acid in pure glycerol is neutralised with barium ethylate. The liquid remains limpid, and diluted with ten times its volume of water gives a colloidal solution of barium sulphate, without any precipitation taking place. Solutions of metallic salts, with the exception of mercuric chloride and salts of barium, determine the precipitation of the sulphate.—Constitution of the tetramethyldiaminobenzhydrylmethylenic compounds. The replacement of the hydroxyl of Michler's hydrol by the alkylmethylenic residues: R. **Fosse.**—The action of alkalis on mono- and di-methylarsinic acids and on their iodo-substituted derivatives: M. **Auger.**—The lactone of 3:4-dioxybutyric acid: P. **Carré.** Details are given of the most advantageous method of preparing the dioxybutyric acid from monochlorohydrin, and of the isolation of the lactone.—The double phosphate of magnesia and monomethylamine: Maurice **François.** Magnesium phosphate cannot be employed to separate ammonia from methylamine, since the latter forms a double phosphate analogous to the ammonio-phosphate. Magnesium phosphate in excess can be used to separate ammonia or methylamine from di- and tri-methylamine.—A modification of the properties of gluten in presence of sulphurous acid: J. **Dugast.**—The increase of the vital capacity and thoracic perimeter in children: M. **Marage.** A set of respiratory movements was taken by the children for five minutes twice daily. The beneficial effects were very marked, and are set out in tabular form.—The action of the zinc ion in microbial media: Joseph **Mendel.**—Contribution to the study of the constitution of proteid materials. A new method of hydrolysis with hydrofluoric acid: L. **Hugonenq** and A. **Morel.** Hydrofluoric acid at 20 per cent. strength, and at the temperature of the water bath, possesses many advantages as a reagent for the hydrolysis of proteid materials. It gives a complete hydrolysis, and causes less secondary changes than the reagents at present used.—Researches on the hybrids of barley: L. **Blaringhem.**—The hovering of birds: P. **Amans.**—Reply of M. Marcel **Deprez** to the criticism in the preceding note.

## DEVELOPMENT OF ASTRONOMY.

*A History of Astronomy.* By W. W. Bryant. Pp. xiv+355. (London: Methuen and Co., n.d.) Price 7*s.* 6*d.* net.

IT is somewhat difficult to decide on the attention to be devoted to a volume so small as the present one, as it is from the first apparent that as a "history" justice could only be done even to a few sections of the subject. The intention of the author appears to have been to give a more or less popular account of the evolution and progress of the chief divisions of the science, without attempting to render the story complete. Starting with a short review of the astronomical notions of the early races, in the first two chapters the various claims to priority of record are examined, the Chinese data purporting to extend back to 2500 B.C.; the Indian system has tables, &c., supposed to be based on phenomena of the year 3102 B.C.; Egypt and Chaldea are also of very great antiquity, the latter recording the eclipses observed at Babylon in 721 and 720 B.C. In chapters iii. and iv. the advances made by the Greeks and Arabian philosophers are briefly reviewed. The Arabs excelled in methodical accuracy, and modern astronomy owes them an immense debt for the introduction of the decimal notation, replacing the more cumbersome numerical notations of the Greeks and Romans.

The end of these two schools brings the record down to the fifteenth century, when the great revival of philosophical thought in Europe commenced to be widely felt. The work of Copernicus, who was born at Thorn, in Polish Prussia, in 1473, was published in 1543, and practically inaugurated a new era, in that the Ptolemaic system was shown to be inadmissible, and the new Copernican system soon forced its way to the front, as it explained many phenomena which previously gave difficulty. Copernicus, however, was but a theorist, and it was by Tycho Brahe, born of a noble Danish family in 1546, that the great observational advancement of the sixteenth century was made. The story is then continued, giving the successive advances made in turn by Kepler, Galileo, Newton, Laplace, and the seventeenth and eighteenth century early astronomers Flamsteed, Halley, Bradley, and Herschel. Up to this stage the treatment has been chronological, but from this point the author, apparently finding difficulty in correlating the overwhelming flood of new observations which marked the end of the eighteenth and the whole of the nineteenth century, takes a series of subject divisions, and gives the main features of progress in both theory and observation relating to each. This naturally leads to various redundancies, and we doubt if the non-expert reader will obtain a clear idea of the chronological progress during these later times.

Chapter xv. is devoted to the modern development of observatories and instruments, which is very interesting reading. No mention is made, however, of the great influence on instrument design which has resulted from the use of the horizontal telescope in conjunction with a moving mirror of the Foucault siderostat or Lippmann cœlostat type, as is done at Paris, London, and at several stations in America. Chapter xvii. deals with the discoveries connected with the physical nature of the sun, the periodicity of the sun-spots, faculæ, &c. In the two following chapters the spectroscopic researches in connection with the sun are related from the time that Kirchhoff made his historic observation of absorption in 1859. Naturally the enormous development of this branch of astronomy since the 'eighties has made it impossible for the author to give more than a superficial narration of the progress made, but what he has included is both useful and interesting.

Chapters xx. to xxvi. deal with the individual members of the solar system. Most of this calls for little comment; in the chapter on Mars, predominance is given to the "carbonic acid" theory of the polar caps, but as we know from the recent researches of Lowell, it is now conclusively proved that water vapour in quantity does exist on the planet, and it is therefore unnecessary to discuss the more improbable theory. The concluding remark in this chapter is somewhat ungracious in an impartial review of the history of the subject; scepticism regarding the Lowell Observatory announcements is practically non-existent in the minds of anyone competent to appreciate the work done at that institution. Although open-minded in general, remarks like this show a tendency to urge an isolated opinion on matters requiring very wide discussion. In general, it may be said that these chapters on the solar system are very well up to date, and a short *résumé* is added giving the more modern theories of cosmogony, in which the simplicity of the original nebular hypothesis of Laplace has gradually given way to more modified views, no one of which, however, is at present definitely accepted.

Comets, meteors, and the Zodiacal Light are dealt with in chapter xxvii., the various cometary theories being very ably described without introducing any technicalities. Chapters xxviii.–xxxii. are occupied with the history of stellar research. The introduction and design of star catalogues of various degrees of precision, down to the great international *Carte du Ciel*, zone work, observations of proper motion and parallax, double star systems, variable stars, clusters and nebulæ, &c., are described in their order of development. The penultimate chapter, on stellar spectroscopy, occupies but twelve pages, reviewing briefly the classifications of Secchi, Vogel, Pickering, Lockyer, and Huggins. A curious statement is that the star Sirius has but little atmosphere, as indicated by its thick hydrogen lines and thin metallic lines. Surely the opposite is the case; for the hydrogen absorption lines to be so wide requires a very extensive atmosphere, at the base of which there must be a very considerable gravitational pressure. Little mention is made of the enormous progress made during recent years by the investigations of "enhanced lines" in stellar classification, although this is now

K

accepted as a criterion for the differentiation of several of the stellar groups.

Approached with the above reservations the volume is certainly attractive, and the only serious omission appears to be the complete absence of references to sources of the information, so that a reader desirous of further study on any point is left entirely unaided.

The plates chosen for illustrating the volume are excellent and beautifully reproduced. The usefulness of many of them to the beginner will be somewhat impaired on account of the orientation letters being entirely omitted, and in several cases the plates are oriented differently from the majority, thereby leading to further confusion. Illustrations of many old portraits and ancient impressions of the solar and stellar systems are included, which will be the more interesting in that they are not easily available elsewhere. The index, well planned in general, contains many useless references, in some cases quoting names which, when referred to, prove to be merely names with no record of work done or other points of interest.

It will thus be evident that opinions on the volume will probably diverge along two lines; to the more advanced reader it is likely to appear superficial, as only touching with note-like brevity a few of the many chapters of the science; to the reader merely interested in astronomical development, however, it should appeal as a popular and very attractive account of many interesting sections of nature-study.

## *VON RICHTHOFEN'S CHINESE DIARIES.*

*Ferdinand von Richthofen's Tagebücher aus China.* Ausgewählt und herausgegeben von E. Tiessen. Two vols., illustrated. Vol. i., pp. xv+588; vol. ii., pp. iv+375. (Berlin: Dietrich Reimer, 1907.) Price 20 marks.

WHEN Ferdinand von Richthofen's life was ended his great work on China still remained unfinished. The third volume was not only unwritten, but had become unwritable, for, besides a description of southern China, it was intended to contain an account of the culture, civilisation, and organisation of China as a whole, and, apart from the magnitude of the subject, the complete alteration in the conditions of this "unchanging" country since the date of his travels had made much of his observation and experience inapplicable to the existing state of affairs. Besides the missing volume of his great work, von Richthofen also left unfinished the popular account of his travels, a work which he regarded as a duty owed to his fellow-men by every traveller in unexplored or little-known countries, and had, indeed, nearly half completed when the publication of his great work was assured, and monopolised the whole of the time and energy which was not devoted to his duties as professor. To fill in, so far as was possible, these gaps in his published work, and to meet a generally felt wish among Baron von Richthofen's old students and friends, Herr Tiessen, with rare skill, has compounded from von Richthofen's unpublished manuscripts, his diaries, and his letters home, one of the most interesting and enlightening books of travel which have been published.

On August 3, 1868, von Richthofen left San Francisco with the deliberate intention of undertaking a geological examination of China. His hope was that if he could manage to spend a year in that country he would be able, by the importance of the results, to interest the Government and obtain from it the assistance needful for the prosecution of his purpose. This first year of work was provided for by the enlightened liberality of Californian capitalists, who foresaw the practical importance of a scientific investigation of the resources of China, and, through the Bank of California, provided funds for an expedition. Arriving in China, von Richthofen was soon disillusioned of any hope of assistance from the Government, but nevertheless, and in spite of every discouragement, determined to pursue steadfastly his resolve. After some short excursions, mostly devoted to the examination of real or reputed discoveries of coal or ores, his first important journey was the descent of the Yangtse and the examination of its banks from Hankow to its mouth. This journey was an important one in more than one way, and in none more so than in the acquisition of Paul Splingaert, a Belgian, who had acquired an intimate colloquial knowledge of the Chinese language and an insight into the character and habits of thought of the Chinese people. The value of his services appears repeatedly throughout the book, and the importance of the results of von Richthofen's travels is very largely due to the fortunate combination of the man who knew how to collect and utilise information with the man who was able to obtain it. On this journey, too, von Richthofen made the first of those observations on the loess which led to the development of his well-known and now generally accepted theory of the origin of that remarkable formation; between Nankin and Chin-kiang he found remains of Helix in the loess near the hill of Fangshan, and remarks that this discovery is inconsistent with the theories of Pumpelly, who regarded the loess as a fresh-water, or of Kingsmill, who looked upon it as a marine, deposit.

The next journey took him through the province of Shantung, where he discovered large and important coalfields, and was the first to recognise the value of Kiao-chau as a port of access to, and an outlet for, the mineral wealth of the province, a discovery of which the German Government took advantage at a later period. After a long journey through Mongolia to Pekin and back to Shanghai, he accepted a proposal from the Shanghai Chamber of Commerce for an exploration of the interior of China; and so, in spite of the failure of his hopes of Government support, von Richthofen found himself in a position to carry out the design with which he left America, and on January 1, 1870, set out from Canton on the first of his two great journeys through the heart of the Chinese Empire, which ended with his return on May 21, 1872, to Shanghai; whence, after a stay of five months, devoted to preparing a report on his travels for the Shanghai Chamber of Commerce, he returned to his native land after an absence of just over twelve and a half years.

These are the travels of which we are given a simple and straightforward account devoid of all scientific technicalities. Those who wish to make use of von

Richthofen's scientific work must look elsewhere; but in this book they will find, not only an interesting account of his journeys, but a marvellous revelation of the real China. On almost every page of the narrative stand prominent, not merely the sources of China's weakness, but also the enormous latent power of the country, and there is borne in upon one an almost oppressive feeling that a China awakened, reformed, and patriotic could set the world at nought, and a China ambitious besides would be a real yellow peril. But all those who knew the late Baron F. von Richthofen will value this book less for its description of China than as a picture of its author; on every page of the narrative his simplicity, honesty, and nobility of character stand forth, his steadfastness in pursuing the course he had set before him in spite of discouragement, the intrepidity and tact which extricated him from difficult and dangerous situations, when set upon and mobbed by the colliers in Shantung, when he visited the bitterly anti-foregn "university" of Yolushan, and especially in the extremely critical occurrence which put an end to his further travels, all stamp him as a true representative of that aristocracy, not merely of birth, but of intellect and character, which by common consent raises some individuals far above the level of the great mass of their fellow beings. No more acceptable or worthy memorial of their author could well have been contrived than these two unpretentious volumes.

## THE GENERA OF FLOWERING PLANTS.

*Genera Siphonogamarum ad Systema Englerianum conscripta.* By Dr. K. W. von Dalla Torre et Dr. H. Harms. (Leipzig: W. Engelmann, 1900–1907.)

THE completion of the "Genera Siphonogamarum," by Drs. K. W. von Dalla Torre and H. Harms, will have been welcomed by all students of the taxonomy of siphonogams—or, as we are still used to say, phanerogams—and no doubt also by many other botanists. Invaluable as Engler and Prantl's "Natürliche Pflanzenfamilien" is as the embodiment of the most recent researches in the systematic botany of phanerogams, it suffers from one serious omission, the lack of all references to the original descriptions of the genera and their subdivisions. To fill that gap was the primary object of the publication of the "Genera Spihonogamarum." At the same time it was intended to make the synonymy of the genera as complete as possible, and give a comprehensive description, on the one hand, of their disposition within the families and the Englerian system generally, and, on the other, of their subdivisions. Lastly, the work should serve as a catalogue for those botanical collections which are arranged after the "Natürliche Pflanzenfamilien"; and there is no doubt that in most respects the problem has been solved in an admirable way.

The book consists of two parts. The first part (pp. 1–637) is headed by an "Enumeratio Familiarum Siphonogamarum," and contains the disposition of the systematic units above the rank of species, whilst the second (pp. 638–921) is taken up by an "Index Nominum." The basis of the whole work is, as indicated in the title, Engler and Prantl's "Natürliche Pflanzenfamilien"; but where the disposition or the conception of the units has been superseded by more recent monographs, or otherwise proved untenable, due notice is taken of the changes entailed thereby. The decision whether a proposed alteration was to be adopted or not must frequently have been a very difficult and delicate task for the authors; but, on the whole, they seem to have acted with much tact and sound judgment. The genera are given their successive numbers in the system in heavy type, whilst their places within the families are indicated by figures in light type. The references in the index are to both sets of numbers, which makes the index very handy as a collection catalogue. All citations are accompanied by the dates of publication, so that the settlement of questions of priority is greatly facilitated. The reference to the original publication is followed by references to Endlicher's "Genera Plantarum," Bentham and Hooker's "Genera Plantarum," and Engler and Prantl's "Natürliche Pflanzenfamilien," and by a note containing the approximate number of species known, and a very concise indication of the geographical distribution. Then the synonyms are enumerated in their chronological sequence, each starting a fresh line, and lastly we are given the disposition of the subdivisions of the genus with the corresponding synonyms.

Frequent use of the book has revealed here and there errors, almost exclusively in the reference figures, but not more than one has to be prepared for, in a work that contains almost 43,000 names, with as many references. There is, however, one weak point which cannot be passed without criticism. As the references to the two "Genera Plantarum" of Endlicher and of Bentham and Hooker stand, they suggest that a given genus admitted by the authors of the "Genera Siphonogamarum" is also admitted as such by those earlier authors, whilst in fact it merely means that they have dealt with it in some way on the page quoted, and, indeed, frequently stated that they do not consider the genus as tenable. For instance, under Ligularia we find "B.H. II., 449," but if we turn to p. 449 of vol. ii. of Bentham and Hooker's "Genera Plantarum," we find that Ligularia is there actually reduced to Senecio. Thus the impression is created that the conception which the authors of the "Genera Siphonogamarum" have of Ligularia is supported by the authors of "Genera Plantarum," whilst just the opposite is the case. The addition of "sub Senecione" in the case quoted would have been sufficient to make that clear. This is, however, practically the only serious blemish in a work which must have taxed the judgment and patience of the authors to the utmost.

The execution of the typography in a book like the present is, of course, of paramount importance, and it may be stated at once that it leaves nothing to desire, with the possible exception that the type used in the "Index" for the numbers of the genera admitted might have been a little heavier. Inconvenient is the throwing together in the index of the letters I and J, for which there is no justification. It must lead to confusion, and the authors have fallen into their own trap, for instance, in writing Jonidium for Ionidium (ἴον-ἴδ-ιον). And why Rhaphanus instead of the Linnæan "Raphanus," and on the other hand Raphia and Rigiostachys (ῥαφίς and ῥίγιος, στάχυς) instead of Rhaphia and Rhigiostachys? There is everything to be said in favour of rendering ῥ throughout by "rh"; but if this rule is not adopted, it would be better to adhere to the original spelling of the authors.

Those who have watched the nomenclatoric movement of the 'nineties and the first years of the present decade with some apprehension lest the continuity and uniformity of botanical nomenclature should be seriously impaired will be greatly relieved in finding on the examination of the "Genera Siphonogamarum" that this danger is practically averted. The book was finished up to the "Index," when, in 1905, the Vienna Congress adopted the new rules concerning the nomenclature of phanerogams; but in as far as these rules coincide in all essential points with the so-called Berlin rules which governed the nomenclature of the "Natürliche Pflanzenfamilien," the generic nomenclature of the "Genera Siphonogamarum" may well be considered as a practical and comprehensive test of the working of those rules. This being so, it is highly gratifying to see that the concord in generic nomenclature of the two leading schools of systematic botany, the older Kew school and the younger Berlin school, is practically absolute. Out of the total of, roundly, 10,000 genera, there are only 86 in regard to which the nomenclatoric standard of the "Genera Siphonogamarum" and the Kew practice, judged by Bentham and Hooker's "Genera Plantarum" and the "Index Kewensis," differ, and most of them are small genera, with few exceptions affecting none but purely scientific interests. Moreover, most of these discrepancies admit of easy correction, and where there is any serious doubt it may be left for the next International Botanical Congress to decide. This surprising concord in the generic nomenclature of the phanerogams is a veritable triumph of common sense which, it may be hoped, in the interest of science, will in time also conquer the opposition of the American school, which still holds out for a nomenclature of its own.

OTTO STAPF.

## *SCIENCE IN THE TEXTILE INDUSTRIES.*

*The Structure of the Cotton Fibre in its Relation to Technical Applications.* By Dr. F. H. Bowman. Pp. xx+470. (London: Macmillan and Co., Ltd., 1908.) Price 8s. 6d. net.

THE manufacture of a textile fabric mainly consists of a series of mechanical processes whereby the raw fibrous material is transformed first into a coherent thread and finally into a complex structure. As might be expected, therefore, the introduction of scientific method into the textile industries has mainly shown itself on the mechanical side, that is, in the improvement of the machinery used in the various stages of manufacture, much of which has been developed to a high state of perfection.

There are, however, many other directions in which scientific investigation can be directly brought to bear in textile manufacture, and the author of the book under review was a pioneer in one such direction thirty years ago, when he first investigated the microscopical structure of the cotton and wool fibres in relationship to the various processes of spinning, weaving, dyeing, and finishing.

The present volume, dealing with the cotton fibre, is the first of a series of three, and those to be subsequently issued will deal with wool, silk, &c. It comprises a very full account of the origin and development of the cotton fibre, its microscopical structure, and the chemistry of cotton cellulose and its derivatives. These chapters are followed by others giving details regarding the strength and variation of the fibre and of spun yarns of various counts and twists. Other less satisfactory sections deal with the various theories of dyeing and with dyeing processes, and in a final chapter the methods of detecting various fibres and of analysing a mixed fabric are described. Of the eighty illustrations and diagrams with which the book is illustrated, many are coloured, and, like the paper and type, are excellent. An exhaustive table of contents and trustworthy index add to the value of the book, and the introduction of a glossary shows that the author has spared no trouble to make the book complete. Some of the definitions in the latter would, however, bear revision, *e.g.* "*Complementary colour*—the remaining colours in a beam of light which are necessary to make white light." "*Hydroxyl*—the substance produced by the union of a single atom of hydrogen and oxygen."

One of the first duties of a reviewer is considered to be that of pointing out errors and omissions in the book with which he is dealing. This at any rate has the advantage of indicating that he has read the book with some care; and it may be mentioned therefore that there are misprints on line 1, p. 57, and on line 4 of the table on p. 150. Also that incorrect formulæ are given for cellulose on pp. 144 and 145, and for nitrobenzoic acid on p. 407.

Perhaps the most valuable feature of the work is to be found in the record which it contains of the author's laborious and long-continued investigation of the microscopical structure of cotton both during growth (for which purpose he cultivated cotton plants in a greenhouse), when fully matured, and at all subsequent stages of manufacture. Dr. Bowman's sketches showing the structure of fibres have been long accepted as standards, and have been reproduced in nearly all modern works on spinning, dyeing, &c.

Another highly commendable feature is the insistence upon due regard being paid to the interdependence of the various processes of manufacture. This is a point the importance of which is frequently overlooked, but one which, as the author states, is essential to perfection of result.

The issue of the remaining two volumes of the series will be looked forward to with much interest.

WALTER M. GARDNER.

## OUR BOOK SHELF.

*The Geology of Coal and Coal-Mining.* By Walcot Gibson. Pp. x+341. (London: Edward Arnold, 1908.) Price 7*s.* 6*d.* net.

THIS book is the first of a series of works on economic geology under the general editorship of Dr. J. E. Marr, F.R.S. The author is a recognised authority on the coal-bearing rocks of this country and of South Africa, and his introduction to the geology of coal is a welcome addition to technical literature that cannot fail to prove of great educational value to mining students. General principles of practical significance are dealt with in detail, and the world's coalfields are briefly described. The chemical and physical characters of coal are clearly explained, and chapters are devoted to coal as a rock, the formation and origin of coal, the distribution of coal, fossils as zonal indices, prospecting, the study of an exposed coalfield, and the study of a concealed coalfield. The coalfields of Great Britain are described in three chapters, dealing respectively with the southern, midland, and northern districts, whilst the remaining four chapters are devoted to the coalfields of Continental Europe, the North American coalfields, the coalfields of Africa, India, Australia, and South America, and the coalfields of China, Central Asia, Japan, New Zealand, and the Dutch East Indies.

The book is illustrated by eight well-reproduced plates of fossils. The palæontological chapter will undoubtedly prove most useful, as many mining engineers still fail to appreciate the value of fossil evidence, and the information given by the author will enable the student to see how far one part of the Carboniferous formation may be distinguished from the other. Besides the plates, there are in the text thirty-seven sketch-maps and sections of the various coalfields. Although somewhat crudely executed, these illustrations are clear and instructive. The least satisfactory chapter in the book is that describing the coalfields of Continental Europe, which is disfigured by a number of typographical errors, such as "Taplitz" for Teplitz, "Peckkohle" for Pechkohle, "Creusot" for Le Creusot, "Asturia" for Asturias, and by eccentricities in geographical nomenclature, such as "Pologne" for Poland, "Cracovie" for Cracow, and "the province of Oviedo in Asturia" for the province of Oviedo, or, as it was formerly termed, Asturias.

*Die Vegetation der Erde.* VIII. Grundzüge der Pflanzenverbreitung in Chile. By Dr. Karl Reiche. Pp. xiv+374. (Leipzig: W. Engelmann, 1907.) Price 30 marks.

THE first half-dozen volumes of the series were concerned with European regions, then followed a monograph on West Australia, after which comes the volume under notice. The State of Chile has been frequently visited by explorers, and among the early writings the histories by Padre Ovallo (1646) and von Diego de Rosales (1647) both claim attention for their phytogeographical descriptions. Subsequently the flora of the country has been studied by many scientific men, including Sir William and Sir Joseph Hooker; but to R. A. Philippi and his son must be accredited the first place in the exploration and identification of the botanical resources of the country, while in recent years the author has contributed in no small measure to a better and more accurate knowledge.

Apart from the consideration of characteristic plants arranged according to their orders, ecology is presented under the various aspects of vegetation forms, plant formations, biology and sketches of the vegetation. The latter are too detailed to convey definite impressions to the general botanist, being more suited to the traveller on the spot; but the morphological notes and catalogue of plant forms present a good idea of the most striking features met with in Chilian plants. Many of the parasites are remarkable, such as the species of Phrygilanthus and Cuscuta, and especially the unique *Pilostyles Berterii*, that lives entirely inside its host except when it thrusts out its small flowers; lianes abound, and various other climbing plants, while epiphytes are not so numerous, but the genus Tillandsia is interesting. The remarks on devices for checking transpiration are supplemented by drawings of leaf-sections, and the notes on the biology of the flowers and fruits are attractive. Comparisons are instituted with the floras of California, New Zealand, and the Argentine as a prelude to a discussion of the origin of the flora.

The author deserves a full measure of praise for the excellent and careful manner in which he has summarised the enormous amount of information contained in more than six hundred contributions. Two distribution charts and fifty reproductions of photographs add to the completeness of the work.

*From a Hertfordshire Cottage.* By W. Beach Thomas. Pp. viii+294. (London: Alston Rivers, Ltd., 1908.) Price 3*s.* 6*d.*

THIS recent addition to the numerous English books dealing with what has come to be known as nature-study is evidently the work of a careful observer of natural phenomena. To a first-hand knowledge of the open-air life of the country Mr. Thomas adds the power of clear and pleasing expression, and his collection of essays deserves to be read widely. The volume is in no sense a text-book; its design is rather to attract attention to the beauties and wonders of familiar natural objects. Some of the essays are sufficient evidence that scientific subjects can be described pleasingly in literary language.

*The Open Air.* By Richard Jefferies. With illustrations by Ruth Dollman. Pp. xii+234. (London: Chatto and Windus, 1908.) Price 5*s.* net.

ALL lovers of nature know the writings of Richard Jefferies, and admire his power of bringing a breath of country air, as it were, to accompany the reading of his essays. Many nature students, whether they have previously made the author's acquaintance or not, will delight in this volume. Miss Dolman has succeeded by her well-chosen and skilfully executed pictures in adding charm to work which was already beautiful.

*School Hygiene.* By Robert A. Lyster. Pp. viii+360. (London: W. B. Clive, University Tutorial Press, Ltd., 1908.) Price 3*s.* 6*d.*

THIS book "largely consists of the material of the various courses of lectures to teachers" in the West Riding and Midlands. But the chapters have none of the looseness usually associated with lectures. On the contrary, the book is succinct and well arranged. It incorporates much of the most recent work. It is well adapted for the training of teachers in school hygiene generally, as well as in the special personal hygiene that forms an indispensable preliminary to an effective system of medical inspection of school children.

*The Ethics of Nature.* By M. Deshumbert. Translated from the French by J. M. Hartmann. With an introduction by Henry James. Pp. 144. (London: D. Nutt, 1908.) Price not stated.

THIS little volume is filled with common-sense teaching. The morality advocated is based upon natural laws, errs rightly on the side of severity, and indicates many conflicts in which the best of men even will find effort enough necessary. Many problems are discussed which have engaged the attention of moralists in every age, and even if they are not solved, the method of dealing with them provides abundant food for thought.

## LETTERS TO THE EDITOR.

*[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.]*

### Uniformity in Lantern-slides.

In illustrating a scientific lecture it is important that lantern-slides produced from photographic negatives should be of uniform density, and should well exhibit the details which they are intended to illustrate. To blame the lanternist for faults which are not his own may give relief to the lecturer's feelings of disappointment, but this plan does not conduce to the success of the lecture.

For some time past I have been experimenting on photometric methods of comparing exposures in printing from negatives of widely different density, and I find that if the tests are made with sufficient care the results exhibit a remarkable degree of uniformity.

A simple photometer can be made of a sheet of white cardboard folded into the shape of an isosceles prism or double inclined plane, the faces of which are illuminated by sources of light placed on opposite sides of the prism, the distances of the sources being regulated according to the law of inverse square. Now let two negatives under comparison be placed side by side in front of the two faces, and examined by the transmitted light reflected from the cardboard. Then, when the negatives look to be of the same density, their exposures will be proportional to the illuminations of the faces, and can be easily compared. If the negatives differ in contrast, this difference will be at once evident on adjusting the illuminations, and either the necessary modifications of treatment can be decided on or badly contrasted negatives can be set aside for intensification or omitted from the series. By a method identical in principle with the above I have been successful in testing the development of negatives and in calculating exposures in bromide enlarging. Two negatives exposed in succession with calculated exposures of twenty-five seconds and fifty minutes have given under similar development equally good prints of almost exactly the same darkness.

G. H. Bryan.

### A Probable New Fluting in the Spectrum of Magnesium Oxide.

There appears to be a well-marked, though faint, fluting in the spectrum of magnesium oxide which has not been hitherto recorded, consisting of seven principal edges and several fainter lines. No mention of it has been found anywhere, and Prof. Kayser, who has seen a photograph, says that it is unknown. If so, this is probably due to the fact that it would be quite invisible against even a weak continuous spectrum.

The wave-lengths of the principal edges have been determined by comparison with lines of zinc, cadmium, and manganese, and are approximately as follows:—4823, 4819, 4810, 4801, 4791, 4780, 4771. The first of these is very faint, and although almost coincident with the Mn line at 4823, appears to have a slightly greater wave-length, and is probably not due to Mn as impurity. The edge at 4780 is rather diffuse, and two faint lines have been measured between it and 4791. Between 4771 and 4731, five lines have been measured, which may also belong to the system.

The fluting is obviously related to that beginning at 5007; the spacing between the edges is of the same order, and it is only well seen when the latter is very intense. Although first observed about twelve months ago, it was only successfully photographed last February. Some of the negatives also show that the series of faint, fine lines on the less refrangible side of the violet magnesium triplet extends much further into the visible spectrum than catalogued by Eder and Valenta.

E. E. Brooks.

Leicester Municipal Technical School, June 18.

### The Halos round Zircons in Biotite.

With reference to the action of radium on glass, and its removal by exposure to sunlight, the following unintentional experiment may possibly be of interest. Many years ago I had a section of a piece of granite prepared, and then another after the stone had been made red hot in an ordinary bright fire.

In the unheated rock the zircons in the brown micas show good halos, and these have not been obliterated by the strong heating. This may be worth mentioning, as the experiment may possibly not have been attempted by anyone else, either from lack of motive or the difficulty of getting a good slice after the rock has been made brittle by the heat.

A. R. Hunt.

Southwood, Torquay, June 20.

## LORD KELVIN'S PHILOSOPHY.[1]

*Explanation in Terms of Force or of Motion? Action across Empty Space or through a Medium?*

One of the most interesting and important outcomes of last year's meeting of the British Association at Leicester was the declaration by Lord Kelvin, during a memorable discussion on the constitution of the atom, in Section A, that he had found it necessary to abandon the attempt to contemplate the material universe explicitly in terms of æther and motion, and for his own part preferred to resort to the Boscovich doctrine of centres of force acting on each other according to some curiously complex law, without specific attention to the hypothetical medium in which such forces may exist.

Now undoubtedly these ancient postulates of matter and force represent the dynamical method first made feasible by Newton's achievement in celestial physics, whereby phenomena were correlated by unexplained particles of matter acted upon by unexplained forces, of statical origin and unknown mechanism, according to a specified law of distance. This was how Newton successfully solved the problems of gravitation, and constructed the working theory of astronomy; but it had been hoped, and by some is still hoped, that the time had now come for seeking to represent, in terms of something simpler and more fundamental, the nature of matter and the origin or inner mechanism of its various forces.

The most powerful and hopeful lever wherewith to attack this great philosophical problem was the kinetic theory of elasticity and rigidity, introduced by Lord Kelvin himself. By this means it has been hoped to express force in terms of the still simpler conception of motion; in fact, to explain all the forces with which physicists have to do—electrical and chemical attraction, elasticity, magnetism, cohesion, and perhaps gravitation—in terms of the internal motions of a universally connecting fluid plenum.

But now the question arises, is it at all certain that the material universe can really be understood in terms of motion alone—motion of an all-pervading continuous fluid known as the æther of space? And would such a solution be satisfactory?

To many it has seemed that this reduction to simplicity was the closest approach to ultimate explanation and unification that could be hoped for in the domain of mathematics and physics; and during the last half-century many steps, apparently in the direction of such an achievement, have been taken by the leaders in these branches of human knowledge.

The mathematical foundation was laid by Helmholtz, when he reduced rotational or vortex motion in perfect fluid under the domain of mathematics; it was followed up by Lord Kelvin's kinetic or gyrostatic theory of elasticity and rigidity; so that mathematicians, such as FitzGerald, Heaviside, Larmor,

[1] Being thoughts suggested by the meeting of the Mathematical and Physical Section of the British Association at Leicester in August, 1907; and referred to in Sir Oliver Lodge's recent Presidential Address to the Faraday Society, May 26, 1908.

Hicks, J. J. Thomson, and others, as well as Lord Kelvin himself, have, from various points of view, endeavoured to devise a scheme of spinning motion in a perfect fluid plenum which should be able to accomplish in general terms all that the æther is known to perform: more particularly that it should be able to imitate its faculty of transmitting the transverse or solid quiverings that we call light, yet without resisting the motion of bodies through it; and at the same time that it should be able to maintain its own turbulent or whirlpool motion in an unconfused and regularly stable condition throughout infinite time. And in this difficult undertaking they have from time to time seemed partially successful; at any rate, they have reached suggestive results and opened up stimulating vistas.

The ether must be incompressible, too, being perfectly continuous without breaks or any kind of atomic or granular structure, save such as may be conferred upon it by reason of its infra-material internal motion. An infinitesimally turbulent liquid of some kind seemed the desideratum, and many have been the attempts to devise such a liquid. An interlaced system of vortex fibres or filaments has to some seemed the most likely device; a similar scheme was a system of plates or laminar vortices; while a third modification conceived it as a collection of connected filaments all in a state of rapid internal motion, though stationary as regards locomotion in space;—what might be called a vortex sponge. By some such means it was hoped to be able to combine the elastic rigidity appropriate to a solid, with the penetrable unresistance to motion of solids through it, characteristic of a perfect fluid, and with the complete incompressibility of an ideal liquid. But the mathematical difficulties of all such treatment have been rather overwhelming; and an uncertainty about the stability or permanence of such a medium has always obtruded itself in a discouraging manner.

In fact, there has always been a troublesome amount of instability in all the schemes that have hitherto been devised, so that none of the expounders of the motion doctrine was able to announce a finally satisfactory result.

Still it was felt by most of those who have worked at the subject that the outlook in this direction would be so bright, if initial difficulties could be overcome, that it was worth a long-continued effort to see if a coherent scheme could be planned on these lines, so as to secure what, if it turned out to be the truth, would surely be a magnificent generalisation.

Indeed, it has sometimes seemed unlikely that a mode of explanation which offered such attractive features, and led so far in the right direction, could, after all, be a blind alley leading nowhere; or, to vary the metaphor, a mere will-of-the-wisp which it was waste of time to pursue.

What has certainly been made out is that motion of atomic structures, in an æther with elasticity postulated, supplies a complete working scheme on which we can rest without inquiring further as to the origin of this elasticity. Beyond this, the attempt to explain the material universe on a purely kinetic basis has not made much progress in quite recent years; and, to those competent to attack it, it has probably seemed better to let the problem lie dormant for a time, until future discoveries in mathematics or in physics threw more light upon the rocky path or provided us with better instruments for climbing it.

During the epoch of waiting it now appears that our venerated chief was deflected from further attempts in this direction, and directed his attention elsewhere. Other methods seemed to him more immediately hopeful; and whereas it had been hoped to explain force in terms of latent motion, Lord Kelvin in later years sought to expound motion in terms of force, giving up the kinetic unification of the material universe in favour of a conception more arbitrary and descriptive, and permitting himself to regard force as perhaps an equally fundamental, perhaps a more fundamental, conception than motion.

It may be that philosophers will concede the (to me) somewhat improbable proposition that an explanation in terms of force and action-at-a-distance will be as satisfactory as an elucidation in terms of motion and a continuous medium. To Lord Kelvin it would appear that both solutions were equally satisfactory, and that it was only a question of which was the most tractable. In any case it is noteworthy that he took up so clear and definite a position; it is the key to much of his recent work, and to the difficulties which he felt in accepting some of the hypotheses which are a natural consequence of the electrical theory of matter and of some of the facts of radio-activity. It now seems not unnatural that he should have sought to express and explain these great results otherwise. His attitude is both coherent and reasonable; though I would urge that most theoretical advance and discovery (in the hands of Maxwell and others) has been along the continuous and medium line, which, if not the line of ultimate explanation, is at any rate that of achievement.

At the same time, it must be admitted that, if a longitudinal impulse is transmitted by an incompressible medium at an infinite pace, the process becomes barely distinguishable from action at a distance, through a force varying according to a specified law. Or—putting what is virtually the same thought in another way—the influence of an electron, or matter-unit, whose field of force extends infinitely in all directions, need not be conceived as limited by some arbitrary boundary beyond which things can be said to be at a distance from it.

It will be remembered that some of the old philosophers saw great difficulties in the abstract conception of motion. It appears as a curious evanescent transition from one place to another, involving the attribute of "time"; it is indeed "not a being but a becoming," when position is taken as the primary conception.

But I urge that it is simplest to regard "position" and "distance" as secondary conceptions, subordinate to and arising out of our perception of motion. Unless motion is supposed to be a thing directly apprehended, it is truly rather an elusive idea. To me it seems a direct apprehension—direct information conveyed by our muscular sense. Space itself seems a *consequence* deduced from our perception of motion; and the idea of time follows from our direct perception of *rapidity* of motion. But probably to Lord Kelvin these things appeared otherwise.

The conclusion of the discussion on the constitution of the atom may be summed up thus:—

The internal energy of Lord Kelvin's model atom is static or potential. The internal energy of the hypothetical atom at which others are working is kinetic.

The disintegration of radium in the former case is comparable to the explosion of an unstable chemical compound, like gun-cotton. In the latter case it must be represented by something more akin to the flying to pieces of a single rapidly spinning unit, such as a fly-wheel.

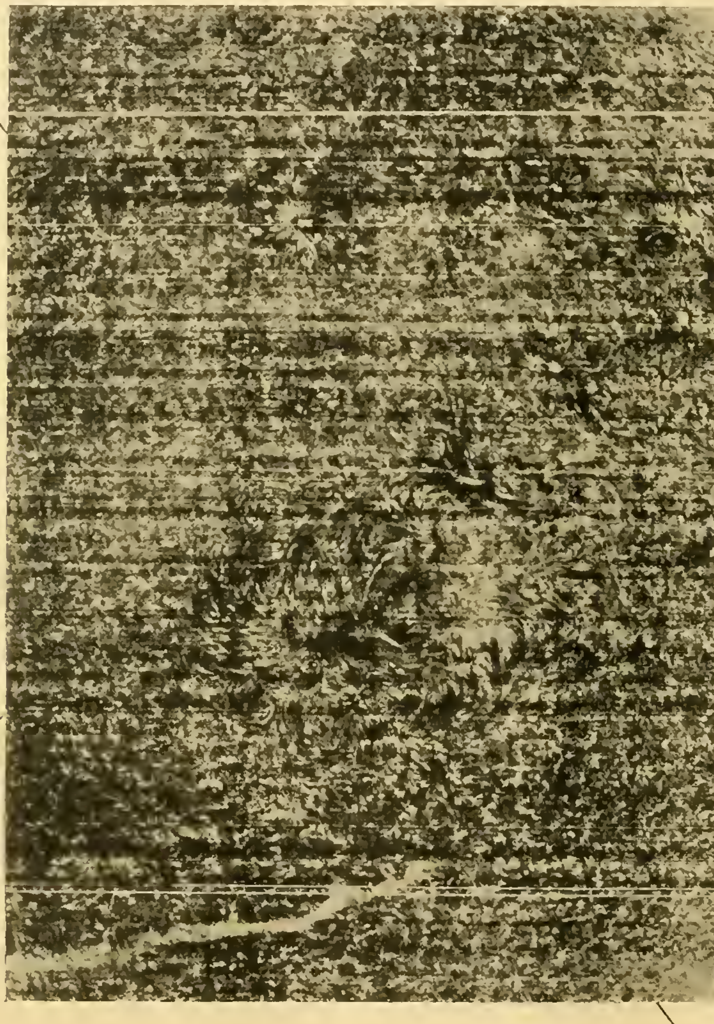
And so for the present the matter stands.

Oliver Lodge.

## RECENT WORK WITH THE SPECTROHELIOGRAPH.

PROFS. HALE AND ELLERMAN, of Mount Wilson Solar Observatory, California, enjoying the advantages of a climate almost unrivalled and an instrumental equipment of the highest class, have already given to the world scientific results worthy even of such a combination. In connection with their more recent work we have received several photographs, one of which is reproduced here. Among the photographs are discs of the sun in the light of iron (λ 4045), and an interesting comparison of the solar surface as seen through the calcium line ($H_2$) and the hydrogen line (Hδ), showing in a striking manner that the regions of maximum radiation of calcium light are regions of absence of hydrogen radiation.

In obtaining photographs of hydrogen flocculi, the hydrogen line Hδ has chiefly been used. In March, 1908, it was found possible, by the use of the new "Pan-iso" plates of Wallace, to secure photographs of the sun with Hα. The comparison of the resulting photographs with those taken in Hδ showed bright flocculi peculiar to Hα, and small dark areas appearing solely in Hδ. Using the various hydrogen lines for the photography of the chromosphere and prominences, the greatest intensity and extent were found in the photographs taken with Hα. These qualities decreased through the hydrogen lines Hβ and Hγ until in Hδ only the brightest parts of the prominences were shown. Considering the integrated hydrogen light of the disc, these facts indicate an increase of relative intensity in the Hα line, or, as put in the letter accompanying the photographs, show that "hydrogen appears in contiguous regions on the sun under some of the peculiar conditions which produce differences in the relative intensities of its lines observed in nebulæ and in stars having spectra of the Wolf-Rayet and other special types."



Negative of a portion of the solar surface in Hα light.

The feature of special interest in the photograph reproduced (which is a negative of part of the solar surface taken in Hα) is the strong suggestion of the existence of vortex systems surrounding the spots. The specially extensive and well-marked phenomena near the centre of the illustration, it is suggested, show that "the prominences surrounding this area . . . are swayed towards the centre, and their appearance strongly suggests the effect of a great whirl rotating clockwise" (*i.e.* N.W.S.E.).

It is to be noticed that the dark hydrogen flocculi appear bright on the negative as reproduced. The photograph was taken on April 30, 1908, 5h. 6m. p.m., Pacific standard time. A direct photograph secured on the same date shows a group of small spots near the centre of this region, while a plate in $H_2$ light shows a calcium flocculus lying above the spots. Neither of the above photographs affords any evidence of whirl. The remarkable features shown in the illustration are thus apparently confined to the higher regions of the solar atmosphere, and are selectively photographed by making use of the special qualities of the hydrogen line Hα, though the general appearance calls to mind the torn edges of a sun-spot as drawn by Langley.

The picturing by spectroheliographic means of the distribution of radiating matter at various solar levels is already well known. The photograph reproduced illustrates what can be done in quite a new way by using this valuable means of acquiring information about solar circulation.

It may be pointed out in passing that the appearances in the great whirl might be explained equally well, or perhaps even better, from the fining away *outwards* of the hydrogen flocculi, as an anti-clockwise whirl outwards from the centre. Occasionally on photographs in "K" light taken at South Kensington, some suggestions of extensive whirl systems surrounding centres of activity are observed.

The relation of the photography of high-level hydrogen flocculi to the recent work of Hale and Adams on the rotational velocities in various latitudes is full of promise and interest. It seems clear from the work up to the present that the retarding influence varying with the solar latitude felt by the spots and lower lying vapours is not operative on the high-level hydrogen.

The rainy season at Mount Wilson having ended, hopes are entertained that material for the further study of these extensive vortices may be obtained, and that the theories of Faye and Emden, both of which assign the origin of sun-spots to vortices, may be tested.

T. F. C.

## *AN INVESTIGATION OF THE SOCIOLOGY AND RELIGION OF THE VEDDAS.*

THE Veddas have long excited the interest of students, as they are generally believed to represent the aboriginal population of Ceylon, and to have remained at that low level of culture which characterises most of the hunting denizens of tropical jungles. Drs. P. and F. Sarasin first investigated the Veddas nearly twenty years ago, and published their results in an important monograph in 1892, which dealt mainly with the physical characters of the people. They put forward the view that the Veddas are the nearest living representatives of that stock from which the Australians, on the one hand, and the Dravidians, on the other, have diverged, and the term Proto-Dravidian has been applied alike to the Veddas and the race which they represent. Although a fair amount is known about the habits and material culture of these jungle-folk, it was felt that their sociology and religion should be thoroughly studied by a trained investigator before it was too late. The matter was brought before the Ceylon Council in the autumn of last year by the Hon. John Ferguson, C.M.G., and Dr. A. Willey, the director of the Colombo Museum, and a grant was made, which has since been raised to 500*l.*, to enable this investigation to be undertaken. Mr. Hugh Clifford, C.M.G., Colonial Secretary of Ceylon, whose interest in the jungle tribes of the Malay Peninsula is so well known, gave the application his warm support.

Dr. C. G. Seligmann was selected to undertake this investigation, for which he was thoroughly qualified by his previous field-work in New Guinea and elsewhere. Dr. Seligmann, accompanied by his wife, arrived in Ceylon in December last, and remained there for five months. During this time only one week was so wet as seriously to interfere with work, and the only real difficulty experienced was to obtain a supply of carriers during the rice harvest, and the period immediately preceding it.

It is, of course, impossible to give even a summary of the results of the expedition until they are published, but the following information will give some idea of the scope of the inquiry. Dr. Seligmann gave most of his attention to the less advanced Veddas, those whom previous writers designate as "jungle-" and "rock-Veddas," but this distinction does not seem to be warranted. The "village" and "coast Veddas" have become so modified by contact and mixture with other races that they do not afford a favourable field for the study of "primitive" conditions. The Veddas are divided into clans, some of which are definitely of inferior status to others, and have to perform certain duties for them; this unexpected circumstance seems to be of old standing. In the majority of communities exogamy is the rule, and with this is associated descent in the female line. In other groups descent is in the male line, and in these cases exogamy no longer exists. Cousin marriages on both sides are the rule, or should be, but the children of two brothers or two sisters may not marry.

The three things that loom largest in the native mind are hunting, honey, and the cult of the dead. The last constitutes almost the whole of the religious life and magical practices of the people; it is the *motif* of almost every dance, and, indeed, Dr. Seligmann is inclined to believe it was originally the source of them all. According to most Veddas, the spirit of every dead man, woman, or child becomes a *yaka* within a few days of death. Some Veddas, however, say that when ordinary persons die they cease utterly, and only a few strong and important men become *yaka*; but in either case the basis of an elaborate system of magic is "possession" by certain *yaka*, who are considered as historical spirits, though little more than their names and, in some instances, their dwelling-places are known. Some *yaka* send success in hunting, and the Seligmanns saw the whole thanksgiving ceremony over a fine buck, in which a ceremonial arrow with a blade more than a foot long and a handle scarcely longer played a prominent part. In some communities the *yaka* beliefs are strongly tinged, if not coloured, throughout by borrowings from what appears to be a simple and probably early form of Hinduism. Dr. Seligmann could not with certainty find any magical practices that were not based on communion with the friendly dead, except those which appear to have been borrowed from the Sinhalese. It is accordingly not surprising that it is generally considered necessary to present an offering to those recently deceased. This must consist of cooked rice and coco-nut scrapings; this food is difficult for them to get, but every Vedda esteems it above all other. The "shaman," called *kapurale* or *dugganawa*, calls upon the *yaka* of the recently deceased man to come and take the offering. The *kapurale* becomes possessed by the *yaka*, who, speaking through the former in hoarse, guttural accents, states that he approves of the offering and will assist his kinsfolk in hunting, often, indeed, indicating the direction in which the next hunting party should go. This is the simplest form of death ceremony, but besides the *ne yaku*, as the spirits of the dead are called, other *yaku* are invoked in most communities. Many generations ago there lived a Vedda, a mighty hunter named Kande, who on his death became Kande Yaka, and who is constantly invoked to grant success in hunting. The majority of Veddas believe that the *ne yaku* go to Kande and become in some sense his attendants. Now Kande Yaka is usually invoked at the beginning of the *ne yaku* ceremony, and in more than one community it was pointed out that the *ne yaku* would not come to the offering unless accompanied by Kande Yaka, who was sometimes spoken of as bringing them.

The mental characteristics of these jungle-folk appear extraordinary to one conversant with Melanesians, since they are really intelligent, and, when cross-examined, are equal to a sustained mental effort that would be beyond the possibility of the brainiest Papuan. The only examples of decorative art are rough rock-paintings in caves, and the village Veddas are incapable even of this slight proficiency in pictorial art. Personal adornment is of the slightest. The absence of tales and legends is almost unbelievable. Dr. Seligmann inquired on this matter of almost every elderly and not too civilised Vedda, and he obtained merely some thirty lines of bald statements which can scarcely be dignified by the name of legends.

Readers of NATURE will remember that their attention was directed to the recent discovery of stone implements in Ceylon, many chippings and implements having been excavated from Vedda caves. Dr. Seligmann has made collections of these, but in one cave which he excavated, out of some three hundred pieces of quartz about four per cent. presented definite appearances of having been worked. That particular cave had Sinhalese carving and stone masonry in and around it. Indeed, he has evidence that the Sinhalese were associated with so-called Vedda caves about the beginning of the Christian era. It seems that even among the "wild Veddas" there has been a much older and more intimate cultural connection with the Sinhalese than the literature of the subject would lead one to suspect.

Dr. Seligmann took a large number of photographs, many of which are very successful, but unfortunately the photographs of the dances of the least sophisticated community are not so satisfactory, as these Veddas would dance only in their usual dancing places, which are deep in the forest, where instantaneous work was practically impossible. A number of plates of the new colour process were taken out, but the results were not very satisfactory. A very complete series of phonograph records of songs were obtained, from lullabies to invocations to the dead. The great achievement of securing the songs of the women was due to the presence and cooperation of Mrs. Seligmann. An unexpected experience in working with the phonograph was its enormous popularity, not simply amazement or wonder, but sheer delight in it.

Many ethnologists have felt how desirable it is that trained women should make investigations in the field, since it was realised that information obtained by men, through men, about the practices and ideas of native women must necessarily be imperfect and biassed. The present expedition has conclusively proved the truth of this; indeed, the mere presence of a woman gave these shy and extremely jealous people such confidence that the Seligmanns were allowed to make their camps close to the Vedda caves. One of the groups of the "wildest" Veddas invited them to share the cave in which the whole community, including the girls and young unmarried women, were living; a surprising offer, as Neville, the most sympathetic of recent observers of the Veddas, records how, as a sign of extreme amity and confidence, he was once allowed to spend a few minutes in the company of the younger women of a community to whom he was well known. It is thus no exaggeration to say that had not Mrs. Seligmann accompanied her husband in this arduous expedition, the results would have been less numerous and important.

A. C. Haddon.

## NOTES.

The list of honours issued on the occasion of His Majesty's birthday includes the names of a few men distinguished for their work in pure or applied science. Baronetcies have been conferred upon Sir T. Lauder Brunton, F.R.S., and Dr. W. Watson Cheyne, C.B., F.R.S. The honour of knighthood has been conferred upon Prof. A. G. Greenhill, F.R.S., Colonel David Bruce, C.B., F.R.S., and Mr. R. A. Hadfield, president of the Iron and Steel Institute last year. Mr. W. H. Power, F.R.S., has been promoted to the rank of K.C.B., Dr. T. H. Holland, F.R.S., has been appointed a Knight Commander of the Order of the Indian Empire (K.C.I.E.), Dr. A. G. Bourne, F.R.S., a Companion of the same Order (C.I.E.), and Dr. W. F. King, chief astronomer, Department of the Interior, Canada, a Companion of the Order of St. Michael and St. George (C.M.G.). Dr. Henry Jackson, regius professor of Greek, Cambridge, is appointed to the Order of Merit, which was designed "to include British subjects who have won conspicuous distinction in the naval and military services, or in letters, art, and science." Perhaps Prof. Jackson's claims to this honour may be understood at Cambridge.

Some reference has been made in the daily papers to the ratio of honours awarded to naval and military men, the suggestion being that the Army receives an undue share of these distinctions. With the demands of the two services for recognition we are not concerned, but the question induces us to ask what ratio exists between the award of honours to men who devote their lives to work which promotes the scientific progress of the country and those who do not? As to the relative value to the nation of scientific and party-political work there can be no two opinions; and statesmen themselves, especially when out of office, are ever ready to acknowledge the important part which scientific knowledge plays in national greatness and development. Judging from their utterances, science should be cherished above all things by the nation which desires to secure advancement; but while it is thus honoured in the abstract, it gives place to party politics when rewards for national service are being distributed. Probably the reason is that the ministers and officials who are chiefly concerned with the affairs of State and Court live in a world in which science and the results of science are almost unknown. This is really the characteristic of the official mind in England. For instance, the Court newsman in his official report of the King's garden-party states that invitations were issued to "representatives of the musical, dramatic, and literary professions." It is a striking illustration of the state of the official mind that representatives of the musical and dramatic professions should be referred to as having been invited to meet their Majesties, while science was not mentioned.

As we went to press yesterday, July 1, the Linnean Society celebrated the fiftieth anniversary of the reading of the joint paper on natural selection by Charles Darwin and Alfred Russel Wallace. At the afternoon meeting a medal, specially struck for the occasion, was presented to Dr. Alfred Russel Wallace, Sir Joseph Dalton Hooker, Prof. Ernst Haeckel, Prof. Eduard Strasburger, Prof. August Weismann, Dr. Francis Galton, and Sir E. Ray Lankester. At the same meeting congratulatory addresses were received from British universities and British and foreign societies and academies. About a hundred of the fellows and guests of the society dined together at the Princes' Restaurant at 6.30, and later in the evening a reception was held at the rooms of the society. We hope to give a full account of the proceedings in our next issue.

M. Henri Becquerel has been elected permanent secretary of the Paris Academy of Sciences for the physical sciences.

Prof. H. H. Turner, F.R.S., has been elected correspondant of the Paris Academy of Sciences in the section of astronomy in succession to the late Prof. Vogel.

The death is announced, at Paris, of Dr. Luiz Cruls, director of the Observatory of Rio de Janeiro.

The annual exhibition of antiquities, from excavations in Upper Egypt during the past season, was opened at the Institute of Archæology, University of Liverpool, on Monday, June 29, and will remain open until Thursday, July 9.

THE Physico-medical Society of Vienna has made the following appointments in connection with the celebration of the centenary of the foundation of the society:—*Honorary Ph.D.*, Sir Victor Horsley, F.R.S.; *corresponding members*, Prof. J. Loeb, Dr. C. S. Minot, Prof. E. Rutherford, F.R.S., and Prof. C. S. Sherrington, F.R.S.

THE council of the Royal Society of Edinburgh has awarded the Neill prize for the triennial period 1904–7 to Mr. Frank J. Cole, lecturer on zoology, University College, Reading, for his papers entitled "A Monograph on the General Morphology of the Myxinoid Fishes, based on a Study of Myxine," published in the Transactions of the society, regard being also paid to Mr. Cole's other valuable contributions to the anatomy and morphology of fishes.

ON July 2, 3, and 4 there will be on exhibition at the Royal College of Surgeons, Lincoln's Inn Fields, W.C., a very remarkable collection of specimens illustrating the diseases, injuries, and racial peculiarities of the ancient inhabitants of Nubia. The collection was made during the archæological survey of the area which will be submerged on raising the level of the Aswan dam. The collection embraces specimens derived from cemeteries, to which Dr. G. A. Reisner has assigned dates ranging from a pre-dynastic to an early Christian period. The collection has been described and arranged under the direction of Prof. Elliot Smith, F.R.S., and Dr. Wood Jones. A report of the first results of the archæological survey of Nubia was recently published (Bulletin No. 1, Cairo, 1908), with an introduction by Captain H. G. Lyons, F.R.S.

THE fifth congress of the International Association for Testing Materials is to be held at the beginning of September, 1909, in Copenhagen, when numerous questions in connection with the testing of metals, hydraulic cements, and miscellaneous materials will be considered, and many other important technical problems will be discussed. To maintain closer contact with the members of the association in the intervals between the congresses, the council has decided to publish from time to time Proceedings of the association. Two numbers have appeared already, and the new periodical will certainly keep members informed of what is being done in the subject in which they are interested. Copies of the Proceedings may be obtained in this country from Messrs. E. and F. Spon. The price of each issue is, to non-members, sixpence.

To mark the completion of the fiftieth year of the existence of the Geologists' Association in November next, it is proposed to issue a volume dealing with the geology of the districts of England and Wales visited by the association since its foundation. The volume will consist of a series of articles by competent authorities on the various localities visited, who will deal with the geology of their district from the point of view of present-day knowledge. The book will be edited by Messrs. H. W. Monckton and R. S. Herries, be illustrated with maps and sections, and probably be ready for publication before the end of the year. We notice that the next long excursion of the association is to be to the Berwyns, from July 31 to August 7, under the directorship of Mr. J. Lomas. The headquarters of the party will be at the Wynnstay Hotel, Oswestry, and persons wishing to take part in the excursion are requested to write to Mr. H. Kidner, excursion secretary, 78 Gladstone Road, Watford.

WE learn from *Science* that an expedition, under the combined auspices of the American Museum of Natural History and the Geological Survey of Canada, is now on its way to the mouth of the Mackenzie River and adjacent country to collect ethnological and zoological material. The party is being conducted by Mr. V. Stefánsson, who is well acquainted with the Eskimos of the region, having wintered with them in 1906, and Mr. R. M. Anderson, a well-known naturalist. The expedition was organised for the purpose of making scientific studies of the Eskimos of the country, of procuring collections illustrating, not only the material cultures of the uncivilised tribes of the region, but also of the zoological conditions which prevail there, and of increasing our knowledge of the geology of the region. The expedition will commence its return journey during the summer of 1909.

THE annual general meeting of the Royal Society of Arts was held on June 24, Sir Steuart Colvin Bayley, K.C.S.I., chairman of council, in the chair. The business of the meeting was the reading the report of the council on the work of the society during the past session, the 154th since the formation of the society in 1754. In referring to the award of the Albert medal to Sir James Dewar for his low-temperature investigations, special stress was laid on the power placed at the disposal of those interested in industrial applications of science by the provision of temperatures so far below any hitherto available, and it was suggested that before long this new power would find numerous practical applications. Amongst the lectures delivered under the various trusts available for such purposes, the course of lectures on industrial hygiene, provided out of funds left some years ago to the society by Mr. Benjamin Shaw, was one of the most important. The award of a medal, under the same trust, to Prof. W. Galloway, for his researches into the action of coal dust in colliery explosions, was also recorded.

THE third international congress on the history of religions will be held at Oxford from September 15–18 next. Prof. E. B. Tylor, F.R.S., is the honorary president, Sir A. C. Lyall the president, and Prof. Percy Gardner the chairman of the local committee. The business of the congress will be conducted in nine sections, and there will be general meetings for papers and lectures of wide importance, as well as meetings of sections. In addition to the addresses by the president and by the presidents of sections, numerous important papers will be read. Among these may be mentioned that of Dr. A. J. Evans, on Cretan religions; M. E. Fourrière, on "le culte du soleil et les sacrifices humains chez les Grecs"; Miss Mary A. Owen, on the Messiah beliefs of the American Indians; Prof. A. H. Sayce, on the influence of Babylonian religion upon Asia Minor and Syria; Mr. W. W. Skeat, concerning Malay religion; and Dr. E. Wallis Budge, on some central African elements in the dynastic religion of Egypt. English, French, German, and Italian will be recognised as official languages. Representatives have been appointed already from many British and foreign universities and learned societies. Offers of papers should be sent to the honorary secretaries, Dr. J. Estlin Carpenter, 109 Banbury Road, Oxford, and Dr. L. R. Farnell, 191 Woodstock Road, Oxford.

THE report of the Rugby School Natural History Society for 1907 appears in an abbreviated form owing to the omission of the reports of the papers read, which are issued in a local journal. Steps have been taken during the year to bring the observing station up to the requirements of the Meteorological Office, and it is hoped that when the next report appears the station will have been re-accorded official recognition.

The contents of the May number of the *Victorian Naturalist* include several papers on the local bird-fauna, one of these being illustrated with an excellent reproduction of a photograph of a black-winged gannet colony. In the course of the same paper it is mentioned that the eggs of the short-tailed petrel, or "mutton-bird" (*Puffinus tenuirostris*), are extensively used as an article of diet by the islanders in Bass Strait, and are of excellent flavour.

The second fasciculus of vol. xxxvii. of *Travaux de la Soc. Imp. des Naturalistes de St. Pétersbourg* is devoted to the (mainly invertebrate) fauna of Turkestan, sections of which are described by specialists. An amphipod from the Issik Kul is made the type of a genus under the somewhat barbarous title of Issykogamarus. Of more general interest is an illustrated account, by Mr. V. A. Faussek, on the minatory attitude assumed by the Russian tarantula (*Trochosa singoriensis*), forming part of a paper on threatening postures in animals generally. The spider in question, which has a dark-coloured body with limbs marked by bold bands of black and yellow, is represented in a coloured plate both in its normal posture and in the threatening attitude, when the body is raised nearly vertically with the limbs extended in a radiating manner.

Four out of the five articles forming the combined first and second parts of vol. xxxviii. of the *Morphologisches Jahrbuch* are devoted to the anatomy of mammals, and of these four three relate to the hind-limb. The longest, and perhaps most important, is a paper by Mr. E. Loth, of Warsaw, on the morphology of the plantar aponeurosis in the Primates, in the course of which it is shown that the different types displayed by this structure accord well in the matter of their inter-relationships with the generally accepted classification of the order. In the second paper Mr. E. Glaesmer discusses the flexor muscles of the lower part of the leg and foot, while in the third Mr. G. P. Frets records the variations observable in the peroneal muscles. The sulci in the brain of the cat, and their individual variation, form the subject of the fourth paper, by Mr. E. Landau, of Dorpat, a large number of examples of the brain being figured.

Among several papers published in various Argentine journals, of which we have received separate copies from the author, Prof. Angel Gallardo, special attention may be directed to one published in vol. xvi. of the *Anales* of the National Museum of Buenos Aires on a remarkable case of mimicry in a caterpillar. The caterpillar, which is rather more than 4 inches in length, is the larva of *Dilophonota lassauxi*, and feeds on *Araujia sericifera*, to the stem and leaves of which it presents a most striking resemblance, both as regards form and colouring, as is shown by a coloured illustration. Pale blue in colour, with three longitudinal stripes of fawn, this caterpillar has two of the anterior segments of the thorax transversely enlarged in such a manner that they closely simulate the nodes of the food-plant. The most remarkable feature in the resemblance is, however, the development of a pair of white knobs on the second of these enlarged rings exactly matching the white knobs on the nodes of the plant, which mark the points of attachment of fallen leaves. The mimicry is one of the most remarkable that has ever come under our notice.

An important contribution to embryology is made by Mr. B. M. Davis in his account of the early life-history of *Dolichoglossus pusillus* (a relative of Balanoglossus, and therefore a representative of the Enteropneusta), issued as vol. iv., No. 3, of the Zoological Publications of California University. The creature, which is of a brilliant orange colour, burrows in the mud on various parts of the Californian coasts, and deposits its eggs on one side of the burrow, as is shown in a coloured plate accompanying the memoir. Its breeding-places at San Pedro were recently destroyed, but the author of the paper was fortunate enough to obtain specimens of the eggs at San Diego Bay. The acquisition of these was of the greatest importance, since the only accounts—by Dr. W. Bateson—of the development of the Enteropneusta previously published are incomplete so far as the early stages are concerned. It will be remembered that certain points of resemblance between Balanoglossus and the lancelet were indicated by Dr. Bateson, and from these resemblances it has been argued that the body-cavities of these two organisms have a similar origin. Certain difficulties have, however, been expressed with regard to the acceptance of this view, and the author of the present paper points out that, if his own interpretations be correct, these difficulties are now converted into impossibilities.

According to a note in the Journal of the Royal Society of Arts, the people of Baltimore seem to have been successful in their warfare with the mosquito. In December, 1906, an ordinance was passed by the City Council, and the sum of 2000*l.* appropriated by it, for the purpose of taking measures to exterminate the insect. The first step taken was a distribution by the police to householders of a notice setting forth the provisions of the law requiring all the cisterns, tanks, and wells to be covered with wire gauze; all pools, ponds, fountains, or other water receptacles not containing fish to be screened or covered with crude petroleum; forbidding any water to remain in any receptacle whatsoever; requiring all privy walls to be covered thoroughly with kerosene every fifteen days; and that water be turned off, and water receptacles emptied, should a house be unoccupied for more than five days. Dr. C. M. Hill, who had charge of the work, brought the matter forcibly before the public by delivering lectures explaining the mode of mosquito extermination, and cards were displayed in the tramcars directing the attention of householders to the importance of their cooperation in the work. Reporting upon the experiment, Mr. Consul Fraser says the result of it is satisfactory, and the City Council has appropriated another 1000*l.* for continuance of the work in 1908. The mosquito has hitherto been the cause of much illness and death in Baltimore.

Information regarding another new rubber plant is collated by Dr. O. Stapf in the *Kew Bulletin* (No. 5). The plant, discovered in Portuguese West Africa, receives the name of *Raphionacme utilis*—Raphionacme being a genus of the order Asclepiadaceæ—and is known in the country of origin as "ecanda" or "marianga." It is peculiar in producing a short herbaceous stem, while the latex is obtained from the tuberous root, that may attain a diameter of 5 inches. There is at present no prospect of extracting the rubber with profit.

Although there has been a notable introduction of new species of Primula within recent years from western China, an additional list, remarkable not only for the number of species, but also for the striking characters of certain of the plants, is chronicled by Mr. Forrest in the Notes from the Royal Botanic Gardens, Edinburgh (April). The species of Primulaceæ there described were collected in western Yunnan and eastern Tibet; they include fifteen new species of the genus, also a few species of Androsace and

Lysimachia. The species Littoniana, falling in the section Capitatæ, produces a deep spike of crowded flowers, in which the red calyces of the buds form a strong contrast to the deep purple expanded flowers. *Primula Forrestii* bears numerous flowers of a deep orange colour, and, judging from the root-stocks, continues to grow for fifty years or longer. Three of the four known species of the unique section Omphalogramma—taking their name from the oval, flattened shape of the seed—are recorded. The list is distinctly one that horticulturists will do well to examine.

The heredity of hair in man forms the subject of an article by Gertrude and Charles Davenport in the May issue of the *American Naturalist*. Starting with the assumption that the straight, cylindrical (Mongolian) type of hair, as agreeing with that of mammals generally, is more primitive than the frizzly, compressed type characteristic of negroes, the authors discuss the Mendelian relations of these and the intermediate wavy and curly types. The results suggest that straight hair is recessive to the frizzly type, although the latter may in some instances fail to dominate. Further, wavy hair is usually, if not invariably, a heterozygous type, and not recessive to a higher (curly) and dominant over a lower (straight) stage. The paper concludes with a summary of the colour of the eyes and hair in the children of parents who are similar or dissimilar in these respects.

In the June number of *Man* Prof. Dubois discusses Mr. J. Gray's investigations on pigmentation by the use of his newly modified Lovibond's tintometer. He accepts the suggestion that hair contains two coloured pigments, orange and black, the black pigment increasing uniformly in amount from blonde to black, the orange pigment remaining practically constant in that hair series. In the red-hair group, on the contrary, the orange pigment is predominant, its increasing amount causing the coloration from light to dark red. Finally, red hair is derived from dark hair by the conversion of more or less of the dark pigment into an equal amount of the orange. This last group, for which he suggests the name pyrrhotism (*pyrrhos* = foxy-red), he considers to result from an easily occurring chemical modification of the melanochrome into pyrrhochrome pigments. But the observed facts are inconsistent with the view of Topinard and others, that red-hairedness may be regarded as having the character of a variety of atavistic origin.

In a short article published in Nature last March (vol. lxxvii., p. 465), attention was directed to the interesting results in reference to the chemistry of Egyptian mummies which had been elucidated by the recent work of Dr. W. A. Schmidt. His conclusions, however, do not seem to have met with universal acceptance, and Mr. F. Lucas has in particular questioned one of them (*Cairo Scientific Journal*, vol. ii., April), namely, that relating to the composition of the bath in which the ancient dead were soaked. According to Schmidt, the "natrum" bath of Herodotus consisted mainly of common salt, and not of "natrum" or crude Egyptian sodium carbonate, which is found encrusted on the bottom and sides of certain lakes in the land of the Pharaohs; if natrum was used at all, it was employed for stuffing the mummy after the pickling bath of brine. Mr. Lucas believes, on the other hand, that "natrum" was actually used in the bath, though in some cases it was applied in solid form, and that the use of common salt was not introduced until the beginning of the Christian era.

Mrs. Andrew Johnson sends us a diagram of a curious ring around the moon observed by her at Arundel on June 11, at 10 p.m., that is, three days before full moon. The ring was not a complete circle, but segment-shaped, corresponding to the phase of the moon at the time. Two mock moons seen respectively to the east and west of the moon itself, and a second halo touching the chord of the segment, were also similarly shaped. The diagram is unsuitable for reproduction, but the distortion of the halo and mock-moons represented by it is of noteworthy interest.

The results of the meteorological observations on the summit of the Sonnblick (3105 metres) for the year 1907 give the mean temperature of January as 4°·6 F., of July as 30°·2; the absolute maximum was 49°·5, in August, and the minimum −18°·2, in January. The precipitation was equivalent to 65·8 inches, in 241 days, of which 5·6 inches fell as rain between May and September. Fog was observed every month, the total number of days being 262; it was least frequent in November, eleven days. The report contains particulars of several other mountain stations, including an interesting account of the Etna Observatory (2950 metres), with a photographic illustration of the volcano as seen from Catania.

Among the various useful articles in the Journal of the Meteorological Society of Japan for January–April (abstracts of which are now given in English), we may mention:—(1) relation between climate and tobacco cultivation, by K. Asakura, and (2) climate and rice crops, by H. Ogiwara, containing interesting particulars of the influence of rainfall and temperature on different stages of the growth of these crops; (3) a summary of the temperature and rainfall observations made during the last three years at stations in south China, by M. Ishida. The tables show that the climate there is not far different from that of the western part of Japan, except that the absolute maximum temperature in south China is more extreme, reaching at times 102°. The Yang-tse-kiang has a great influence in moderating the continental climate. Particulars are given in the April number of the journal of a new system of storm signals introduced in Japan on April 1, showing, during the day time, by means of drums, cones, and balls, the position of the storm centre, its direction of motion, speed, and other details. During the night time lights are displayed, indicating only the position of the storm centre.

The Sierra Club Bulletin (January) contains an article by Mr. G. K. Gilbert on "Lake Ramparts." Special attention is directed to the lake ramparts in the sierra of southern Utah, and the influence of glacial action in their formation is discussed. The absence of ramparts in the lake basins forms the basis of the theory that some force has been exerted to move the boulders to their present positions on the shores. The nature of this moving agency is discussed, the suggestion that the work was carried out by aboriginal inhabitants of the country being dismissed as improbable. The theory which adopts ice as the moving force is supported by the fact that ramparts are found only in cold countries. Mr. Gilbert illustrates this theory by means of sections of sheet-ice, showing modes of cracking and the effects of thrust on the shores, and explains how this action may have transferred the boulders from the lake basins to the shores.

The Berlin Gesellschaft für Erdkunde has issued a bibliography of geographical literature published during the year 1904, compiled by Dr. Otto Baschin, and published under the title of "Bibliotheca Geographica" by Mr. W. H. Kühl, of Berlin. The works are arranged according to subjects included under the two main divisions of general geography and special geography, the latter being subdivided under headings dealing with different countries. In the various subdivisions the works dealt with are classified under the names of the authors, and include publications in several languages.

In an article in the *Cairo Scientific Journal* for March Captain H. G. Lyons, F.R.S., deals with "Some Unsolved Problems of the Nile Basin." Exploration in this region by geographical pioneers has extended our knowledge of its main features, but detailed surveying is needed, especially on the northern margin of the equatorial plateau and of the Abyssinian tableland. In the field of geology Captain Lyons gives a sketch of the history of the Nile Valley, and comments on the secular rise of the lower valley and its future effects on Middle Egypt. Observations are required of the underground water table, its seasonal movement, and level with reference to the river. No definite information can be obtained of the coal or other minerals of commercial value until the early geological history of north-east Africa is better known. The great meteorological problem to be solved is that of the monsoon rains of Abyssinia and the Sudan. The development of rains in equatorial regions, snowfall on the Himalayas, and high-pressure conditions in North Africa are some of the influences to be studied as possibly affecting the Abyssinian rains. Historically, the question of the change of climate in North Africa is of great interest, although other causes should be considered simultaneously in accounting for the decay of the flourishing settlements which once existed in this region. Referring to the oases of North Africa, Captain Lyons reviews briefly the evidence of underground water in the desert, and states the problems of its supply and connection with the Nile.

A good illustration of the power of the weapon which the discovery of the Röntgen rays has placed in the hands of the medical profession is afforded by an article entitled "A Study of Constipation by Means of the X-rays," by Dr. A. F. Hertz, of Guy's Hospital, which appears in the June number of the *Archives of the Röntgen Ray*. After a dose of a bismuth salt has been administered to a patient it is possible to follow by Röntgen-ray photography the passage of the food through the œsophagus, stomach, and intestines, and thus determine the position, and in some cases the nature, of any obstruction which may be present.

The *Physikalische Zeitschrift* for June 15 contains a translation of a paper by Mr. O. M. Corbino, of the University of Messina, on an arrangement for producing almost constant direct currents of high potential. It consists of an induction coil capable of giving a spark of a few centimetres the primary current of which is supplied through a Wehnelt interruptor having a very small anode. The secondary is connected to the terminals of a condenser of a few micro-farads capacity which has a resistance of about 20,000 ohms in parallel with it. Between one terminal of the coil and the corresponding terminal of the condenser a spark gap of 2 mm. is inserted. In these circumstances a direct current of about 30 milliamperes flows through the 20,000 ohms, and its magnitude seems to be little influenced by change of value of the resistance.

We have received a copy of a new quarterly journal published by the Institution of the Post Office Electrical Engineers, and entitled the *Post Office Electrical Engineers' Journal*. The new journal is chiefly devoted to technical matters of interest to Post Office engineers, the articles in the first number dealing with various telegraphic and telephonic subjects. Doubtless sufficient scope exists for such a paper amongst the large staff engaged at home and in the colonies, and if future numbers fulfil the promise of the first, it should go a long way to promote the spirit of fellowship and feeling of common interest which is one of the main reasons for its inception. It is to be hoped the editors will not be led to step outside the legitimate limits of such a more or less private journal by attempting to make it the receptacle for much original research, and thus adding one more to the already excessive number of journals which the electrical engineer must consult. The lighter and social sides also find adequate treatment in the present number, the contributions being in both prose and verse. We wish the new publication all success.

A well-known experiment in physics is to freeze water by placing under the receiver of an air-pump some water in a shallow dish supported above a large dish containing sulphuric acid. Upon exhausting the receiver, evaporation rapidly takes place and the vapour is absorbed by the acid, with the result that the temperature of the water may be reduced to freezing point. We have recently had an opportunity of seeing the Raplin Hand Ice Machine, made by the Pulsometer Engineering Co., in which this principle is put to commercial use. The apparatus consists of a large bottle containing the sulphuric acid, and connected with the air-pump and a carafe or an ice-mould by means of pipes. A wheel turned by hand serves to actuate the pump, which reduces the pressure and also rocks the acid-container, so that the acid is splashed thoroughly and the absorption of the vapour by it is thus facilitated. In three or four minutes a carafe of ice-cold water can be produced, and a block of ice weighing about 1 lb. in twenty minutes. Half a gallon of acid constitutes a complete charge, and will serve to cool from fifty to one hundred carafes of water to freezing. The machine provides an interesting and handy means of reducing temperature by rapid evaporation.

The Select Committee of the House of Commons on the question of proposed daylight saving legislation has now completed its inquiry, and agreed upon its report. The report is understood to be favourable to the principle of the Bill introduced earlier in the session on the subject by Mr. Robert Pearce. The committee is in favour of the introduction of a Bill to achieve the object in view by an alteration of clocks to the extent of one hour at 2 a.m. on the third Sunday in April and by an hour's alteration in the opposite direction on the morning of the third Sunday in September.

A very useful classified list of Smithsonian publications available for distribution has been published by the Smithsonian Institution of Washington. The volumes and pamphlets are arranged conveniently according to subjects. Applicants for these publications must state the ground of their requests, as the institution is able to supply papers only as an aid to the research or study in which the applicant is especially interested. The volumes of contributions and of miscellaneous collections are distributed only to public libraries and to learned societies. Unfortunately, we have no agency in this country which is in a position to aid the spread of scientific knowledge in a similar way and on the same generous scale as the Smithsonian Institution.

## *OUR ASTRONOMICAL COLUMN.*

ASTRONOMICAL OCCURRENCES IN JULY:—

July 4. Opposition of Juno.
7. Uranus in opposition to the Sun.
,, Saturn. Outer minor axis of outer ring $=5''\cdot68$.
9. 12h. 57m. Minimum of Algol ($\beta$ Persei).
12. 9h. 46m. ,, ,, ,,
16. 10h. 59m. to 12h. 3m. Moon occults $\tau^2$ Aquarii (mag. 4·3).
18. 16h. 11m. Saturn in conjunction with Moon. Saturn 3° 2′ N.
22. 16h. 35m. Western elongation of Saturn's Satellite Titan.
25. 10h. Mercury at greatest elongation, 19° 50′ W.
27–31. Epoch of the Aquarid and early-Perseid meteors.
29. 15h. Vesta 0° 1′ S. of Moon.
,, Venus. Illuminated portion of the disc $=0\cdot153$.
30. 16h. Eastern elongation of Saturn's Satellite Titan.

A BRIGHT METEOR.—A magnificent meteor, with a long path and very slow motion, was observed on June 28 11h. 12m. by Mr. Denning at Bristol, and by the Rev. John Brown at Brighton. At Bristol, the apparent course was recorded as from $276°+23°$ to $1°+48\frac{1}{2}°$, while at Brighton the object passed just under the stars $\beta$ and $\gamma$ of Ursa Major, and just above Cor Caroli, the direction being from $\beta$ Scorpii.

Mr. Denning has investigated the real path, and found the heights eighty-seven to fifty-four miles over Dorchester, Dorset, to Kineton, Warwick. Length of observed flight 123 miles, and velocity $17\frac{1}{2}$ miles per second. Radiant point $240°-20°$, and about 10° W. of the usual radiant of the June shower of Scorpiid fireballs. The meteor had a bright train of sparks, and sailed along a considerable arc (70°), the duration at Bristol being estimated as seven seconds and at Brighton six to eight seconds.

COMPUTED MAGNITUDES FOR HALLEY'S COMET BEFORE PERIHELION.—In No. 4254 of the *Astronomische Nachrichten* (p. 99, June 13) Prof. J. Holetschek discusses the probable magnitudes of Halley's comet during the two oppositions which are to come before it arrives at perihelion. Monthly ephemerides show the probable positions of the comet for October, 1908, to March, 1909, according to the assumptions that perihelion passage will take place on May 16, 1910, thirty days earlier or thirty days later, and the geocentric and heliocentric distances are also shown. Then follows the table giving the probable magnitudes for the same period, and also for September and October, 1909. From this we see that for October 2, 1908, the probable magnitude is 18·2, the comet increasing in brightness until, on October 2, 1909, its magnitude should be 14·6.

THE REVISED HARVARD PHOTOMETRY.—We have just received a copy of vol. l. of the Annals of the Astronomical Observatory of Harvard College, in which is published the revised Harvard photometry. This comprises a catalogue of the positions, photometric magnitudes, and spectra of the 9110 stars, mainly of magnitude 6·50 and brighter, which were observed with the 2-inch and 4-inch meridian photometers, in all parts of the sky, during the years 1879 to 1906. Some idea of the magnitude of the work may be gathered from the fact that the observations involved a total number of 1,082,060 photometric settings. In the catalogue itself the stars are given consecutive numbers, and are arranged in order of R.A. as usual. Then follows the designation for each star in other catalogues, the position for 1900, the magnitude, the residuals, and the combination of letters and figures which denotes the spectral type. It is proposed by Prof. Pickering that the abbreviation H.R. shall be used when referring to a star's designation in the present catalogue. Several pages of "remarks" which follow the catalogue proper give valuable notes concerning stars which are in any way peculiar.

THE PARALLAXES OF NEBULÆ.—From a re-discussion of Prof. Wilsing's results for the parallaxes of the two nebulæ G.C. 4964 and N.G.C. 7027, Herr Einar Huss, of Stockholm, derives new definitive values which, in each case, show a reduction of the negative values obtained by Prof. Wilsing. For G.C. 4964 the latter observer found the parallax $-0''\cdot083\pm0''\cdot025$, whereas Herr Huss derives the value $-0''\cdot063\pm0''\cdot050$; for N.G.C. 7027 the respective values are $-0''\cdot172\pm0''\cdot068$ and $-0''\cdot110\pm0''\cdot021$. Taking into account the facts that the observations were made at about the same epoch, and that the objects are in the same part of the sky, Herr Huss considers that there is evidence that, of the two, the nebula N.G.C. 7027 is the more remote (*Astronomische Nachrichten*, No. 4254, p. 96).

OCCULTATION OF JUPITER'S SATELLITE II. BY SATELLITE I. In No. 4255 of the *Astronomische Nachrichten* (p. 110, June 18) Prof. Hartmann places on record the results obtained from observations of the occultation of J. ii. by J. i. on February 24. The observations were made with the 50 cm. refractor of the Potsdam Observatory, a power of 450 being used, and the best value for the time of the middle of the conjunction is given as 9h. 45m. 32s. ± 5s. (M.E.T.).

SOLAR PROMINENCES IN 1907.—Prof. Riccò's summary of the results of the prominence observations made at the Catania Observatory during 1907 appears in No. 5, vol. xxxvii. (p. 83), of the *Memorie della Societa degli Spettroscopisti Italiani*; the usual data regarding the latitudes, heights, and extensions at the base are given, and the complete results summarised. The mean heliographic latitude, for both hemispheres, was 29°·4, being 1° less than in 1906; a notable maximum occurred in the third quarter in latitude 80°–85° south. In the northern hemisphere, for the whole year, there were two well-defined maxima (in latitudes 50°–60° and 20°–30°), and in the southern hemisphere there were three (latitudes 10°–20°, 40°–50°, and 80°–90°). During the first five months the number of prominences in the northern hemisphere preponderated, but for the last seven months the southern hemisphere showed the greater numbers; the numbers observed for the whole year were 381 and 447 respectively.

THE TEMPERATURE AND STRUCTURE OF THE SUN.—In a lecture delivered before the Philosophical Society of Washington, and now printed as a bulletin of the society (vol. xv., pp. 75–101, May), Dr. O. Lummer gave an interesting and suggestive *résumé* of our present knowledge concerning the probable temperature and structure of the sun. From a discussion of the laws of radiation as applied to the observed solar values, he arrives at the conclusion that the temperature may, with reasonable certainty, be assumed to be about 7000°. As such a temperature surpasses the critical temperature of all terrestrial substances, Dr. Lummer concludes that a sharp limit between a liquid and a gaseous mass on the sun is physically impossible. On the basis of this conclusion he discusses the probable structure of the sun's envelopes, and finds that most of the spectral phenomena observed, *e.g.* the broadening of lines in sun-spots and the distortion and displacement of various lines in prominences, can be accounted for by the assumption that they are produced by anomalous dispersion in the various layers of the sun's atmosphere.

## *THE ROYAL SOCIETY CONVERSAZIONE.*

THE annual conversazione to which ladies as well as gentlemen are invited by the Royal Society was held in the society's rooms at Burlington House on Monday. Most of the objects of scientific interest exhibited on this occasion were the same as those shown at the conversazione in May, and already described in these columns (May 21, p. 58). A few additional exhibits may, however, be referred to here to supplement the previous article. As before, we summarise the descriptions in the official catalogue, after arranging together related subjects.

*Dr. George E. Hale and Mr. Ferdinand Ellerman:* Astrophysical photographs taken at Mount Wilson Solar Observatory, Pasadena, California.—*The Director of the Meteorological Office:* Zoetropic apparatus exhibiting the progress of a travelling storm-centre and the circulation of air associated therewith. By means of a series of maps, upon which the isobaric lines and corresponding steps of the trajectories are drawn, and an ordinary zoetropic apparatus, viz. a revolving drum with slits through which the succession of maps is seen, the spectator is enabled to see both processes in progress, viz. the march of the depression and the course of the air in the various parts of the depression.—*Mrs. Hertha Ayrton:* The residual motion of water moving in stationary waves. When a liquid rises and falls in rhythmical wave motion its particles do not simply swing to and fro, returning, like pendulums, to their starting points after each oscillation, but each particle takes up a new position after each oscillation, so that it traces out a path for itself, only returning after many oscillations to the point from which it started. This general movement, which takes place in conjunction with the oscillatory movement, is called the residual motion of the liquid. It takes the form of vortices of peculiar shape, which are exactly the opposite of the ripple-forming vortices to which obstacles under the water give rise, since a single residual vortex is only completed in many oscillations, while each ripple-forming vortex is born and dies in a single swing.

*Prof. A. M. Worthington, C.B., F.R.S.:* Recent instantaneous photographs of splashes.—*Dr. W. J. Russell, F.R.S., and Mr. O. F. Bloch:* Photographs of flowers, &c., in natural colours (Lumière process).—*Mr. H. G. King and Mr. R. Kerr:* "Master gauges" or "standards" for extremely accurate measurements, the invention of Mr. C. E. Johansson, of Sweden. By using these gauges separately or combined together, more than 80,000 different sizes can be obtained, any of which sizes are accurate to within 0·00004 inch at 66° F. The steel is so treated as to reduce to a minimum any chance of change after being hardened. The gauges are used where extreme accuracy is required, as in the manufacture of machine parts, tools, and various instruments; also for "marking off" dies on surface plates and for testing them when machined, &c. Two of these blocks put face to face can sustain a pull of $11\frac{3}{4}$ lb., or 22 lb. to the square inch.—*Mr. Frederick Iles:* (1) "Irisographs," or chemical designs. "Irisography" is a method of producing coloured designs by means of chemical solutions applied in spots upon unsized paper, and subsequently developed by the central application of a compound solution which, spreading by capillary attraction, and coming into contact with the previously applied spots, combines with and reacts upon them to produce designs of varied outlines and colours. (2) "Caleidographs." Original designs executed by aid of the caleidograph on china, glass, paper, and on prepared glass plates. The "caleidograph" is an instrument to facilitate the working out or elaboration of simple or complex designs composed of geometrical curves and lines, either upon paper or on the actual articles of china, glass, metal, &c.

*Dr. J. A. Fleming, F.R.S.:* Transmission of signals by electromagnetic induction between oscillatory circuits, and their reception by means of a glow-lamp detector. At one end of the principal library a square circuit was set up in which high-frequency oscillations were created by the discharge of a Leyden jar charged by an induction coil. The coil was actuated by a coal-gas mercury break, and the spark was in a silencing chamber with air-blast arc destroyer. The oscillations were cut up into Morse signals by a punched tape and relay in the primary circuit. One hundred feet away was a similar receiving circuit, in which oscillations were created by induction transmitted from the sender, and were detected by a glow-lamp detector or oscillation valve and telephone. Messages and signals thus sent formed a small-scale exhibition of high-frequency inductive wireless telegraphy.—*Dr. Alexander Muirhead, F.R.S.:* A combined Kelvin siphon recorder and cable relay. The latest form of the Kelvin siphon recorder has been converted into a successful cable relay by simply substituting fine gold wire for the silk fibre which connects the siphon to the vibrator.

*Mr. Leonard Hill, F.R.S.:* (1) Self-contained diving dress (made by Messrs. Siebe, Gorman and Co., Ltd.). Air-pump, pipe, and life-line are done away with, and the diver is connected to the surface by a telephone cable only. Attached to the back of the ordinary diving dress are cylinders containing air with 50 per cent. oxygen. The oxygen mixture is delivered to the helmet by a pipe, to which a reducing valve is attached. The supply is 4 litres per minute, and lasts two hours. Two caustic soda boxes are connected by a pipe with the helmet, and by a second pipe to an aspirating arrangement placed in the oxygen delivery tube. The force of the oxygen mixture escaping through a narrow jet is used to aspirate the air in the helmet through the soda boxes, which purify it from the exhaled carbonic acid. (2) Life-saving apparatus for use in mines (made by Messrs. Siebe, Gorman and Co., Ltd.). The apparatus, perfected out of that of Mr. Fleuss, consists of a breathing bag, and cylinders of compressed oxygen, carried by straps passing over the shoulders, and so hung that the man is free to do work. The dress allows the man to be stripped to the waist in hot atmospheres.—*Prof. Arthur Gamgee, F.R.S.:* Photographs, drawings, and plans exhibiting the apparatus employed by Prof. Gamgee in his research on methods for the continuous (photographic) and quasi-continuous registration of the diurnal curve of the temperature of the animal body.

*Dr. G. H. Rodman:* A series of stereoscopic radiographs of molluscal shells. Prior to the application of the Röntgen rays to this branch of zoological research, it was necessary to sacrifice the specimen in order to disclose the internal anatomy of the columella and whorls—a course obviously undesirable in the case of a rare and possibly unique shell. In some of the examples shown the radiograph has been so made as to show the equivalent of both horizontal and vertical sections.—*Mr. H. S. Leigh:* Living examples of the leaf insect from the Seychelles, *Phyllium crurifolium*, Serville. The Phylliums afford one of the most striking examples of protective resemblance. The specimens are not only very similar to leaves in shape and colour, but in their peculiar movements imitate the shaking of the leaves. The resemblance to vegetable structures is carried still further, since the eggs bear a marked likeness in shape and colour to certain seeds.—*Prof. J. Cossar Ewart, F.R.S.:* Hybrid between a Prejvalsky mare (*Equus prejvalskii*) and a Highland pony. This is one of six hybrids bred from wild horses imported from Mongolia. With the exception of the one exhibited, the hybrids are out of pony mares. All six hybrids are males, and two foals out of pony mares by a hybrid bred at Penycuik in 1905 are males. The hybrids support the view that a wild horse of the Prejvalsky type took part in the making of domestic horses. Four of the six hybrids were bred at Woburn by his Grace the Duke of Bedford.—*Mr. F. Enock:* Insect intelligence, as exemplified in the life-history of the wood-boring wasps (Crabronidæ). All hymenopterous insects show a high degree of intelligence. One species of Crabro fills its cells with one, and only one, species of insect; another with one kind of beetle; a third with homopterous insects.

*Dr. A. S. Woodward, F.R.S.:* Photographs, by Mrs. E. von Kaufmann, of portions of carcases of a mammoth and rhinoceros found preserved in petroleum at Starunia, Galicia. These specimens were obtained in an ozokerite mine while sinking a shaft through the deposit of an old marsh which was saturated with petroleum.—*The Director-General, Survey Department, Egypt:* Plans, photographs, and objects illustrating the archæological survey of that portion of the Nile Valley which will be submerged by the Aswan reservoir when its level is raised. A detailed survey of the valley and the ancient sites is being made, and the anatomical study of all human remains found is being carried on simultaneously with the archæological investigations. Numerous pre-dynastic cemeteries have been found, and the present evidence shows that in these times Lower Nubia and Egypt formed one ethnological territory, both districts being in the same state of culture. From the first dynasty their history diverges; in Egypt the race remains unchanged, and culture shows a progressive development; in Nubia the race becomes mixed with a strong infusion of negro blood, and culture lags behind that of Egypt.—*Miss M. Helen Tongue:* Bushmen paintings copied by the exhibitor from the caves and rocks in Cape Colony, Orange River Colony, and Basutoland. The paintings, which are found on the walls or roofs of rock shelters or caves, generally in sandstone districts, have been coloured with iron oxides, or with ochres mixed with fat. The date of the work varies. In Cape Colony the latest paintings must be nearly a century old. In Basutoland there may be some of a later date; probably most are older. The pictures have been carefully traced, and the colours and background copied as exactly as possible.

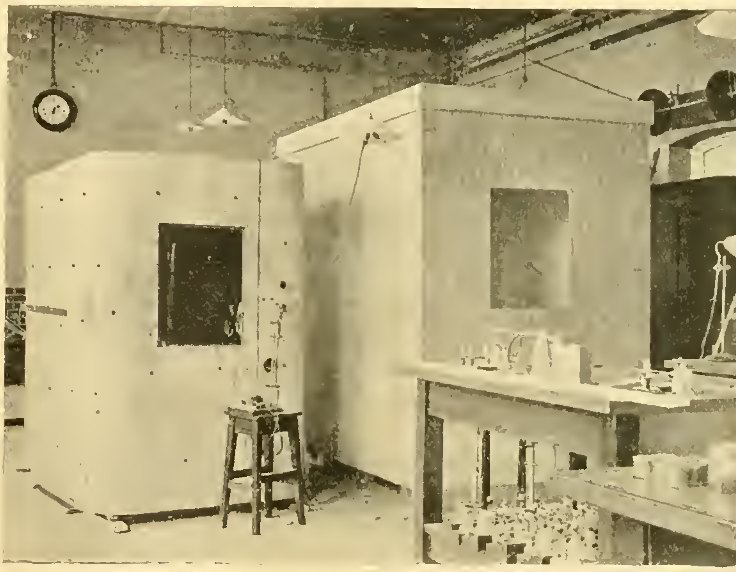
## A CALORIMETER FOR DETERMINING THE RELATION BETWEEN HEAT-PRODUCTION AND MUSCULAR WORK.

IN the physiological laboratory of the University of Sheffield a calorimeter has been erected on the model of Atwater and Benedict's calorimeter, now carried by Prof. Benedict to a great state of perfection in the Nutrition Laboratory at Boston, U.S.A. The Sheffield copy is not at present a complete one, and its limitations are best detailed by a brief description of the problem in the solution of which it is hoped immediately to play some part. This problem is the nature of the physicochemical process underlying the phenomenon of muscular contraction, upon which some work has been in progress in this laboratory already along somewhat different lines.

A precise statement of the relation existing between muscular work and heat production is a necessity for the final solution of this question. Even before precision can be hoped for, additional information may be of much value in deciding the comparative value of different lines of attack. Thus, it having been already shown that the energy liberated is entirely to be assigned to the combustion of food, the question arises as to whether the contraction is the direct consequence of the combustion which takes place at the same time, or as to whether it is not rather the consequence of some preceding combustion. In the latter case there would be nothing remarkable in the proposition that the combustion responsible was in the main an occurrence taking place during a preceding contraction. Each contraction might, so to speak, wind up a spring for release in the next contraction. The usual view is that contraction and the combustion responsible for it are concomitant; the view of the Sheffield laboratory is that they are not. The second point of view can be at once supported by the well-known fact that fatigued muscle is apparently a more economical heat engine than muscle in good condition, giving off less waste heat for an equal amount of external work done. Such a fact loses all peculiarity if it is considered merely as a failure on the part of the fatigued muscle to provide for succeeding contractions. It is in the hope of collecting further data of this kind that the calorimeter has been constructed. The immediate necessities, therefore, are a calorimeter within which prolonged muscular work can be performed, and from which a complete statement of the amount of work done and heat given off can be obtained. Benedict's original instrument offers much more information than this, since it is a complete respiration calorimeter, providing by its use data for a perfect balance-sheet both of chemical material and energy. It is hoped to raise the Sheffield apparatus to the same level of perfection, so that it may be placed at the disposal of investigations of a more general kind when additional financial aid has been obtained.

The calorimeter has been constructed by Messrs. George, of Birmingham, who have followed the detailed instructions provided by Benedict in the publications of the Carnegie Institution, Washington. At one stage of construction it was examined by Prof. Benedict, and then met with his approval. He was kind enough to make important suggestions, which have since been carried out.

A small room, 8 feet by 6 feet by 5 feet, has been built of copper sheets carefully soldered together and stiffened by an external wooden framework, to which they are fixed. On the outer surface of the framework zinc sheets have been fastened, forming a second metal covering. The double-walled metal box so formed rests on rails within a double-walled wooden house enclosing it. Thus the walls, copper, zinc, wood, and wood separate three layers of air external to the chamber. The accessory arrangements of the calorimeter render it possible to maintain the zinc sheath and the two outer layers of air at the same temperature as that of the copper box, whatever that may be. Heat is thus prevented from escaping from the walls of the copper chamber. This end is secured by heating and cooling apparatus in the two outer air spaces, resistance wires and cold-water pipes. The degree to which the heating and cooling mechanism is resorted to in each of these spaces is determined by the observation of electrical currents from one hundred and fifty sets of thermocouples arranged in two series, a series indicating differences of temperature between the copper and zinc sheaths, another indicating differences between the two outer air spaces. Each series is divided into zones, so that the state of the roof, the floor, or each of three zones in the side walls can be separately observed. The heating and cooling mechanism is similarly subdivided. The observer seated outside the calorimeter can rapidly test each segment of the calorimeter in turn, and rapidly balance any difference found by adjustments of rheostats admitting more or less current to the heating wires, and taps admitting more or less water to the cooling pipes.



Calorimeter for physiological experiments at Sheffield University. The metal chamber on the left is now enclosed in the wooden house on the right. The spots on the wall of the metal chamber are tubes in which the thermocouples now lie.

The difficulties in construction up to this point lie mainly in the thermocouples and their fixation. It is a difficult matter especially to prevent risks of short-circuiting and displacement from incapacitating those placed to read differences of temperature between the copper and zin., since the subject within the calorimeter by movements causes awkward bulgings of the metal.

A second difficulty in construction is the necessity for an absolutely air-tight copper chamber admitting no air save through the pipe provided, and allowing none to escape save through the exit tube. There are a number of apertures which have to be carefully sealed. Thus the window through which the subject enters is subsequently glazed. There is also an air lock through which material can be passed into and out of the chamber. This is guarded by a double port. There are also four tubular openings through which pass telephone wires and wires to an electromagnet and to the copper disc of a bicycle ergometer, a cable from the beam of a balance placed above the calorimeter, the entrance and exit tubes of the radiator system of water-pipes, and a lever for adjusting the position of shields covering the radiator system. All these apertures are sealed in various ingenious ways, but none too securely. Doubtless practical experience will both provide and remove fear of defects in this direction. When to this is added the risk introduced by every screw passing through the copper, such as, for example, those necessary for the fixation of the bed, the balance beams from which the radiator system is suspended, &c., there is at present fear enough. It was in indicating points such as this that Prof. Benedict's visit was of so much value.

The heat produced within the copper box, carefully prevented from escaping from its surface in the manner described, is carried out in a stream of water constantly driven through the radiator system. The quantity of water passing is varied with the necessities of the moment, and is necessarily much greater when the subject is at work on the ergometer. The water passing is weighed on exit in a meter, and its temperature on entrance and exit observed. The former is practically constant, the latter kept as constant as possible by variation in the rate of water flow. These data form the main items in the statement of heat produced, though other important items, such as the amount of water condensing on the radiator pipes within the chamber, the water evaporated and carried through with the air leaving the chamber, are duly considered and provided for. Thermocouples are placed in the tubes through which the air finds entrance and exit, in quantity 75 litres per minute, so as to ensure the detection of any difference of temperature. Any difference found is corrected by increased heating of the entering air.

In Benedict's calorimeter the air is driven from the chamber through a closed system of tubes back to the chamber again. In this system are interpolated sulphuric acid and soda lime absorbers of a necessarily very large size, determined by the large mass of air in motion per unit of time. The oxygen consumed is made good by admission of oxygen from a cylinder of the compressed gas. In the Sheffield apparatus this will not, at first at least, be attempted. Dried air heated and passed into the chamber will be driven out through a sulphuric acid absorber, no attempt being made to do more than take a determination of the water.

## *RECENT RESEARCHES IN THE STRUCTURE OF THE UNIVERSE.*[1]

I CONSIDER it an uncommon privilege to lecture on the structure of the universe in the country of the Herschels. Even now their celebrated gauges are unrivalled, and they still form one of the important elements on which any theory of the stellar system must be based. It is well known that the plan of these gauges consisted in directing the telescope successively to different points all over the sky, and simply counting the number of stars visible in the field.

There is one fact clearly brought out by these gauges to which I must direct your attention. It is that in the outward appearance of our nightly sky, as seen with the telescope, there is a great regularity. In the Milky Way, that belt which we see with the naked eye encircling the whole of the firmament nearly along a great circle, the number of stars, as seen in Herschel's 20-feet reflector, is enormous. On both sides this apparent crowding of the stars diminishes very gradually and regularly until, near the poles of the Milky Way, we come to the poorest parts of the sky.

Let us look at this phenomenon somewhat more closely. If we direct our telescope first towards the part of the Milky Way near Sirius, and if from there we gradually work up towards the North Pole of the Milky Way in the constellation called the Hair of Berenice, we shall clearly perceive this gradual and regular change in the number of stars. Now if we repeat the same process, beginning from some other point of the Milky Way, say in Cassiopeia or the Southern Cross, we shall find that, not only is there a similar gradual change, but we shall approximately go through the same changes.

At the *same* distance from the Milky Way we shall find, approximately, the same number of stars in the field of the telescope. Put in other words, the richness of stars varies regularly with the galactic latitude; it varies relatively little with the galactic longitude.

Imitating most of the investigators of the stellar system, we will therefore disregard the longitude and keep in view only the changes with the galactic latitude. In reality this comes to being satisfied with a first approximation. For, in reality, there are differences in the different longitudes, especially in the Milky Way itself. But even here the differences are not so great as seems commonly to be supposed. There is every reason to believe, therefore, that our approximation will be already a tolerably close one.

### *Real Structure.*

Meanwhile, what the Herschel gauges teach us is only relative to the outward appearance of the sky. What is the real structure of the stellar world? If we see so many stars in the field, with the telescope directed to the Milky Way, is it because they are really more closely crowded there, as Struve thinks, or is the view of the older Herschel correct, who imagined that the greater richness is simply a consequence of the fact that we are looking in deeper layers of stars; that our universe is more extensive in the Milky Way than it is in other directions?

Imagine that we could actually travel through space. For instance, imagine that first we travel in the direction of the constellation Cassiopeia. If we travel with the velocity of light, not so very many years would pass before we get near to some star. Proceeding on our journey for many, many more years, always straight on, we will pass more stars by and by. How will these stars look thus viewed from a moderate distance—say, from a distance as that of the sun? Will they all be found to be of equal luminosity, as Struve practically assumed? And in this case are they as luminous as our sun, or more so, or less so? Or are they unequal? If so, how many of them are brighter than our sun, how many fainter? Or, to be more particular, how many per cent. of the stars are 10, 100, 1000, &c., times more luminous than our sun? How many are equal to the sun, or 10, 100 times fainter? In a few words: What is the nature of the mixture? or, lastly, what is the *mixture law* of the system of the stars?

Furthermore, in travelling on, shall we find the stars in reality equally thickly, or rather thinly, crowded everywhere? Or shall we find that after a certain time, which may be many centuries, they begin to thin out, as a first warning of an approaching limit of the system? Is there really such a limit, which, once passed, leads us into abysses of void space?

Herschel thought there was such a limit, and even imagined that his big telescope penetrated to that limit; that is, he assumed that his telescope made even the remotest stars visible. On this supposition is based his celebrated disc theory of the system.

Again, we may condense these questions in this single query: How does the crowding of the stars, or the *star-density*, that is, the number of stars in any determined volume (let us say in a cubic light century), vary with the distance from our solar system?

But there is more. We supposed that our journey went straight on in the direction of Cassiopeia, which is in the Milky Way. What if our journey is directed to the Pleiades, which are at some distance from that belt, or to the Northern Crown, which is still further, or to the Hair of Berenice, which is furthest of all from the Milky Way? For different regions *equally* distant from the galaxy we have seen that outward appearances are the same. We may admit, with much probability, that in space, too, we would find little difference. Summing up, the problem of the structure of the stellar system in a first approximation comes to this:—

*To determine, separately for regions of different galactic latitude, in which way the star-density and the mixture vary with the distance from the solar system.*

I think that there is well-founded hope that, even perhaps within a few years, sufficient materials will be forthcoming which will allow us to attack the problem to this degree of generality, with a fair chance of success. At the present moment, however, our data are yet too scanty for the purpose. Still, they will be sufficient for the derivation of what must be in some sort *average* con-

[1] Discourse delivered at the Royal Institution on Friday, May 22, by Prof. J. C. Kapteyn.

ditions in the system. The method of treatment will not be essentially different from that which will be applied later to the more general problem, but we have provisionally to be content with introducing the two following simplifications :—

(1) We will assume that the *mixture* is the same throughout the whole of the system.

(2) We will not treat the different galactic latitudes separately.

The consequence will be that the resulting variations of density to which our discussion leads will not represent the actual variations which we would find if we travelled in space in any determined fixed direction, but a variation which will represent some average of what we would find on all our travels if we successively directed them to different regions of the sky.

Our present problem will thus be confined to finding out :—

(*a*) The mixture law.

(*b*) The mean star-density at different distances from the solar system.

If time allows, I will, at the end of this lecture, say a few words on the restrictions introduced, and the way to get rid of them.

As it is not given to us to make such travels through space as here imagined, we have to rely on more human methods for the solution of our problem.

*Determination of Distance.*

It is at once evident that there would be no difficulty at all if it were as easy to determine the distance of the stars as it is to determine the direction in which they stand. For in that case the stars would be localised in space, and it would be possible to construct a true model from which the peculiarities of the system might be studied.

It is a fact, however, that, with the exception of a hundred stars at most, we know nothing of the distances of the individual stars.

What is the cause of this state of things? It is owing to the fact that we have *two* eyes that we are enabled not only to perceive the direction in which external objects are situated, but to get an idea of their distance, to localise them in space. But this power is rather limited. For distances exceeding some hundreds of yards it utterly fails. The reason is that the distance between the eyes as compared with the distance to be evaluated becomes too small. Instruments have been devised by which the distance between the eyes is, as it were, artificially increased. With a good instrument of this sort distances of several miles may be evaluated. For still greater distances we may imagine each eye replaced by a photographic plate. This would even already be quite sufficient for one of the heavenly bodies, viz. for the moon.

At one and the same moment let a photograph of the moon and the surrounding stars be taken both at the Cape Observatory and at the Royal Observatory at Greenwich. Placing the two photographs side by side in the stereoscope, we shall clearly see the moon "hanging in space," and may evaluate its distance.

But already for the sun and the nearest planets, our next neighbours in the universe after the moon, the difficulty re-commences.

The reason is that any available distance on the earth, taken as eye-distance, is rather small for the purpose. However, owing to incredible perseverance and skill of several observers, and by substituting the most refined measurement for stereoscopic examination, astronomers have succeeded in overcoming the difficulty for the sun. I think we may say that at present we know its distance to within a thousandth part of its amount. Knowing the sun's distance, we get that of all the planets by a well-known relation existing between the planetary distances.

But now for the fixed stars, which must be hundreds of thousands of times further removed than the sun. There evidently can be no question of any sufficient eye-distance on our earth. Meanwhile, our success with the sun has provided us with a new eye-distance, 24,000 times greater than any possible eye-distance on the earth. For now that we know the distance at which the earth travels in its orbit round the sun, we can take the diameter of its orbit as our eye-distance. Photographs taken at epochs six months apart will represent the stellar world as seen from points the distance between which is already best expressed in the time it would take light to traverse it. The time would be about sixteen minutes.

However, even this distance, immense as it is, is on the whole inadequate for obtaining a stereoscopic view of the stars. It is only in quite exceptional cases that photographs on a large scale—that is, obtained by the aid of big telescopes—show any stereoscopic effect for fixed stars. By accurate measurement of the photos we may perhaps get somewhat beyond what we can attain by simple stereoscopic inspection, but, as we said a moment ago, astronomers have not succeeded in this way in determining the distance of more than a hundred stars in all.

How far we are still from getting good stereoscopic views appears clearly from the stereoscopic maps which your countryman, Mr. Heath, constructed, making use of the data obtained in the way presently to be considered. In order to get really good pictures, he found it necessary to increase the eye-distance furnished by the earth's orbit 10,000 times. Are there, then, no means of still increasing this eye-distance?

*Motion of Solar System through Space.*

There is one way, but it is a rather imperfect one. Sir William Herschel was the first to show, though certainly his data were still hardly sufficient for the purpose, that the whole of the solar system is moving through space in the direction towards the constellation of Hercules. Later observations and computations have confirmed Herschel's conclusions, and we have even been able of late to fix with some precision the velocity of this motion, which amounts to 20 kilometres per second. This velocity is a 15,000th part of the velocity of light. In the 150 years elapsed since Bradley determined for the first time the position of numerous stars with modern precision, the solar system must thus have covered a distance of exactly a hundredth part of a light-year, *i.e.* we are thus enabled to make pictures of the sky as seen from points of view at a mutual distance of a hundredth of a light-year. Our eye-distance of sixteen light minutes is thus increased more than 300-fold. True, this distance falls still considerably short of that adopted by Heath, but it appears that, for a considerable part of the stars, it is, though not nearly so great as might be desired, still in a certain way sufficient.

There is, however, a difficulty in the way, which prevents our pictures from giving a stereoscopic view of the stars at all, and thus prevents the determination of the distance of any star in this manner. The difficulty is that the changed directions in which, after the lapse of 150 years, we see the stars is not exclusively the consequence of the sun's motion through space, but is due also to a real motion of the stars themselves. The two causes of displacement which, in the case that we take the diameter of the earth's orbit as eye-distance, are separable by means of a simple device, become inseparable in the present case. In order to see whether this difficulty be or be not absolutely insuperable, I will take a parallel case *on the earth*.

At a certain distance we observe a cloud of insects hovering over a small pond. In order to evaluate the distance separating the insects from our eye, suppose that we make a photograph; then, after a few seconds, a second one from a slightly different standpoint. It must be evident that even if we have used an instrument which clearly shows the individual insects, the two pictures put in the stereoscope will not furnish a stereoscopic view of them individually; on the contrary, the picture as seen in the stereoscope will be perfectly chaotic. The reason, of course, is that in the interval between the taking of the two photographs the insects have moved. Does it follow that no evaluation of the distance can be obtained?

The answer must be, of any individual insect, *no*; but of the cloud, as a whole, we can evaluate its distance provided that the cloud, as a whole, has not moved; or, expressed more mathematically, provided that the centre of gravity of the cloud has not moved, we can derive the *average* distance [1] of all the insects. We shall be sure of

[1] The expression *average distance* ought, strictly speaking, to be replaced by the distance corresponding to the *average parallax*. For clearness sake I have ventured here and in what follows to substitute one expression for th other.

the immobility of the centre of gravity if we know that the direction of the motions of the insects is quite at random; but this is by no means required. The motion may be preferentially in a horizontal plane or along a determined line, say along the longer axis of the pond, provided only that the motions in any two opposite directions are equally frequent.

Not only that, even if the cloud, as a whole, is not immovable, we are not necessarily helpless. For, if the insect cloud and the photographer were both on a sailing vessel, circumstances would be the same as on the mainland, though now the cloud is in motion. Only, instead of the absolute displacement of the photographic apparatus, we must know the displacement relative to the ship, or rather *relative* to the *insect-cloud*. This, then, finally is the real thing wanted. We may obtain the distance of the insect-cloud, or, what comes to the same, the average distance of its members, as soon as we are able to find out the displacement of our point of view with regard to the centre of gravity of the cloud.

Our case is much the same in the world of the stars.

We shall be able to determine the average distance of the members of any arbitrary group of stars provided that we can find the motion of the solar system, both in amount and in direction, relative to the centre of gravity of the group.

Now, astronomical observations such as those which led the elder Herschel to his discovery of the solar motion through space enable us to determine the *direction* of the sun's motion relative to such groups as the stars of the third, fourth, &c., magnitude. Spectroscopy enables us to determine the *amount* of that motion.

We must be able, therefore, to find out the average distance of the stars in these groups. For other groups, such as the stars having an apparent centennial motion of 10″, 20″, &c., there is a difficulty. Still, however, we have succeeded in overcoming this difficulty by a somewhat indirect process, and pressing into service the stars of which the individual distances are known. This, then, is the upshot of astronomical work on the distances.

*What we know about Star-distance.*

*By direct measurement we know the distance of some hundred individual stars.*

*For the rest we know the average distance of any fairly numerous group of stars of determinate apparent magnitude and apparent motion.*[1]

The question is, Can this imperfect knowledge of the distances be considered as in any wise sufficient for obtaining an insight into the real arrangement of the stars in space? I think it can, and I will now try to show in what manner.

(*To be continued.*)

[1] At the present moment some objection might certainly still be made against the generality of this statement In fact, the scarcity of spectroscopic data is the cause that, though the determination of the solar motion separately for such groups as the stars of determinate magnitude and proper motion is quite possible, it has not yet been carried through. As a consequence, the results used in what follows still rest on the assumption that the centres of gravity of all the groups considered are at rest relative to each other. That this assumption must be probably true follows from the near identity of the *direction* of the sun's motions, furnished by the several groups.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

OXFORD.—The following is the text of the speeches delivered by Prof. Love in presenting recipients of the degree of D.Sc. *honoris causa* at the Encænia on June 24:—

FULGENCE RAYMOND.

Antequam de huius viri laudibus loquar, breviter dixerim centum fere abhinc annos celeberrimam medicorum scholam Parisiis exstitisse, eandem sæculo proximo exeunte, Charcotio familiam ducente, maxima laude floruisse. Charcotio successit Fulgentius Raymond, magistro discipulus clarissimus: quo rem feliciter navante valetudinarium Salpetriense, in quo quasi in aliquo orbis terræ theatro partes primarias agit, omnium in se ora convertit. Hic excultæ sunt plurimæ rationes, quæ ex eo pendent quod hi præ se ferunt qui affirmant posse corpori ægrotantis ipsam mentem mederi: quo in genere hic noster, dum de cerebri et de medullæ spinalis natura docte luculenterque disserit, laudem maximam consecutus est. Felicissimum profecto amicitiæ inter Britanniam et Galliam reconciliatæ documentum duco, quod hic vir de medicorum apud Gallos insignissimorum usu et rationibus magno medicorum nostrorum conventu Londinii nuper contionatus est.

JETHRO JUSTINIAN HARRIS TEALL.

Descriptioni Geologicæ, impensis publicis faciendæ, quæ saxorum solo Britannico subiectorum naturam, qua vi conflata sint, quo tempore coorta exquirit, præfectus est Jethro Justinianus Harris Teall. Qui vir, quo melius rem tantam conficeret, non in uno tantum genere laudis excellit: neque enim solum rationes quæ latissime patent animo comprehendere, sed etiam minutissima quæque et observare et repræsentare miro modo potest. His artibus usus, cum saxorum diversissimorum compages scrutaretur, omnia e montibus vi ignea liquefactis exorta esse cognovit: idem mutationes quas hæc saxa patiuntur gravi pondere oppressa subtilissime enarravit. Quo ingenio, qua peritia in hoc genere usus sit declarat ille liber de Insularum Britannicarum Petrologia conscriptus, quem aureolum esse ego iure dixerim.

JAMES WARD.

Inter Psychologos nemo clarior est quam Jacobus Ward, qui Psychologiam, cuius scientiæ proprium sit singulorum sensus tractare, non ex alia scientia pendere sed sui iuris esse constanter asseverat: cuius in ore semper est vox illa "Ego sum. Nihil mihi hoc verius?" Qui vir ita priorum repertis usus est ut erroribus vitatis longius progrederetur: idem si quid boni usquam invenisset non aspernatus novam, quæ latissime pateret, rationem excogitavit et necessitudinem quandam inter mentem nostram et rerum naturam intercedere docuit. Psychologiam etiam cum aliis scientiæ generibus artissime cohærere monstravit et omnibus qui cognoscendi ratio quæ sit investigant vel hominum moribus student utilissimam esse contendit. Neque ei satis erat huic scientiæ novum quasi fundamentum præbere, sed multorum diverso in genere philosophorum opiniones reprehendit: quæ omnia in libro paucos abhinc annos edito pervulgata cum iis qui rerum naturæ investigandæ operam dant tum iis qui philosophiæ potissimum incumbunt maxime profuerunt.

MANCHESTER.—Lord Morley, Chancellor of the University, has nominated the following as recipients of honorary degrees on the occasion of his installation, which has been fixed for July 9:—the Right Hon. A. J. Balfour, Mr. E. J. Broadfield (treasurer of the University), Mr. Andrew Carnegie, Lord Courtney of Penwith, Lord Curzon of Kedleston, Sir Ed. Donner, Bart., Dr. A. M. Fairburn (principal of Mansfield College, Oxford), Sir Frank Forbes Adam (chairman of the university council), the Right Hon. R. B. Haldane, Sir H. F. Hibbert (chairman of the Lancashire Education Committee), Sir W. H. Houldsworth, Bart., Prof. Henry Jackson, Sir William Mather, Mr. J. Cosmo Melvill (donor to the Manchester Museum of the Cosmo-Melvill herbarium), and Sir Edward Maunde Thompson. In addition, the following honorary degrees will be conferred:—*LL.D.*, Mr. A. J. Evans (keeper of the Ashmolean Museum) and Mr. William Farrer (editor of the "Victoria County History of Lancashire"; *D.Sc.*, Emeritus Prof. Gamgee.

Mr. R. E. Slade has been elected to a Gartside travelling scholarship. Dr. Hans Geiger has been re-appointed to the Harling fellowship in physics.

THE Countess of Bective will present the prizes at the Horticultural College, Swanley, Kent, on Tuesday, July 14. Sir John Cockburn, K.C.M.G., will take the chair at 4 p.m.

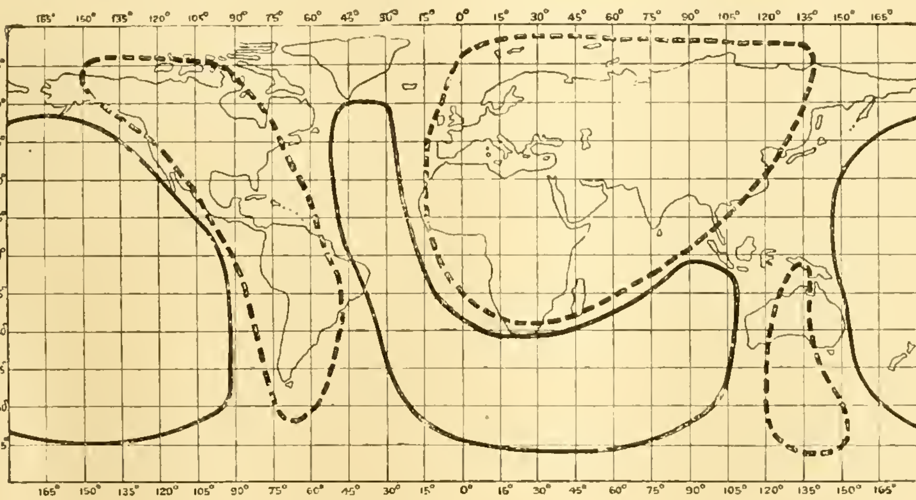
WE are glad to be able to announce that a petition for a charter for a University of Bristol has been sent to the Privy Council. A concordat is being arrived at between University College, Bristol, and the Merchant Venturers' Society, which has for many years been identified with work of technical and secondary education in the city. The most liberal support for the University scheme has come from various members of the Wills family, no less a sum than 135,000*l.* having been promised toward its realisation by them. Of this amount, Mr. H. O. Wills has promised 100,000*l.*, Lord Winterstoke (formerly Sir W. H. Wills) 20,000*l.*, and Sir Frederick Wills 10,000*l.* More money is, however, still required to establish the University in a satisfactory manner; and it is to be hoped that other merchant princes of Bristol will follow the magnificent example which the Wills family has given them.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Royal Society**, April 30.—"Note on the Representation of the Earth's Surface by Means of Spherical Harmonics of the First Three Degrees." By Prof. A. E. H. **Love**, F.R.S.

In a previous paper the author had concluded from dynamical considerations that those elevations and depressions on the surface of the globe which correspond with continents and oceans should be capable of being represented, in respect of their main features, by means of spherical harmonics of the first, second, and third degrees. A rough spherical harmonic analysis of the



actual elevations and depressions yielded a rather imperfect representation of the surface, which nevertheless offered a general resemblance to the actual distribution of land and water. It had, however, certain definite defects. To alter the computed figure it is necessary to change appropriately the coefficients of the spherical harmonic expression by which it is proposed to represent the elevation of the surface above the mean level. In the present paper there is recorded the best of many sets of trial coefficients, and the result is shown on the accompanying chart. In this chart the fine continuous line is a rough outline of the actual land of the globe, drawn in such a way that all degrees of latitude or of longitude have the same value on the map; the heavy line is the zero line of the surface harmonic with the chosen coefficients; the dotted line is the contour line along which the computed elevation is equal to one-tenth of its maximum value.

"The Relation between the Crystalline Form and the Chemical Constitution of the Picryl Derivatives." By G. **Jerusalem** and Prof. W. J. **Pope**, F.R.S.

By a method which depends upon dividing up the space occupied by a crystalline substance into polyhedral cells, each of which is assumed to be the habitat of but one atom, Barlow and Pope have been able to determine the general relation which exists between crystalline form and chemical constitution. They conclude that the polyhedral cells, each of which represents the domain of one atom and which fit together without interstices to form the crystal structure, possess volumes which are approximately proportional in magnitude to the lowest valencies exhibited by the elements which they respectively contain. The assemblages obtained by packing together the atomic domains mentioned are partitionable into identical units, each of which represents in composition, constitution, and configuration a chemical molecule of the substance concerned. The relation between the crystalline form and chemical constitution of a series of substances is conveniently illustrated by comparing the dimensions of polyhedra, of which the volumes are represented by the sum, W, of the valencies of the atoms composing the molecules, and of which the relative dimensions are the crystallographic axial ratios $a:b:c$. The dimensions referred to are termed the equivalence parameters $x:y:z$, and are calculated from the relations that $a:b:c=x:y:z$ and $xyz=W$.

In the present paper the above considerations are applied to a number of derivatives of picric acid and allied substances; it is shown that in this series one of the three equivalence parameters remains approximately constant, and has about the value of $z$ in the equivalence parameters of crystalline benzene, namely, $x:y:z=3{\cdot}101:3{\cdot}480:2{\cdot}780$. The direction in which the dimension $z$ is measured in benzene is that in which columns formed by superposing triangularly arranged groups of three polyhedra, each occupied by a carbon atom, occur throughout the assemblage representing crystallised benzene. It is concluded that the crystal structures of the picryl derivatives are derived from that of benzene by moving the columns of carbon domains apart and packing the substituting groups in between them in accordance with the method already described by Barlow and Pope.

"On the Hysteresis Loss and other Properties of Iron Alloys under very Small Magnetic Forces." By Prof. Ernest **Wilson**, V. H. **Winson**, and G. F. **O'Dell**. Communicated by Sir William H. Preece, K.C.B., F.R.S.

The experiments were carried out on two alloys of iron, namely, "stalloy," of which the distinguishing feature is that it contains about 3 per cent. of silicon, and "lohys," which is a good sample of transformer plate. The principal object of the research is to find the magnetic properties of these materials under small magnetising forces, especially as regards hysteresis loss. Information is also given on the specific resistance and temperature coefficients of the materials.

For the magnetic tests the specimens are in the form of rings composed of stampings, and the ballistic galvanometer method has been employed.

Lord Rayleigh found by the magnetometer method that in the case of Swedish iron the permeability was nearly constant when the magnetic force (H) varied from 0·00004 to 0·04. In the present experiments the permeability also tends to become constant, the limiting values being 260 for stalloy and 222 for lohys. As regards the maximum value of the permeability, the results obtained have been compared with published figures for a very pure iron and a good sample of plate rolled from Swedish iron. For these materials the maximum permeabilities are respectively 5480 and 4450, and occur for values of the magnetic induction (B) of 9100 and 7000 respectively. For stalloy and lohys the maximum permeabilities are 4520 and 3280, and occur for values of B of 5000 and 5500 respectively.

As regards hysteresis loss, the following figures are given in full, as they form the most important part of the paper. The loss for stalloy is somewhat lower than that for the pure iron specimen above alluded to, while that for lohys is slightly higher.

| Stalloy | | | Lohys | | |
|---|---|---|---|---|---|

| 11500 | 5·71 | 3110 | | | |
| 13480 | 16·20 | 4530 | | | |

The stalloy specimen requires careful attention in order that a truly symmetrical hysteresis loop may be obtained, more especially for values of B between 200 and 8000. In an extreme case, after reducing the force H from about 63 to 0·712 without subjecting the specimen to a series of reversals of the magnetic force as it was reduced, a complete hysteresis loop was obtained. This loop is unsymmetrical in the sense that if the axis of H be so placed that the coercive forces are equal, the positive and negative values of the maximum induction B are not equal, but the positive and negative values of the residual magnetism are equal. The value of the permeability defined as the ratio of half the total change of magnetic induction to the maximum value of H is less than is the case when the loop is truly symmetrical. In the table the figures for loops which are not quite symmetrical are indicated by an asterisk.

The Steinmetz coefficients have also been investigated, the relation being ergs per cycle per cubic centimetre $= \alpha B^{\beta}$. Both coefficients vary considerably. For stalloy the coefficients are very nearly constant between values of B of 600 and 11,000; over this range $\beta = 1{\cdot}71$ and $\alpha = 0{\cdot}000342$. For values of B from 0·937 to 8·25 the coefficient $\beta$ is as high as 2·69. In the case of lohys, between values of 500 and 8000 for B, the values $\beta = 1{\cdot}62$ and $\alpha = 0{\cdot}00122$ approximately hold. In this case also the coefficient $\beta$ rises to a high value when B is small.

Another matter investigated is the value of $\int H dB / H_0 B_{max}$, where $H_0$ is the coercive force. Dr. Sumpner has pointed out that this quantity is a linear function of $B_{max}$ over a large range. For stalloy and lohys the relation only holds apparently between values of B of 1000 and 9000.

The specific resistance and temperature coefficients were obtained in the case of each of the materials. The following figures are in each case the mean of the results of three independent experiments:—

| | Mean specific resistance at 15° C. in $10^{-6}$ ohms per c.cm. | Mean temperature coefficients 0° to 50° C. | Mean temperature coefficients 0° to 100° C. |
|---|---|---|---|
| Stalloy ... ... | 49·63 ... | 0·000975 ... | 0·00103 |
| Lohys ... ... | 14·25 ... | 0·00424 ... | 0·00446 |

It will be seen that stalloy has a high specific resistance, which is important in connection with eddy current loss, as this is thereby reduced.

May 28.—"Effect of a Cross Wind on Rifled Projectiles." By A. **Mallock**, F.R.S.

The effect of wind on rifled projectiles is important for practical reasons, especially in the case of small arms, but the object of the present note is not so much to determine the actual effect of wind as to show that accurate experiments on the subject would afford valuable information concerning the flight of projectiles in still air.

It is easily shown that if the air resistance acts always in the direction of the resultant of the velocities of the wind and the projectile, the angle made by the resultant velocity with the line of aim remains constant throughout the range.

In order, however, that the resistance may act in the direction of the resultant velocity, the projectile must be symmetrical about that direction. This, in the case of any form except a sphere, means that the principal axis of the projectile must take the direction of the resultant velocity.

If this is assumed and we take $v_0$ as the initial velocity of the shot, $w$ as the velocity of the wind ($w/v_0$ being small), and $\eta$ as the coordinate of the shot perpendicular to the line of aim, we have at the time $t$

$$\eta = \frac{w}{v_0}(v_0 t - R) \text{ or } w\left(t - \frac{R}{v_0}\right) \qquad (1)$$

This result was first given by Captain Younghusband, R.N., and would be correct if the axis of the projectile set itself in the direction of the resultant velocity from the very beginning.

At first, however, the axis makes an angle $w/v_0$ with the velocity resultant, and the resistance has therefore a horizontal component at right angles to that resultant, for the same reason that a small angle between the axis of the projectile and the tangent to the trajectory produces an upward force on the former.

The question, then, as to how far (1) may be looked on as giving a true value for the effect of the wind turns on the rate at which the projectile can set its axis in the direction of the velocity resultant.

It is shown, however, in a former paper,[1] that to produce a given angular velocity of the axis of a projectile the couple must vary as the fourth power of the linear dimension.

For a given inclination of the axis to the direction of motion the couple applied by action of the air will vary as the cube of the linear dimension; thus the angular velocity of the axis will be inversely as the linear dimension, or, in other words, the time for a given angle will be as the linear dimensions.

For a given inclination the lateral force will be as the square of the linear dimension, and the distance to which the lateral force will carry the projectile while turning through the angle $w/v_0$ will be proportional to the linear dimension.

Thus instead of the expression in (1) we should write

$$\eta = AL + w(t - R/v_0), \qquad (2)$$

where L denotes the linear dimension and A some constant depending on the form, weight, and initial velocity of the projectile.

If careful experiments were made on wind deflection, the velocity of the wind being recorded at several positions along the range at the instant that each shot was fired, the value of A might be determined, and therefrom the angle which the axis of a projectile fired in still air makes with the tangent to the trajectory.

**Physical Society**, June 12.—Dr. Charles Chree, F.R.S., president, in the chair.—Experiments on a directive system of wireless telegraphy: E. **Bellini** and A. **Tosi**. The authors describe the results obtained in the course of their work upon a further development of their original directive system. In the earlier method previously described (*Electrical Engineering*, ii., p. 771, 1907, and iii., p. 348, 1908) it was not possible to say from which side of the receiving station the transmitted waves arrived, for though the radiation was practically confined to the plane of the aërial system, it was emitted equally in the opposite direction to that desired. In the new unilateral system the waves are sent in a single direction only, and the problem of getting rid of the backwardly extending radiation has thus been solved. The method adopted consists in superposing a bilateral directive system, as previously described, upon an ordinary or vertical antenna system. The system of unilateral directive wireless tele-

[1] "The Behaviour of Rifled Projectiles in Air," Roy. Soc. Proc., vol. lxxix., p. 547.

graphy described in the present paper is of special interest owing to the facility with which it is possible to change over from one system to the other, thus, from the ordinary vertical antenna system to the bilateral directive or the unilateral directive, or *vice versâ*. The aërial arrangements, moreover, remain exceedingly simple. When a message from a station of unknown position is expected, the vertical antenna or ordinary system would be employed; on once effecting reception, one can pass to the bilateral or unilateral directive system, and thus determine the direction and on which side the transmitting station lies, at the same time making oneself independent of other transmissions. In the same way, with the transmission, the vertical antenna would be employed for calling up an unknown station or for simultaneously sending to several stations; on getting a reply the operator can readily determine the position of the receiving station, with the aid of the unilateral system, and thenceforth will transmit solely in that direction.—The lateral vibration and deflection of clamped-directed bars: Dr. J. **Morrow.** This is an investigation of the problems which arise in connection with the lateral vibrations of clamped-directed bars. The term "directed" is used to describe the extremity of a bar which is constrained to maintain its original direction, but is free to take up any position of lateral deflection. These terminal conditions are mentioned in Rayleigh's "Sound," but are dismissed on the ground that the directed end cannot be realised experimentally. In the present paper, however, it is shown that the "directed" end is of great importance and of frequent occurrence in engineering practice, and, further, that by the aid of a simple device it can easily be investigated in the laboratory.—The resistance of a conductor of uniform thickness whose breadth suddenly changes, and on the shape of the stream-lines: Prof. C. H. **Lees.** A knowledge of the resistance of a conductor the section of which suddenly changes is of considerable practical importance, but mathematical difficulties have prevented an exact solution of the problem. The paper shows that the resistance between two transverse sections through points situated at considerable distance from the change of section on opposite sides of it is equal to the sum of the resistances of the portions of conductor between each of the two sections and the change of section, each considered as part of an infinite length, plus the resistance of a length of either conductor equal to its breadth multiplied by an expression given.—The inductance of two parallel wires: Dr. J. W. **Nicholson.** When direct and return currents flow in two wires of great length, and the alternation is not rapid, the effective self-induction per unit length of the system may be calculated readily by simple integration. If the wires have radii $a$, $b$, and permeabilities $\mu$, $\nu$, and if C be the distance between their axes,

$$L = 2 \log c^2/ab + \tfrac{1}{2}(\mu + \nu).$$

This formula is often of little practical use when the frequency of alternation is several thousands per second. Such frequencies are of constant use in practical work. For example, in the measurement of small inductances by Mr. Campbell's method, it is necessary to employ long leads in order to keep them at some considerable distance from the bridge and other circuits. The self-induction of these leads must be small, and a calculation of its value is very desirable. The general case presents very great mathematical difficulty, but the solutions given in the paper appear to include most cases of practical utility.—Homogeneous secondary radiation: Dr. **Barkla** and Mr. **Sadler.**—(1) Note on the amount of water in a cloud formed by expansion of moist air; (2) an elementary treatment of the motion of a charged particle in a combined electric and magnetic field: Prof. **Morton.**

DUBLIN.

**Royal Irish Academy,** May 11.—Dr. F. A. Tarleton, president, in the chair.—A synopsis of Irish algæ, freshwater and marine: J. **Adams.** After an historical account of past investigations on Irish algæ, and the various attempts to divide the country into botanical districts, there follow complete lists of the genera and species, and their geographical distribution in each of the four provinces is briefly indicated. For facility of reference the genera and species belonging to each of the main groups of algæ are arranged in alphabetical order. In all, 2224 species are included, 1379 species being fresh-water and 845 species marine. A summary of the total species recorded for each province is given, followed by a brief description of the local distribution of the rarer or more interesting species. At the end is a bibliography in which all known sources of information on the distribution of Irish algæ are indicated.

May 25.—Dr. F. A. Tarleton, president, in the chair.—Some unpublished work of the late Prof. Charles J. Joly, F.R.S., on geometry, part i.: Rev. W. R. Westropp **Roberts.** The author discusses curves, both plain and twisted, by expressing the coordinates of such curves in terms of a parameter, and deduces from this point of view the nature of their singularities.—Some general principles of the theory of dimensions: E. E. **Fournier d'Albe.** The author discusses the methods of discovering relations between physical quantities by means of their dimensions. He shows that when the quantity investigated is purely mechanical, and expressible in terms of length, mass, and time, it can depend upon not more than three independent variables, which are also purely mechanical quantities. When the number of fundamental units is increased, as by adding angle, temperature, or electric quantity, the number of independent physical variables is increased in proportion. The attempts to account mechanically for forces acting at a distance by means of dimensional formulæ are criticised.

PARIS.

**Academy of Sciences,** June 22.—M. H. Becquerel in the chair.—Study of the phenomena shown by concave wings in the stationary, floating, and hovering flight of birds: Marcel **Deprez.** A calculation of the horizontal and vertical components of the forces resulting from the action of air in motion on the surfaces of wings, supposed curved. The formula arrived at contains no other experimental condition than the mass of unit volume of air, thus dispensing with the empirical coefficients commonly employed.—M. Gaillot was elected a correspondant in the section of astronomy, in the place of the late M. Trepied.—The analysis of polymorphic curves: Émile **Borel.**—The orientation of an anisotropic ellipsoid in a uniform field: Georges **Meslin.**—The nature of charges of positive electricity and the existence of positive electrons: Jean **Becquerel.** The recent work by the author on the magneto-optic phenomena of the rare earths over a wide scale of temperature leads to the view that positive electrons exist; Lilienfeld has also obtained phenomena which he attributes to positive electrons, but these results have been negatived by Bestelmeyer and Marsh. In the present paper an account is given of experiments with a modified form of Crookes's tube. The results confirm the hypothesis of the existence of positive electrons.—The photographic registration of sound vibrations: Georges and Gustave **Laudet.** These photographs, which were obtained by purely mechanical means and without the aid of a microphone, are distinguished by the clearness of the line produced. Reproductions of the vowels and the sibilants *s* and *z* and of the word Laudet are given. No details are given of the method employed.—The relation between the biochemical effects of radiations and the quantity absorbed: H. **Guilleminot.** In studying the biochemical effects of the X-rays, it is more important to make quantitative measurements on the energy absorbed in the material than to measure the energy of the incident bundle. Fluoroscopic measurements of the incident rays show great divergences between the biochemical effects of the X-rays and the radium rays; these discrepancies disappear when the amount of energy really absorbed in the two cases is studied.—The heat of neutralisation of acetic and benzoic acids by aniline in benzene solution: Léo **Vignon** and M. **Évieux.** Aniline does not react to form salts with acetic and benzoic acids in benzene solutions. Aniline benzoate and acetate are destroyed by solution in benzene.—A new method of separation of silica and tungstic anhydride: Ed. **Defacqz.** At a red heat silica is not reduced by hydrogen, whereas tungstic anhydride is readily reduced to lower oxides under the same conditions. The latter are readily removed by heating in a current of chlorine, forming volatile chlorides and oxychlorides, the silica remaining unchanged in the boat.—A new automatic principle applied to the carburettor: A. **Lauret.** A description of a new form of carburettor for internal combustion engines possessing the advantages of being free from moving parts, strictly automatic in its action, and freedom from liability to derangement.—The constitution of some derivatives of diphenylmethane and the preparation of some orthodiamines of this series: H. **Duval.**—The αα-dialkyl-β-ketonic alcohols and their transposition by dehydration: E. E. **Blaise** and I. **Herman.** The course of the transposition under the influence of alkalis of the ketone

$$CH_2(OH)—C(CH_3)_2—CO—C_2H_5$$

is shown to consist probably in a dehydration to

$$—CH—C(CH_3)_2—CO—C_2H_5,$$

followed by a migration of a methyl group resulting in the ketone

$$CH_3—CH=C(CH_3)—CO—C_2H_5.$$

—Study of the molecular concentration of the liquids of the organism in the pathological state: Adolphe **Javal.** The cryoscopic constant of liquids extracted from pathological growths is generally greater than the normal figure $-0^{\circ}\cdot56$, and it is shown that this cannot be accounted for by the presence of an abnormal excess of sodium chloride. The amount of nitrogenous products in these pathological fluids is above the normal, but is insufficient to account for the observed hypertonicity.—A chemical character differentiating the orthoses and the microclines: Ph. **Barbier.** The orthoses uniformly contain small quantities either of lithium or rubidium, frequently both; these elements are absent from the microclines. The exact method of separating these alkalis is given in detail.—*Synalpheion giardi*, an entoniscian parasite of *Synalpheus longicarpus*: H. **Coutière.**—The comparative anatomy and histology of the Blochmann glands in the Tectibranchs: Rémy **Perrier** and Henri **Fischer.**—Chromatic reactions and classification of the leucocytic granulations of the invertebrates: M. **Kolmann.**—Vascular elasticity and its variations: Gabriel **Arthaud.**—The acetyl derivative of atoxyl in sleeping sickness: Paul **Salmon.** The acetyl derivative of atoxyl has been in the form of sodium salt (sodium acetyl-para-amido-phenylarseniate) in experiments on the treatment of sleeping sickness. It possesses the advantages of being perfectly soluble, sterilisable at 100° C. without decomposition, and less toxic than atoxyl itself. Experiments on rats, guinea-pigs, and apes infected with *Trypanosoma gambiense* demonstrate that acetyl-atoxyl may be administered in doses four times as great as atoxyl, causing the disappearance of the trypanosome from the blood of the animals.—The geological constitution of the *massif* of Beni Snassen, Morocco: Louis **Gentil.**—The eolian origin of the finely divided minerals found on the sea floor: M. **Thoulet.** An account of a quantitative study of atmospheric dust collected on the tower of Nancy Cathedral, 75 metres above the ground.—Two new sheets of the industrial map of zoology of the coasts of France: M. **Joubin.**—The torrential origin of ruin-shaped limestone rocks: E. A. **Martel.**—The radio-activity of the waters of Ax (Ariège), demonstrated by photography: F. **Garrigou.**—Rain and the state of water-courses: Paul **Garrigou-Lagrange.**—The ablation of the glacier at Chamonix during fifteen years and during fifty years: J. **Vallot.**—New magnetic determinations in the western basin of the Mediterranean: Charles **Nordmann.**

NEW SOUTH WALES.

**Linnean Society,** March 25.—Mr. A. H. Lucas, president, in the chair.—Notes on the native flora of New South Wales, part vi., Deepwater to Torrington and Emmaville: R. H. **Cambage.** Although the locality the flora of which is described lies to the west of the Great Dividing Range, a large percentage of the plants noticed occur also in the Sydney district. The similarity of the two floras is attributable to somewhat similar geological formations, for while the Sydney rocks are sandstone, the acid granites of Torrington contain quite 75 per cent. of silica, and the soil derived therefrom approximates to that of a sandstone area. Reference is made to the occurrence of both inland and coastal plants, an association which is intelligible on the ground that the effect of higher altitude is counterbalanced by that of a more northerly latitude.—Note on the breeding habits of the red-bellied newt (*Molge pyrrhogastra*, Boie): E. R. **Waite.**

CAPE TOWN.

**Royal Society of South Africa,** April 6.—Mr. S. S. Hough, F.R.S., president, in the chair.—Transvaal sea-level temperatures: R. T. A. **Innes.** The object of the paper was to find what reductions applied to temperature readings in the Transvaal would reduce them to sea-level temperatures. For this purpose, a curve was plotted with the temperature entered horizontally and the altitudes vertically. This was assumed to be a parabola, and the correction was calculated on this assumption. A comparison with Buchan's maps in Bartholomew's Meteorological Atlas showed great differences. These the writer attributed to the fact that Buchan had no South African data on which to base his correction.—The geology and mineralogy of Albany: Prof. **Young.** The author described the evidence he had of volcanic action having occurred in the Albany district along a line of crustal weakness running east and west some miles to the south of Grahamstown. He described some investigations he had carried out on some of the rocks and minerals found in the neighbourhood of this volcanic line. The evidence goes to show that the district is mineralised with gold and other rare metals, and that a mineral grease or oil occurs in association with the rare metals. He also suggested several chemical reasons to account for the failure of most South African assayers to detect these metals, while the European assayers have found them in several hundreds of samples from Albany during the last two years.

## AFRICAN NATURE NOTES.

*African Nature Notes and Reminiscences.* By F. C. Selous. With a foreword by President Roosevelt. Pp. xxx+356; illustrated. (London: Macmillan and Co., Ltd., 1908.) Price 10s. net.

MR. SELOUS has been well advised to commit to a book his recollections of natural history in connection with the big game of Africa. There is still a branch of zoological science which may be called by the nearly discarded title of "natural history" instead of biology; and although the latter is the more important type of research, biologists are probably the first to desire to couple with their knowledge of the body of the dead organism accurate information as to its life-habits; for this must evidently furnish the necessary explanation of peculiarity of structure while being frequently an additional aid to classification.

Mr. Selous has long been celebrated as one of the first among big-game hunters and collectors for a period of something like thirty years. He, and a few like him, have enormously increased our knowledge of the world's larger mammalian fauna. Unfortunately he has few compeers in proportion to the army of useless game-slaughterers who are devastating the world and destroying what remains of its notable birds and mammals.

The national collection in the British Museum is an eloquent testimony to the fact that many victims of Mr. Selous's unerring rifle have not died in vain, have not been killed uselessly. At the same time, his pursuit of big and small game in South and East Africa, Asia Minor, and in America has been accompanied by most careful note-taking as to the life-habits of the creatures he pursued—pursued very often not to kill, but to observe.

In the book under review, the two preliminary chapters call into question theories as to the protective coloration of mammals and birds, and the value of supposed recognition marks. President Roosevelt joins with Mr. Selous in somewhat decrying the cogency of theories in vogue. It would seem to the reviewer that both writers were a little querulous in their desire to differ from a number of established authorities on zoology (most of them field naturalists also).

The coloration and marking of living creatures—let us say for the moment beasts and birds—arises from such a complication of causes that it can only as yet be explained partially, and by a variety of reasons. One of these is that the greater magnificence of appearance in the male serves to attract the notice and compliance of the female. This has been contested by some writers, but it still remains a valid theory. The most important explanation, however, yet advanced for the colour or markings of the majority of animals is that their appearance is thereby adapted to their surroundings, and enables them either as pursuer or pursued to escape observation. It would seem to the reviewer that in the main few persons who have studied wild life can refuse to believe in the existence and practical value of protective or assimilative coloration.

Who, for example, that has seen a bittern amongst the reeds and tree stumps can refuse to believe that for some purpose best known to itself the creature is posing in such a way that its marking, colouring and attitude deceive the eye of everything that is not a bittern?

Even the magnificent crimson and blue-green bee-eaters of tropical Africa have a way of perching on bare bushes so that they exactly resemble large crimson flowers. The precise purpose in this deception is no doubt to attract insects on which they pounce. The reviewer has witnessed this deception repeatedly, thinking at a little distance that he was gazing at a magnificent example of an Erythrina shrub in full flower until the flowers flew away.

Mr. Selous repudiates the idea that giraffes can find any advantage in resembling tree trunks that have been blasted by lightning, as they do invariably when they are immobile and holding their necks very erect. The reviewer can aver that in Eastern Equatorial and South-west Africa he has been repeatedly deceived (although his sight is good enough to be compared with that of a negro) by this appearance of the giraffe sentries. They were old males or females, whose colouring at the distance seemed resolved into black and white, and they appeared remarkably to resemble the trunks of the acacia trees that have been blasted by lightning and stripped by storms.

Innumerable other cases of deception in coloration on the part of large and small game could be cited.

Mr. Selous asks what use it is, since the carnivora almost invariably hunt by scent and at night. He seems to forget that the most dangerous of all carnivores is man, predatory man, and that man has co-existed with most modern types of birds and beasts for hundreds of thousands of years, back to the end of the Tertiary period at any rate, quite long enough for giraffes, antelope, deer, and innumerable other beasts (and birds) to have developed a special aptitude and cunning for evading his observation. For man, since even before he was truly man, has invariably hunted by *sight*, and not by scent.

It is scarcely necessary to state that Mr. Selous's notes on the life-history of the lion, the spotted hyena, the Cape buffalo, and the rhinoceros are interesting, original, and obviously true. This is no second-hand information; a good deal of it, moreover, is quite novel. Mr. Selous discountenances the idea that the lion advances on his prey by tremendous leaps; rather (according to him) it comes rushing on all four legs as a dog might do, and uses its teeth for the death-stroke in preference to a blow or tearing with the paw and claws. The advantage of the curved claws and strength of limb would rather lie in their enabling the lion to hold on to his prey while the great canine teeth severed arteries and pierced brain cases or spinal columns. The lion, he thinks, developed its mane in the colder climate of Europe or western Asia before it followed the big game into Africa (the last refuge of the latter before the advancing power of Neolithic man). But if protection from cold and wet be the inducement which led to the development of a mane in the male lion, how about the lioness? The more probable explanation is that the mane of the lion arose both as a male ornament and as a protection for the throat and chest in sexual combats with other males. Mr. Selous comments on the distinctly spotted limbs possessed by some adult lions and lionesses; he quotes the special name given to this type by Boer hunters. He will have been interested in the paper by Mr. R. I. Pocock in the Annals and Magazine of Natural History (November, 1907) on the significance of the pattern—the rosettes, spots and stripes—of the cubs of lions (and of pumas).

The author's notes on the fluctuations of the abundance and distribution of the tsetse fly and its correlation with the abundance or scarcity of the buffalo are important contributions to a subject of great economic importance. His remarkable sporting adventures are the more thrilling because of their obvious truth, and the quiet style of narration.

The last chapter in the book is as valuable as any in a work which is interesting from beginning to end. It is devoted to the Bushmen of South Africa—more especially the Masarwa dwelling on the verge of the Bechuana countries.

Mr. Caldwell's drawings are admirable (especially the study of galloping gemsbuck). Very interesting are the photographs and description contributed by an American sportsman, Mr. Max Fleischmann, of a rhinoceros being dragged under water (presumably) by crocodiles.

H. H. Johnston.

## *WATER POWER.*

*Hydraulics and its Applications.* By A. H. Gibson. Pp. xvi+757; with diagrams and illustrations. (London: Archibald Constable and Co., Ltd., 1908.) Price 18*s*. net.

IN this intensely practical age, science is chiefly exploited for utilitarian ends. The fascination of experimental research lies, as Cap'n Cuttle would observe, "in the application thereof." We seek to know, not for any mere pleasure to be derived from the acquisition of knowledge, but in order to bring that knowledge to bear upon everyday problems of life, labour, and economy.

There is something, therefore, particularly fitting and appropriate in the title of Mr. Gibson's book, "Hydraulics and its Applications," for hydraulics is an eminently practical branch of natural science. Moreover, it is a science difficult to define in that it has no fixed limitations. It embraces the study of all questions in hydro-mechanics in which the motion of water produces or is connected in any way with useful work. In a very special sense it lies within the province of the engineer and the manufacturer.

On its theoretical side, hydraulics presents a number of difficulties. Assumptions have to be made which are not strictly justifiable in reality; yet without them the solution of problems would be well-nigh impracticable. There is, therefore, something necessarily of the nature of compromise about the subject, and Mr. Gibson strikes this keynote at the outset of his work by explaining that the questions of hydraulics can only be discussed on the basis of the assumption that water is a perfect fluid (which it is not), absolutely non-viscous and inelastic, with the introduction of empirical constants to bring theoretical results into conformity with the records of actual observation.

Despite, however, the very practical suggestion of its title, Mr. Gibson's treatise must be set down as primarily a theoretical work. It postulates a knowledge of mathematics and mathematical processes which the ordinary practical man unfortunately rarely possesses. And while the operator, as distinct from the experimentalist, will no doubt fully appreciate the useful data contained in the volume and the information condensed into working formulæ, he will at the same time be inclined to regret that Mr. Gibson has not dealt a little more completely with the practical side of the subject, by describing in greater detail the remarkable variety of ways in which hydraulic machinery is utilised in commerce, manufactures, and the arts.

Commencing with two prefatory chapters on hydrostatics and the physical properties of water, in which such matters as capillarity and the laws of floating bodies are briefly discussed, the author introduces his main subject in chapter iii. by describing the experimental results obtained by Profs. Osborne Reynolds and Hele-Shaw in regard to stream line flow. The motion of fluids is then mathematically investigated and its phenomena explained in relation to pipes, bends, vortices, and orifices. This leads on to the laws of fluid friction and the resistance of ships, whence the author reverts once more to pipe and channel flow, and the various sources of loss of head and velocity. Chapter x. takes up the question of impact of jets and of pressure on submerged planes. It is not until chapter xi. is reached that the practical side of the subject comes under discussion, and then the various and well-known types of water-wheel are duly described and illustrated, including the Pelton motor. Chapter xii. deals with turbine forms, and chapter xiii. with the theory of turbine design. In chapter xiv. there is an account of the hydraulic reciprocating engine, with examples of the Brotherhood and Rigg machines. Chapters xv. to xvii. are devoted to pumps, including the hydraulic ram. The transmission of energy by means of pressure mains forms the subject of chapter xviii., while the final chapter contains a brief review of a number of important appliances: lifts, hoists, jacks, cranes, and jiggers. It is this latter portion of the book—the manipulative aspect of hydraulics—that one would have liked to see expanded, even, if necessary, at the expense of some of the earlier mathematical matter. The commerce of Great Britain is essentially maritime, and a very large proportion of port and harbour machinery is hydraulic. Dock gates, sluice penstocks, capstans, coal elevators and tips are worked in the great majority of cases by hydraulic power, and despite their importance none of these appliances is illustrated in the book. Quay cranes also, a most important class, are not represented, though some of them are capable of dealing with loads up to 150 tons.

We think that in one or two cases the matter might have been arranged to rather better advantage, but, on the whole, we have no hesitation in saying that the book is an excellent contribution to the literature of the subject, and embodies the result of no little personal investigation and research. It is specially a student's book, and will appeal more particularly to those who are already equipped with some fundamental knowledge of hydraulics. The book is clearly printed and well illustrated.

## THE DISCOVERY OF THE WEIGHT OF THE AIR.

*Essais de Jean Rey*, 1630. Édition nouvelle avec commentaire par Maurice Petit. Pp. xxvii+191. (Paris: A. Hermann, 1907.) Price 7 francs.

SHORTLY after Lavoisier had presented an account of his researches on calcination to the Academy of Sciences, the French chemist Bayen discovered in the Bibliothèque royale a small volume dated 1630, in which the discoveries and views of Lavoisier were seen to be anticipated by nearly a century and a half. This volume was the "Essays de Jean Rey sur la Recerche de la cause pour laquelle l'Estain et le Plomb augmentent de poids quand on les calcine," of which a translation in English was published some years ago under the auspices of the Alembic Club (1895). By a curious coincidence, the title of Lavoisier's memoir, "Sur la calcination de l'étain dans les vaisseaux fermés et sur la cause de l'augmentation de poids qu'acquiert ce métal pendant cette opération," was almost identical with that of Rey's essays; and it is remarkable that the study of the behaviour of the same metal, tin, when calcined, led both chemists to arrive at a correct interpretation of the nature of combustion.

The salient characteristic of Rey's work is that he concentrated his attention on the increase of weight of metals during calcination, and was thus led to recognise that the air has weight prior to the investigations of Torricelli in 1643 and of Pascal in 1648. The increase of weight was explained as follows:—

"Ce surcroit de poids vient de l'air, qui dans le vase a esté espessi, appesanti et rendu aucunement adhesif, par la véhémente et longuement continuée chaleur du fourneau; lequel air se mesle avecques la chaux (à ce aydant l'agitation fréquente) et s'attache à ses plus menuës parties."

The object of the new edition of Rey's works appears to be, not so much to direct attention to the part played by Rey as chemist and precursor of Lavoisier, but to put in a claim on his behalf as the discoverer of the weight of the atmosphere and as inspirer of the later work of Torricelli and Pascal. When's Rey's "Essays" were printed in 1630 at Bazas, in a form hardly likely to attain much publicity, a copy came into the hands of a certain Frichet, a lawyer of Bordeaux, who placed the results before a circle of learned friends who assembled weekly in the rooms of the Père Mersenne at the monastery of Les Minimes, in Paris. Père Mersenne became the correspondent of Jean Rey, and, it would appear, communicated the latter's investigations to Torricelli, Galileo, Descartes, and Pascal, with whom he was in constant correspondence. Thus Rey's book "loin d'avoir été un éclair de génie inconnu, ignoré, comme on l'a supposé jusqu'ici, devient le point de départ de cette mémorable campagne scientifique qui se termina par les victorieuses expériences de Rouen et du Puy-de-Dôme."

In support of these contentions a number of letters of Jean Rey and of Père Mersenne are published, and the relationship of Mersenne with his great contemporaries traced in detail. Frémy long ago expressed the conviction that the lack of appreciation of Rey's work as compared with that of Torricelli and Pascal was "one of the great injustices committed in the history of science." The editor of the new edition of the "Essays" aims at rectifying this injustice, so that Jean Rey may take rank not merely as a chemist and first discoverer of the part played by air in combustion, but as one of the founders of modern physics.

W. A. D.

## OUR BOOK SHELF.

*Plant Anatomy from the Standpoint of the Development and Functions of the Tissues, and Handbook of Micro-technic.* By Prof. W. C. Stevens. Pp. xii+349. (London: J. and A. Churchill, 1908.) Price 10s. 6*d.* net.

ACCORDING to the axiom that the greater contains the less, there is justification for the title of the book, but so far as histology is distinguished from anatomy, the contents pertain rather to the domain of histology. This does not, however, correctly explain the nature of the subject-matter, as the author has followed the modern, and one has no hesitation in saying the best, practice of uniting the study of form and function; in fact, each chapter is devoted to a separate physiological problem. The arrangement is an excellent one for an elementary book, but it must be added that there is no attempt to rise beyond elementary facts. The difficulties of the stelar theory are avoided by reverting to the older conception of protoderm, procambium strands, and fundamental meristem. "Bast fibres," as here explained, also show a return to an older, though in this case less acceptable, definition, and the nicer subtleties of distinction between fibrous cells and wood fibres are omitted. The careful and detailed descriptions of such processes as the conduction of water and solutes through the stem will be fully appreciated, but in places the author shows but small regard for the intuitive perception of the student (*vide* figs. 56, 87, and 92). The practical examples quoted at the end of the chapters are useful, and the general presentation of the subject-matter is marked by clearness and coordination.

Following on the course of anatomy is a handbook of micro-technique. This science has been eagerly absorbed by American students sojourning in Europe, with the result that their experience has spread like leaven throughout the numerous colleges and universities in the United States. The instructions here conveyed represent the most modern and approved practice. In this country it is not the custom to push students into complex fixing and staining methods until they reach the advanced or research stage, so that it appears inconsistent to devote a third part of an elementary manual to highly technical methods. The last three chapters, on reagents and processes, microchemistry of plant products, and detection of adulterations in foods and drugs, would, if published separately, provide a most useful and attractive summary for advanced students.

*Elements of Angling. A Book for Beginners.* By H. T. Sheringham. Pp. xvi+259. (London: Horace Cox, 1908.)

We always open Mr. Sheringham's contributions to angling literature with the expectation of being beguiled by very pleasant reading, and, incidentally, of acquiring much useful information. In the case of his "Elements of Angling" we were in no wise disappointed. The book is primarily addressed to and intended for the young angler, that is, the angler young in his art, for our author will not acknowledge that any man is too old to begin; it is wide in its scope, but does not enter into so much detail as to be likely either to confuse or weary a prospective fisherman. If such a term may be excused, we would describe it as an elementary text-book of fresh-water fishing, and, like many other text-books, we think it is well worthy of study even by those well versed in the subject of which it treats.

The information and advice given are throughout of an eminently practical nature, and Mr. Sheringham is not above citing his own misfortunes as an example and warning to those whom he would instruct. Fishing for coarse fish, whether on the bottom or at the surface, is clearly and concisely dealt with, and much practical information as to gear and baits is given. The trout is discussed at somewhat greater length, and the differences in the tackle required for wet- and dry-fly fishing, together with the reasons for such differences, are clearly explained; the grayling has a chapter to itself, and, as in the case of the trout, a short but well-selected list of the flies of most general utility is given.

Exigencies of space prevent the salmon and salmon-fishing from being dealt with at great length, but this, we think, is right in the case of a fish the capture of which depends so much upon a thorough knowledge of the particular water to be fished. Care is, however, taken to direct attention to the differences between salmon and trout, whether as parr or adults, and to the difficulty which sometimes attends the recognition of a well-mended kelt and its distinction from a clean fish. While on the subject of specific distinctions, we notice that Mr. Sheringham regards the "bull-trout" as a distinct species (*Salmo eriox*), and states that it is found in the Tweed and in some rivers of the south and west; surely there is some confusion here that might well be cleared up in future editions. Last, but not least, there is an excellent index. L. W. B.

*Elements of the Theory and Practice of Cookery.* By Mary E. Williams and Katharine R. Fisher. Pp. xix+347. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1907.) Price 4*s.* 6*d.* net.

Domestic science and art, so far as they relate to cookery, are here combined to produce an educational and practical course of work. The book is not merely a collection of recipes, but a guide to the experimental study of principles and their application in the selection and preparation of food. The instructions for experiments and other work are explicit, and much good advice is given as to the conditions of healthy living and intelligent housecraft. Unfortunately, as many of the terms used in describing the utensils and ingredients required are unfamiliar in British homes and schools, the book is at a disadvantage on this side of the Atlantic, though its merits are many.

## LETTERS TO THE EDITOR.

### Spectrum of the Radium Emanation.

A few months ago, through the generosity of the Academy of Sciences of Vienna, one of us was loaned a radium preparation containing about 250 mg. of radium. Observations were at once begun to purify the emanation produced by it, and to determine its volume. An account of these investigations was read before the Academy of Sciences of Vienna on July 2. It was found that the maximum volume of the emanation per gram of radium was in good accord with that to be expected from calculation (about 0·6 cubic mm.), and the initial volume was about one-tenth of that determined by Ramsay and Cameron (Journ. Chem. Soc., p. 1266, 1907). In the course of this work we have had occasion to test the purity of the emanation by the spectroscope, passing an electric discharge in the capillary in which the volume was measured. We have on four different occasions during the last two months determined the spectrum of the radium emanation by visual observations, using a direct-reading Hilger spectroscope, leaving a more accurate determination of its spectrum until the measurements of the volume had been completed. We have now photographed the emanation spectrum, using a prism of 2 inches base. Pure emanation, corresponding to the equilibrium amount from 130 mg. of radium, was condensed by liquid air in an exhausted spectrum tube of about 50 cubic millimetres capacity, provided with thin platinum electrodes. Two photographs were immediately taken, one giving about thirty of the more intense lines, and the other, with much longer exposure, showing more than one hundred lines. For a comparison spectrum a helium tube was used. The colour of the discharge in the tube was bluish. Visual observations of the spectrum were made during the exposure of the photographs.

When the emanation was condensed in a side tube by means of liquid air, the great majority of the lines vanished at the moment of condensation, which was readily noted by the phosphorescence of the glass. The colour of the discharge then completely changed, and became of a pale rose colour. At the instant of volatilisation, the emanation lines flashed out again. The hydrogen lines were visible in the spectrum, and these became much more brilliant when the emanation was condensed. In the electrodeless discharge of previous experiments, the hydrogen lines were never observed. Their occurrence in the present experiment was probably due to the platinum electrodes. By observations of the intensity of the phosphorescence when the emanation was condensed, it was noted that the amount of pure emanation in the tube gradually diminished with increase of time of discharge. The spectrum of the emanation, however, persisted until practically all the emanation had been driven into the walls of the tube. The phosphorescence on the walls of the tube showed that the occluded emanation was fairly uniformly distributed. This effect has been observed by us on several occasions.

The first determination of the spectrum of the emanation was made in 1904 by Ramsay and Collie, who determined the wave-lengths of about eleven lines by visual observations. As shown by them, the spectrum of the emanation is a bright line spectrum with sharply defined lines. We observed also visually a weak band spectrum in the yellow, which slightly decreased in intensity when the emanation was condensed. This, however, may not be connected with the emanation itself. The wave-lengths of the lines of the photographic plate were accurately measured, using a Kayser's measuring machine. The accuracy obtained is indicated by the agreement of the wave-lengths of some of the hydrogen lines with their known values. In most cases, for well marked lines, the error is not more than half an Angström unit. The following table gives the wave-lengths of the more prominent lines. The wave-lengths of the lines initially determined by Ramsay and Collie (marked R. and C.) are added for comparison.

Visual observations of three of the more prominent lines in the yellow and green are also given:—

| Intensity | Observed λ | Remarks | Intensity | Observed λ | Remarks |
|---|---|---|---|---|---|
| 5 | 5721 | (Visual) (R. & C. 5725) | 15 | 4350·3 | |
| 8 | 5589 | (Visual) | 7 | 4340·9 | H = 4340·66 |
| 3 | 5393 | " | 4 | 4225·8 | |
| 4 | 5084·5 | | 10 | 4203·7 | |
| 4 | 4979·0 | R. & C. 4985 | 7 | 4188·2 | |
| 10 | 4861·3 | H = 4861·49 | 20 | 4166·6 | |
| 4 | 4817·2 | | 10 | 4114·9 | |
| 5 | 4721·5 | | 2 | 4102·2 | H = 4101·85 |
| 10 | 4681·1 | R. & C. 4690 | 4 | 4045·4 | |
| 10 | 4644·7 | R. & C. 4650 | 15 | 4015·0 | |
| 8 | 4625·8 | R. & C. 4030 | 12 | 3982·0 | |
| 7 | 4609·9 | | 7 | 3957·5 | |
| 4 | 4604·7 | | 4 | 3917·5 | |
| 7 | 4578·7 | | — | 3888·9 | H = 3889·15 |
| 9 | 4509·0 | | 6 | 3867·6 | |
| 10 | 4460·0 | | 10 | 3753·6 | |
| 8 | 4435·7 | | 7 | 3739·9 | |
| 6 | 4391·8 | | 10 | 3664·6 | |
| 4 | 4372·1 | | 5 | 3622·2 | |

A more detailed list of lines will be published later. We understand that Sir William Ramsay showed a photograph of the spectrum of the emanation at the meeting of the Royal Society on June 25. It will be of interest to compare the two spectra.

### The Recent Nocturnal Glows.

THE peculiar light phenomenon at midnight on June 30, which was seen, according to the papers, on the northern part of the sky at Copenhagen, Königsberg, Berlin, Vienna, Biala, and other places, was also observed by me at Prague. At 1h. 30m. a.m. on July 1, I saw in the direction N.E. and N.N.E. a peculiar strong orange-yellow light over the horizon, the colour of which was more orange in its lower parts and more yellow in its higher parts. Its upper limit was lying twenty to thirty degrees above the horizon. The whole sky was cloudless. Other people saw it here at 11 p.m. on June 30.

It is reported that magnetic disturbances were experienced on the telegraphic lines, but I saw no trace of the characteristic auroral bands or columns. I may be allowed to add that, according to Arrhenius, this time of the year corresponds to the minimum of auroral display (activity). Interesting is the fact that a high barometric maximum was lying in the north, and that we had winds from that direction for a whole week.

BOHUSLAV BRAUNER.

Bohemian University, Prague, July 4.

### A Long-lived Solar Halo.

THERE has been visible here to-day a solar halo remarkable both for its vivid intensity and for its protracted duration. It was first noticed by me at 12.35 p.m. It then formed an unbroken ring, of which the most intensely luminous portion was to the south of the sun, and the least luminous portion to the west-north-west. Half an hour later the southern and northern quadrants of the circle were equally bright, but the northern appeared the more compact and definite; meanwhile, the eastern and western portions continued comparatively feeble, more especially the latter. *These conditions remained unchanged for fully* $1\frac{1}{2}$ *hours!* After 2.15 p.m. the northern segment of the halo was alone conspicuous, and after 3.30 p.m. the ring was never again complete, though two mock suns (to the southward and eastward respectively) still testified to the original configuration. By 4.50 p.m. nothing remained but a diffused, pale rainbow-coloured mock-sun to the north of the sun; but after 5.15 p.m. this became less indefinite, and by 6 p.m. fully a semicircle of a halo was again traceable above the sun, but this faded gradually, nothing surviving after about 6.20 p.m. The unusually strong tone of rusty orange colouring, and the conspicuous darkness of the region enclosed, made the halo an unusually striking object when at its best (12.30 to 2 p.m.).

Throughout the day cirrus cloud has strewn the sky in most interesting disorder and variety of forms. Telescopic observation of the sun's image showed (in the features of atmospheric distortion of the sun's limb) the existence of two distinct drifts of the atmosphere, viz. an upper current, *of great velocity*, passing over from the south-east above the drift from north-north-east that alone affected the local weather-cocks and chimneys' smoke. I may add that my experience as an observer of halos (both solar and lunar) has led me to the conclusion that cirrus clouds, or the conditions conducive to the formation of cirrus cloud, do not in themselves constitute the whole cause of the formation of halos, but that these are further the outcome of *cross-currents* in the region of cirrus formation.

CATHARINE O. STEVENS.

10 Woodstock Road, Oxford, June 30.

P.S.—Portions of solar halos were also seen here intermittently during July 1 and 2, thus giving a record of three successive days of halo formation.

### Genial June.

THE month just past has fully upheld its character, as it did in the Jubilee year, 1887, and on other occasions.

There were a great number of dates suitable for observation (sixteen out of the last seventeen), but I found shooting stars rare.

The nights before June 29 were, I thought, unusually dark, the stars and Milky Way being beautifully bright and distinct; but on June 30 the firmament was abnormally luminous, with a very strong glow all over the north at midnight. Few stars could be seen, and the Milky Way was hardly distinguishable. On July 1 the phenomena of the previous night were repeated in rather a different aspect. There were many clouds of various tints, and the light was again intensely strong, the northern sky being involved in a brilliant aurora. I have never seen June nights so dark, and the Milky Way so gorgeously displayed in the heavens, as this year to June 28, nor have I ever noticed the sky so bright as it appeared on the nights of June 30 and July 1.

The aurora offered so vivid a spectacle that on the dates mentioned the shades of night may be said to have been quite dispersed, for even at midnight the reflected light from sky and cloud was so strong that terrestrial objects could be seen just as at dusk, say at about 10 p.m. on an ordinary June night.

W. F. DENNING.

Bristol, July 2.

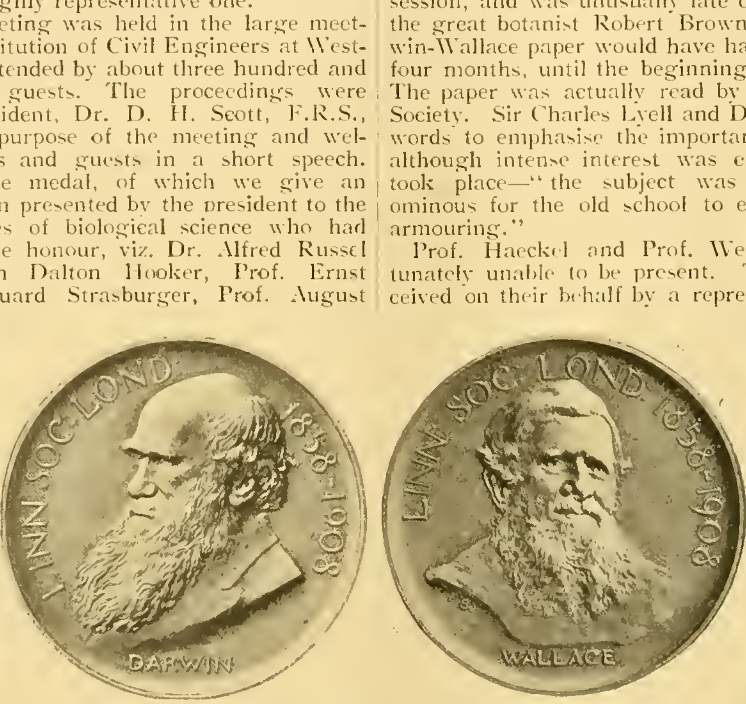
## *THE DARWIN-WALLACE JUBILEE CELEBRATION AT THE LINNEAN SOCIETY.*

ON July 1, 1858, Sir Charles Lyell and Dr. J. D. Hooker communicated to the Linnean Society a remarkable paper entitled "On the Tendency of Species to form Varieties; and on the Perpetuation of Varieties and Species by Natural Means of Selection," by Mr. Charles Darwin and Mr. Alfred Wallace. The history of this paper is familiar to every student of biology. Darwin had for many years been studying the question of natural selection and its bearing upon the origin of species, but, although his views were well known to several intimate friends, he had refrained from publishing them, and was still occupied in the collection of evidence when he received from Wallace a manuscript essay "On the Tendency of Varieties to Depart indefinitely from the Original Type," in which the same ideas were set forth. At the request of the author this manuscript, after perusal, was forwarded by Darwin to Sir Charles Lyell, with the added suggestion that the essay should be published as soon as possible. After consultation with Hooker, Darwin was induced to allow an extract from his own work on the subject to be published simultaneously.

The reading of this joint paper at the Linnean Society formed the starting point of a revolution in scientific thought the effect of which it would be impossible to overestimate, and the Society has duly recognised the importance of the occasion in the commemoration which took place last week.

A peculiarly gratifying feature of the proceedings was the presence at the afternoon meeting of Dr. Wallace and Sir Joseph Hooker, and the fellows of the society and their guests thus had the remarkable privilege of hearing an account of the great event of fifty years ago from the lips of two of the principal actors therein. The society is also to be congratulated on the very cordial response made to their invitation by the numerous universities, academies and learned societies to which it was sent, the gathering being in all respects a thoroughly representative one.

The afternoon meeting was held in the large meeting room of the Institution of Civil Engineers at Westminster, and was attended by about three hundred and fifty fellows and guests. The proceedings were opened by the president, Dr. D. H. Scott, F.R.S., who explained the purpose of the meeting and welcomed the delegates and guests in a short speech. The Darwin-Wallace medal, of which we give an illustration, was then presented by the president to the seven representatives of biological science who had been selected for the honour, viz. Dr. Alfred Russel Wallace, Sir Joseph Dalton Hooker, Prof. Ernst Haeckel, Prof. Eduard Strasburger, Prof. August Weismann, Dr. Francis Galton, and Sir E. Ray Lankester, the copy given to Dr. Wallace being in gold and the others in silver. Each medallist was addressed by the president in an appropriate speech in which his claims to the distinction were duly set forth, and all were received by the audience with great enthusiasm.



The Darwin-Wallace Medal of the Linnean Society.

Dr. Alfred Russel Wallace, in replying, spoke of the actual relations between Darwin and himself, and of the share which each had contributed to the theory of natural selection. With characteristic modesty he laid stress upon the fact that the idea had occurred to Darwin nearly twenty years before it occurred to himself. In endeavouring to explain why the same solution of the problem of the origin of species had occurred to both of them, he pointed out that a closely similar course of events had led up to the same result in each case. Both Darwin and Wallace had the passion for collecting, and both in early life had been ardent beetle-hunters. Thus they had been led to take an intense interest in the mere variety of living things and to seek for an explanation thereof. Later on both become travellers, collectors and observers in some of the richest and most interesting portions of the earth, and had forced upon their attention all the strange phenomena of local and geographical distribution, with the numerous problems to which they give rise. Then, finally, at the critical period when their minds were freshly stored with information and reflection upon the problem to be solved, both had their attention directed to the system of positive checks expounded by Malthus in his essay on population. "The effect of this," continued Dr. Wallace, "was analogous to that of friction upon the specially-prepared match, producing that flash of insight which led us immediately to the simple but universal law of the 'survival of the fittest,' as the long-sought *effective* cause of the continuous modification and adaptation of living things."

Sir Joseph Hooker, in his address, dwelt upon the considerations which determined Mr. Darwin to agree to the proposal of his friends for the joint publication of his own and Mr. Wallace's theories by the Linnean Society. He also pointed out that at the meeting Mr. Darwin was unable to be present, being himself very ill, and with scarlet fever and diphtheria raging in his family. The meeting was the last of the session, and was unusually late owing to the death of the great botanist Robert Brown, otherwise the Darwin-Wallace paper would have had to wait for at least four months, until the beginning of the next session. The paper was actually read by the secretary of the Society. Sir Charles Lyell and Dr. Hooker said a few words to emphasise the importance of the event, but although intense interest was excited, no discussion took place—"the subject was too novel and too ominous for the old school to enter the lists before armouring."

Prof. Haeckel and Prof. Weismann were unfortunately unable to be present. The medals were received on their behalf by a representative of the German Embassy, and a short address from Prof. Haeckel was read by the Zoological Secretary. Prof. Haeckel laid stress upon the importance of the theory of organic evolution, and described the foundation by himself of a new phyletic museum at the University of Jena.

Prof. Strasburger dwelt upon the influence of the Darwinian teaching upon his own career and that of Haeckel, and Dr. Francis Galton replied briefly to the president's speech. Sir E. Ray Lankester addressed the meeting at greater length, and struck a fresh and appropriate note in emphasising the share taken by Huxley in the great controversy to which the Darwin-Wallace theory gave rise. He concluded by expressing the opinion that at the present day "not only do the main lines of the theory of Darwin and Wallace remain unchanged, but the more it is challenged by new suggestions and new hypotheses the more brilliantly does the novelty, the importance, and the permanent value of the work of these great men to-day commemorated by us, shine forth as the one great and epoch-making effort of human thought on the subject."

The presentation of the medals was followed by the reception of the delegates of corporate bodies. Of the colleges and schools connected with the early training of Darwin and Wallace, Christ's College, Cambridge, was represented by the master, Dr. Peile; Shrewsbury School by Mr. C. J. Baker, chief science master, and Hertford Grammar School by Mr. G. W. Kinman, headmaster. The other bodies represented were the University of Oxford (Dr. Warren, Prof. Poulton and Dr. Church); the University of Cambridge (Dr. Francis Darwin); the University of St. Andrews (Prof.

Scott Lang); the University of Glasgow (Prof. J. G. Kerr); the University of Aberdeen (Lieut.-Col. Prain); the University of Edinburgh (Prof. I. B. Balfour); the University of Durham (Prof. M. C. Potter); the University of London (Sir W. T. Thiselton-Dyer); the University of Manchester (Prof. Weiss); the University of Wales (Prof. Phillips); the University of Birmingham (Sir Oliver Lodge); the University of Liverpool (Prof. Herdman); the University of Leeds (Prof. Blackman); the University of Sheffield (Prof. Denny); University College, Nottingham (Prof. Carr); University College, Bristol (Prof. Lloyd Morgan); the Royal Swedish Academy of Sciences (Prof. Lönnberg); the Royal Society (Sir Archibald Geikie); the Society of Antiquaries (Lord Avebury); the Royal Irish Academy (Dr. Scharff); the Manchester Literary and Philosophical Society (Mr. C. Bailey); the Royal Society of Edinburgh (Prof. D'Arcy Thompson); the Geological Society of London (Prof. Sollas); the Cambridge Philosophical Society (Dr. Harmer); the Royal Astronomical Society (Mr. Newall); the Zoological Society (Mr. Boulenger); the British Association (Sir David Gill); the Entomological Society of London (Mr. Waterhouse); the Royal Microscopical Society (Lord Avebury); the Chemical Society (Dr. Horace Brown); the Malacological Society (Mr. Byrne); the British Academy was represented by Sir E. Maunde Thompson.

Dr. F. Darwin and Sir W. T. Thiselton-Dyer spoke on behalf of the universities and schools, and Prof. Einar Lönnberg and Sir Archibald Geikie on behalf of the academies and societies represented. Prof. Lönnberg announced that his gracious Sovereign, His Majesty King Gustaf of Sweden, had ordered him to convey to the Linnean Society his hearty greetings and sincere felicitations on this occasion. He also presented a very beautifully illuminated address from the Royal Swedish Academy of Sciences, and a silver copy of the Linnean medal of the Academy struck in commemoration of the Linnean celebrations of last year. Several other addresses were also presented by the delegates.

The concluding speech of the afternoon was delivered by Lord Avebury, who described, in an extremely interesting manner, his own intimacy with Charles Darwin, laying especial emphasis upon his peculiarly amiable personal character and upon the devotion shown by Mrs. Darwin to her husband and children. He referred to the quiet life at Down, and told the delightful story of one of Mr. Darwin's gardeners, who thought it was such a pity that his master had not got something to occupy him, for he wandered about the garden doing nothing, and would stand for as much as ten minutes at a time gazing at a flower!

After the afternoon ceremony, ninety of the fellows and their guests dined together at the Princes' Restaurant, the party including Sir George and Lady Darwin, Dr. F. Darwin and Mr. W. E. Darwin, while foreign biologists were represented by Profs. Hubrecht, Lönnberg, Strasburger and Warming. There were no speeches, and at nine o'clock the company adjourned to the rooms of the Linnean Society at Burlington House, where a reception was held by the president and Mrs. Scott. Two short lantern lectures were delivered during the course of the evening, one by Prof. Seward on "The Jurassic Vegetation of the World: a Study in Plant-migration," and the other by Dr. Smith Woodward, on "The Evolution of Mammals in South America." Various exhibits especially appropriate to the occasion were also shown in the library. Amongst these were a beautiful series of insects from the Hope collections in the Oxford University Museum, exhibited by Prof. Poulton and Mr. J. C. Moulton, in illustration of the phenomena of mimicry and variation. Other collections of insects illustrating special points connected with the theory of evolution were exhibited by Dr. Dixey, Col. Manders, and Dr. Longstaff; while Mr. R. A. Rolfe exhibited some beautiful flowers of natural hybrid odontoglossums with their parents.

We believe the Linnean Society intends to publish a full account of the proceedings, together with the addresses and speeches, which should form an extremely interesting record of a very impressive and memorable occasion.

A. D.

## THE DAYLIGHT SAVING BILL.

If anyone is in search of an object-lesson in the necessity for the introduction of some science into general education he will do well to give his attention to the proceedings in connection with the Daylight Saving Bill. He will probably find therein so much confusion of thought that he will feel some training in clear thinking to be imperatively demanded, though there is an off chance that he will be depressed beyond recovery by the contemplation of the report of the Select Committee on the bill which appeared in the newspapers on July 3.

To begin with the original short title—the Daylight Saving Bill—it will be conceded that no action of Parliament will produce any effect upon daylight. One may save gas or electric-light, and make more use of daylight, but to talk of "saving daylight" is metaphor intelligible enough for ordinary purposes, but not suitable for legislation. When a legislative act begins with metaphor it is not matter for wonder if it eventuates in allegory, and sooner or later that must be the end of the bill.

It would conduce to greater clearness if we knew exactly what is "the principle of the bill." It is designed to make every item in "the trivial round and common task" happen an hour earlier in the summer months than in the winter, but it does not propose that. It proposes the ingenious and apparently simple expedient of moving the clocks on an hour in April and back again in September, and it is assumed that the other will be a natural consequence. Whether the purpose or the proposal of the bill constitutes its principle has never been stated. The confusion of ideas is most insinuating; a person who approves of earlier hours in summer is quite likely to find himself committed to the "principle of the bill." When the Astronomer Royal was under examination before the Committee the confusion was most evident to the looker-on. The witness was definitely opposed to any alteration of the clocks, and yet seemed to suggest that the proposal of the bill should be referred to working men. The question that he wished referred was whether they desired to be made to get up an hour earlier in the morning than they do now—there is no such proposition in the bill—not whether the designation of a particular hour of the day should be five or six—but that is in the bill and nothing else.

Cross-examination by members of the Committee turned largely upon this confusion about the principle of the bill, and upon a further confusion of ideas between having different time standards in different geographical localities and different time standards in the same locality at different times of the year. The reasoning which implies that if the one is found to be practicable objection to the other must be merely indolence or conservatism would be really worth analysis at any time of the year except the dog days. Take an example under the bill. Standard Greenwich time is to be kept for astronomical and for navigation purposes, and standard Irish time is also to be undisturbed; but "local" time is to be established in Great Britain and Ireland an hour in advance of standard time. A steamer is announced to leave Dublin at half past twelve every night, Sundays excepted. What will the announcement mean?

There are already two interpretations. Only experience can tell whether it means 12.30 or 12.55 a.m. G.M.T.; but with the permission of the bill there will be four times which will be legal tender for this denomination, viz. 11.30 p.m., 11.55 p.m., 12.30 a.m., 12.55 a.m., G.M.T., and any one of them may be understood or misunderstood in the circumstances.

The tone of the Select Committee's report indicates that it thinks confusion between these four times will be obviated with a little practice, and if not, the number of people who travel from Dublin is so small compared with the number of those who do not that they can be disregarded.

Some ingenious advocate of the bill has endeavoured to justify it by a confusion of ideas which finds an analogy between the zone adjustment of standard time for longitude and changing the nominal hour of noon as an adjustment for latitude. The double-edged nature of the false analogy appears to have been overlooked. If sunrise is earlier, sunset is later, and if 11 should be called 12 on account of the earlier sunrise, *ex equali* 1 should also be 12 on account of the later sunset; this kind of argument, hollow as it is, has misled a newspaper, generally intelligent, into the grave error of accusing Scottish clocks of "lying" because the time of sunset in the far north, as recorded by them, differs by an hour from the scheduled time of sunset for Greenwich! What sort of clock would the leader writer of the *Westminster Gazette* prescribe to tell the truth in latitude 70°, where at certain times of the year there is no sunrise and at others no sunset?

There is a further delightful confusion about the bill not being compulsory which enables its advocates to ride away from all sorts of difficulties by explaining that if you find it inconvenient you can use Greenwich time as now. In the report they dispose in that way of the difficulties of American business as well as those arising in connection with astronomical, nautical, and scientific work. Any occupation which uses self-recording instruments can also be disposed of quite easily by calling it scientific and allowing it the liberty which, according to the promoters, is not infringed by the act.

What does this liberty mean? By establishing "local" time without compulsion, are either or both local time and Greenwich time to be legal? And if so, at whose option? May the North-Western Railway adopt the act and the Midland decline? And must the option be exercised once for all at 2 a.m. on the third Sunday in April? or can any person change his mind afterwards? Can anyone legally claim to go to business by Greenwich time and then revise his opinion and demand to leave by local time? Possibly the advocates of the bill are acting upon the assumption that the convenience of the new time will assert its own compulsion as Greenwich time has done, in every town in Great Britain except the ancient city of Canterbury. If it does it will be for some other reason than that which has been so effective in the case of Greenwich time.

The confusion is worse confounded by the report of the Select Committee. The new time is to be called local time, and the short title of the bill is changed; it is now called the "Local time (Great Britain and Ireland) Bill." What kind of confusion are we in now! We thought we knew what local time meant. But between the third Sunday in April and the third Sunday in September we are to have the option (there is no compulsion in the bill) of keeping our clocks at local time, and then 5 p.m. as by law "established" will be, we suppose, five hours after local noon, or should it be five local hours after noon and four, or is it six, hours after Greenwich mean noon? Local time must not be confused with middle European time, though the figures will be identical; that is disapproved by the report.

After an elaborate inquiry, which included a prolonged consultation with the Astronomer Royal, the Committee seems to have lost sight of the fact that local time has already a perfectly definite meaning, and connotes a time measurement based on "local noon," which is late on Greenwich noon, not an hour in advance of it, as the revised bill declares, for nearly all places in Great Britain and Ireland.

It seemed incredible at the outset that serious men of business should really confuse themselves between altering the clocks, which was the proposal, and altering the time of occurrence of events, which was the purpose. It seems more certainly incredible that after prolonged inquiry the Committee should have failed to understand that local time has already a meaning, and cannot, even by Act of Parliament, be made to connote middle European time during the summer months. Yet that is the effect of the bill in its revised form.

If this new definition of local time is final, the report, which originated with metaphor, cannot, after all, be more than allegory; but what lesson the allegory is intended to convey is still a mystery.

What has tickled the fancy and captivated the imagination of the advocates of the measure is that since the introduction of telegraphs and standard time the control of clocks from Greenwich is so completely organised that its very existence is unknown to, perhaps, ninety-nine people out of a hundred, who have come to regard clocks as final timekeepers instead of Greenwich mean time. If this control, which works so smoothly and so surely, were modified so as to make clocks skip an hour in April, every subsequent event would be made an hour earlier, and yet we should be using the same Bradshaw and the same Postal Guide. The apparent simplicity and the completeness of the operation are very attractive. But one would suppose that the operation would at least require the connivance and active assistance of the controllers of all the clocks, certainly those of all the public clocks in Great Britain and Ireland. That the promoters know to be impossible, so, by the bill, the change is imagined to take place—it cannot actually take place—in the deadest of the dead of night, when there will be practically nobody to see that the clocks are not moved. This, again, is curious in an Act of Parliament. To prescribe that a certain operation shall take place at a time which has been selected because presumably there will be fewer people in a position to carry out the order than at any other time, is fine allegory but bad legislation.

Herein is further confusion of ideas arising from the notion that if an order is given to alter the clocks subsequent events will be thereby accelerated. Subsequent events may be accelerated, but it will be in pursuance of orders to accelerate them. It is inconceivable, for example, that such a body as that which controls the North-Western Railway will be content to alter the clocks in the dead of night and expect all subsequent events advanced an hour without express orders given to everybody concerned to accelerate by an hour whatever he has to do on Sunday, or for the large majority on Monday morning. In that case it is clear that the operative cause lies in the orders given, and not in the alteration of the clocks, which is a mere trivial circumstance, and might be omitted without any diminution of the effect of the orders. In like manner you may inform a post-office official that you are going to alter his clock to-morrow morning, but unless you make it clear to him at the same time that he has got to be at work an hour earlier he will certainly regard your time-keeping with aloof interest. Anybody who has the real authority to order the day's work to begin earlier will not care much about altering clocks.

Nor is it likely, as the Committee seems to think, that because Parliament may decide to change the denomination of the hours they will thereby change the meaning of all the statutes in which hours are mentioned. To assume that public houses will regard themselves as closed an hour earlier because the clocks are moved leaves out of account the ingenuity of those who are affected. Our lawyers have not altogether lost their cunning; indeed, the bill might have been promoted by one of that profession, for there will be delightful opportunity for argument as to whether 12.30 a.m. "local" time (= 11.30 p.m. G.M.T.) is to-day or yesterday, and as to which of the two 12.30's is in the forenoon. What, indeed, shall we do with such appendages as noon, a.m., and p.m.? Will the denominations run 11 a.m., 12 a.m., 1 noon, 2 p.m., and so on? If so, 12.15 a.m. might become quite an interesting time for a lawyer.

Into this whirl of confusion of ideas it seems hardly safe to entrust a few timid scientific considerations. That we should have a system of keeping time under which, in spite of all principles of continuity of measurement, the numbers between 2 a.m. and 3 a.m. on the third Sunday in September will be travelled over twice, and the same numbers will have different meanings, would be roughly brushed aside by the remark that as nothing happens between 2 and 3 on the third Sunday in September it does not matter. It is the bold assurance of knowledge of the important and the unimportant which strikes the cautious scientific observer with a cold shudder. On the staircase leading to the committee room where this document has been evolved there is an inscription to the effect that copies of the imperial standards of length and weight are built into the wall to make sure that they shall never again be lost through fire. Reading this in passing, one carries away an impressive idea of the sanctity of standards, to find that in the committee room such an idea is regarded as quite early-Victorian. If it would make things more comfortable for a majority of the electors to have an inch off the standard yard, why not have it off? The yard is there; you have only to dig it up. There is no difficulty about it. Those people who would be inconvenienced can use the old yard if they like, and, anyway, they do not count.

What is true of the immured standards, the result of prolonged labour of a Royal Commission, is equally true of the time standard which represents generations of eminently successful work at the Royal Observatory. Yet how can one convey to legislators that a fluctuating standard is unscientific, and that by scientific one means suitable for general acceptance, and for permanent use, and not merely suitable for a few persons of special occupation and training? Are they only to be convinced by the method of trial and failure, the crudest, the most childish of all methods, that the relations of science and practical life are indescribably numerous; that if they adopt a scheme of time designation that has no scientific basis it must result in failure, however bold its promoters may be in rejecting eighths or neglecting quarters: that the advance from the "local" time of fifty years ago to "standard" time of to-day was a step well thought out, and one that cannot be reversed by the introduction of a new and really nondescript time under the old name?

Of course, there remain the great salient objects, the earlier hours of work in summer combined with the undisturbed Bradshaw and the continuity of the Postal Guide. Compared with these the continuity of time measurement is dismissed as a slight matter of no importance to practical people, a piece of scientific pedantry. But let it be remembered that the whole structure which Bradshaw and the Postal Guide represent has been reared upon the basis of an unalterable standard time, and that not even the most experienced legislator can follow out the consequences of taking out the corner-stone of that structure.

In the meantime there is plenty of room for the activity of reformers in the direction of earlier hours. It may be noticed that a large majority of workers, both in town and country, whose work does not depend upon facilities for correspondence, already commence work at 6 a.m., and for them noon is the central hour of the day. The latest people are the office people, who wait for their letters to be sorted. In these days of competition, if there is an early worm anywhere the early bird will not be very far off, and attendance is governed by facilities. It is a curious fact that, although early train facilities are so plentiful and so cheap, except on Sundays, that many clerks come to London in advance of their business hours because they can take advantage of them, there are only two post offices in the London area open for the transaction of telegraphic business before 8 a.m. on Sundays and barely a dozen on week days; in the country districts there are none. Early telegraphic facilities are formulated upon quite the opposite principle from that of workmen's trains; they are very expensive. Yet anyone blessed with a neighbour who is engaged in having his house built, altered, repaired, or painted will be aware that 8 a.m. is a very belated shot at the commencement of the working day. The conclusion that one comes to is that the number of people for whom postal and telegraphic facilities are matters of business, and who therefore keep late hours, are relatively few. To change the hour of work for the millions who begin at six in order to give the thousands that begin at 10 an extra hour of daylight, which is already theirs if they like to use it, seems no more reasonable than to disregard the requirements of Continental correspondence, as the Committee does, because it is only one-eighth of the whole.

Finally, there is another quite interesting confusion of ideas about the purpose of the bill. Its promoters are sanguine that when it is passed there will be longer use of daylight for outdoor sports and exercise with the same time for work, recreation and sleep as before, and yet the day is to remain twenty-four hours.

For most people the days are pretty full already. "Six days shalt thou labour and do all that thou hast to do" is a commandment which many people find it very hard to keep. To put in an extra hour's occupation in the day would not be possible for them. To make up for the light hour saved, a dark hour ought to be cut off.

When the bill is in operation there will be exactly the same interval between leaving off work and the commencement of the "halls" as before. If the workers take advantage of the extra hour of daylight for open-air recreation, which comes to them as a sort of free gift by a manipulation of the clocks, it is much to be feared that there will arise a strong temptation to crowd the day, already so overcrowded that no time is left for such an occupation as reading, with an additional hour of glorious life reckless of the loss of health and strength that, in the long run, follows insufficient sleep. In spite of the prolonged inquiry, the Committee's proposal, although it is ostensibly an appreciation of daylight, appears to many persons, and those not all indolent or conservative, to be nothing more or less than a proposal for a leap in the dark.

## WOMEN AND THE FELLOWSHIP OF THE CHEMICAL SOCIETY.

THE women, like the Peris at Heaven's Gate, have knocked at the door of the Chemical Society and have asked to be let in. Their request, as will be seen from the correspondence which we print below, has been referred to the whole body of the fellows, and there are those among them who are much perturbed in consequence. The more excited ones, we understand, are all for banging, barring and bolting, unmindful of the portents that a banging, barring and bolting policy is nowadays a bit discredited. Others, and we trust, for the fair fame and credit of the society as a scientific organisation, that they are the majority, are of opinion that the time has come when its fellowship should be rendered accessible to women. At least, so say the 312 fellows (including 10 past presidents, 12 vice-presidents, and 29 members of council, past and present), among whom are 33 Fellows of the Royal Society, and the heads of the chemical departments of nearly all the most important universities and colleges in the kingdom, who have now moved the council, by the most influentially signed memorial that body has ever received, to consent to the referendum.

It is difficult to know on what grounds the admission of duly qualified women to the society should be refused. Those who desire admission have been adequately trained in science, and most of them are graduates. They are, as pointed out by Sir Henry Roscoe in a letter to the *Times* of July 3, *de facto* chemists, engaged either as lecturers or demonstrators of chemistry in various schools or colleges throughout the country; some of them act as research assistants to professors of chemistry, or cooperate with them in the work of original inquiry; one or two are employed as works-chemists. The objects of the Chemical Society are defined to be the promotion of chemistry, and of those branches of science immediately connected with it, by the reading, discussion, and subsequent publication of original communications. It cannot be denied that women have contributed their fair share of original communications. Indeed, in proportion to their numbers they have shown themselves to be among the most active and successful of investigators. The society consents to publish their work, which redounds to its credit. Why, then, should the drones who never have done, and never will do, a stroke of original work in their lives be preferred to them simply because they wear a distinctive dress and are privileged to grow a moustache?

The women-chemists will doubtless smile at the futility of the adverse arguments which appear above the names of the two honorary secretaries of the society. They will have their own opinion concerning the arduous nature of chemical work, about which they know quite as much as those who profess so tender a solicitude for them. As to their chances of success in life, they have shown that they are quite able to hold their own, in spite of the alleged "overcrowded state of the profession." Overcrowded state of the profession, forsooth! With a delicious but wholly unconscious *naïveté*, the banging, barring and bolting people have herein revealed the true inwardness of their opposition. It is the argument of the weak-kneed—of persons whose *Zunftgeist* has warped their judgment and disturbed their mental balance. We trust the main body of the society will treat the argument with the contempt it merits. It is astonishing how unscientific some so-called scientific persons can be. Apparently they fail to perceive that this request on the part of qualified women to be permitted to share the benefits and material advantages which arise from the cooperation of scientific workers in a common calling is the natural and logical result of affording women facilities for the cultivation of science in practically every university in the country. The study of science, even professionally, is no longer the exclusive prerogative of men. It was inevitable that among the many hundreds of women who are now passing through these universities, or through colleges in close association with them, there should be some who are attracted to science as a calling, or who should find in its pursuit a congenial occupation. They are surely entitled to make their own choice of their life's work. Why, then, should obstacles be thrown in their way? They ask for no favour—only for fair play and fair treatment, and it is the banging, barring and bolting people who, from unworthy motives, would deny them both.

A perusal of the correspondence which we publish below, and especially of the significant letter of the past presidents of the society accompanying the memorial addressed to the council which they have caused to be distributed to the fellows of the society, indicates pretty clearly to what lengths certain individuals are prepared to go in resisting the claims of the women. The memorial, it will be seen, expressed the personal opinion of the 312 signatories that the time had come when the fellowship should be rendered accessible to women, but that weighty fact is not mentioned in the letter which appears above the names of the secretaries. This was neither fair to those who signed the memorial nor to the women whose cause they had taken up. It is possible that this *suppressio veri* was unintentional, nor is it likely, we imagine, that there is any *arrière pensée* in the redundant words to which the past presidents direct attention and which serve only to confuse the issue. But those who drafted the letter and the accompanying ballot-paper must at least be held responsible for the bungling, maladroit manner in which the matter was presented to the fellows. It is a question for the society whether its true interests would not be better served by the transference of its secretarial business to more competent and more judicious hands.

*Letter from the Secretaries of the Chemical Society to the Fellows.*

BURLINGTON HOUSE,
PICCADILLY, W.
*June*, 1908.

DEAR SIR,

The Council of the Chemical Society have received a petition praying for an inquiry as to the views of the Society as a whole on the question of admitting women to the Fellowship.

Accordingly, the Council invite very careful consideration of the following brief statement of the chief arguments which have been used both for and against the admission of women.

It is proper to point out that the Council were advised on a former occasion by Counsel that there is some doubt whether, under the existing Charter, women are admissible as Fellows; it is also well to remember that if admitted to this status, women would be eligible, like other Fellows, for a seat on the Council and to hold office.

Those who support the view that steps ought to be taken in order to provide for the admission of women to the Fellowship point out—

(1) That the petition has been signed by 312 Fellows (including 10 Past Presidents, 12 Vice-Presidents, and 29

Members of Council, past and present), among whom are 33 Fellows of the Royal Society and the Professors of Chemistry or Heads of Chemical Departments of nearly all the most important Universities and Colleges in the country.

(2) That a number of women are now devoting themselves to the science of Chemistry, the study of which it is the chief object of the Chemical Society to promote. It is shown that they are capable of independent work by the facts stated in the petition; moreover, in the Transactions from January to May this year there are four papers by women authors independently of others in which they appear as joint authors.

(3) The Chemical Societies of Berlin and America and the Institute of Chemistry admit women to full privileges of membership. The Chemical Society itself has placed the name of Madame Curie among those of its Honorary Members.

(4) A small number of women chemists attend the meetings of the Society regularly as visitors, and no inconvenience has arisen from their presence. They ask that they should be admitted in order that, in addition to exercising the voting powers, they may use the Library and receive the publications of the Society on the same terms as Fellows; at present they have to pay the higher price of publication charged to the general public.

(5) The Society numbers more than 2800 Fellows, while the number of women desiring admission at the present time is about 20; this number will probably increase as time goes on, but judging by the experience of other Societies, it is not likely greatly to exceed that number in the present generation. Should the number rise to as many as 50, their numerical strength would remain wholly insignificant in regard to the conduct of the Society's affairs; consequently, any fear that female influence might hereafter dominate the Council, or even that one woman might be elected to the Council except only in recognition of her scientific ability, is not worth consideration. As to the undesirability of substituting one sex for another in offices of employment, little argument can be based on such a consideration so long as men continue to hold many of the teaching posts in women's colleges.

(6) There is reason to believe that in the event of a decision in favour of applying for a supplemental Charter, the cost, or a large part of it, would be borne by the women chemists and their friends.

On the other hand, those who are unwilling to admit women to the Fellowship of the Chemical Society urge that—

(1) The expense, probably amounting to several hundred pounds, which would be incurred by the Society if a supplemental Charter is necessary, is not justified by the small number of new Fellows likely to seek admission.

(2) It may be gravely doubted whether the deliberate encouragement of women to enter the chemical profession would not operate unfavourably on women themselves in view of the arduous nature of chemical work.

(3) Although it is true, as urged by supporters of the petition, that the number of women seeking admission is small, it is also claimed as a reason for admission that the volume of chemical work contributed by women is increasing rapidly. So long as the women who desire admission remain in such disproportionate minority, there will be an inevitable—although, of course, involuntary—tendency to overestimate their contribution to chemical knowledge and practice. An illustration of this principle may fairly be drawn from the petition itself, where figures are adduced to show that during the past thirty-five years women have been associated with 103 Papers contributed to the Transactions of the Society, but it is not stated, though equally true, that while the total number of Papers printed during that period exceeds 3400, only twenty-three are in the names of women alone.

(4) Even assuming that these 23 contributions were independent of masculine inspiration, it may be questioned whether women have, as a group, shown marked aptitude for chemical pursuits, particularly when it is recalled that the authors in question have worked almost exclusively in collegiate institutions.

(5) Moreover, by being welcomed as guests to the Society, women have been able to enjoy that chemical atmosphere and intercourse which Fellowship of the Society involves.

(6) As regards the admission of Madame Curie to Honorary Membership, it must be borne in mind that Honorary and Foreign Members have no voting powers, and are not eligible for office.

(7) Briefly stated, the position of those unfavourable to the admission of women is that, whilst gladly offering to those women who already have become chemists measures which would give them the benefits derived from attendance at the meetings, they deem it inexpedient publicly to encourage women to adopt chemistry as a professional pursuit, since such a course would tempt them into a career in which they may ultimately not find employment in view of the already over-crowded state of the profession.

Other minor considerations might be mentioned on both sides, and rejoinders to all the above statements are generally obvious. The Council therefore hope that every Fellow will carefully consider the arguments on both sides, and give them the weight which each, respectively, appears in his judgment to deserve.

You are requested, after making the necessary deletion, to return the enclosed ballot paper to the Secretaries in the accompanying envelope, which envelope must be endorsed with your signature. *Unsigned envelopes and signed ballot papers will be invalid.*

The ballot will close on the first day of October next.

We are, Sir,
Yours faithfully,
M. O. FORSTER,
ARTHUR W. CROSSLEY.
(*Hon. Secretaries.*)

*Letter from Past Presidents communicating the Memorial to the Fellows.*

OXFORD,
*1st July*, 1908.

DEAR SIR,

In the letter, which has been sent by the Secretaries of the Chemical Society to every Fellow, on the question of admitting Women to the Fellowship, reference is made to a petition received by the Council. We think it desirable that the petition itself, which is not only a petition but a declaration of opinion on the part of a large body of the Fellows of the Society, should be made known generally, together with the names of those by whom it was signed. Accordingly we enclose herewith a copy of the petition as presented to Members of the Council.

Before the issue of the voting papers the attention of the Secretaries was called to an ambiguity which is due to the introduction of the words "the full rights and privileges of." We suggest that those Fellows who are in favour of the admittance of women to the Fellowship, and not only to "the full rights and privileges of the Fellowship," should strike out these words. It would clearly be possible, however unreasonable, to create a class who, though not actually Fellows, were admitted to all the rights and privileges of the Fellowship. That such a class should be created is not the question which the Council were asked and consented to put.

We are, Sir,
Yours faithfully,
(*Signed*)
WILLIAM ODLING.
WILLIAM CROOKES.
A. VERNON HARCOURT.
HENRY E. ROSCOE.
HUGO MÜLLER.
W. J. RUSSELL.
T. E. THORPE.
J. EMERSON REYNOLDS.
WILLIAM A. TILDEN.
R. MELDOLA.
ALEX. CRUM BROWN.

*Memorial addressed to the President and Council of the Chemical Society.*

GENTLEMEN,

We, the undersigned Fellows of the Chemical Society, being of opinion that the time has come when the Fellowship of the Society should be rendered accessible to women, request the Council to take such steps as may appear desirable to ascertain the wishes of the Society as a whole in regard to this question.

We understand that there is now an appreciable and increasing number of women of University training engaged in advanced teaching, and in original investigation in chemistry, who desire admission to the privileges of the Fellowship, and as the Chemical Society was founded for the advancement of Science, it seems to us neither just nor expedient that a body of highly qualified workers should be excluded solely by reason of sex.

From the following table, compiled from the Society's journal of the past 35 years, it will be seen that the number of Papers contributed either alone, or jointly, by women is increasing rapidly :—

| | No. of papers published in Proceedings | Transactions |
|---|---|---|
| 1873–82 | 2 | 2 |
| 1883–92 | 7 | 7 |
| 1893–02 | 45 | 33 |
| 1903–07 | 66 | 61 |

We may further point out that not only have women contributed original memoirs to these publications, but they have rendered valuable service to the Society as abstractors and in the compilation of the Indexes.

As is well known, the Chemical Societies of Berlin and America, the Society of Chemical Industry and the Faraday Society, admit women on the same terms as men, and our Society has found a place for Madame Curie among the Honorary and Foreign Members: we consider, therefore, that the restriction should be removed under which the Chemical Society denies to women chemists the advantages extended to them by the sister Societies at home and abroad.

We are, Gentlemen,

Your obedient Servants.

Here follow the names of the 312 Fellows (including 10 Past Presidents, 12 Vice-Presidents and 29 Members of Council, past and present), among whom are 33 Fellows of the Royal Society and the Professors of Chemistry or Heads of Chemical Departments of nearly all the most important Universities and Colleges in the country.

## *NOTES.*

In connection with the celebration of the tercentenary of the birth of Evangelista Torricelli, an exhibition will be held at Faenza from August 15 to October 15. Included in the programme, and associated with an international section for physical apparatus, in celebration of Torricelli, a prize of 2000 lire is offered for an instrument in connection with meteorology or physics of the earth. The instrument must be exhibited, and show real novelty, either in its principle or in its application of a principle already known. For further particulars application should be made to Dr. W. N. Shaw, F.R.S., Meteorological Office, 63 Victoria Street, London, S.W.

From July 1 the morning hour of observation in the British Isles for the Daily Weather Report of the Meteorological Office has been changed from 8 a.m. to 7 a.m., and that of the midday observation from 2 p.m. to 1 p.m. At only two of the twenty-nine stations have the earlier observations been found impracticable. Simultaneously, arrangements have been made for the transmission of the telegraphic reports from all the stations, except one, at which the early observations are made, and for attendance at the office in Victoria Street at the same hour to receive the messages. It is anticipated that the revised arrangements, by which the observations in this country become synchronous with those of France, Belgium, Holland, Germany, Denmark, Iceland, Norway, and Sweden will lead, when fairly established, to a considerable acceleration of the morning reports.

Brilliant sky-glows were observed in many different parts of the United Kingdom on the night of June 30 and on several succeeding nights, the phenomenon being apparently at its maximum intensity on the night of July 1. The whole of the northern part of the sky, from the horizon to an altitude of about 45°, and extending to the west, was suffused with a reddish hue, the colour varying from a pink to an Indian red, whilst to the eastward of north the colouring was distinctly a pale green. No flickering or scintillation was observed on the reddened sky, nor was there any tendency to the formation of the streamers or luminous arch characteristic of auroræ. Cirro-stratus clouds near the horizon were tinged with the same colour as the surrounding sky. A special feature in connection with the phenomenon was the prolongation of twilight, extending almost to the following daybreak, and from the experience cited by many observers in various parts of Great Britain the light at midnight was sufficient to allow of fairly small print being read without any aid from artificial light. These nocturnal glows were preceded by a drought extending in London, as well as in several other parts of England, to about sixteen days, and it was followed by severe thunderstorms on the night of July 3 and on the succeeding day. The fine weather in many parts of the country has, however, remained unbroken, so that no relation between the display and disturbed weather can be claimed. Miss C. O. Stevens, who describes a long-sustained solar halo in our correspondence columns, made observations of the coloured skies on the nights of June 30, and July 1 and 2, until daybreak obliterated them. She says :—"The naked-eye evidence favours the view that the phenomenon was due, in part at least, to auroral display, both in the brilliant white and delicate green patches of light that were of rather inconstant brilliance, and in the spreading of the rosy light into the far south and south-west at 1.45 a.m. on July 1." We are informed, however, that spectroscopic observations failed to give any evidence that the phenomenon was auroral in character.

The death is announced, at the age of eighty-four, of Prof. J. V. Barbosa du Bocage, director of the Zoological Institute at Lisbon.

The death is announced, in his seventy-third year, of Prof. C. Schrader, the leading authority in Germany on the Assyrian language and Assyrian civilisation.

The prize of 10,000 francs (400*l.*) offered by M. Armengaud to the first aëroplane to remain in the air for a quarter of an hour was won by Mr. Farman on Monday, at a competition held at Issy-les-Moulineaux, under the auspices of the Aéro Club. Mr. Farman made a flight with his apparatus which lasted 20m. 20s. according to the official timing. He covered a distance of about eleven miles.

Count Zeppelin last week made a remarkably successful flight in his new airship. The airship started on its voyage from Friedrichshafen at 8.30 a.m. on July 1, and headed for Switzerland. After executing evolutions over Lake Constance, the airship proceeded in the direction of Lucerne, where it was seen at 12.30 p.m. The return northwards was over lakes Zug and Zürich, and the airship was observed over the town of Zürich at 2.20 p.m. The airship's floating shed on Lake Constance was reached at 8.30 p.m. The distance covered is estimated at 250 miles, and the journey lasted twelve hours. The greatest height reached by the airship's own engine-power is stated to be some 750 metres, and the highest speed 15·3 metres per second. It will be remembered that the previous record voyage of Count Zeppelin was in September last, when the airship was in the air for eight hours and a half. We notice that Count Zeppelin has received a telegram of congratulation from the German Emperor.

THE Institution of Electrical Engineers has bought the unexpired lease of seventy-six years of the Medical Examination Hall, on the Victoria Embankment, from the Royal College of Physicians and the Royal College of Surgeons. The purchase price agreed upon is 50,000*l.*, the annual ground rent being 2201*l.* The Institution of Electrical Engineers will take possession of their new premises on June 1, 1909. It is expected that the building will provide adequately for the needs of the institution, and afford suitable accommodation for its library.

THE Antarctic Expedition, which is to leave shortly under the leadership of Dr. Jean Charcot, has, according to the *Globe*, been granted a subsidy of 24,000*l.* by the French Government. Dr. Charcot's vessel, the *Pourquoi Pas*, has been specially built for ice work. The party will include a biologist, a meteorologist, two astronomers, and several naval officers. Dr. Charcot expects to be away two years. Coal will be taken in at Punta Arenas, and the base of the operations in case of need will be the island of Port Charcot, where the leader spent a year in 1903. It is interesting to note that it is intended to take two motor sledges on the expedition.

A REUTER telegram states that Commander Peary left in the *Roosevelt* on his expedition to the North Pole on July 7. The *Roosevelt* has been provisioned for three years, although her commander hopes to accomplish the journey to the Pole and back in half that time. At Whale Sound Commander Peary will take on board twenty-five Eskimo hunters and dog drivers with their families, making between forty and fifty persons. The expedition will require from 200 to 250 dogs. Commander Peary hopes to accomplish the object of the expedition and return by October, 1909. For winter quarters he will endeavour, a *Times* correspondent states, to force the *Roosevelt* to the same point on the north shore of Grant Land that he occupied in the winter of 1905–6. Commander Peary only lacks 1000*l.* of the 10,000*l.* needed to equip the ship adequately for a two years' voyage.

THE first international congress concerned with questions of the production of low temperatures and their application to industrial and sanitary purposes is to be held in Paris from October 5–10 next. The congress is being assisted by the French Government, by several municipalities, by commercial companies, and other bodies. The programme which has reached us shows that the business of the meetings will be transacted in six sections, dealing respectively with the following subjects:—section i., low temperatures and their general effects, president, Prof. d'Arsonval; section ii., freezing mixtures and machines, president, Prof. H. Leauté; section iii., application of low temperatures to foods, president, M. A. Gautier; section iv., application of low temperatures to other industries, president, M. E. Tisserand; section v., applications of low temperatures to commerce and transport, president, M. Levasseur; and section vi., legislation, president, M. J. Cruppi. The sections are subdivided somewhat minutely, and the specialist will have every opportunity of acquainting himself with modern views of every aspect of the subject. The general president of the congress is M. André Lebon, and the general secretary M. J. de Loverdo, 10 rue Denis-Poisson, Paris (17e).

IN the House of Commons on Monday, Sir E. Sassoon asked the President of the Board of Trade whether his attention had been directed to the issue of the report of the Select Committee on the Daylight Saving Bill, and, if so, whether the department had expressed any opinion relative thereto. In reply, Mr. Churchill said:—"I have read the report of this committee with much interest and with a lively recognition of the advantages which the Bill in question appears at first sight to offer to all classes, and especially to the working classes. I have arranged for the whole subject to be carefully examined by the Board of Trade in consultation with representatives of trade, labour, and transport interests. Pending the result of this examination it is not possible for me to express an opinion." We refer elsewhere in the present issue to some of the objections to this proposal to juggle with time-keepers. In rural industries the hours of work are adapted to hours of daylight at different seasons of the year, and this is also the case with workers in building and engineering trades. The proposal to legislate for national self-deception in time reckoning because of the late hours now kept in cities is as unscientific as it would be unworkable. It would be just as reasonable for Parliament to decide that a temperature of, say, 50° should be called 40° in summer and 60° in winter.

THE death is announced, from Berlin, of Prof. Oskar Liebreich, the pharmacologist, in his seventieth year. We learn from the *Times* that Prof. Liebreich early devoted himself to the study of technical chemistry under Fresenius at Wiesbaden. At the age of twenty-seven he was appointed to the department of the Pathological Institute by the late Prof. Virchow, who formed a high opinion of his abilities. In 1872 Dr. Liebreich became director of the Pharmacological Institute in Berlin. His name will always be associated with the introduction, in 1872, of hydrate of chloral as a therapeutic agent, which has since been used widely as an anodyne and narcotic. He was an authority on the treatment of lupus, and published a number of works and special articles on this and other questions of therapeutics.

THE seventh International Congress of Applied Chemistry is to be held in London from May 27 to June 2, 1909, under the hon. presidency of Sir Henry Roscoe, F.R.S., he himself being the acting president. It is hoped that the Prince of Wales will open the congress. The meetings will be held in the University Buildings, in the Imperial College of Science, and in the Central Technical College. The special sections and their presidents will be as follows:—analytical chemistry, Dr. T. E. Thorpe, C.B., F.R.S.; inorganic chemistry and allied industries, Dr. Ludwig Mond, F.R.S.; (*a*) metallurgy and mining, Sir Hugh Bell, Bart., (*b*) explosives, Sir Andrew Noble, Bart., K.C.B., F.R.S.; organic chemistry and allied industries: (*a*) organic products, Prof. W. H. Perkin, F.R.S., (*b*) colouring substances and their uses, Prof. Meldola, F.R.S.; industry and chemistry of sugar, Mr. Richard Garton; starch industry: (*a*) starch industry, Dr. Horace T. Brown, F.R.S., (*b*) fermentation, Mr. John Gretton, M.P.; agricultural chemistry, Lord Blyth; hygiene, medical and pharmaceutical chemistry—bromatology, respectively, Sir J. Crichton Brown, F.R.S., Mr. N. H. Martin, and Mr. R. R. Tatlock; photographic chemistry, Sir W. de W. Abney, K.C.B., F.R.S.; electrical and physical chemistry, Sir John Brunner, M.P.; and law, political economics, and legislation with reference to chemical industries, Lord Alverstone. The provisional programme has been drawn up; it comprises the opening meeting in the Albert Hall, a conversazione at the Natural History Museum, a banquet at the Crystal Palace, and lectures by Profs. Haller, Otto Witt, and Nasini, and by Sir Boverton Redwood. Committees have been formed in foreign countries to organise the work of the sections, and an executive committee has charge of the arrangements at home. It is anticipated that the congress will be largely attended; meetings in Paris, Berlin, and Rome were attended by about 3000 chemists. The honorary secretary is Mr. William Macnab, of 10 Cromwell Crescent, S.W.

Dr. Luiz Cruls, whose death we recorded in our issue of July 2, was born at Diest, in Belgium, in the year 1848. The early years of his manhood were devoted to the military service of his country as an officer in the Engineers. In 1881 he accepted the post of director of the observatory at Rio de Janeiro, and from that date he took a prominent part in scientific work in Brazil. In addition to the directorship of the observatory, he held the post of professor of geodesy and practical astronomy in the military academy. He was also the head of many scientific commissions appointed by the Brazilian Government, among others of that for the exploration of the central plateau of Brazil, and the report of this commission forms an important part of his scientific work. His remaining contributions tn scientific literature were of an astronomical or meteorological nature. One of the most important was a report on the observations of the transit of Venus, made at Punta Arenas in 1882. Numerous other astronomical papers appeared in the *Comptes rendus* of the Academy of Sciences of Paris. A detailed discussion of the climate of Rio de Janeiro calls for special mention among his meteorological works.

Among the list of new fungi determined by Mr. G. Massee, and recorded in the current number of the *Kew Bulletin*, there is a notable species from Grenada, *Nectria theobromae*, a parasitic fungus that forms "bleeding" wounds on the bark of cacao trees. From Old Calabar was received an edible agaric, *Volvaria esculenta*, that grows on coffee pulp. *Boletus curtipes* furnishes the first record for the genus from South Africa.

When visiting the German colonies in tropical Africa, Dr. W. Busse paid special attention to the effects of the grass fires periodically kindled by the natives, and has summarised his observations in the *Mittheilungen aus den deutschen Schutzgebieten* (vol. xxi., part ii.). The original motive would be to clear the land for cultivation, or by burning the old stems to induce a fresh growth of young shoots, and occasionally to drive the wild game for a battue. The general result has been to produce, as in Togoland, the "steppe" vegetation where originally forests existed. Although directly and indirectly the consequences are in the main disastrous, it is noted that by the destruction of dangerous insects fires may serve to check such evils as the "surrah" disease.

A substantial account of the Fucaceæ, prepared by Mr. K. Yendo and published in the Journal of the Royal College of Science, Tokio (vol. xxi., article 12), forms a welcome addition to algal literature. With regard to distribution, it is noted that species of Fucus and Pelvetia are confined to the north, Cystoseira to the Loochoo Islands, and a boundary between cold and warm sea forms can be set at Kinkwasan Island on the east and Ojika peninsula on the west. Sargassum is the largest genus, with forty-one out of fifty-nine recorded species, and six species are assigned to Cystophyllum. *Coccophora Langsdorfi* is an interesting species with a perennial knotty stump, from which arise two distinct kinds of branches; similar differentiation is noted for an alga that is made the type of a new genus, Ishige. A series of fine illustrations adds to the value of the critical notes on the various species.

An interesting contribution to the cytological structure of cœlenterates is made by Mr. H. B. Bigelow, who has studied the cell divisions in *Gonionemus murbachii*, and has published his results in the Bull. Mus. Comp. Zool. at Harvard College (vol. xlvii.). The nuclei possess in somatic cells about twenty-four chromosomes, and the nucleolus is regarded as consisting of a peripheral shell of chromatin enclosing a non-chromatic substance. During the reductions, suggestive stages were made out recalling the observations made by Korschelt on Ophryotrocha. The chromosomes arise by stages closely resembling those seen in a somatic mitosis. There is, however, an early synapsis-like ("pseudosynapsis") appearance which Bigelow interprets as an artefact. The modified spireme forms a reticulum, which then breaks up into about twenty-four spherical chromatin masses. This fact is remarkable, inasmuch as there are twenty-four somatic chromosomes, but in the preceding spermatogonial mitoses each of these arises by the coalescence of two "chromomeres." The author regards, on grounds which do not seem to us to be conclusive, the twenty-four chromatin spheres, not as the equivalents of somatic chromosomes, but as chromomeres, and hence concludes that a reduction has already occurred. But it seems at least as probable that we are really dealing with a belated pairing, to form the pseudochromosomes, and this would bring the process into line with some cases of the sort already known elsewhere. The details given of the maturation of the egg seem not to be opposed to such a view. The author is excessively cautious in drawing conclusions, and whilst this is a wise position to adopt for the present, it is to be hoped he will continue his observations so as to enable him to put forward his interpretation with more confidence.

In 1811 the Spanish Viceroy of Mexico addressed to the authorities in California a series of questions designed to procure information regarding the Indian population attached to the Missions, their manners and customs, religious beliefs, and social condition, and the results produced on them by missionary teaching. The original replies to this series of interrogatories, prepared by the authorities of the leading missions, now form part of the Bancroft Library at the University of California, and have been translated and published as the first Bulletin of the eighth volume of their Transactions, with excellent annotations by Mr. A. L. Kroeber. The replies are naturally of varying degrees of value. Some exhibit a good knowledge of the people among whom the authors worked; and they generally display a spirit of tolerance towards non-Christian beliefs, thus forming an interesting picture of native society before it had been much influenced by Europeans, and long before the period of scientific ethnology. In particular, the accounts of the vulture sacrifice as a mode of commemorating the dead, the feathers of the bird being used as a dress of a boy who danced before the community; and the use of jimson-weed (*Datura meteloides*) as a means of producing the ecstatic condition in youths at the initiation ceremony, when they saw visions, and were instructed in the religious beliefs and practices of the tribe, deserve special notice.

In an address delivered before the National Geographic Society of America, published in the May number of the

*National Geographic Magazine* under the title of "An American Fable," Mr. Gifford Pinchot, chief of the United States Forest Service, raises the question of the exhaustion of the national resources, a subject which has recently been discussed by President Roosevelt. The growth of the forests at present is, he states, but one-third of the annual consumption, and the timber will last only twenty years at the existing rate of expenditure. For a country so largely dependent on wood for building and fuel, the result of the wasteful policy of the last half-century will be disastrous, and Canada, the only available source of supply, will soon need all her timber for her own use. The anthracite coalfields, again, are said to be in danger of exhaustion in fifty years, and the bituminous coal will fail early in next century. Some of the older oilfields are already worked out; the natural gas has been wasted, burning night and day in many townships. Iron deposits grow less every year. The ranches in the west feed only half the cattle which they would produce under intelligent management, and the prices of meat are rapidly rising. The present, he observes, is one of the most critical epochs in the national history, and disaster is sure to occur unless a policy of conserving these resources is enforced. The only practical remedy, he suggests, for this dangerous state of things is the appropriation of the vast supplies of water power for the production of electrical energy to take the place of coal for machinery, heating, and illumination. If these fall into the hands of trusts the prospect is gloomy in the extreme. "We are no more exempt from the operation of natural laws than are the people of any other part of the world."

The new Bernese Alpine Tunnel and the Lötschberg Railway are discussed in an article by Dr. C. Koppe in *Himmel und Erde* for April. In pointing out the hindrance caused by the Bernese Alps to the utilisation of the Simplon Tunnel route, Dr. Koppe emphasises the great commercial advantages, not only to Bern and north-west Switzerland, but also to the western Rhine district, which would follow the construction of a railway connecting Brieg, at the northern end of the Simplon Tunnel, with Bern. The first part of the line, from Spiez to Frutigen, has been constructed for several years, and it has been decided to continue this line to Brieg, a tunnel being pierced through the Bernese Alps at Lötschberg. The building of the lines from Brieg and Frutigen to the south and north of the tunnel entrance will be commenced in the summer of 1908, and the whole international railway, Bern, Lötschberg, Simplon, should be completed in five years. The Bernese Alpine Railway Company was formed in July, 1906, and the work of triangulation carried out in the autumn of the same year, accurate data being obtained for fixing the length and direction of the tunnel. The three mountains situated on the line of the tunnel, First, Immenengrat, and Wildelsiggrat, were used as bases for the survey. Boring was commenced in the spring of 1907, electric power being derived from works at Spiez and Gampel. Dr. Koppe gives a detailed description of the proposed line from Frutigen, through Mitholz and Kandersteg, to the tunnel entrance, and also of the line from Goppenstein to Brieg, noticing the numerous small tunnels and viaducts which will be required.

We learn from the *Bulawayo Chronicle* that at a meeting of the Rhodesian Scientific Association on May 19, the Rev. Father E. Goetz, S.J., read a useful paper on the rainfall of Southern Rhodesia, based on observations at about fifty stations, reduced to the period 1888–1907. Among the principal results we note that Mashonaland, as a whole, has an annual average of more than 30 inches; the eastern range of high altitudes has 40 inches and upwards, while on the slopes towards the Zambesi and Limpopo the average is between 25 and 30 inches. Matabeleland is much less favoured; along the watershed the average is 25 east of Bulawayo and 20–25 west of that place. Between April and October not more than an inch of rain falls on an average in Rhodesia, west of the eastern range of high altitudes; from October to March 90 to 98 per cent. of the year's rainfall takes place. Reference must be made to the original paper for many very interesting details in connection with the *régime* of the rainfall and the influence of wind direction. With regard to the question of cycles the author states that, although there are only ten years' barometer observations available, his inquiries show that investigation on the line of a 19-year variation in the barometer and of a corresponding variation in the rainfall might perhaps be continued with profit.

Prof. Silvanus P. Thompson's "Kelvin Lecture," delivered to the Institution of Electrical Engineers on April 30, has been issued as a separate pamphlet by Messrs. Spon. It consists of a sketch of the life and work of Lord Kelvin, and gives within its short compass a more vivid picture of the great master than have several more lengthy accounts.

The Sanitas Electrical Co., Ltd., of New Cavendish Street, London, W., has sent us a profusely illustrated and conveniently arranged catalogue, running to 338 pages, dealing with electromedical apparatus which the company is prepared to supply. The catalogue provides remarkable evidence of the numerous applications in medical and surgical science of the Röntgen and other rays. Incidentally, the appliances described in the catalogue serve to illustrate the debt of gratitude which mankind owes to the men of science upon whose work, often little recognised, these remedial measures are based.

M. P. Villard exhibited before the Société Française de Physique on May 4 an experiment in which the Aurora Borealis was produced artificially (see Nature, September 5, 1907, vol. lxxvi., p. 481), and a complete description of the method used is given by M. Villard in the June number of the *Journal de Physique*. A large exhausted flask is placed between the poles of an electromagnet, and a stream of kathode rays is shot into the flask in a direction oblique to the magnetic field. In these circumstances the rays become a luminous spiral with its axis directed towards one of the poles of the magnet. At a point near this pole the path of the ray is nearly reversed, and the spiral proceeds towards the other pole, at which the reversal is repeated. Owing to the axes of the spirals being slightly inclined to the lines of the field, they generate a spheroidal surface coaxial with the field with a circular piece cut out at each pole. According to the theory which this experiment at once suggests, in our observation of the aurora we are looking at the edge of one of these openings from underneath, the spirals coming nearest to the earth's surface at these points and being most luminous.

Messrs. Leitz, of Wetzlar and London, have submitted for our inspection one of their prism binoculars of improved design. Like the majority of modern instruments of this type, these are constructed on the principle of Porro's erecting prisms, but several additional patents on details enable special points of excellence to be claimed. The tubes are provided with focussing arrangements and inter-pupillary adjustment. For the former, the focussing is done separately for each eye by rotation of the eye-pieces, controlled by a scale for future setting. Although at first this may appear more inconvenient than the usual double screw motion of both tubes, this is not found to be the case during continued usage, and the makers are enabled to introduce the very desirable feature of making the prism cases quite dust and moisture proof, which is almost impossible when sliding tubes are employed. As issued, the magnifying power is 6, and the field of view about 7°. With respect to the varying opinions as to the best arrangement of the object-glasses for stereoscopic effect, Messrs. Leitz have decided that the advantages of placing them further apart than the pupillary distance are questionable, and so the object-glasses are fitted at the same interval as the eye-pieces. The binocular is made of a specially strong light metal, the weight being only 12 oz. without case. We can without hesitation speak very highly of the optical performance of this instrument. The definition is remarkably crisp, and the image very achromatic and quite sharp up to the edge of the field of view.

A general index to the annual volumes, sixteen in number, published by the Geological Survey of Canada since 1884, has been compiled by Mr. Frank Nicolas and issued at Ottawa by the Geological Survey. The index runs to 1014 pages, and contains about 180,000 references. It should prove of great service to investigators anxious to refer expeditiously to the annual volumes of the Canadian Survey. The present catalogue, combined with the index previously published, and dealing with the publications from 1863 to 1884, forms a complete means of reference to the English edition of the volumes issued by the Geological Survey of Canada.

## OUR ASTRONOMICAL COLUMN.

Radial Velocities of Ninety-nine Stars.—The largest single contribution to line-of-sight work yet made appears in No. 5, vol. xxvii., of the *Astrophysical Journal* (pp. 301–24, June). The results were obtained by Prof. Küstner and Dr. Zurhellen, at the Bonn Observatory, during the years 1903–7, and include the provisionally determined velocities of ninety-nine stars of the second and third spectral types down to the fourth visual, or fifth photographic, magnitude.

A three-60°-prism spectrograph by Töpfer, giving a well-defined spectrum between $\lambda\lambda$ 4150 and 4500, was employed, the temperature being automatically controlled by electric means; at H$\gamma$ the linear dispersion is such as to give 15·2 tenth-metres per millimetre.

Although the present values for the radial velocities are only provisional, it is expected that they will not be greatly modified in the final definitive results. In addition to fifteen previously known variable velocities, the ninety-nine sets of results include those for three other stars, $\delta$ Tauri, $\epsilon$ Böotis, and $\mu$ Pegasi, the radial velocities of which are suspected to be variable. The comparison spectrum employed in each case was that of the iron arc, Kayser's values of the wave-lengths being taken; Rowland's values were taken for the stellar lines. As the observations included some 7500 complete measures of about forty-four different stellar lines, Prof. Küstner expects that their discussion will provide good exact values for the relative wave-lengths of the latter, and also indicate their dependence on the type. In discussing the determination of the constant correction, due, first to the absolute errors of the wave-lengths adopted, and, secondly, to the personal and instrumental errors, Prof. Küstner considers as invalid the control usually obtained from plates exposed on the sun, moon, or larger planets. He believes that a source of light, of precisely known radial velocity and *as similar as possible to the star*, should be observed, and suggests the employment of the brightest minor planets or of Jupiter's satellites for this purpose. After many experiments, and at Dr. Zurhellen's suggestion, he employed spectrograms of the bright isolated peaks seen at the moon's terminator, and found the results to be satisfactory. These indicate that a small negative correction of about −1·0 km. should be applied to the results now published. Of the constant radial velocities determined, that of $\eta$ Cephei, −85·98 km., is the largest.

The Observation of Coloured Stars.—In No. 4252 of the *Astronomische Nachrichten* (p. 57), Herr Osthoff discusses at some length the changes of the colour perception of the eye, and shows that these changes depend upon the physiological condition of the observer as well as upon the intensity of the colour of the observed object and upon the instrument used. A table containing the results of his own observations between January, 1894, and November, 1898, shows the variation of the difference between his estimates of colour and the catalogue colour of the stars observed; other tables show the variation of the eye's colour-perception for red and yellow stars respectively, and it appears that the eye is more uncertain in estimating the red than the yellow. The importance of this fact in observing the magnitudes of coloured variable stars is pointed out. There is some indication of a periodical change in the individual eye, but the observations are not sufficiently numerous to establish this.

Photometric Observations of Eros.—During the period September, 1907, to January, 1908, Dr. Paul Guthnick made a number of photometric observations of Eros at the Berlin Observatory, and now publishes and discusses the results in No. 4249 of the *Astronomische Nachrichten* (p. 1, vol. clxxviii.). From his discussion he is unable to establish with certainty the existence of any short-period light-variation. On plotting the light-curve, taking into account the phase-variations, and trying periods of 5·24h., 5·28h., and 5·32h., he obtained a negative result. It appears certain that during the greater part of the opposition any short-period variation was imperceptible.

The Photography of Very Faint Spectra.—The expedient of slightly fogging plates on which it is proposed to photograph faint objects is generally known, but is apparently not so generally adopted. Having recently employed this procedure very successfully in the photography of faint spectra, Mr. R. W. Wood, of the Johns Hopkins University, describes his method and results in No. 5, vol. xxvii., of the *Astrophysical Journal* (p. 379, June). The curve representing the action of light on a sensitised plate is at its commencement flat, but after reaching a certain point it begins to rise much more rapidly; Mr. Wood's supplementary exposure carries the darkening of the plate to this point, so that the radiations he is wishing to photograph commence their action at that part of the curve where a given exposure is much more effective in producing density than if it were applied alone. By a judicious use of the method he has succeeded in reducing the exposure, necessary to produce a certain density, by one-half. The preliminary exposure needed is very small; with a gas flame turned down until the yellow tip was but 3 mm. or 4 mm. high, four seconds at a distance of about two metres was found to be sufficient.

## JULY AND AUGUST METEORS.

THE meteoric season of July has again returned, bringing with it all the interesting associations attached to this period in previous years. Early Perseids will now be occasionally seen with their rapid flights, and leaving streaks upon their paths, but they will be directed from the southern region of Cassiopeia instead of from the place 45°+57°, as at the maximum epoch on August 11–12. Many long-pathed and slow-moving Aquarids will also be noticed from the point about 339°−10°, and this display generally develops its richest features near the end of July, on about the 28th to 30th.

A few years ago I sifted all my observations at the July and August periods with a view to find the most active radiants determined at Bristol, and the number of meteors recorded from them. Omitting Perseids, the following is a list of the principal systems:—

| Radiant R.A. ° | Dec. ° | Periods July 20–Aug. 16 meteors | Aug. 19–25 meteors |
|---|---|---|---|
| 7 | +11 | 31 | 26 |
| 9 | +39 | 44 | 5 |
| 24 | +42 | 35 | 23 |
| 30 | +36 | 43 | 12 |
| 47 | +43 | 59 | 25 |
| 61 | +48 | 21 | 26 |
| 271 | +48 | 32 | 9 |
| 291 | +60 | 44 | 69 |
| 292 | +52 | 72 | 9 |
| 304 | −12 | 31 | — |
| 312 | +12 | 30 | 9 |
| 315 | +48 | 38 | 10 |
| 315 | +78 | 24 | 6 |
| 333 | +48 | 53 | 6 |
| 333 | +28 | 37 | 8 |
| 333 | +71 | 50 | 31 |
| 339 | −10 | 237 | 20 |
| 348 | +50 | 52 | 17 |
| 345 | +1 | 28 | 29 |

The complete table of showers, rich and feeble, appeared in *Astronomische Nachrichten*, No. 3874. About eighty-five systems in all were displayed between July 16 and August 20.

It would be interesting if some of these streams could be re-observed during the oncoming return of the Perseids and their radiant points re-determined. The positions given in the table may be relied on as accurate to within 2° of probable error, but some of the radiants are more exact than others, the centres having been more sharply defined. In the case of showers of swift, streaking meteors, the intersecting points of the flights can generally be ascertained with great precision.

Special attention seems necessary to be given to the period about July 11–12, when the first signs of the Perseids decidedly begin to be manifested.

This year moonlight will seriously interfere with observations for about a week near July 13 and August 12. The maximum display of Perseids will be partially overpowered by the radiance of our satellite, but some brilliant meteors will be observed at about the epoch August 9–13 should the skies be clear. W. F. DENNING.

## MAGNETIC RESOLUTION OF SPECTRAL LINES.

PROF. P. ZEEMAN, continuing his investigations on the occurrence of asymmetric separation of spectral lines in a magnetic field (see NATURE, April 30, vol. lxxvii., p. 615), describes a series of observations on asymmetrical triplets (*Konink. Akad. Wetens. Amsterdam*, p. 566, March 27). As a method giving independent confirmation of the previous work was desirable, he decided to investigate the new series by means of the Fabry and Perot interferometer, using the *étalon*—that special form of the instrument in which the distance between the silvered surfaces is kept constant, about 5 mm. The variations of wave-length may in this case be determined either by continued measurements of the same interference ring or by the method of coincidences, regulating the magnetic force in such a manner that a ring which expands by increasing magnetic intensity coincides with a contracting ring. The system of rings was formed in the focal plane of a small achromatic lens of 18 mm. aperture and 12 cm. focus. This focal plane coincided exactly with the plane of the slit of a one-prism spectroscope, the width of the slit being so reduced that the rings produced by the two yellow mercury lines at λλ 5791 and 5770 could be observed separately.

Reproductions of the appearances presented with magnetic field off and on are included with the paper, made from enlarged negatives. The measurements given indicate conclusively that the positive results concerning asymmetric resolution in strong fields have a real significance, and a very interesting discussion of the results is appended. Taking Lorentz's equation for determining $e/m$, and accepting J. J. Thomson's value of $e=1\cdot1\times10^{-20}$ electromagnetic units, the number of electrons per unit volume causing the radiation of the yellow mercury line 5791 in a vacuum tube appears to vary from $8\times10^{16}$ to $4\times10^{16}$ with magnetic fields varying from 29,220 to 9130 Gaussian units. In these experiments the temperature of the vacuum tube was between 100° C. and 120° C.; the corresponding vapour pressures of mercury, according to Hertz, would be 0·29 mm. and 0·78 mm. respectively, and it is calculated that the number of electrons participating in the emission of line λ 5791 is of the same order of magnitude as the number of atoms present.

A number of observations made by Mr. Jack in the physical laboratory at Göttingen are also recorded, showing the asymmetrical separations of lines of wolframium and molybdenum. The paper concludes with a question as to the possibility of the wave-length of the central line of a triplet being changed by the action of the magnetic field as compared with the unmodified line, and some observations made with an echelon appear to indicate that some lines undergo in strong fields displacements of the order of six or ten thousandths of an Angström unit, in most cases towards the red. This is to be further treated in a subsequent paper.

## SOCIAL ANTHROPOLOGY.

PROF. J. G. FRAZER has made a good start in the work of his chair at the University of Liverpool by his opening address on "The Scope of Social Anthropology." It is characterised by all the lucidity of exposition and grace of style which we are accustomed to expect from the author of "The Golden Bough." His main object is to plead for the systematic study of savages, who represent an arrested, or rather retarded, stage of social development. They are, he is careful to point out, primitive only in a relative, not in an absolute, sense: that is, they are primitive in comparison with ourselves, not in comparison with primæval man, of whom we know nothing, and, so far as we can see at present, are likely to learn nothing.

The province of social anthropology falls into two departments, one embracing the customs and beliefs of savages, the other including such relics of these as have survived in the thought and institutions of more cultured peoples. The first department may be called the study of savagery, the second the study of folk-lore. The government of mankind, he goes on to show, is always and everywhere essentially aristocratic, that is to say, the dull-witted majority always follows the keener-witted minority. In the mental, no less than in the physical sphere, the struggle is internecine; but in the end the better ideas, which we call the truth, carry the day. Hence, even in a civilisation like our own, we find the lower classes still following magical and other primitive practices of the same kind. Not that schemes for the regeneration of society form part of his programme. The study of the past must throw light upon the problems of the present, but the exploration of schemes of social reform is the business of the sociologist, not of the social anthropologist.

Dr. Frazer closes a remarkable address by an impassioned appeal for the more careful study of that savagery which is so rapidly disappearing. "How shall we of this generation look when we stand at the bar arraigned on a charge of high treason to our race, we who neglected to study our perishing fellow-men, but who sent out costly expeditions to observe the stars and to explore the barren ice-bound regions of the poles, as if the polar ice would melt and the stars would cease to shine when we are gone?"

## RECENT RESEARCHES IN THE STRUCTURE OF THE UNIVERSE.[1]

### II.

*Localisation of the Stars in Space by a Sorting Process.*

THE method may be best explained as a *sorting* process. The process was not actually followed; it would have been too laborious, and would have met with some difficulty.[2] But the difference is immaterial, and the present description has, I think, the advantage in point of clearness. Let each of the stars of the second, third, &c., to the eighth magnitudes be represented by a little card on which are inscribed the apparent magnitude and the apparent proper motion of the star. Then imagine three sets of boxes.

Fig. 1.

*Classification according to Magnitude.*

1st Set.—*Apparent magnitude boxes* represented in Fig. 1.—In the box for the second apparent magnitude, as many cards are put as there are stars of the second magnitude in the sky. The total numbers of stars for each magnitude are inscribed on the lid. We thus see that there are in the whole of the sky forty-six stars of the second magnitude, 134 of the third, and so on.

*According to Magnitude and Proper Motion.*

2nd Set.—*Magnitude-motion boxes* (Fig. 3). The stars in each of the former series of boxes are re-distributed over a series of boxes, each of them containing stars of a determined apparent motion. By way of an example, Fig. 3 shows this new classification for the stars of the *fifth* apparent magnitude. There is, of course, another such series for each one of the apparent magnitudes. Those for the *fifth* have been distributed over twenty-eight new boxes. In the first have been collected the cards representing the stars with a proper motion of 0″ to 1″ per century. The average motion is 0·5, and this has been inscribed on the lid. The little arrow indicates that this number represents a motion. The number 5 surrounded by a star refers to the fact that we have exclusively to do with stars of the fifth apparent magnitude. The second box contains the stars with proper motion between 1″ and 2″ per century, &c. For the larger motions the limits have been taken somewhat wider. In the eleventh box the motions 10″ to 15″ are contained, in the thirteenth those between 20″ and 30″, and so on. The number of star-cards in each box has been inscribed on the lower right-hand corner of the lid. The figure thus shows, for instance, that there are in the sky ninety stars of the fifth magnitude having a proper motion between 0″ and 1″ per century. We have thus arranged the stars according to both the rough criteria of distance at our disposal; for we know perfectly well that in a very general way the fainter the stars and the smaller their apparent motion the further they must be away.

For each of the groups thus obtained we are now able, according to what has been said before, to derive the *mean* distance. This determination being made, we obtain the mean distances expressed in light-years which have been inscribed on the lid with the letter MD prefixed. Already we may see now how incorrect it is to imagine all the stars of the fifth magnitude to be placed at one and the same distance, as Struve did. According to the numbers in our figure, the distance varies from 1670 light-years for the stars of the first box to eleven light-years for those of the last. It is true that just the data for these extreme boxes are the most uncertain; still, it is evident that even in these mean distances there must be an enormous range.

But to proceed. The eighty-six stars in our sixth box (see Fig. 3) are at an average distance of 248 light-years.

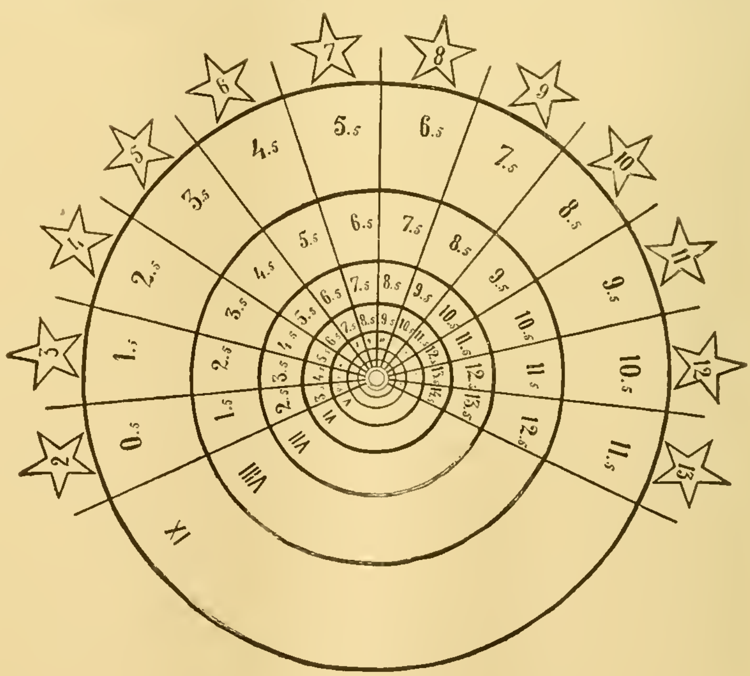


FIG. 2.

Are we compelled to stop here and to *assume* that the real distance of *all* the individual eighty-six stars is 248 light-years? If it were so we would *surely* still have gained a considerable advantage over Struve. For, owing to want of other data, he saw himself compelled to treat all the stars of the fifth magnitude, that is, the whole of the twenty-eight groups in our boxes, as if they were all at the mean distance of the whole. But yet there would remain in our solution a defect *of the same kind*, and it

[1] Discourse delivered at the Royal Institution on Friday, May 22, by Prof. J. C. Kapteyn. Continued from p. 212.

[2] For many of the stars used the proper motion is still not known. What is known, however, is the percentage of the stars of each magnitude having a determined proper motion. This knowledge enables us to put in every box the required *number* of cards showing a determined proper motion, and this is all that is wanted in what follows.

would be impossible to say in how far the results definitively to be obtained would be influenced. Happily there is an escape.

For our last classification, the classification in the distance-boxes, it is of no particular advantage that every individual star gets in its proper distance-box. It will be sufficient to know how many stars will finally be found in each distance-box. If this result is obtained, we shall presently see how easy it becomes to study the problem put at the beginning of this lecture. Our aim will be evidently reached if we can find out *how many per cent.* of the stars in any one box have such and such a distance. Now, in order to determine these percentages, it will be sufficient to investigate *a sample* of our stars.

*Stars of Measured Distance taken as a Sample.*

Happily there is the possibility of taking a sample that will help us out of the difficulty, for, as we know, there are in the sky a hundred stars of which astronomers have succeeded in determining the individual distance with some accuracy. We take these as our sample. They are distributed over a great many of our boxes.

We take them all out, having a care to note for all of them the mean distance of the stars in the box to which they belong. For all the hundred stars we now compare their mean distances to their true distances, and thus find out how many per cent. of them have true distances between *two* and *three*, *four* and *five tenths*, and so on, of the mean distance.

*3rd Set.—Distance boxes.* These percentages are all we want for our last distribution, the distribution over the distances. It is true that our sample is a somewhat undesirably small fraction of the whole; it shows besides some other weak points, but it appears happily *a posteriori* that even rather considerable uncertainties in these percentages have but an unimportant influence on the results. We are thus at last enabled to distribute our star-cards according to the true distances. I made the distribution over the spherical shells shown in Fig. 2.

The dimensions of these shells have been so chosen that if a star is removed from one shell to the next further one, the observer at the centre will see the star grow fainter by just one magnitude, that is, it will grow very nearly $2\frac{1}{2}$ times fainter.

The figure is not well fitted for bringing out the details of our results. The shells become too narrow towards the centre, and the more central ones do not allow of the insertion of sufficiently clear figures. For this reason I constructed Fig. 4. The numbers valid for the several spherical shells have here been entered in equally broad horizontal rows. The drawing does not therefore show the real dimensions, but these as expressed in light-years, which may be read off on the right-hand side of the drawing. We thus see that the central sphere extends to a distance of twenty-one light-years, that the second spherical shell extends from twenty-one to thirty-three years, and so on. In these rows a last set of boxes is placed. There is a box for each apparent magnitude in each of the rows. The stars of the boxes of Fig. 3 are thus, of course, all contained in the vertical row of boxes, corresponding to apparent magnitude five in Fig. 4.

*Distribution according to Distance Illustrated by Example.*

In order to illustrate by an example how the stars of the boxes in our Fig. 3 are distributed over our different shells, that is, over our *distance boxes* of Fig. 4, take the seventh box. It contains seventy-seven stars at a mean distance of 220 light-years. Our countings on the sample showed that about *one-fifth* of the stars have *true* distances which are between 37 per cent. and 59 per cent. of their *mean distance* (derived from their apparent magnitude and proper motion). Therefore about one-fifth of our seventy-seven stars must have true distances between 37 per cent. and 59 per cent. of 220 light-years, that is, between eighty-two and 130 light-years—or, finally, fifteen stars of our box must find their place in the fifth shell of Fig. 4, that is, in the box corresponding to the fifth apparent magnitude in that shell. In precisely the same way I find that twenty-one of them must be placed in the sixth shell, eighteen in the seventh, ten in the eighth, and so on.

If, after that, we repeat the process for all the remaining boxes of Fig. 3, we get, for the fifth apparent magnitude, the numbers inscribed on the lower side of the boxes corresponding to that magnitude in Fig. 4.

Further than for the eleventh shell no numbers have been entered. They become too uncertain. As, however, we know the *total* number of stars of each apparent magnitude, we know the aggregate number which remains to be distributed over the whole of the further shells.

What has here been explained for the stars of the fifth magnitude has been also done for the other magnitudes between the second and the eighth. The whole of the results are shown in our Fig. 4.

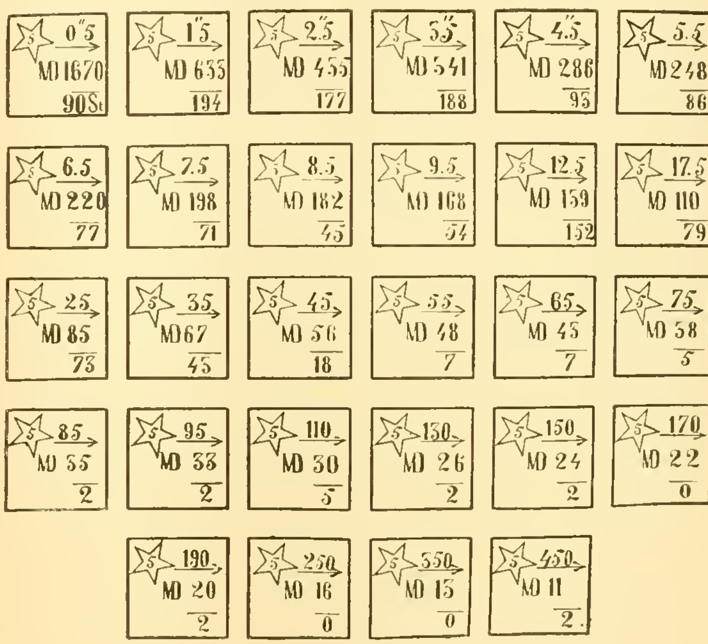

Fig. 3.

*Stars of Equal Luminosity brought together.*

The main result of the investigation is embodied in these numbers—and *first*, in every box stars have now been brought together of equal absolute magnitude—that is, of equal luminosity. For as the stars in each box are at the same distance, and as, at the same time, they are of equal *apparent* brightness, they must, of necessity, be of equal total light-power, that is, according to our definition, of equal luminosity or absolute magnitude. For the absolute magnitude of a star I have taken the magnitude the star would show if placed at a distance of 326 light-years. The choice of just this number is simply a matter of convenience, and need not be explained here.

As a consequence, the stars at a distance of 326 years, which to us appear as stars of the fifth magnitude, will have also the absolute magnitude five. Those of the same apparent magnitude, but at a distance of 517 light-years—that is, just one shell further—must have the absolute magnitude four in order to show us the same brightness, notwithstanding the greater distance. Now our eighth shell lies just between these limits of distance. In the middle of this shell, therefore, the stars of apparent magnitude five must have absolute magnitude 4·5. In the box, therefore, belonging to the fifth apparent magnitude, eighth shell, all the stars are of absolute magnitude 4·5. In the ninth shell a star must already have the absolute magnitude 3·5 in order to shine as a fifth apparent magnitude at this greater distance, and so on. In this way the absolute magnitudes were found which in our figure have been inscribed on the lids of the boxes.

We are now able to derive at once the *mixture law*, *i.e.* the proportions in which stars of different absolute magnitude are mixed in the universe. For in one and the same shell (eleventh) we find two stars of absolute magnitude −1·5, as against three of magnitude −0·5, fifteen of absolute magnitude 0·5, seventy-six of absolute magnitude 1·5, &c.

That is, our results for the eleventh shell furnish us with the proportion in which stars of absolute magnitude −1·5, −0·5, &c., to 4·5, are mixed in space. The tenth shell gives the proportions for all the absolute magnitudes between −0·5 and 5·5, and so for the rest. All the shells together give the proportions for the absolute magnitudes

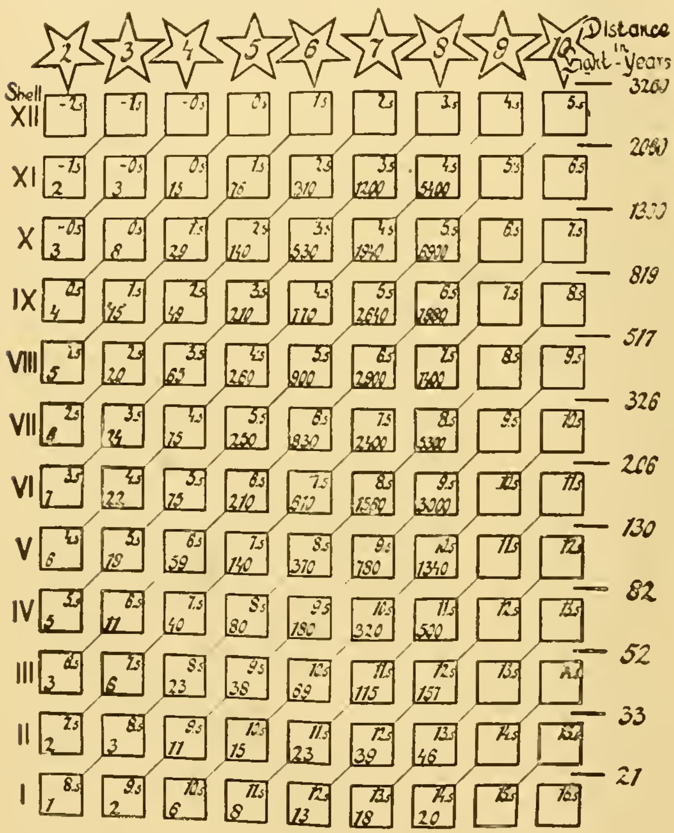

Fig. 4.

−1·5 to 14·5, that is, for a range of not less than sixteen magnitudes. Not only that, but most of the proportions are determined independently by the data of quite a number of shells. So, for instance, the proportion of the stars of absolute magnitude 4·5 to those of absolute magnitude 5·5. Each of the six shells from the fifth to the tenth furnishes a determination of this proportion. All of them are not equally trustworthy. If we take this into account, we find that the agreement of the several determinations is fairly satisfactory. By a careful combination of all the results, a table representing the law of the mixture of the stars of different absolute magnitude was finally obtained. Rather than show you the direct result, however, I will first replace the absolute magnitudes by luminosities expressed in the total light of our sun as a unit. This will have the advantage of presenting a more vivid image of the real meaning of our numbers.

By photometric measures it was found that the sun, placed at a distance of 320 light-years, would shine as a star of magnitude 10·5. In other words, the sun's absolute magnitude is 10·5. A star of absolute magnitude 9·5 will, therefore, have 2·5 times the light-power—that is, 2·5 times the *luminosity* of the sun. A star of absolute magnitude 8·5 will again have a luminosity which is 2·5 times greater, and so on.

Such results evidently enable us to transform our absolute magnitudes into luminosities. Thus translated, I found the results shown in the following table.

*Luminosity Table.*

Within a sphere having a radius of 555 light-years, there must exist:—

| | | | | |
|---|---|---|---|---|
| 1 star | 10,000 | to | 100,000 | times more luminous than the sun |
| 46 stars | 1,000 | ,, | 10,000 | ,, ,, ,, ,, |
| 1,300 ,, | 100 | ,, | 1,000 | ,, ,, ,, ,, |
| 22,000 ,, | 10 | ,, | 100 | ,, ,, ,, ,, |
| 140,000 ,, | 1 | ,, | 10 | ,, ,, ,, ,, |
| 430,000 ,, | 0·1 | ,, | 1 | ,, ,, ,, ,, |
| 650,000 ,, | 0·01 | ,, | 0·1 | ,, ,, ,, ,, |

This table represents what, up to the present time, we know about the mixture law.

The fainter the stars, the more numerous.

The rate at which the numbers increase with the faintness is particularly noticeable for the very bright stars.

Passing to the fainter stars, this rate gradually diminishes, and it looks as if we must expect no further increase in number for stars the luminosity of which falls below one-hundredth of that of the sun. Meanwhile, this is simply a surmise. For stars of this order of faintness data begin to fail. Here, as in nearly every investigation about the structure of the stellar system, the want of data for stars below the ninth apparent magnitude makes itself very painfully felt.

But let us come back to our Fig. 4. I will *first* remark that, knowing the mixture law, we can predict the number of stars that we shall get in the empty boxes belonging to the ninth, tenth, &c., magnitude, as soon as continued astronomical observations will permit us to include these stars in our discussion. For the mixture law, as derived just now, shows that in our universe the stars of absolute magnitude 5·5 are 3·5 times as numerous as the stars of absolute magnitude 4·5.

Now as in the eleventh shell the number of stars of the absolute magnitude 4·5 is 5400 (see Fig. 4), there must be 3·5 times 5400, that is, 18,900 stars of absolute magnitude 5·5 in this shell. These belong all in the box of the ninth apparent magnitude of this shell. In the same way we obtain the number of stars to be expected in the boxes of the tenth, eleventh, &c., apparent magnitude for all our shells down to the eleventh. There is exception only for the boxes belonging to the lower shells, for which the absolute magnitude would exceed 14·5.

It is evident, however, that the number of stars in these exceptional boxes must be small, and for what follows they are of little importance.

*Star-density.*

*In the second place*, our boxes now also lead to the determination of the *star-densities*. For the volumes of the consecutive shells are perfectly known; they are in the proportion of 1 : 3·98. For the sake of convenience, let us say that the volume of each shell is exactly four times that of the next preceding one. Now, to take an example of the determination of the densities, consider the ninth and tenth shells (see Fig. 4). In the ninth there are forty-nine stars of absolute magnitude 2·5. Therefore, if in the tenth the stars were as thickly crowded as in the ninth, there would occur in this shell four times forty-nine, that is 196 stars of this absolute magnitude 2·5.

In reality we find but 140 of these stars. The conclusion evidently must be that the star-density in the tenth shell is about 140/196, that is, about two-thirds of that in the ninth shell. A similar conclusion is obtained by comparing the number of the stars of absolute magnitude 3·5 in the two shells. The values obtained from the magnitudes 0·5 and 1·5 may be neglected. Owing to the exceedingly small number of stars, they must necessarily lead to untrustworthy results. From all the rest I found that the density in the tenth shell must be about 64 per cent. of that in the ninth shell. The proportion between the densities in the other shells was determined in exactly the same way.

A slight defect in our results was then discovered. We should exceed the limits of the time allowed for this lecture by entering into a consideration of this defect. It must be sufficient to state that it was not difficult to remove it. After that it appeared that the density in the first six of our shells is nearly the same. The density in these shells, that is, in the neighbourhood of our sun, is such that about 2000 stars of a luminosity exceeding one-hundredth that of the sun must be contained in *a cubic light-century*. After the sixth shell the density diminishes gradually at such a rate that in the eleventh shell the density has fallen to about 30 per cent. of what it is in the vicinity of the solar system.

In what precedes we tried to give a solution of the problem put at the beginning of this lecture—a solution, however, which embraces only that part of the universe which is contained within a distance of about 2000 light-years from our solar system. Is there no possibility of getting beyond this distance?

I think there is, but, of course, you will not be astonished to find that the certainty of our conclusion diminishes as we get deeper and deeper into the abysses of space.

One of the reasons why the method thus far applied breaks down beyond the eleventh shell is that our data about proper motion are not refined enough to determine this motion with sufficient accuracy as soon as it is below 1″ in a century. Even the somewhat greater motions are rather uncertain. The proper motions thus cannot help us much beyond a certain distance. But we have still one valuable element for the solution of our problem. This element is the total number of stars separately for the apparent magnitudes. Thanks mainly to the photometrical researches at the Harvard Observatory, it has become possible to determine with considerable accuracy the total number of stars of the first, second, &c., to the eleventh magnitude; with a fair degree of accuracy even those for the magnitudes down to the fourteenth (inclusive).

The density in the shells beyond the eleventh, not only for the stars down to the eighth apparent magnitude, but, according to what has been said a moment ago, also for the apparent magnitudes of nine, ten, &c., to fourteen, has to be determined in such a way that the addition of all the numbers in any one vertical column of Fig. 4 produces just these totals for the corresponding apparent magnitudes.

It can be proved that after the eleventh shell the density must, on the whole, continue to diminish. If we assume that this diminution is gradual and proportional to the increase in distance, it becomes very easy to determine the rate of this diminution, and consequently the distance at which the density becomes *zero*, that is, the distance at which we reach the limit of the stellar system. We cannot enter into fuller particulars here. It must be sufficient to say that in this way we are led to conclude that the further diminution of density must be slow, so slow that in the assumption made above the limit of the system is only reached at a distance of some 30,000 light-years.

### *Hypotheses Underlying the Results.*

In conclusion, a few words on the question, In how far are the results now obtained to be considered as established?

The answer must be, They can be considered to be established only in so far, and no further, than we can trust the truth of the hypotheses which still underlie our reasoning.

For future consideration there thus remains the question, In how far can we test the validity of these hypotheses?

These hypotheses are the following:—

(1) The mixture was assumed to be the same at greater and smaller distances from the solar system.

(2) The same was done for different distances from the galaxy.

(3) The universe was assumed to be transparent, that is, it was assumed that the absorption of light in space is *zero*.

Can we get rid of these hypothetical elements?

I think we can, at least to a very great extent.

As to the *first*. Our Fig. 4 already goes far in enabling us to judge whether it is true or not. For evidently both our sixth and our ninth shell give the nature of the mixture, at least of the stars of absolute magnitude 3·5 to 6·5. Therefore, so far as these stars are concerned, we are able to see whether or not the mixture is the same at the distance of 650 light-years as it is at the distance of 170 light-years. Likewise, the figure enables us to make the comparison in other cases. As soon as we possess the necessary data for a longer range of apparent magnitudes, say down to the fourteenth or fifteenth, we shall be able to dispense to a very large extent with our first hypothesis.

As to the second, the possible variation of the mixture with the distance from the Milky Way, it is largely only the question of treating the stars in different galactic latitudes separately. So far as I can see, there are no particular difficulties in the way of such a separate treatment, at least not since the nature of certain anomalies in the distribution of stellar motions has been elucidated.

### *Absorption of Light in Space.*

Last, not least. Is the universe really absolutely transparent? There are reasons which make this seem very doubtful. A couple of years ago I obtained some evidence in the matter which shows that the absorption of light in space, if it exists to an appreciable amount, must at least be so small that over a distance of a hundred light-years not more than a few per cent. of the light can be lost. To determine so small an amount to within a small fraction of its total value will be a difficult task indeed. Still, we can even now see definite ways, which, given the necessary data for very faint stars and nebulæ, will probably enable us to overcome this last difficulty.

This want of data for very faint stars, which, in the present investigation, makes itself felt at every step, has led a number of astronomers to concerted action.

The express purpose of their cooperation is to collect data of every kind for stars down to the faintest that can practically be reached. As complete observation and treatment of these numberless stars is out of the question, the plan is confined to a set of samples distributed over the whole of the sky.

### *Conclusion.*

If, at the end of this lecture, somebody summarises what has been discussed by saying that the results about the structure of the universe are still very limited and not yet free from hypothetical elements, I feel little inclined to contradict him. But I would answer him by summing up in another way, viz.:—

Methods are not wanting which, given the necessary observational data obtainable in a moderate time, may lead us to a true, be it provisionally still not very detailed, insight into the real distribution of stars in space.

I think this time need not exceed some fifteen years. They to whom such a time may still seem somewhat long may be reminded of the fact that we shall have finished our work before any but a very few of our nearest neighbours in space can be aware of the fact that we have begun, even if we could send them a message now by wireless telegraphy travelling at the speed of light.

## *UNIVERSITY AND EDUCATIONAL INTELLIGENCE.*

ST. ANDREWS.—Besides the gifts of Diplodocus to the British Museum and to the museums of Paris and Berlin, Dr. Andrew Carnegie has, at the instigation of Dr. Holland, presented a neatly mounted example (cast) of the hind limb of Diplodocus to the University Museum, St. Andrews—another of the very munificent donations which mark the period of office of the late Rector of the University.

As the contributions toward the re-endowment of Oxford University have reached a total of more than 100,000*l.*, the second donation of 10,000*l.* promised by Mr. W. W. Astor has now been received by Lord Curzon of Kedleston, the chairman of the fund.

ON July 10 the administrative staff of the technological branch of the Board of Education will remove from South Kensington to the new offices of the Board in Westminster. All correspondence on and after July 9 should be directed to the secretary, Board of Education, Whitehall, with the exception of letters for the Victoria and Albert Museum, the Royal College of Art, and the Solar Physics Observatory, which should continue to be addressed to the offices of the Board of Education, South Kensington.

ON Tuesday, July 7, the King, accompanied by the Queen, opened the new buildings of the University of Leeds. In the course of his reply to an address presented by the Vice-Chancellor, the King said:—" My interest in the great cause of education is well known, and I note with gratification the ever-widening basis of the instruction now undertaken by our great educational institutions. The high standard of moral and intellectual discipline for which our schools and universities have been distinguished has not been lowered, nor has the pursuit of literary and historical studies been checked by the inclusion in the university curriculum of those scientific studies, and especially of those branches of applied science for which such ample provision has now been made. I rejoice to think that the opportunities open to the young men of our great industrial communities of acquiring a knowledge of subjects of commercial utility in an atmosphere of academic culture are being so greatly increased, and I find it difficult to express my appreciation of the manner in which the great responsibilities which rest with the authorities and teachers of a university such as this have been discharged. It is a source of pleasure to me to know that you have provided also for the study of the theory and practice of agriculture, for I am convinced that the best possible results cannot be derived from the industry and natural ability of our farmers unless they are properly instructed in the scientific aspects of their work." When the University was founded, the Privy Council stipulated that a building fund of 100,000*l.* should be formed, and this amount has now been raised. The new buildings include a number of independent blocks, namely:—(1) extension of main buildings, providing accommodation for arts subjects, zoology, and botany, including new botanical and zoological laboratories; (2) extension of present engineering laboratory in a separate large wing at the rear of the main building; (3) large new block of buildings for electrical engineering; (4) large new block of buildings for mining, fuel, and metallurgy; (5) large temporary building for physical laboratory and organic chemistry laboratory. Increased support from the Treasury is needed if the work provided for in these new buildings is to be carried on efficiently. We hope to give an account of the new buildings in our next issue.

## SOCIETIES AND ACADEMIES.

### LONDON.

**Entomological Society**, June 3.—Mr. H. Rowland-Brown, vice-president, in the chair.—*Exhibits.*—H. St. J. **Donisthorpe**: Pseudogynes of *Formica sanguinea*, caused by the presence of the beetle *Lomechusa strumosa* in the nest, from the New Forest.—H. J. **Turner**: Living larvæ of *Coleophora maritimella* on *artemisia*, and also a species of Asilidæ and its prey.—C. J. **Gahan**: (1) Living specimens of a "leaf-insect" from the Seychelles, bred in England by Mr. St. Quentin, probably *Pulchriphyllium crurifolium*, S.; (2) some Lampyridæ of considerable interest collected by Mr. E. E. Green in Ceylon, and including both sexes of the genera Lamprigera and Dioptoma, the females of which had hitherto been unknown, those of both genera being larviform. Attention was directed also to the existence in China, Ceylon, and the Malay Peninsula of remarkable larviform females greatly resembling in form the females of the American group Phengodini, and being somewhat similarly provided with rows of luminous points. G. C. **Champion**: Specimens of *Dromius angustus*, Brullé, and *Cryptophagus lovendali*, Ganglb., recently recorded by him from Woking and the New Forest respectively; also two species of the Staphylinid genus Leptotyphlus and one of the Curculionid genus Alaocyba, the exhibitor mentioning that these extremely minute blind insects were much smaller than any known British representatives of the S. European groups in question.—Colonel C. **Swinhoe**: Several boxes of butterflies taken during the present year (1908) in the Canary Islands, chiefly from Grand Canary and Teneriffe. Colonel Swinhoe observed that, with the exception of *Lycaena webbianus*, all the species met with suggest a foreign origin.—*Papers.*—Notes on the value of the genitalia of insects as guides in phylogeny: W. **Wesché**.—Certain Nycteribiidæ, with descriptions of two new species from Formosa: Hugh **Scott**.—Further studies of the Tetriginæ (Orthoptera) in the Oxford University Museum: Dr. J. L. **Hancock**.—Mimicry in tropical American butterflies: J. C. **Moulton**.—Heredity in *Papilio dardanus* from Natal, bred by Mr. G. F. Leigh, of Durban: Prof. E. B. **Poulton**.—New species of Hesperiidæ from Central and South America: H. H. **Druce**.

**Royal Meteorological Society**, June 17.—Dr. H. R. Mill, president, in the chair.—The Hong Kong typhoon of September 18, 1906: L. **Gibbs**. Judged by anemometer records, the typhoon was by no means a severe one, as the highest average hourly wind velocity was seventy miles.—An elementary explanation of correlation, illustrated by rainfall and depth of water in a well: R. H. **Hooker**.

**Chemical Society**, June 18.—Sir W. Ramsay, K.C.B., F.R.S., president, in the chair.—The thermal decomposition of hydrocarbons, part i., methane, ethane, ethylene, and acetylene: W. A. **Bone** and H. F. **Coward**. The results of a systematic investigation of the modes of decomposition of the four hydrocarbons at temperatures between 500° and 1200° were described, and it was shown that methane, which is by far the most stable of the four hydrocarbons, and a principal product of the decomposition of the other three, decomposes for the main part directly into carbon and hydrogen. The methane formed during the decomposition of the other three hydrocarbons can be explained on the supposition that "residues" such as $:CH$ and $:CH_2$ are directly "hydrogenised" in an atmosphere rich in hydrogen.—The rusting of iron: W. A. **Tilden**. It was shown that (1) oxygen or air with liquid water are alone necessary to produce rusting of iron; (2) that water alone attacks iron slowly, producing a film of what is probably ferrous hydroxide; (3) that iron rust always contains ferrous oxide; and (4) that rusting is due in the first instance to electrolytic action, promoted in all ordinary cases by the existence of carbonic acid in water exposed to the air, and by the presence in iron of various compounds of carbon, silicon, phosphorus, and sulphur.—Studies on zirconium: E. **Wedekind** and S. J. **Lewis**.—The constituents of Canadian hemp, part i., apocynin: H. **Finnemore**. The principal constituent of the root of *Apocynum cannabinum* is identical with the crystalline apocynin of commerce, which is identical with the acetovanillone obtained by Tiemann from *iso*eugenol, and

M·O

has the constitution HO  CO.CH$_3$.—A new synthesis of apocynin: H. **Finnemore**. The author has synthesised this substance from vanillin by an application of the Grignard process.—The constitution of diazonium perbromides: F. D. **Chattaway**.—Cholestenone: C. **Dorée** and J. A. **Gardner**. Cholestenone produced by the oxidation of cholesterol reacts with ozone, giving an ozonide which probably has the formula $C_{27}H_{44}O.O_7$. This, when decomposed by water, gives carbon dioxide and a ketomonocarboxylic acid, $C_{26}H_{42}O_3$, identical with that obtained by Windaus. Cholesterol on similar treatment gives an ozonide, $C_{27}H_{46}O.O_3$, which also evolves carbon dioxide on treatment with water.—Solubility of silver chloride in mercuric nitrate solution: B. H. **Buttle** and J. T. **Hewitt**. Morse's view that when mercuric nitrate is present in large excess, chlorine occurs only as $HgCl^{\cdot}$ ions, is confirmed.—The relation between absorption spectra and chemical constitution, part ix., the nitroso- and nitro-groups: E. C. C. **Baly** and C. H. **Desch**.—Benzeneazo-2-pyridone: W. H. **Mills** and Miss S. T. **Widdows**.—The electrolytic chlorination of the salts of some organic acids: J. K. H. **Inglis** and F. **Wootton**.—The action of nitrous gases on di*cyclo*pentadiene: A. **Rule**. The gaseous products from the action of nitric acid on arsenious oxide bring about the formation of a mixture which on separation by means of alcohol was found to consist of the ψ-nitrosite and the dinitro derivative of the hydrocarbon.—An alternative structure for the supposed stereoisomeric α-osazones: F. D. **Chattaway**.—The formation of 4-pyrone compounds from acetylenic acids, part ii.: S. **Ruhemann**.—The fluorescence of platinocyanides: L. A. **Levy**. Barium platinocyanide exists in two forms identical in crystalline form, but which exhibit a remarkable difference in physical properties. One variety is golden-yellow, and only very slightly fluorescent, the other being bright green and very fluorescent. The two forms have the same chemical composition, and are isomeric modifications. Similar phenomena are exhibited by the calcium salt, and to a certain extent by the cerium salt.—The preparation of disulphides, part ii., the action of alkalis on sodium alkyl thiosulphates: T. S. **Price** and D. F. **Twiss**. The interaction between alkalis and sodium ethyl and benzyl thiosulphates in aqueous solution has been studied. The chief organic product of the action in each case is the corresponding disulphide, the main step of the reaction being probably represented by the equation

$$R.S_2O_3Na + NaOH = RS— + Na_2SO_3 + —OH.$$

—Note on the formation of lead ethoxide: F. M. **Perkin**. When thin sheets of lead are boiled in alcohol or suspended in the vapour of boiling alcohol no action takes place, but if they are suspended over absolute alcohol and ozone is bubbled through it, in a short time the surface of the lead becomes tarnished, and then assumes a brownish-yellow colour due to the formation of lead ethoxide, $Pb(OEt)_2$.—Some reactions of phenylhydrazine with metallic cyanides and other salts: R. de J. F. **Struthers**. Phenylhydrazine in alcoholic solution combines with cuprous cyanide in ammoniacal solution to form an insoluble compound, $2CuCN,3C_6H_5.NH.NH_2$. Cobalt cyanide exerts a powerful catalytic action on phenylhydrazine, 0·03 gram to 0·04 gram sufficing to determine the decomposition of 5 c.c. or 6 c.c. of phenylhydrazine with almost explosive violence. Nickel cyanide has a similar but less powerful action.—The formation of polyiodides in nitrobenzene solution, part iii., the chemical dissociation of the polyiodides of the alkali metals and ammonium radicals: H. M. **Dawson**.—The hydrolysis of amygdalin by emulsin, part ii.: S. J. M. **Auld**. It is shown that amygdalin is derived from an αβ-disaccharide, the β-dextrose residue being attached to the benzaldecyanohydrin nucleus. Mandelonitrile glucoside is formed as an intermediate product during the hydrolysis of amygdalin by emulsin, the biose ether-linking breaking preferentially.—A new form of potash bulb: A. E. **Hill**. This is figured in the Proc. Chem. Soc., xxiv., 182.

EDINBURGH.

**Royal Society**, June 15.—Dr. R. H. Traquair, vice-president, in the chair.—The reducing action of electrolytic hydrogen on arsenious and arsenic acids when liberated from the surface of different metals: W. **Thomson**. The hydrogen liberated from the five metals lead, zinc, cadmium, tin, and silver converted arsenious acid ions into arseniuretted hydrogen with about equal velocity. The reaction could be measured during small intervals of time, and the velocity of reaction was practically that of a unimolecular reaction. Arsenic acid was much more difficult to reduce than arsenious acid. Lead, however, converted it into arseniuretted hydrogen with a velocity nearly equal to that with which it reduced arsenious acid. Zinc, with a higher supertension equivalent, reduced it at only about a third of the velocity, whilst silver reduced none at all under the conditions of the experiment.—The theory of the microbarograph, and on some observations with the Dines-Shaw instrument: Prof. **Chrystal**. The mathematical theory, which was an application of the laws of viscosity of gases, showed that with external pressure increasing at a steady gradient the microbarograph tended to a maximum, that a wave-like variation of pressure was recorded on the instrument with the crests and troughs preceding in time the corresponding rounded crests and troughs in the external variation, but that with a sharp, abrupt change in the rate of change of the pressure the corresponding pinnacles and troughs on the instrumental record occurred simultaneously with the external changes. Observations had been made at three stations in the neighbourhood of Lochs Tay and Lochearnhead with the object of measuring the rate of progression of rapid oscillations of pressure across the district. It was found that the majority of these were from the west, in this respect resembling cyclonic depressions, and that their speeds of progression also varied within much the same limits which characterised the progression of cyclones.—The effects of chloroform on the metabolism: Prof. Noel **Paton**. The object of the paper was to study the conditions under which late chloroform poisoning occurred. From a series of experiments on the administration of chloroform to dogs by the respiratory passages, by the stomach, and under the skin, the conclusions were drawn that when given by the mouth and hypodermically chloroform acted as a poison, decreasing the activity of the liver, but that when administered through the respiratory passages it increased the disintegration of the protein in the body and stimulated the liver. The reason of this was demonstrated in a second paper, by Miss Dorothy **Lindsay** and Prof. **Paton**, in which it was shown that chloroform given by the lungs was rapidly taken up and rapidly eliminated, but when administered by the other methods it was slowly taken up and slowly eliminated, and got fixed to the liver in large quantities.—Asteroidea, Ophiuroidea, and Echinoidea of the Scottish National Antarctic Expedition: Prof. **Koehler**. Of the ninety-four species collected, seventy-six were records from Antarctic and sub-Antarctic regions, including forty-one new species and two new genera.—Holothuroidea of the Scottish National Antarctic Expedition: Dr. Clement **Vaney**. Of the thirty-four species described twenty-one were new. Nearly all the new species are from very high southern latitudes, and from depths of 1400 to 2600 fathoms. Both these papers were communicated by Dr. W. S. Bruce.

PARIS.

**Academy of Sciences**, June 29.—M. Bouchard in the chair.—Observation of the partial eclipse of the sun of June 28, 1908, at the Observatory of Paris by various observers: B. **Baillaud**. Observations were made of the contacts and length of the common chord of the two discs, and numerous photographs were taken. The observers were MM. Bigourdan, Schaumasse, Chatelu, Popoff, Puiseux, and Baillaud.—Decomposition of the alcohols under the catalytic influence of wood charcoal (braise de boulanger): Georges **Lemoine**. Details are given of the products obtained by the catalytic decomposition of methyl, ethyl, normal propyl, isopropyl, and isobutyl alcohols in presence of charcoal. The results varied somewhat with the nature of the charcoal employed, but the main reaction was the production of hydrogen and the aldehyde, differing from the reaction with purified animal charcoal, the latter giving chiefly water and the corresponding olefine. The temperatures at which the decompositions took place were considerably lower than those at which the alcohol was decomposed in the absence of charcoal.—A new mineral species and the minerals which accompany it in the tourmaline layers of Madagascar: A. **Lacroix**. The new mineral is a silicate of aluminium, calcium, beryllium, magnesium, lithium, sodium, and potassium, the formula proposed from the analyses being

$$10SiO_2,8Al_2O_3,5 \cdot 5(Ca, Be, Mg)O,1 \cdot 5(Li, Na, K)_2O,7H_2O,$$

and for which the name bityite is proposed.—A new rheograph designed for the projection of the curves of alternating currents: Henri **Abraham** and J. **Carpentier**. The instrument is on the lines of one described in 1897, and is distinguished by the fact that its moving parts are relatively heavy, and capable of carrying a mirror of large surface. A demonstration of the apparatus was given before the academy.—Electrocapillary measurements by the method of large drops: M. **Gouy**. The capillary electrometer giving only relative figures, the present paper is concerned with absolute measurements. The drop of mercury must be rigorously hemispherical, and this was secured by carrying it in a glass vessel, optically worked, of 40 mm. radius. Results are given for solutions of sulphuric acid, sodium sulphate, hydrochloric acid, and the iodide and bromide of potassium.—The action of metallic oxides on the primary alcohols: Paul **Sabatier** and A. **Mailhe.** The oxides examined fall into four groups:—(1) not undergoing reduction, and exerting no appreciable effect on the primary alcohols under 400° C.; (2) those rapidly reduced by the alcohol to the metal or lower oxide; (3) those which are not reduced, but decompose the alcohol catalytically into aldehyde and hydrogen, or ethylenic hydrocarbon and water; (4) oxides slowly reduced, exerting a catalytic action. The detailed results will be given in a later paper.—Observations on the sun made at the Observatory of Lyons during the first quarter of 1908: J. **Guillaume.** Observations were made on forty-one days, and the results are given in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—Ruled surfaces: A. **Demoulin.**—The canonical products of infinite genus: Arnaud **Denjoy.**—The partial differential equation of vibrating membranes: M. **Sanielevici.**—The existence of spark lines (enhanced lines) in flames at various temperatures, and on the modifications which they undergo: G. A. **Hemsalech** and C. **de Watteville.** The intensity of numerous iron lines has been studied by the authors' method in flames of different temperatures (air-coal gas, oxygen-coal gas, and oxygen-hydrogen), and it is found that the spark lines are most marked in the coolest flame, air-coal gas, and hence it is concluded that the action of the temperature cannot be considered as the fundamental factor in the production of the enhanced lines.—The preparation of the alkaline chloroiridites: M. **Vèzes.** A claim for priority against M. Marcel Delépine.—The molecular weights of the phosphoric acids determined by cryoscopy: H. **Giran.** The molecular weights found in acetic acid solution fall with the age of the solution; the true molecular weight for each acid at the moment of solution is deduced from a time curve. The formula deduced from these experiments for metaphosphoric acid is $5(HPO_3)$, for pyrophosphoric acid $3(H_4P_2O_7)$, and for orthophosphoric acid $2(H_3PO_4)$.—The magnetic oxides of chromium: Ivan **Shukoff.** From the magnetic properties of the mixture of oxides obtained by gently heating chromic anhydride, there would appear to be a magnetic oxide of chromium of the composition $Cr_4O_9$.—The tellurides of arsenic and bismuth. The cryoscopic constant of tellurium: H. **Pélabon.**—The mechanism of the synthesis of the cyclic nitrogen compounds: L. J. **Simon.**—The method of Messinger and Vortmann for the estimation of some phenols. The separation of salicylic acid: J. **Bougault.** By the action of iodine and an alkali upon salicylic acid, a red, insoluble substance is produced, which can be used for the quantitative determination of salicylic acid.—Three new primary alcohols resulting from the condensation of sodium benzylate with propyl, butyl, and isoamyl alcohols: Marcel **Guerbet.**—Researches on *bis*-azoic compounds: H. **Duval.**—The products of condensation of *ortho*- and *para*-nitrobenzyl chloride with acetylacetone: M. **Mech.**—The origin of the colouring matter of red grapes and other vegetable organs: J. **Laborde.**—The oxidation of eugenol by the oxidising ferment of fungi and by perchloride of iron; the preparation of dehydroeugenol: H. **Cousin** and H. **Hérissey.** Oxidation of eugenol both by ferric chloride and by the biochemical method gives a new phenol, dehydrodieugenol, the acetic and benzoic esters of which are described.—The influence of certain combinations of iron compared with the peroxydases in the catalysis of hydriodic acid by hydrogen peroxide: J. **Wolff** and E. **de Stœklin.**—The influence of the temperature of sterilisation of must and that of fermentation on the bouquet of wines: A. **Rosenstiehl.** Both the temperature of sterilisation and of fermentation of must can be lowered with advantage to the quality of the wine produced.—The comparative development of tubercles and roots: G. **André.**—The development of the notochord in the bony fishes: Louis **Roule.** From a study of the development of the notochord in the common perch (*Perca fluviatilis*), the author comes to the conclusion that there is not a complete homology between the notochord of Vertebrates and Tunicates.—Bulbular epistasy of nasal origin: Pierre **Bonnier.**—The geology of eastern Corsica: Pierre **Termier** and Eugène **Maury.**—The rameal origin of ulodendroid cicatrices of *Bothrodendron punctatum*: Armand **Renier.**—Report of the committee appointed to consider the distribution of the Bonaparte fund for 1908.

NEW SOUTH WALES.

**Linnean Society,** April 29.—Mr. A. H. S. Lucas, president, in the chair.—A revision of the Australian species of Adelium (Coleoptera): H. J. **Carter.** When Blessig reviewed the Australian Heteromera in 1862, fifteen species of Adelium were recognised. In the meantime, the number of described species has increased to eighty. The opportunity of comparing his collection with types in the British Museum and in the Paris and Brussels Museums during a recent visit to Europe had enabled the author to submit the species to a critical revision, the outcome of which is a proposed reduction of the number to fifty-four, by the reference of ten species to other genera, and the omission of synonyms. It is also noted that the so-called species of Adelium of New Zealand and New Caledonia belong to different genera, so that it is probable that the genus Adelium is confined to Australia and Tasmania.—A revision of the Thynnidæ (Hymenoptera) of Australia, part ii.: R. E. **Turner.** Part ii. of the revision deals with the genus Thynnus. The species are very diverse in appearance and structure, but it is thought to be best, in the present state of knowledge, to group them in subgenera rather than to propose an excessive number of new genera, some of which might have to be sunk when additional material is available. The Australian species number 213, and fall into ten subgenera.

## EXPERIMENTAL ENTOMOLOGY.

*Experimentelle Entomologische Studien vom physikalisch-chemischen Standpunkt aus.* By Prof. P. Bachmetjew. Zweiter Band; mit 25 Tafeln. Pp. xvi+944+cviii. (Sophia: Staatsdruckerei, 1907.)

ALTHOUGH it is well known that many excellent observers have of late years devoted their attention to experimental work of which insects are the subject, it is probable that few students of entomology have realised hitherto how large is the mass of material that has now been accumulated in this department of research. The present work is somewhat of a revelation. Its tale of nearly a thousand pages consists almost entirely of a condensed account of the investigations conducted by various experimenters on the influence of external factors on the phenomena of insect life. Even so, the list is not quite complete, for, though the author, working under many difficulties, has displayed an amount of industry in collecting his material that is really astonishing, we could yet name more than one memoir bearing on the subject that seems to have escaped his vigilance. We note, for example, the omission of any reference to the striking experiments of Mr. G. A. K. Marshall on South African Lepidoptera. Nevertheless, the compilation has, on the whole, been admirably executed, and Prof. Bachmetjew's bulky volume will be indispensable to those workers in the subject who wish to have the results of nearly all previous investigations in a readily accessible form. The amount of labour saved to his colleagues in entomology by the author's determination to record every relevant fact hitherto ascertained by experiment is quite incalculable.

The work is divided into two parts, the first dealing with the actual results obtained by various investigators, the second giving the theoretical conclusions considered by these and other authorities to be warranted by the experiments in question. As might be expected, these speculative opinions are of very unequal value, and it is to be observed that the author makes little or no attempt to decide between them when they are contradictory, or to condemn them when erroneous. He has rather set before himself the task of recording without distinction, not only every fact relating to his subject, but also every conclusion at any time suggested, whether the latter be good or bad. His own views, save on a few points, are not much in evidence. It is clear from this that the book has serious limitations; these, however, do not prevent it from being extremely useful within the scope allowed it by its author. The insects dealt with naturally belong almost entirely to the order of Lepidoptera.

The effects of the various external factors are considered in their relation to the time occupied in development, to the size and form of the perfect insect, and to its ultimate colouring and pattern. Under each of these main heads the influence is considered of climate, moisture, temperature, light, the colouring of the surroundings, food, including chemical food-material artificially employed, electricity, magnetism, friction, artificial constriction, pressure, gravitation, and other factors.

The author defers to a future treatise the questions of seasonal dimorphism, protective resemblance, mimicry, and parthenogenesis. The omission of these subjects, especially of the first three, marks a further limitation of an important character, for they often have a special bearing on the interpretation of such facts as are here recorded. Indeed, inasmuch as an appreciation of the significance of the changes induced by the operation of external factors is often entirely dependent on a knowledge of the insect in question in its relation to seasonal, mimetic, and cryptic conditions, the present treatise, useful as it is, can only be considered as a partial introduction to the theory of the subject.

The book is fitly dedicated to Dr. Max Standfuss, of Zürich, whose experiments, conducted on a very large scale, have, perhaps, done more than those of any other investigator to establish our knowledge of the effects of temperature applied during the immature stages on the form and colouring of the perfect insect. His experiments in hybridisation, although carried out before attention had been generally directed to the epoch-making work of Mendel, are also very worthy of note. Next to Standfuss's experiments, perhaps the most important work of this nature is that conducted through many years by Mr. F. Merrifield at Brighton, and we are glad to see that due prominence is given to his admirable investigations in Prof. Bachmetjew's pages. Among other work carried out by English experimenters is that of Prof. Poulton, which also comes in for appreciative notice, but here we cannot fail to observe the somewhat unfortunate effect of the author's determination to reserve the question of protective coloration for future treatment. Much of the significance of Poulton's results on the effect of surrounding objects on the colouring of larvæ and pupæ is thus for present purposes lost. It is from their bearing on evolutionary problems that data of this kind derive their highest interest, and we must once more remark on the opportunities thus missed by the author. We may hope, however, that the omission is only of a temporary character, and that we shall yet see a treatise from his hand which will throw fresh light on many questions of primary importance in the study of evolution.

The plates consist for the most part of graphic representations of the statistical results furnished by the tables in the body of the work. They are useful as exhibiting series of facts in a form which by most people is more easily appreciated than a bare numerical statement.

It will have been gathered from the foregoing remarks that Prof. Bachmetjew's volume is mainly designed as a work of reference. In accordance with this plan, the literature of the subject has been very carefully catalogued, and the bibliography, which occupies seventy-seven pages at the end of the book, besides occasional lists given in the text, is of a very full description. It is true that there are omissions, but these do not appear to be numerous.

The author is already favourably known for his excellent *résumé* of observations and experiments relating to temperature in insects, this, with the present volume, constituting the first two instalments of his projected "Experimental Studies in Entomology." The production of the third volume of the series will be awaited with interest. F. A. D.

## INFINITE SERIES.

*An Introduction to the Theory of Infinite Series.* By T. J. I'A. Bromwich. Pp. xvi+511. (London: Macmillan and Co., Ltd., 1908.) Price 15*s.* net.

THE first impression this book is likely to produce is that, considering its title, it is very big. However, it is not diffuseness that is to blame for this; the fact is that quite a third of the volume consists of matter that does not strictly come under the title, but is either introductory or supplemental. Thus we have an appendix dealing with irrational numbers and limits; another on logarithms and exponentials; a third on infinite integrals and gamma functions.

It is pleasant to find the author adopting Dedekind's definition of an irrational number, the only one which is really scientific. In the second appendix, the exponential function is introduced after the logarithm, but as the latter is defined by an integral, this does not matter much. There can be little doubt that for methodical treatment, the integral definition of $\log z$, with the elements of the theory of complex integration, is by far the most satisfactory; and it does not introduce any gratuitous difficulties. The third appendix is interesting, because it introduces recent results obtained by the author, Mr. Hardy, and others, which illustrate very clearly how the problems of series are complicated when we pass to integrals over an infinite range. In passing, it may be observed that Mr. Bromwich refers with due appreciation to Mr. Gibson's excellent text-book on the calculus.

Passing on to the main subject of the book, it is curious to note how much there is that is comparatively recent. Of course, Abel and Cauchy were the great pioneers; but if we take, for instance, the distinction between uniform and non-uniform convergence, this does not seem to have been fully recognised before Stokes's paper of 1847 (see Mr. Bromwich's note, p. 115); and the new definitions of the "sum" of a divergent series are creations of yesterday.

The subject last mentioned is discussed in chapter xi., mainly after Borel and Cesàro, and is a good example of the extension of mathematical terms. Borel gives a process by which, from a divergent series (or sequence) $\Sigma$, we can in certain cases find an expression $S(\Sigma)$ which is finite. Moreover, if $\Sigma$ is a convergent series, $S(\Sigma)$ is the sum in the ordinary sense, and if $S(\Sigma)$, $S(\Sigma')$ exist, then $S(\Sigma+\Sigma')=S(\Sigma)+S(\Sigma')$. Mr. Bromwich makes some very interesting comparisons between this recent theory and some of Euler's transformations of divergent or oscillating series. Like Fourier, Euler had a wonderful instinct, which led him right, even when his logic was defective.

It is fairly plain that, with the exception of convergent series, there is no one definition of the sum superior to all others; different definitions may be useful for different purposes. Again, with regard to ordinary series, there is no universal test for convergency, except, of course, the definition; and the same remark applies to integrals with infinite limits. Oddly enough, one of the most useful tests for the convergence of a series (p. 35) is practically due to Gauss.

One of Mr. Bromwich's great merits is that he constructs examples to show the fallacy of various plausible assumptions which have occasionally misled even the elect. For instance (p. 99), we have a product $\Pi(1+u_n)$ which is convergent, although $\Sigma u_n$ and $\Sigma u_n^2$ both diverge. The discussion of double series is also very instructive. The fact is that any actual case of summation is the construction of a linear sequence $s_1$, $s_2$, $s_3$, &c.; so-called derangements or permutations of series are best regarded as constructions of new series, the terms of which have a one-one correspondence to those of the first. Two series thus related may, or may not, have the same sum.

Attention should be directed to the discussion (pp. 157–60) of certain Fourier series, especially as to the limiting form of the curve

$$y=\sin x+\tfrac{1}{2}\sin 2x+\ldots+n^{-1}\sin nx,$$

when $n$ increases indefinitely. Reference might have been made to the correspondence in NATURE, vol. lix. (1898), in which Willard Gibbs and Prof. Michelson took part. The point is that the limiting form is not a mere zig-zag but a zigzag with projecting spines.

Finally, a word may be said about the examples, which are very numerous and diversified. It is perhaps a trifling matter in itself, but to some minds it will give satisfaction, that as modern analysis is becoming assimilated, illustrations of it are being produced which have something of the elegance and individual beauty of the Cambridge or Oxford problem of years gone by. After all, a plant must grow before it flowers. G. B. M.

## STUDIES IN EDUCATION.

*The Demonstration Schools Record.* Being Contributions to the Study of Education by the Department of Education in the University of Manchester. No. 1. Edited by Prof. J. J. Findlay. Pp. xvi+126. (Manchester: The University Press, 1908.) Price 1*s.* 6*d.* net.

THE work before us is to be regarded rather as an introduction to future issues of the "Record" than as an arranged and classified record of the results of educational observation and experiment. Here the authors take us into their confidence; we are told what their view of a demonstration school is, what questions they hope to solve, and on what principles they think the answers should be sought. When the future volumes are available the record will be one in which full confidence can be placed; it will not be a statement of partial facts selected consciously or unconsciously to fit a particular theory. For this reason, as well as for the clear statement of some of the educational problems involved, those interested in educational progress will give the volume a cordial welcome. At the same time, it seems a little doubtful whether such facts should be published as that not only the mental achievements, but the "nature, instincts, experience, *and ideals*" of each child are noted and tabulated by the students in training. The files are no doubt kept with scrupulous privacy under lock and key. But if through parents buying the book and leaving it about, or talking about it, the children get to know of this dissection, the injury to character might be serious.

The general scheme of the school work will have the full approval of modern educationists, who will envy Prof. Findlay and his colleagues the opportunity of putting their theories into practice. Particularly valuable are Prof. Findlay's observations on the relation of the school to civic and corporate life, and especially his conviction that the parents are to be brought into the closest possible touch with the educational as well as the social aspects of the school work. It is indeed only when we have educated the parents that we can hope to have the full measure of success in educating the children.

As to details, the scheme of science teaching seems excellently conceived. That of French shows careful work in accordance with the direct method, the psychology of which is so well explained by Prof. Findlay's paper (reproduced p. 69). It is to be hoped that in future issues the relation of practice to theory will be dwelt on; for instance, one wants to know *how* "the general efficiency of the school *in other departments* affects vitally the success or failure" of the French teaching (p. 71). The scheme for history and handwork combined has at least the merit of boldness. With the object of increasing the sympathy with social rather than personal interests, biography has been discarded, and interest in the material world takes its place until the children are nine years old. From six to seven some elementary facts about the food, clothing, housing, &c., of present-day life are taught, with practical applications. From seven to nine the children are "prepared for more systematic study of the historical beginnings of the nation to which they belong" by being made to imagine themselves first as Tree-people, then as Cave-dwellers, then as Red Indians, then as pastoral tribes, and lastly as Saxons, and there is plenty of scope for handwork in reproducing the material conditions of the life of the different periods. Then, judging from the record, it would seem that at nine they are plunged straight into the *details* of the history and literature of the period from 1625–1660. For 1908 this was apparently the course for all children from nine to fourteen years of age.

The chapter on the social aspects of child study is not convincing, and scarcely seems to have been written in such close contact with the life of the school as the others. It shows a tendency to vague language and uncertain generalisations which seem out of place in the record of a demonstration school.

It is legitimate to hope that the future volumes will answer more of the questions they raise.

## ELEMENTARY ELECTRICITY.

*An Introduction to Electricity.* Being a translation of the second edition of "Einfuhrung in die Elektrizitatslehre," with corrections and additions by author. By Bruno Kolbe. Translated by Joseph Skelton. Pp. xii+430. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1908.) Price 10*s.* 6*d.* net.

THE editor offers this volume as a satisfactory introduction to the science, both for students and for "the man in the street." So far as the former is concerned, the claim may be dismissed at once; the book is too inaccurate; and the "man in the street" must have a remarkable mind if he gets what he wants from Prof. Kolbe. We should have imagined that he required a clear statement of principles, and was not greatly concerned with experimental evidence. Prof. Kolbe gives him an overwhelming mass of experiment—(it is only fair to say that the experiments are often highly ingenious)—accompanied by confusing and misleading deductions.

Comprehension is rendered more difficult by the failure of the translator to eliminate the syntax of the original. We may be misrepresenting the author, but the following argument appears to be a simplified form of his treatment of the fundamental conceptions, charge, potential and capacity. Unit charge is defined as that on a certain proof ball after contact with a certain conductor charged to its spark potential. Successive charges are communicated to an electroscope, and a scale defining the magnitude of charges is graduated. The electroscope is then connected by a wire to various points of a charged conductor; the constant reading is defined as the "degree of electrification" (potential) of the conductor. It will be noted that in order that these definitions may agree with those used in stating the fundamental theorems, the capacity of the electroscope must be infinite in comparison with that of the proof ball, and infinitesimal in comparison with that of any conductor of which the potential is to be measured. After a long digression we come to capacity, for which two electroscopes measuring potential are required. The author appears to graduate the scales as before, and to assume that similar readings denote similar "degrees of electrification"; of course they will do so only if the capacities of the electroscopes are the same. After another chapter and a half we find the ordinary definitions of charge and potential; the former is shown experimentally to agree with that adopted previously (experimental complications are unknown to the fortunate author); but though the quantitative agreement of the latter with "degree of electrification" is asserted and assumed subsequently, no attempt is made to prove it. No indication is given of the connection of potential with field strength. In rejecting symbols, Prof. Kolbe appears to have rejected the whole of the logic of which those symbols are the ordinary expression.

Two glaring blunders should be noted in the same part of the book. The author tries to prove that there can be no charge inside a solid conductor without assuming the inverse square law; of course the proof is fallacious. He also states that the action of a flame in discharging an insulator is similar to that of points on a conductor.

The remainder of the book is much better than the portion on electrostatics; but there are several errors, and, as usual, the author tries to cover too much ground. When will authors realise that there is no royal road to learning in science or elsewhere? If those who have special aptitude for these studies require years of work to grasp the fundamentals of electricity, is it likely that the "plain man" will get any good from reading 400 "elementary" pages attempting to deal with the whole subject? Such publications only increase the number of persons who talk and write about things of which they imagine themselves masters, but are in reality ignorant.

## OUR BOOK SHELF.

*Handbook of Flower Pollination, based upon Herman Müller's Work "The Fertilisation of Flowers by Insects."* By Dr. P. Knuth. Translated by Prof. J. R. Ainsworth Davis. Vol. ii. Pp. viii+703. (Oxford: Clarendon Press, 1908.) Price 31*s*. 6*d*. net.

As stated in our review of the first volume (vol lxxiv., 1906, p. 605), Knuth's "Handbook of Flower Pollination" is an encyclopædic work, and the second volume, which is now before us, dealing as it does with the various methods of pollination in fifty-six families of dicotyledonous plants, is even more directly a book of reference than the first volume, which was of an introductory nature. In this second volume the author deals seriatim with all the genera and species in the natural orders under consideration, describes the structure of the flowers in so far as it affects directly or indirectly the mode of pollination, and cites the various direct observations on pollination made by himself or others. To each species of plant is appended a list of the insects which have been observed visiting the flowers, together with a statement as to whether the insects in question were devouring or collecting pollen or sucking nectar.

The translator has facilitated the use of the volume, which will be more frequently consulted than read through, by repeating more fully the titles of the books and papers referred to than is the case in the original. Few, if any, of these references are more recent than 1898, the date of publication of vol. ii. in the German edition, though the list of references in the first volume of the translation is brought up to 1904.

No doubt the labour involved in bringing up to date the various recorded visits of insects to flowers would have been very considerable, but on points of a more general character the translator might have added some additional information in the form of footnotes. Thus in dealing with those Papilionaceæ which have so far been recognised as self-sterile, the translator might have mentioned the more recent investigations of Kirchner, and might have referred to the illuminating generalisation of that author, who found that while so many perennial Leguminosæ are self-sterile, all the self-fertile forms of Papilionaceæ are annuals which are dependent for their continued existence on each year's successful crop of seeds, and cannot, therefore, afford to be self-sterile. Similarly, in dealing with the genus Alchemilla, mention might have been made of the recent investigations of Strasburger and others on the phenomenon of apogamy so characteristic of a certain section of this genus.

A useful improvement is the addition to the translation of a list of the natural orders dealt with in this volume, which will be as welcome to English readers as the more general introductory volume has proved itself to be.

*The Theory of Ions: a Consideration of its Place in Biology and Therapeutics.* By Dr. W. Tibbles. Pp. ix+131. (London: Rehman, Ltd., 1908.) Price 2*s*. 6*d*. net.

This is a bright little book written with the object of pointing out the bearings of physical chemistry on physiological processes. Dr. Tibbles, however, like Pauli, from whose book copious quotations are made, is rather inclined to make the phenomena of ionisation and the behaviour of colloids explain too much. There is no doubt that physical chemistry will in the future make clear a good deal of what is at present obscure in bio-chemistry; but a full appreciation of this effect cannot be gained until two things have occurred; one of these is a settling of the many vexed points of quite a fundamental nature between the physical chemists themselves, and the other is a fuller knowledge of the chemistry of protoplasm in general and of the protein constituents of protoplasm in particular.

At the present day there is probably only one sentence in the book with which all will be in agreement, and that is, "We are far from a satisfactory insight into the nature of the effect of ions."

The author gives a fairly accurate account of the advances recently made in physiological chemistry, although it will probably be found too compressed to appeal to any but those fully up in the subject. His nomenclature is not uniform, and is therefore confusing to the reader; thus he sometimes speaks of proteins, sometimes of proteids; in some places of amino- and in others of amido-acids; there are a number of uncorrected press errors, for instance, glycyl-glycyl for glycyl-glycine. The close similarity of the words absorption and adsorption should have rendered him especially careful in proof-correcting, especially where both are mentioned on the same page. He also gives us the rather startling information that choline is present in bile salts.

The work does not profess to contain anything original; it is rather a compilation from previous writers strung together with the object of emphasising the importance of a knowledge of solutions in the elucidation of physiological, pathological and therapeutical problems. Dr. Tibbles is not always judicious in his selections or judicial in their valuation. For instance, the old theories of Pflüger, Latham, Loew, and others on the distinction between living and dead proteins are all advanced as though they were still tenable and of equal value with the views of Fischer which depend on actual work and not on mere speculation.

Still, the book is interesting, and contains many suggestions of importance, but the author has not realised that it is not possible to write a complete text-book of organic chemistry, bio-chemistry, physical chemistry, therapeutics and immunity within the short compass of 130 small pages, or that the ionic theory or any other theory, however new and attractive, is sufficient to explain the universe.

*The Libraries of London: A Guide for Students.* Prepared by R. A. Rye. Pp. 90. (London: The University of London, 1908.) Price 6*d*. net, post free 9*d*.

The libraries described in the book, with the exception of those of certain schools of the University, and that of the Royal Botanic Gardens, Kew, lie within the London County boundary. The information about each of the very large number of London libraries is just what a student wants to assist him in his search for books on a particular subject. Few persons, unless they have made special inquiries, can have any idea of the immense number of books available in London for reference by the seeker after knowledge or recreation. Students owe a debt of gratitude to the Senate of the University of London for giving instructions for the preparation of this guide, and to Mr. Rye for his complete understanding of their needs.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### The Spectrum of Radium Emanation.

In Nature of July 9 a letter from Prof. Rutherford appears giving an excellent corroboration of measurements of the spectrum of radium emanation which we communicated to the Royal Society on July 1. There can, therefore, be no doubt of the accuracy of Prof. Rutherford's measurements. When Mr. Watson, who is engaged in measuring accurately with a 10-foot grating the secondary spectrum of hydrogen, has finished his task, we shall be able to introduce some small corrections in our figures.

### The Kinetic Energy of the Ions emitted by Hot Bodies.

In a paper communicated to the American Physical Society at the New York meeting on February 29, the writer, in collaboration with Dr. F. C. Brown, showed that the part of the translational kinetic energy of the negative ions emitted by hot platinum, which depends on their component of velocity normal to the emitting surface, has the same mean value as the corresponding quantity for a molecule of gas at the temperature of the metal, and, further, that that component of the velocity is distributed among the different ions according to Maxwell's law of distribution of velocity among the molecules of a gas. Since then Dr. Brown has succeeded in showing that the same laws hold for the positive ions emitted by hot platinum.

Using a different method, the writer has succeeded in measuring the portion of the kinetic energy of the ions which depends on their component of velocity parallel to the emitting surface. Within the limits of experimental error, this quantity has the same mean value, for both positive and negative ions, as the corresponding quantity for a molecule of gas at the temperature of the metal, and is distributed among the different ions according to Maxwell's law.

Taken together, these investigations show that the ions emitted by hot platinum, under normal conditions, are identical, as regards their kinetic properties, with the molecules of a gas of the same molecular weight, at the temperature of the metal. It follows, by an application of the kinetic theory of gases, that the same thing holds for the free electrons inside the metal. This result has an important bearing on the electron theory of metallic conduction and of the emission of electromagnetic radiation by hot bodies.

This is the first direct experimental confirmation of Maxwell's laws relating to the distribution of velocity among a collection of moving particles in a state of statistical equilibrium.

The full account of these researches will shortly appear in the *Philosophical Magazine*.

### Absorption of X-Rays.

Some of the most interesting observations made in the investigation of the properties of homogeneous beams of Röntgen radiation are those exhibiting the connection between the absorption of X-rays and the emission of secondary X-rays from the absorbing substance. Many elements—probably all—when subject to a suitable primary beam, are the source of a homogeneous Röntgen radiation which is characteristic of the element emitting it. The following conclusions concerning the emission of this radiation have been found to be perfectly general, so far as experiments have been made.

When a very absorbable primary radiation is incident on a given element, the homogeneous radiation characteristic of that element is not emitted in appreciable intensity.

As the general penetrating power of the primary radiation is gradually increased, the absorption decreases only up to a certain point. When the penetrating power becomes greater than that of the radiation characteristic of the absorbing element, the absorption of that primary radiation begins to increase, and a secondary homogeneous radiation begins to be emitted. Then there is a rapid and considerable increase in both the absorption of the primary rays and in the emission of secondary rays. When the general penetrating power is increased still further, the absorption decreases again in the usual way, and the intensity of secondary radiation decreases at the same rate —in some cases at least—as the ionisation produced by the primary beam in air.

The special absorption of the primary rays thus connected with the emission of secondary rays is a considerable fraction of the total absorption—thus in iron the increase is about double the absorption previous to the emission of the rays.

Experiments have not been made to determine if all the extra energy absorbed appears as energy of secondary radiation, but from observations of the absorbability of the secondary radiation and of the ionisation it produces, it appears probable that a large proportion is re-emitted.

The energy re-emitted in the form of a radiation of more absorbable type is in some cases sufficient to make the total ionisation produced in an electroscope placed immediately behind a thin absorbing sheet of metal greater than that produced by the direct unabsorbed primary beam.

The emergent radiation is then a mixture of two homogeneous radiations, the proportions of which depend principally on the coefficients of absorption of the incident radiation, and of the radiation characteristic of the metal in the metal itself, the coefficient of transformation of one into the other type of radiation, and the thickness of the absorbing plate. A copper radiation may, by transmission through an iron plate, be transformed so completely as to be almost indistinguishable from pure iron radiation, but it does not then proceed in the direction of propagation of the incident radiation; it is emitted from the atoms in approximately equal intensity in all directions.

What has previously been described as the special power of a homogeneous radiation of penetrating the element emitting it and elements of neighbouring atomic weight (Phil. Mag., September, 1907, p. 408) may be more precisely stated thus:—A radiation which is more absorbable, equally absorbable, or only slightly more penetrating to most substances than the radiation characteristic of the element upon which it is incident, is absorbed much less than one of more penetrating type. It also produces little or none of the characteristic secondary radiation which is produced by the more penetrating radiation.

The special power of an ordinary heterogeneous primary radiation after transmission through an absorbing substance of penetrating further layers of that substance is due to two causes—(1) the special absorption of those radiations capable of stimulating a homogeneous secondary radiation, (2) the superposition on the primary radiation of that secondary radiation.

A full account of these experiments and a discussion of the results will be published shortly.

## The Form of Birds' Eggs.

In NATURE of June 4 (pp. 111–3), in a paper by Prof. D'Arcy Wentworth Thompson read before the Zoological Society, April 28, the way in which form in birds' eggs is to be accounted for is discussed. Referring to the accepted causes of variation in form of eggs, Prof. Thompson says:—"Whatever truth there be in these apparent adaptations to existing circumstances, it is only by a very hasty logic that we can accept them as a *vera causa* or adequate explanation of the facts; and it is obvious to my mind that in attempting to deal with the forms assumed by matter, whether in the organic or the inorganic world, we ought first to attempt to deal on simple physical lines with the forces to which it has been subjected, that is to say, the intrinsic forces of growth acting from within, and the forces of tension and pressure that may have acted from without."

In other words, for the antecedent cause (adaptation to surroundings) is substituted modification resulting therefrom or the consequential cause; and far from it being "very hasty logic" to assume the former, it is, to my mind, hasty logic to rule it out and to substitute for it an *effect*. In any case, the consequent is not a "*vera causa* or adequate explanation," as must at once be apparent. Again, force or energy determines the "forms assumed by matter"; and in a question of this kind we cannot compare the inorganic and organic worlds, since in the latter we find conscious effort and thought an attribute, so far as we know, not applicable to the former, and in causation either can play a very effective part. In regard to adaptation to surroundings or influence of external conditions, which to all is not meaningless, we may state the following premises:—

(1) There is a distinct evolution in form from a spherical, through various forms of ellipse, to the elongated conical egg-shell of the guillemot cited.

(2) In abnormal and embryonic eggs, normally non-spherical, there is often a reversion to the spherical form.

(3) Certain types of eggs characterise birds morphologically allied, addicted to the same mode of life, and subject to the same incident physical surroundings.

(4) Correlated with identity of form is unity of type in coloration, and it seems reasonable to suppose that this is due also to influence of surroundings—arising from which adaptations, protective resemblance, &c., may become necessary.

(5) When an egg retains permanently a form that it appears reasonable to regard as suited to environment, the same type of egg is not usually found to characterise other birds habituated to a different environment.

From (5) and the preceding premises, even though partly inferential, we may logically conclude that the form of eggs is connected with environment, for experiment, indeed, shows that all types of egg but that of the guillemot will roll off a table more readily than the latter, to instance one case alone; and it is generally admitted that the most potent factor in the production of modifications is the influence of environment. Furthermore, the egg-shell is not an indispensable product of reproduction, but has become necessary as a result of the acquired characters of different species of terrestrial organisms, so that we may regard this as further evidence of the influence of surroundings upon the bird and its egg; and thus variation in nesting-site, contributing to variation in form of egg, appears to follow by means of modifications arising from the causes indicated.

The determination of a force, in fact, is antecedent to its consequential mode of action. The latter is surely not an efficient cause, but an effect of an antecedent which we *may* call an efficient cause if we like. The one is subjective, the other objective, in nature, and these cannot be substituted. Function in an organ, or mode in which an organ performs its function, is not equivalent to cause. On this and the influence of surroundings reference may be made to the writings of Sir Ray Lankester ("Embryology and Classification," pp. 36–9), on the influence of memory and energy in evolution, Prof. Cope (*Amer. Nat.*, 1882, pp. 454–60), Ribot ("Heredity"), Hyatt ("Bioplastology," pp. 60–87), Herbert Spencer ("Principles of Biology").

Whether we regard the corpuscular or germ-plasm theory as the only tenable one, or whether we favour the dynamical theory, we can, I think, in either case allow that memory persists; and if it persists can it not recall in answer to stimulus a response given by the ancestor of a species? Cells may contain or retain by virtue of memory the characters of the species, but effort or energy is no doubt the means by which a response to stimuli, causing new characters to arise (and become fixed), may be conveyed. We may regard it as feasible that modifications are indirectly due to the influence of energy and memory on the germ-plasm, the specific type preserver, and that heredity or variation may be influenced in nature by the characters acquired by incidence of physical surroundings, whilst a response in an organism to outside stimuli creates a response from within, stimuli acting from within and without reacting upon one another. An organism being "a combination of rhythmically acting parts in moving equilibrium," it follows that "a change to a new state of equilibrium" will bring "the actions of all organs, reproductive included, into harmony with these actions," and the fact that "the units and the aggregate must act and react upon each other" (Herbert Spencer) more or less illustrates the view adopted. When the influence of memory and energy, and the reactions they give rise to, are duly appreciated, the recurrence during successive generations of identical characteristics is more readily understood, and the action of pangenesis becomes obscure if this excludes the perpetuation of all characters arising during the phylogeny of the group or the history of the individual.

The validity of the mode in which eggs assume different forms described by Prof. Thompson I freely admit, but in claiming it, as he does, as a cause of their variation I cannot agree with him, since mode of action follows determining cause, and, as Hyatt says, "The action of physical causes takes effect upon an irritable plastic organism which necessarily responds to external stimulant by an internal reaction or effort."

Leicester Corporation Museum, June 17.

## Lord Kelvin's Philosophy.

THERE is one word in Sir Oliver Lodge's interesting article, under the above heading, published in NATURE of July 2, to which I think some exception may reasonably be taken. In speaking of explanation in terms of force and action-at-a-distance, or in terms of motion and a continuous medium, Sir Oliver says that "To Lord Kelvin it would appear that both solutions were equally satisfactory, and that it was only a question of which was the most tractable." It is the word "equally" which is rather strong. He might indeed, as Sir Oliver says, prefer "to resort to the Boscovich doctrine"; but he would only do so in virtue of the tractability of the process, leaving aside for the time the question of the greater fundamentals. It was not at all a question of philosophy. It was a question only of the desirability of partial progress in place of no progress. His philosophy was Newtonian, postulating forces but reserving a medium.

In attempted explanation of certain elastic qualities in matter, he postulated a "simplest" Boscovichian system. That failing, he adopted a "second-simplest" system. Similarly, in attempted explanation of matter and energy, he postulated a simplest foundation in his vortex theory. That failing, he would doubtless have gladly framed a second-simplest foundation had he seen it to be possible. He was content to wait, meanwhile continuing his attack on the unknown along more presently promising lines.

In a letter of date December 1, 1905, referring to the molecular (Boscovichian) theory of magnetism and the "interesting truth" which it represents, he said "which will be added to when we know the physical quality of a molecular magnet and its relation to ether and to torrents of electrons through ether." In this spirit he was willing to wait for a knowledge of the physical quality underlying any other Boscovichian figuration.

### The Magnetic Separation of Heavy Minerals in the Field.

For some time I have been trying to find a simple and rapid field method of separating the magnetic and faintly magnetic from the non-magnetic minerals in the residue obtained by panning a river sand or gravel. In the laboratory this is usually done by means of the electromagnet. I have experimented in the field with a portable electromagnet, but, apart from the disadvantages of weight, bulk, and clumsiness of manipulation, the dynamo is readily liable to go out of order and render the whole apparatus useless. My colleague, Mr. Longbottom, has experimented with a compound magnet composed of three or four simple horseshoe magnets bound together and fitted with adjustable poles. This gives admirable results, and is to be recommended for fractional separations, but the constant adjusting and re-adjusting of the poles becomes tedious in actual practice.

I find, however, that all the advantages of the electromagnet can be obtained in the field by the combined use of an ordinary large (8-inch) horseshoe magnet and a penknife. A small quantity of the residue to be examined is taken, and the magnetite removed in the usual way. The magnet is then held vertically over the sample, and the bright steel blade of a penknife laid flat across one of the poles with the back of the blade downwards. By gradually approximating the point of the blade to the other pole, and thus narrowing the space between the poles themselves, the power of the magnet is increased, and not only iron ores, but all the dark-coloured silicates and garnets can be rapidly and completely removed from the sample. The residue may then contain such valuable minerals as tinstone and monazite, which when in small quantity are frequently masked by the other minerals present. This method has the further advantage that any single grain can be rapidly tested by turning the point of the blade slightly down below the level of the poles and bringing it close to the grain in question.

As an invaluable field method, as a useful laboratory method where an electromagnet is not available, and as an actual working method for teachers of practical geology, I can recommend the one above described for simplicity, inexpensiveness, and trustworthiness.

### The Sky Glows.

These phenomena on about June 30 and July 1, referred to in my letter (Nature, July 9, p. 221), I termed displays of Auroræ, and was prompted to apply that title by the descriptions given in some of the London newspapers, which stated that well-defined streamers had been observed from the metropolis.

But certain features of the glows struck me as being essentially different from exhibitions of normal Auroræ Boreales. No streamers whatever were seen here, but my view is somewhat restricted at low altitudes, and I thought they might have evaded recognition. The clouds observed were of peculiar character, and some of them showed traces of spiral formation. Though thin, they were strongly illuminative, and stars shone through them with surprising distinctness.

Here the display ranged over four nights, for on June 29 the sky was very light, and stars and Milky Way extremely faint, but clouds were very prevalent. On July 2 some attractive, coloured-cloud scenery was presented in the north-west and north, but the sky had not the bright, weird aspect it wore on preceding nights, and after midnight I saw nothing unusual.

Sounds proceeding from the north were strikingly audible in the still air, and I never remember to have heard the noise from distant railway trains in north-east so loudly before.

Whatever the true nature of the recent exhibition may have been, it is certain that something in the air exercised the capacity of reflection in a very high degree. The period was one of great heat and thunderstorms.

During past years, while engaged in meteoric or telescopic observation, I have occasionally noticed great differences in the transparency of the air. Occasionally the lightness of the firmament has struck me as being due to influences beyond local atmospheric causes. The variations have been great without palpable reasons, but no doubt there are different explanations applicable, though the observer finds it difficult to assign satisfactory ones in all cases.

W. F. Denning.

### A Remarkable Solar Halo.

On July 2, one of the days on which Miss Stevens saw a halo at Oxford (Nature, July 9, p. 221), a very bright halo was visible in the neighbourhood of Torbay. I first noticed it about 9 a.m., and it remained visible well into the afternoon. It attained its greatest brightness from 11 a.m. until noon. On looking at it through dark glasses it exhibited a somewhat remarkable form; the main halo had the usual radius of about 22°, but east and west were arcs of which the greatest distance from the sun was about 25°; these arcs gradually ran into the 22° halo. The effect was somewhat as though an elliptical halo were superposed on a circular one, the parts where the two coincided being of enhanced brightness. Below the sun there were at times fragments of halo at 44°. Masses of cirrus drifting from an easterly direction passed across the halo at times and partially obscured it, but probably had no part in its formation; it could be seen shining through the thinner parts of these clouds, and it regained its brightness as soon as they passed over. The halo was evidently formed by thin clouds above the ordinary cirrus, but no definite structure was visible to enable one to determine which way this layer was moving.

### Proposed Admission of Women to the Fellowship of the Chemical Society.

As president of the Chemical Society, I shall be glad if you will publish the accompanying letter referring to the correspondence as to the admission of women to the Fellowship of the Chemical Society which appeared in Nature of July 9.

W. Ramsay.

You have doubtless received a letter emanating from Oxford dated July 1 enclosing a circular and copy of the petition recently presented to the Council of the Chemical Society requesting the Council "to take such steps as may appear desirable to ascertain the wishes of the Society as a whole in regard to this question."

The envelope enclosing the above communications bore the familiar printed address-slips which might well lead Fellows to conclude that they were issued by authority of the Council. This is not the case.

The Council resolved that the statement of arguments on both sides which was issued to Fellows on June 23 was better calculated to elicit an unbiassed opinion of all Fellows if sent alone.

The course adopted by the signatories of the Oxford circular of July 1 is, therefore, not only unauthorised, but is in direct opposition to a resolution of the Council of which the signatories are members.

W. Ramsay (*President*).
Horace T. Brown (*Foreign Secretary*).
Alex. Scott (*Treasurer*).
M. O. Forster, Arthur W. Crossley (*Secretaries*).

### Linnæus's Authorities.

I should be very much obliged if any of your readers could supply me with the full titles of the works cited by Linnæus as follows in the twelfth edition (1766) of the "Systema Naturæ," p. 33:—

"Bont. jav. 84 *t.* 84; Koep. itin. *c.* 86; Dalin. Orat. 5."

I have looked up the works of Bontius in the British Museum, but they are not *ad hoc*. Also where, if anywhere, did D. Braad publish an account of his journeys to India?

Karl Pearson.

Biometric Laboratory, University College, London.

## THE MINES OF THE BRITISH EMPIRE.[1]

THE aim of Mr. Stokes's work on the mines of the Empire is to supply the non-technical reader with a description of the historical, physical, and industrial features of the principal centres of mineral production in the British Dominions beyond the seas. The bulk of the volume is based upon information collected during a tour of the Empire extending from January, 1906, to the beginning of 1908; and the author, who is an experienced technical journalist, has produced a book of conspicuous literary merit that cannot fail to prove of service as a work of reference. The illustrations, sixty-eight in number, are excellent reproductions of photographs, and have been carefully chosen to illustrate the importance of the mineral industry of the Empire.

The value of the annual mineral yield of the Empire now exceeds 200,708,000*l*. The quantity and value of the mineral products form a good barometer of industrial prosperity, and such statistics bear expressive testimony to the influence of the Empire as a factor in the mineral industry. Statistics for 1906 show that the Empire produced of the world's total yield the following percentages:—Gold, 60; silver, 12; tin, 73; copper, 9; lead, 15; iron, 18; nickel 60; manganese, 40; coal, 30; asbestos, 90; graphite, 45; mica, 90; and diamonds, 98. Similarly the influence of the mining industry upon the growth and welfare of the Empire is exhibited by the statistical history of the several colonial mineral territories. Thus the aggregate yield to the end of 1906 of Ballarat and Bendigo, Australia, discovered 1851, was 276,500,000*l*.; of the Witwatersrand, since 1885, was 162,000,000*l*.; of Kimberley, since 1869, was 85,000,000*l*.; of Broken Hill, New South Wales, since 1883, was 42,000,000*l*.; of Kalgoorlie, Australia, since 1893, was 37,000,000*l*.; of Mysore, India, since 1880, was 26,000,000*l*.; of Klondike, Canada, since 1896, was 24,500,000*l*.; of Charters Towers, Australia, since 1872, was 23,000,000*l*.; and of Mount Morgan, Australia, since 1882, was 13,000,000*l*.

Although the mines of the United Kingdom are excluded from the scope of the volume, the vast field covered will be evident from the following enumeration of the thirty-six chapters into which the work is divided:—Mine labour; mica and manganese in India; Burma rubies and petroleum; the Kolar goldfield; gems and graphite in Ceylon; industrial and geological conditions of the Malay States; Chinese and European mining methods in the Malay States; Bendigo and Ballarat, Victoria; gold and copper in Queensland; New South Wales mineral production; silver, lead, and zinc at Broken Hill, New South Wales; methods of extraction at Broken Hill; Mount Lyell copper mine, Tasmania; Mount Bischoff tin mine, Tasmania; gold, silver, and lead in Tasmania; north-eastern tinfields, Tasmania; growth of the gold industry of Western Australia; ore treatment at Kalgoorlie, Western Australia; Wallaroo and Moonta copper mines, South Australia; chief mineral localities of New Zealand; Waihi gold mine, New Zealand; mineral production of South Africa; Cape Colony, Orange River Colony, and Transvaal diamonds; mining in Rhodesia; Transvaal gold; Rand ore extraction and treatment; administration, labour, and working costs in the Transvaal; progress of the mineral industry of Canada; silver at Cobalt, Ontario; nickel at Sudbury, Canada; asbestos fields of Quebec; gold and copper at Rossland, British Columbia; Boundary copper district, British Columbia; Klondike alluvial gold; West Africa and the Sudan; and other British dependencies (British North Borneo, Labuan, and Sarawak, Fiji Islands, British New Guinea, Cyprus, Nigeria, British Central Africa, Uganda Protectorate, Newfoundland, British Honduras, Leeward Islands, Barbados, British Guiana, and Trinidad). From this enumeration it will be gathered that the chief mineral products of the Empire dealt with include gold, tin, copper, silver, lead, zinc, nickel, manganese, iron, antimony, bismuth, molybdenum, tungsten, coal, oil shale, petroleum, mica, graphite, asbestos, diamonds and other precious stones. So vast is the subject as a whole that congratulations are due to the author for the able and concise manner in which he has described the manifold characteristics of mineral occurrence and of methods of working in a form as lightly technical as is consistent with accuracy.

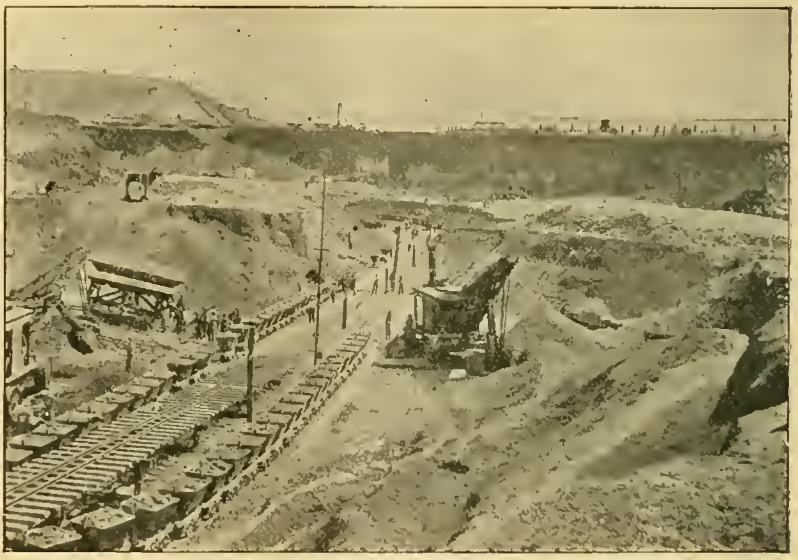

FIG. 1.—Premier (Transvaal) Mine in 1905. From "Mines and Minerals of the British Empire."

A perusal of the author's well-filled pages shows that the old established mining fields are constantly presenting fresh features, but that new discoveries attracting universal attention can be recorded but twice or thrice in a decade. Compared with preceding periods, and notably with the decade 1882–1891, which saw the discovery of the Witwatersrand, Mount Morgan, Sudbury, Waihi, and Broken Hill, the past ten years have not been marked by many new discoveries, the Premier diamond deposit in the Transvaal, which since 1902 has yielded 3,300,000*l*., and the silver veins of Cobalt, Ontario, which since 1903 have yielded 1,100,000*l*., having been the most brilliant discoveries. The Premier mine, which produced the diamond weighing 3025 carats now in the King's possession, is shown in the accompanying illustration (Fig. 1); and the character of the narrow rich veins, averaging 4 inches in width, at Cobalt is shown in

[1] "Mines and Minerals of the British Empire." By Ralph S. G. Stokes. Pp. xx+403. (London: Edward Arnold, 1908.) Price 15*s*. net.

Fig. 2. At surface, where the veins have been affected by atmospheric agencies, there is a high proportion of metallic silver. Much of the ore shipped in 1904 was largely composed of native silver. The discovery at Cobalt is an indication of Canada's bright prospects of becoming a more important mineral-producing country. In North America the territory controlled by Great Britain exceeds that of the United States. But of this immense area of 3,600,000 square

FIG. 2.—Metallic Outcrop of Silver Ore, Cobalt. From "Mines and Minerals of the British Empire."

miles only a very narrow fringe has even been explored, and yet the rocks of which a very large proportion of the unexplored area is in all probability composed are those which in the United States carry the most valuable mineral deposits. Here, and in other parts of the Empire, the world awaits the establishment of new mining regions to compensate for the steady impoverishment of the old.

## THE SECONDARY OSCILLATIONS OF OCEANIC TIDES.[1]

TIDAL observers have long known that at certain stations, mostly situated on bays or indentations of the coast, the simple curve of the tide-gauge is complicated by oscillations of level, often of considerable range and regularity of period. At first sight nothing could be further removed from the study of earthquakes than these irregularities of the tidal oscillation, but a connection has been discovered by the Japanese Earthquake Investigation Committee, whose diverse activity leads it to the study, not only of everything directly or indirectly connected with earthquakes, but also of everything which resembles their effect. The discovery, by Prof. Omori, that the periods of the earthquake-produced sea-waves were not uniform at neighbouring stations, but in each case agreed with those of the secondary oscillations of the tidal curve, naturally led to an investigation of this phenomenon, which has been noticed and made the subject of speculation by various observers. The investigation was carried out under the direction of Prof. H. Nagaoka, and has been published in a bulky and profusely illustrated quarto volume.

After a description of the improved and portable form of tide-gauge which was invented for the investigation, the ordinary limnograph being unsuitable and the ordinary tide-gauge too cumbrous, we have a detailed account, illustrated by reproductions of the tide curves and charts, of the records from fifty-one stations on the Japanese coasts. A general summary of the results is given, from which it appears that on the open Pacific coast, or in a bay of considerable area communicating with the sea by a narrow outlet, the tide curve is of a simple character, the secondary oscillations being small and irregular; but in more open bays, the breadth of which is not too large in comparison with their length, secondary oscillations are conspicuous, and often show great regularity of period. Simultaneous observations at different places along the shore-line showed that the phase of oscillation was usually the same throughout the bay, and that the oscillations which were conspicuous within the bay could be detected, with the same phase, but much reduced amplitude, at its mouth. From this it appeared that the whole mass of water in the bay was in simultaneous oscillation in a stationary wave, analogous to the sound-wave in an open organ pipe, and that the bay selected from the multitudinous ocean waves of various period the particular one to which it was able to respond, and, like a resonator with sound-waves, magnified and made it conspicuous.

This conclusion was verified by experimental investigation. Models, to scale, of the bays were made and sunk to the appropriate level in a large tank of water; in this tank was immersed a leaden ball which, being attached to a simple or a horizontal pendulum, could be set in oscillation with any desired period, and by its movement communicate to the water in the tank a periodic oscillation, unaccompanied by any appreciable surface-wave; reflection from the walls of the tank being checked by a thick layer of damping material—wood-shavings, to wit. By exciting waves with this arrangement the water in the model of the bay was put into standing oscillation, the amplitude of which was generally small; as the period of the pendulum approached the proper period of the bay, the amplitude of oscillation gradually increased, and, when the period exactly coincided with that of the model, the amplitude reached its maximum, continuing, with a regular period, after the pendulum was stopped. The phase of the water particles was the same for all parts of the bay when the oscillation was a fundamental one, but a binodal or trinodal oscillation was easily produced in an elongated bay.

An ingenious development of the experiment consisted in sprinkling aluminium powder on the surface of the water and photographing the model with a camera suspended vertically above it; by giving an appropriate length of exposure, the movement of the particles reproduced the course of the stream-lines on the resulting photograph. In Fig. 1 we reproduce one of these photographs, showing the motion where the induced wave is the fundamental oscillation, in which the mouth of the bay is a node for

[1] "An Investigation on the Secondary Undulations of Oceanic Tides, carried out by the Order of the Earthquake Investigation Committee during 1903-6." By Drs. K. Honda, T. Terada, Y. Yoshida and D. Isitani. Preface by Prof. H. Nagaoka. Pp. viii+113; 95 plates, 2 frontispieces. Published as No. 26 of Publications of the Earthquake Investigation Committee in Foreign Languages, and as vol. xxiv. of the Journal of the College of Science, Imperial University of Tokyo. (Tokyo, 1908.)

vertical and a loop for horizontal motion, while the head is a loop for vertical and a node for horizontal

FIG. 1.—Model of Aomori Bay, showing stream lines of fundamental oscillation: period 4·453 in model, representing 303 m. in the bay itself.

motion. The period of this oscillation in the model was 4·45 seconds; the factor, corresponding to the scale adopted, being 4090, this represents a period of

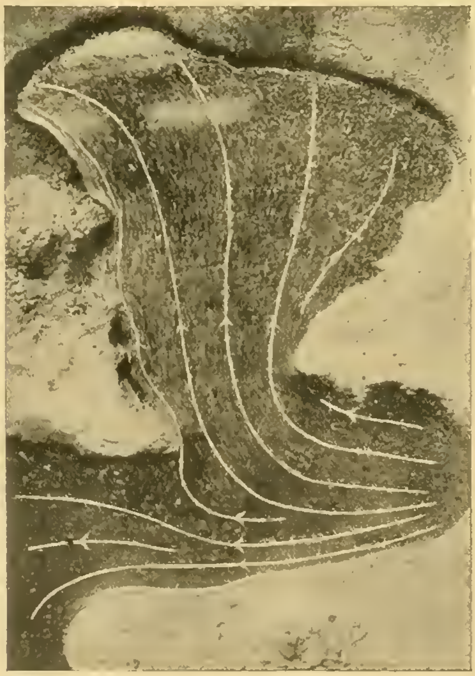

FIG. 2.—Model of Aomori Bay, showing stream lines of lateral oscillation: period 1·63 in model, representing 108 m. in the bay itself.

303 m. in the actual bay, in which a periodic oscillation of 300 m. was observed. Besides this fundamental wave, the water within the bay could be set into lateral oscillation, as shown in Fig. 2, with a period of 1·60 s. in the model, representing 108 m. in the actual bay, where a well-marked regular undulation of 103 m. was observed.

The account of the experiments is followed by a mathematical treatment of the subject, and a calculation of the periods of the stationary waves for each of the bays investigated, a calculation which gave results in general, and sometimes in close, accordance with the observed periods. Finally, there is a suggestion that the great increase in the range of tides near the head of large bays may be partly due to this cause. The Bay of Fundy is celebrated for the great range of the tide near its head, where the difference between high and low water is from 50 to 70 feet, while near the mouth the range is not more than 7 to 10 feet; the difference is partly attributable to the banking of the tidal wave as it travels up a narrowing channel, but, the fundamental period of oscillation of the bay being about twelve hours, it is by no means improbable that this has a material effect in increasing the range of the semi-diurnal tide, with which it approximately agrees in period.

We have indicated sufficiently the scope of this important memoir, the unseismological interest of which has been recognised by its simultaneous appearance as one of the publications of the Earthquake Investigation Committee and as a volume of the Journal of the College of Science of Tokyo.

## VESTIGES OF SCALES IN THE FOX.

IN the case of such a familiar animal as the fox it might well have been supposed that everything worth knowing in the matter of its bodily structure had already been recorded. That this is not so is demonstrated in an article by Mr. K. Toldt, of Vienna, published in the April number of the *Zoologischer Anzeiger*, where it is shown, on what appears to be practically conclusive evidence, that the fox is descended from ancestors the bodies of which appear to have been clothed with horny scales like those of the pangolins, or scaly ant-eaters. Although these scaly ant-eaters are the only living mammals the bodies of which are completely covered with overlapping scales, armadillos furnish us with an example of another type of armour in the same class; while there are several groups of mammals in which some portion of the body is scaly. In the rat, for example, the whole tail is scaled, and more or less distinctly scaled areas are met with in several porcupines and certain other rodents, as well as on the tail of the great South American anteater. In all cases where hairs grow from the body between the scales (as they almost invariably do), such hairs, in place of being scattered about in an irregular manner, have a certain definite arrangement. They grow, for instance, in isolated bundles, arranged in some cases in groups of three or four, and placed at regular intervals from one another.

From the fact that the hairs are arranged in this peculiar and definite fashion in a number of species which show no traces of scales, it has been suggested that such mammals trace their descent from scale-clad ancestors.

Careful examination of the skins of young foxes has enabled Mr. Toldt to announce, not only that the hairs are arranged in this peculiar fashion, namely, in groups of three bundles, each containing some fourteen or fifteen hairs, but likewise that the skin itself actually exhibits a structure such as would be presented by that of a pangolin after the scales had been pulled out. Viewed through a microscope, the skin presents, in fact, the appearance of a roof covered with overlapping rounded tiles, with the triply-arranged bundles of hair growing between each "tile." Moreover, when seen in cross-section, the skin is observed to be thrown into a series of ridges or steps, each of which represents the free edge of one of the "tiles." To explain such a structure otherwise than as representing the bed of a scaly armour seems impossible, or at all events illogical, and we are accordingly compelled to accept the author's view that the fox is descended from scale-clad ancestors. No actual traces of scales have been observed in any of the skins yet examined, but Dr. Toldt suggests that such might be detected if a large series of skins of young fox-cubs were examined under proper conditions.

Although no mention of this point is made by the author of the paper referred to, the fox is just one of those animals which might naturally be expected to retain traces of its descent from reptilian ancestors. There is good reason to believe that the extinct mammal-like reptiles of South Africa were the immediate forerunners of the primitive carnivora or creodonts of the Tertiary period; while it is certain that from these latter are descended the modern carnivora, among which the fox, in common with the other members of the dog tribe, is one of the most primitive and least specialised representatives.

## NOTES.

A STATUE to Bunsen, raised by public subscription, will be unveiled at Heidelberg on August 1.

WE regret to see the announcement of the death of Lord Blythswood, F.R.S., at seventy-one years of age.

SIR WILLIAM H. WHITE, K.C.B., F.R.S., has been elected chairman of the council of the Royal Society of Arts for the ensuing year.

PROF. GEORGE HALE, director of the Mount Wilson Observatory, California, has been elected a foreign correspondant in the astronomical section of the Paris Academy of Sciences in succession to the late Prof. Asaph Hall.

DR. BOUCHARD has been elected president of the Paris Academy of Sciences in succession to M. H. Becquerel, who was recently appointed permanent secretary of the academy. Prof. Émile Picard succeeds Dr. Bouchard as vice-president.

THE congress of meteorologists representative of the United Kingdom and of the British colonies and dependencies, which it was proposed to hold in Quebec in the last week of this month, has been postponed until next year.

THE well-known expert on turbines and hydraulic engineering, Prof. A. Stodola, of the Zürich Polytechnic College, has been awarded the Grashof gold medal of the Society of German Engineers.

THE council of the Society of Engineers and the council of the Civil and Mechanical Engineers' Society have approved a scheme of amalgamation which is expected to meet with the cordial support of the members of both bodies. This is a welcome innovation in the policy of technical societies, as of late years there has been a growing tendency to form new societies, and the consequent overlapping of work has rendered bibliographical research increasingly difficult.

A THOROUGHLY representative exhibition of mining machinery was opened at Olympia by Lord Strathcona on July 11. An interesting popular feature of the exhibition, which will remain open until July 31, is a series of realistic scenes giving an excellent idea of the practical working side of the Empire's mining industries. These scenes represent prospecting for diamonds in South Africa, gold mining in the Transvaal, alluvial gold mining in the Klondyke, hydraulic gold mining in New Zealand, tin mining, coal mining, granite quarrying, and Bath-stone mining.

IN the House of Commons on July 8, Mr. Dundas White asked the Prime Minister whether the Government would give facilities for the passing this session of the Daylight Saving Bill, now entitled the Local Time (Great Britain and Ireland) Bill; and, if so, whether the Government would propose amendments making clear that the adoption of the proposed modification of time was not compulsory, and substituting for the term local time some less ambiguous term. In reply, Mr. Asquith said:—"The Government have no intention of giving facilities for the passing of the Daylight Saving Bill."

IN the Chancery Division of the High Court, Mr. Justice Eve has just decided that china clay is a mineral within the meaning of the Railway Clauses Consolidation Act, 1845. The right to work china clay in some land purchased by the Great Western Railway Co. was claimed by the vendor to the company and owner of the adjoining land. Notice of this claim was given to the railway company, which brought the action for an injunction to restrain the owner from excavating the land near and under their line in Cornwall to get china clay, on the ground that the product obtained was not a mineral in the sense of the Act of 1845. Mr. Justice Eve, however, decided against this view, and gave judgment for the defendents. A full report of the judgment appears in Wednesday's *Times*.

WITH a view to obtain accurate information regarding the nature and extent of the damage done by rats in the United Kingdom, the committee of the Society for the Destruction of Vermin has prepared a schedule of questions for wide distribution. It is desired to obtain information from all persons who are in a position from their own experience to give particulars concerning temporary or permanent rat plagues, the damage done by rats, the steps taken to prevent such damage, and the results obtained. The secretary of the society, Mr. A. E. Moore, 95 Wigmore Street, London, W., will be glad to send a copy of the schedule of questions to any person who is able and willing to send information.

THE Paris correspondent of the *Times* announces that M. Henri Deutsch de la Meurthe has offered a new prize of 1000*l*. for the first aërial automobile apparatus, either lighter or heavier than air, which will transport Commandant Renard to England. If he is conveyed by an automobile balloon, the descent must be made at Aldershot Camp. If he goes on an aëroplane, however, it will only be necessary to reach the English coast. From the same source we learn that Commandant Renard, in some comments on the recent exploits of Mr. Henry Farman at Issy les Moulineaux and of M. Delagrange in Rome, referred to the fact that both aëronauts have remained more than fifteen minutes in the air, and remarked, "In less than two years the distance traversed by an aëroplane has passed from twenty-five mètres—the famous preliminary bound of M. Santos Dumont in October, 1906—to nearly twenty kilomètres, a proportion of 1 to 800." At that rate, within two years it will be possible to make journeys of twenty days without stopping. At all events, there is nothing extraordinary, says Commandant Renard, in thinking that journeys of several hours, and even of an entire day, will soon become quite normal.

The *Comptes rendus* of the Paris Academy of Sciences for June 29 contains the report of the committee appointed to consider the distribution of the Bonaparte fund for 1908. The committee has considered 107 applications for assistance from this research fund. Some of these, it is mentioned, do not comply with the conditions laid down by the founder, Prince Roland Bonaparte, and others are for work entirely outside the field of the Academy of Sciences. The committee excludes also demands for assistance in researches in medicine, surgery, and general biology, since the funds of the *Caisse des Recherches scientifiques* are exclusively reserved for biological studies. Ten grants are recommended as follows:—(1) 2000 francs to L. Blaringhem for a continuation of his important studies on the variation of species and the experimental methods for the creation of new species of plants; (2) 2000 francs to Dr. Billard to enable him to pursue his studies on the hydroïds; (3) 2000 francs to Dr. Estanave to furnish him with the means of continuing his researches on direct vision projection in relief, with special reference to radiography; (4) 2500 francs to MM. Fabry and Buisson for a continuation of their work on the establishment of a system of standard wave-lengths. The grant is to be applied to the purchase of a plane grating, a metal concave mirror of large diameter, and two plane mirrors required for a study of the differences between the lines of the solar spectrum and those of the electric arc; (5) 5000 francs to M. Gonnessiat for the purchase of astronomical instruments for the observatory of Algiers; (6) 2000 francs to Dr. Loisel for the continuation of his actinometric observations at the Observatory of Juvisy; (7) 2000 francs to M. Dongier for the establishment of apparatus for the simultaneous study of the rainfall and atmospheric potential; (8) 2500 francs to M. Perot for the spectroscopic study of the light from the sun by interferential methods; (9) 2000 francs to M. Matignon for the determination of specific heats at high temperatures; (10) 3000 francs to P. Colin for the publication of a map of South Imerina. These recommendations were adopted by the academy.

The "Brisbane beds" of Queensland, at one time supposed to be of Jurassic age, form the subject of an article by Mr. S. B. J. Skertchly in the first number of a new serial, the *Queensland Naturalist*. Their plant-remains prove them to be of early Tertiary age—perhaps equivalent in time to the Laramie beds of the United States.

Among other American papers, we have to acknowledge the receipt of one by Mr. C. S. Townsend on the taxonomy of the more typical flies, with descriptions of new genera and species, forming part of vol. li. of Smithsonian Miscellaneous Contributions; also one by Alice Robinson, issued as No. 5 of vol. iv. of the Zoological Publications of California, on the incrusting chilostomatous bryozoans of the Pacific coast of North America.

In an article communicated to the current volume of the Journal of the Asiatic Society of Bengal, Mr. R. B. Sanyal urges the importance of establishing an aquarium for scientific research in Bengal. The author quotes Lieut.-Colonel Alcock to the effect that the ideal situation for such an establishment would be the Orissa coast, in the immediate neighbourhood of the sanatorium at Puri. With some modification of the salt-excise, it is believed that a fishing and dredging station on this coast would yield a large revenue from dried fish, fish-oil, isinglass, &c., while from the scientific point of view such an establishment would almost certainly result in discoveries of profound interest and importance.

We have to acknowledge the receipt of four parts (vol. xxiii., Nos. 5–8) of the Journal of the College of Science, Imperial University of Tokyo. No. 5 is devoted to the appendicularians (such as Kowalevskia, Fritillaria, and Oikopleura) met with in Japanese waters in the Noctiluca-plankton, the author, Mr. T. Aida, giving elaborate details of their anatomy. New cicadas from Europe and the Mediterranean region generally are described by Dr. S. Matsumura in No. 6, while in No. 7 Mr. S. Tanaka gives descriptions of fourteen Japanese fishes regarded as new. Finally, in No. 8, Mr. I. Ikeda gives full details of the structure of three remarkable forms of Japanese echiurid gephyrean worms of which preliminary descriptions have appeared elsewhere. The paper is illustrated by four plates, of which the first is coloured.

The first article, comprising 360 pages, of vol. viii. of the Bulletin of the Illinois State Laboratory is devoted to the organisms and their seasonal distribution of the plankton of the Illinois River, based on the results of observations and collections made from 1894–9. The plankton of fresh waters, observes the author, Dr. C. A. Kofoid, differs from that of the sea in the almost universal absence of larval forms of life, in the smaller number of invertebrate groups represented, and in the smaller size of the species. Notwithstanding this lack of the larger forms, the Illinois plankton represents a larger quantitative amount of organic matter per cubic metre of water than is the case with marine plankton. The relative abundance of diatoms, of green and blue-green algas, and of chlorophyll-bearing flagellates, apparently affords abundant sustenance for the animal section of the plankton.

It has long been a puzzle how the "oystercatcher" opens the shells of the mussels which form its main diet. The question has been set at rest by an article contributed by Mr. J. M. Dewar to the June number of the *Zoologist*. The great majority of the molluscs are opened from the dorsal border, when the valves are gaping, by the bird thrusting its beak into the aperture and then using it as a lever, at the same time severing the adductor muscles. If one of the valves be fractured in the process, the lever-action becomes unnecessary. About 9 per cent. of the mussels are opened on the ventral border, where the aperture for the byssus renders them as vulnerable when the valves are closed as when open. Mussels presenting this aspect are carefully searched for by the birds. Finally, about 13 per cent. of the mussels are attacked at the posterior extremity of the shell.

In a special report issued by the Government of Egypt, Captain Stanley Flower has published an account of his round of visits to the menageries, aquariums, and museums of Europe in 1907 for the purpose of acquiring information which might prove advantageous to the establishment under his care at Giza. Much of the interest of the report is centred on the notices of local and private collections of which the general public knows but little. Among the latter, special reference may be made to the wonderful collection of living fresh-water fishes maintained by Captain J. A. M. Vipan in two special buildings in the garden at Stiblington Hall, near Peterborough. Among the rarities in this collection may be mentioned specimens of the bichir (Polypterus) from the Gambia, and Russian sterlets presented by H.I.M. the Czar of Russia. Mr. F. E. Blaauw's collection of mammals and birds at Gooliust, near Hilversham, also comes in for commendation. The report concludes with a list of the antelopes seen by the author in the course of his tour and one of those now living in the Giza Gardens. Captain Flower, we notice, uses the name *Portax picta* for the nilgai and *Oreas canna* for the eland, thereby demonstrating that modern emendations in nomenclature are still by no means universally accepted.

WE have also received a copy of the report of the Giza Zoological Gardens for 1907, illustrated with a coloured plan. The year appears to have been an unusually successful one, the number of visitors and the amount of money taken at the gates being in excess of any previous season. Captain Flower directs special attention to the circumstance that both kudu and addax have bred in the menagerie.

A FLORA of the Austrian Duchy of Styria, "Flora von Steiermark," prepared by Dr. A. von Hayek, is announced by the publishing firm of Gebrüder Borntraeger. To the special section consisting of an enumeration of the plants will be added a general survey of plant distribution in the duchy and in neighbouring countries. The work is to appear in about eighteen monthly parts, each costing three marks. The first part contains the pteridophytes and a few pages of the gymnosperms. The features of the work are the analytical keys to the orders, genera and species, brief diagnoses and localities for each genus and species, and references to literature. Considerable interest attaches to the flora, as certain ranges of the eastern Alps lie within the province, and the vegetation in the lowlands shows affinities with the flora of Illyria.

A SHORT account—accompanied by excellent illustrations —of the anatomical features of the extranuptial nectaries of certain plants is contributed by Mr. K. Ono to the Journal of the Royal College of Science, Tokyo (vol. xxiii., article 3). On the ground of development, the writer distinguishes two types of nectaries, those derived from epidermal cells only, as in species of Polygonum, and those derived from both hypodermal and epidermal cells. It is stated that in some cases the secretion from the glandular cells is forced into a space between them and the cuticle, until finally the liquid escapes by rupture of the cuticle; in other cases it is believed that the secretion permeates the cuticle. Physiological experiments indicated that the secretion is mainly controlled by internal conditions, and that of external factors moisture is the most important.

THE idea has been mooted, and has met with some measure of acceptance, that as agricultural land after a repetition of crops of any given species becomes unsuited to the requirements of that species, so, after a proportionately long period, on land bearing pure forest, the seedlings of the crop may eventually fail owing to changes in the properties of the soil. In this connection, Mr. B. O. Coventry contributes an article on alternation of forest crops to the June number of the *Indian Forester*. He instances the observed failure of natural reproduction of the blue pine, *Pinus excelsa*, under its own cover with the incursion of deodar, also the gradual extension of mulberry into a Punjab plantation where originally "shisham," *Dalbergia sissoo*, was dominant. In the North-West Provinces, at a high level, it has been noted that *Quercus incana* is invading the domain of *Pinus longifolia*, and blue pine is advancing into the oak; at another level, *Quercus semicarpifolia* is losing ground to spruce and silver fir. The subject is one that deserves the attention of foresters.

THE attention of geologists may be profitably directed to two important papers on the submarine stratigraphy of the English Channel, published in the Journal of the Marine Biological Association of the United Kingdom, vol. viii., No. 2, in May of the present year. Mr. L. R. Crawshay (p. 99) discusses the conditions under which the stones and gravel on the Channel floor become exposed by a constant drift of the fine material towards the English coast. Mr. R. Hansford Worth contributes (pp. 118–188) a critical review of a large number of specimens dredged up by Mr. Crawshay on the S.S. *Oithona* in 1906, and also describes those collected by previous observers, including his own published work of 1899. The greatest interest centres in the discovery of true chalk, in addition to numerous flints, in the region south of the Eddystone. Flints occur, indeed, in practically all the dredgings. One block of foraminiferal limestone, with Miliolinas, clearly of Eocene age, was found in mid-channel off the Lizard, providing a valuable argument for those who view the Parisian *Calcaire grossier* as having been deposited in a sea spreading eastward from the Atlantic. Mr. Worth brings his conclusions together in the form of an interesting geological history of the depression which resulted in the English Channel.

IN *Meteorologische Zeitschrift* for May, Dr. J. Hann contributed an interesting paper on the problem of the vertical distribution of sea temperature in the eastern Mediterranean. He asks what conceivable physical process would allow the surface temperature to penetrate to a depth of about 500 metres, as has sometimes been assumed, in the period of half a year; the chief object of the paper is to raise a discussion on this question. Dr. Hann thinks that the lower limit of vertical circulation might be assumed to be about 100 metres, and that we should then have to distinguish between three different strata of temperature:—(1) the superficial, to a depth of about 100 metres; (2) from about 500 metres to the bottom, where the temperature is nearly uniform (14° C. to 13°·5 C.); and (3) the intervening space from, say, 100 to 500 metres.

WE have received vol. xlix., part ii., of the Annals of Harvard College Observatory, containing meteorological observations at eight auxiliary stations in Peru for the years 1892–5 from records of self-registering instruments. Although these records are not complete, especially at the mountain stations, where the difficulties of carrying on observations at such great altitudes are considerable, meteorologists are much indebted to the authorities of the college for this valuable contribution, which has been very carefully prepared for publication by Prof. Bailey under the direction of Prof. Pickering. In general, only the hourly means and extreme values for each month are given, but for the mountain stations individual readings are published. The observations at Arequipa for the same period were contained in part i. (to which we have already referred), and the eye observations, with descriptions of the stations and an account of the difficulties connected with them, were given in vol. xxxix., parts i. and ii.

STATISTICS issued by the Home Office show that the total production of coal in the United Kingdom last year was 267,830,962 tons, which is an increase of 16,763,334 tons over that of the previous year. The death-rate from accidents of underground and surface workers as a whole was 1·32 per 1000.

THE Marine Department of the Board of Trade has issued a circular (No. 1443) dealing with the manufacture and testing of steel. The instructions given are based on the reports of the Engineering Standards Committee, and deal with the testing of steel for use in boilers, plates, angle, rivet and stay bars, steel forgings, and steel castings.

In the *Engineering Magazine* (vol. xxxv., No. 3) Mr. H. T. Wade gives an illustrated description of an interesting exhibition, designed to show the best methods of safeguarding workmen and of protecting the general public, which was recently held in New York by the American Museum of Safety Devices and Industrial Hygiene. The exhibition was of great importance in showing that much of the loss of life in industrial operations in the United States is preventable, and that there are already developed methods and appliances that accomplish much in this direction.

The Zoelly turbine is the youngest of the steam-turbines which have risen to any degree of commercial importance, and in view of the fact that it entered a field already occupied by powerful interests and well-established rivals, its progress has been remarkable. Designed by M. Heinrich Zoelly, of Zurich, it was first put on the market in 1904, and has since then been most energetically developed, particularly on the continent of Europe. It is of the compound impulse type, that is, the steam is expanded successively through small ranges of pressure, the velocity acquired during each expansion being utilised by a separate single wheel. Each wheel runs in a compartment by itself, the number of wheels required being determined by the range of expansion through which the turbine has to work, the pressure in each compartment being never less than 58 per cent. of that in the previous one. This limitation enables the full expansion at every stage to be obtained with simple convergent nozzles, which are easier to design and more efficient than the flared nozzles, which become necessary with greater expansion ratios. An exhaustive description of this turbine is given in *Engineering* of July 3, with dimensioned drawings and reproductions of photographs of the 210 horse-power Zoelly turbine direct-coupled to a centrifugal pump shown by Messrs. Mather and Platt at the Franco-British Exhibition.

Messrs. Negretti and Zambra have submitted to us for examination their new prismatic binocular, the "Minim," which they have recently issued. The distinguishing features of the new glass are its compactness, lightness, and small bulk. Its weight is only 10 oz., and it is as small as any other prismatic binocular of the same power, the height being only $3\frac{3}{8}$ inches. These points, however, have evidently been attained without any sacrifice of the essential rigidity of an instrument of such high power. The makers state in their specification that, in order to secure this compactness, lightness, and small bulk, in conjunction with so powerful a magnification as eight diameters, it is of course necessary that the lenses and prisms must be small, and that in consequence the light-transmitting power will, under certain conditions, be smaller than with glasses having large lenses. These conditions, however, are not likely to occur often enough to compensate for a conveniently portable instrument, and on an average day the "Minim" gives ample illumination. The size and shape are such that the binocular can be easily kept in the pocket, and for this purpose it can be supplied in a soft leather case instead of the usual stiff leather sling-case. It is constructed with a well-designed rack focus adjustment on the differential screw principle, giving very easy motion which can be operated by one finger, and which has the additional advantage of not wearing slack with continued use. One eye-lens is separately adjustable for the correction of anisometropia, and both tubes are on the usual swing pivot for adjustment of pupillary distance. The power of eight diameters magnification has been chosen after careful consideration as being the best for ordinary requirements, such as touring and every kind of sport; at the same time, it is not too high for marine work, and is about the limit for holding steady without any subsidiary support. We have also found it extremely useful for many objects in astronomy; for instance, the views of the half-moon on a clear night are magnificent. The general performance of the glass satisfies all of a series of tests on various objects which we have tried. The optical definition is very fine, a pleasing feature being the instantaneous change on either side of the best focus. The images are pleasingly achromatic. We would urge on users of all prismatic binoculars or high-power telescopes that to get critical definition it is necessary to re-focus whenever the distance of the object being viewed is changed, as these instruments have not the latitude in depth of field to which we are accustomed in the ordinary opera-glass of low power.

The last number of the Proceedings of the Royal Society of Edinburgh (vol. xxviii., part iv.) includes a paper of forty-three pages on the problem of a spherical gaseous nebula, continuing and completing Lord Kelvin's work upon this subject. In his last paper, a contribution to Nature of February 14, 1907, Lord Kelvin directed attention to what he called the curious "Perry theorem," which ought to be called the Ritter theorem, namely, that a spherical mass of gas of which the specific heat ratio is less than $1\frac{1}{3}$ must be unstable. What makes a paper of this kind particularly interesting is that Lord Kelvin never satisfied himself with a mere mathematical statement of such a theorem as this; he always sought out the physical meaning of it. It may be said that the paper gives a complete statement of the development of the past work of Lord Kelvin himself, also of Homer Lane, and of Ritter and Perry. It was left incomplete by the author, and it has been well edited by his secretary, Mr. George Green, who has given much time to the calculation of many useful tables of figures.

Messrs. Aston and Mander submit for examination a specimen of the "Compton" slide-rule, which they are selling at nine shillings. As is now universal, the divided surfaces are on white celluloid, and a glass cursor with one cross-line is provided. The radius of the A and D lines are 125 and 250 millimetres respectively, as is usual with rules about 10 inches long. The sine and tangent lines at the back of the slide are graduated from the same end, and in order to be able to read both sines and tangents, or to execute proportions in which one or other come in as factors, without shifting the slide, the slide when reversed is the right way end for end for both at the same time. Of course, as the tangents with this arrangement are read against the D line, they are on twice the scale, and may be read with twice the accuracy. The wood is mahogany, and two celluloid strips are used to face the thin portion of the rule. The two edges are divided, and the inside has the linear divisions continued after the manner of a hat measure. The divisions are fine and accurate, and the working easy and smooth.

The three articles on the work done at the Physikalisch-Technische Reichsanstalt at Charlottenberg during the year 1907, which appeared in the April, May, and June numbers of the *Zeitschrift für Instrumentenkunde*, have now been issued separately, and form very interesting reading. Sufficient information is given to allow the reader to understand the work done and the methods used, and in many cases in which apparatus of a novel kind has been used a figure of it is given. It is scarcely necessary to say that the work is of the highest order, and affords ample evidence of the close association of the institution with the manufacturers of Germany. The idea of publishing in the technical Press an account of work done is a good one, and might well be followed by similar institutions with which manufacturers have not yet learnt to cooperate as much as they might.

THE *Physikalische Zeitschrift* for July 1 contains an account of some observations made by Dr. S. Landau, of Göttingen, on the magnetic rotation of the plane of polarisation in rock salt, Iceland spar, water, and alcohol, with the view of testing the theories which have been advanced in explanation of the phenomenon. His method is a photographic one, the light from an iron arc passing through a polarising prism, the magnetic field, a half-shadow prism, and a spectrograph in succession, the slit of the latter instrument being at right angles to the dividing line of the half-shadow field. Several photographs are taken on the same plate, the polarising prism being rotated through a small angle between each, and from inspection of these the position of the prism for equal intensity of the two halves of a line in any part of the spectrum is found. The author concludes that the electron theory is capable of reproducing all his observations, but that some of the constants which, if only negative electrons are assumed to play a part in the phenomenon, should come out positive, have negative values, and suggest, therefore, that the positive electrons play a part. Against this, however, many objections may be raised.

IN the note upon the seventh International Congress of Applied Chemistry in last week's NATURE (p. 229), it should have been stated that Sir William Ramsay, K.C.B., F.R.S., will be the acting president of the congress, and Sir Henry Roscoe the honorary president. We are informed that Prof. Nasini will not give one of the lectures to the congress, but a lecture will be given by Prof. Paterno, of Rome.

IN the issue of NATURE for June 2, 1904 (vol. lxx., p. 107), an optical illusion observed by Dr. T. Terada, of the College of Science, Tokyo, was described. Dr. Terada directs attention to another illusion he has remarked. After watching drops falling at the rate of about one a second into the centre of a small pool, and so causing circular ripples, he turned his eyes to a spot on a neighbouring bush. The bush appeared to contract slowly towards the point looked at, but the contracting motion was slower than the diverging motion of the ripples. A similar effect was noticed by looking at the ground or at a wall.

## OUR ASTRONOMICAL COLUMN.

SATURN'S RINGS.—The June number of the *Astrophysical Journal* (vol. xxvii., No. 5, p. 363) contains a note by Prof. Wright in which he discusses the bright beads, or knots, which were observed during the recent opposition when the unilluminated surfaces of the rings were turned earthwards. Criticising Prof. Barnard's recent explanation, in which the author supposed the brightness of the beads to be due to light percolating by many reflections through the masses of meteorites composing the rings, he points out that whilst this is probably true for the crape ring, it seems impossible that sufficient light to produce the outer bright knots could pass between the more densely packed meteorites of the outer rings. Then turning to Bond's explanation of the phenomena, Prof. Wright shows that it accounts for the bright outer knots and for the very slight asymmetry which is suggested by comparing the measures of different observers. He further suggests that it is not unlikely that collisions among the meteorites may account for some, at least, of the observed luminosity over the surfaces of the two dense rings and in the knots.

NEW PHOTOGRAPHIC CELESTIAL CHARTS.—On a supplementary sheet to No. 4257 of the *Astronomische Nachrichten*, Prof. Johann Palisa invites subscriptions to a series of photographic star charts prepared by Prof. Max Wolf at Heidelberg. Having received copies of his maps privately from Prof. Wolf, Prof. Palisa found that his work of finding minor planets was reduced by 75 per cent., so he suggested that the sheets should be published, as they will undoubtedly prove very useful in other branches of astronomy. The sheets will be printed on smooth matte bromide paper with a degree *reseau*, and each sheet will include some fifty square degrees, the scale being such that $1^\circ = 36$ mm. This enterprise is purely a private one, of which the cost must be borne by the subscribers, so that Prof. Palisa invites all who wish to subscribe to apply to him as soon as possible, and before December 31 at the latest; the price of the series containing twenty sheets is thirty shillings, and after the date named must be forty shillings. The maps reproduce stars down to about the fourteenth magnitude.

DOUBLE STARS.—An example of the good work that may be done by an amateur astronomer with but a moderate-sized instrument appears in No. 4259 of the *Astronomische Nachrichten*, where a list of double stars discovered and observed by Mr. E. D. Roe, jun., of Syracuse, N.Y. (U.S.A.), with a $6\frac{1}{2}$-inch Clark refractor, is published. His observatory was erected in July, 1906, and by the end of 1907 he had independently discovered some 250 double stars (generally separated by less than 10″), of which he has since identified a number with doubles given by Prof. Burnham. The present list contains the measures of the stars thus identified.

In the same journal Herr J. Fr. Schroeter publishes a list of corrections to Prof. Burnham's "General Catalogue" for double stars included in the Christiania zone.

No. 4260 of the *Astronomische Nachrichten* (p. 185, July 3) contains a discussion by Herr E. Schoenberg, of Dorpat, of the orbits of several double stars, including $\beta$ 581, $\beta$ 883, S Sextantis = AC.5, and $\beta$ 612.

THE ALBEDOES OF JUPITER'S FIRST AND THIRD SATELLITES.—In the July number of the *Bulletin de la Société astronomique de France*, M. Quénisset records some observations made in January and March showing the relatively low albedoes of the surfaces of Jupiter's first and third satellites. The disc of Ganymede when seen outside the planet was quite brilliant, but when projected on to the surface of the planet, during a transit, it became less and less bright until when near the central meridian it was very dark, in fact nearly as dark as its own shadow. This was observed on January 22 and March 12, and the same phenomenon, somewhat less marked, was observed in the case of the first satellite on March 27. As the satellites were projected on the bright equatorial band of the planet, it follows that the albedo of this region must be greatly superior to the albedoes of the two satellites.

A BRIGHT METEOR.—No. 4258 of the *Astronomische Nachrichten* contains a record of a bright meteor observed by Dr. J. Kaván at the Prag-Smichow Astronomical Institute on November 16, 1907. During its flight the meteor was seen to explode into two parts, but no trail, or detonation, was observed. The brightness of the object was about equal to that of Venus, and its flight, as observed by Dr. Kaván, was from $\alpha = 196^\circ{\cdot}2$, $\delta = +57^\circ{\cdot}7$, to $\alpha = 162^\circ{\cdot}9$, $\delta = +46^\circ{\cdot}7$; simultaneous observations by Herr L. Štetka gave approximately the same positions for the appearance and disappearance.

LATITUDE VARIATION.—When the international latitude service was instituted in 1899 the Cincinnati Observatory was asked to cooperate, and has made continuous observations since. As changes in the star-list were made in 1906 it seemed to Dr. Porter to afford a good opportunity to discuss the observations made to that date; this he does in No. 16 of the Publications of the Cincinnati Observatory, giving an historical account of the observations, a description of the instruments and methods used, and a table of the observed latitudes day by day. From the yearly values given it is seen that the different years show considerable fluctuations, signifying that the annual digressions are not symmetrical with reference to the determined mean position.

## ARCHÆOLOGICAL EXPLORATION IN GUATEMALA.

THE first part of the fourth volume of the Memoirs of the Peabody Museum, Harvard University, is devoted to an account of exploration by Mr. Teobert Maler in the valley of the Upper Usumatsintla, or the Usumacinta, as it appears in some modern maps, a river rising in Guatemala, falling into the Gulf of Mexico, and forming for part of its course the boundary between the Peten province of Guatemala and the Chiampas of Mexico. The exploration has thrown much new light on the geography of a region which has up to the present been very imperfectly explored. It is a wild country largely covered with tropical jungle, the main industry, that of lumber, attracting a particularly disreputable class of workmen, while agriculture is confined to a few scattered maize plantations. The author gives a very gloomy account of the population. "The dubious elements," he says, "sunk in sloth, filth, and every possible vice, whose miserable habitations are met with here and there, are constantly shifting since they acquire no fixed property rights." Whoever commits murder across the Mexican border takes refuge in Guatemala, and *vice versâ*. Attempts are, of course, made to secure the extradition of offenders, but these are generally unsuccessful. In fact, the negro is gradually taking the place of the Spanish-Indian population, which, having become enervated and degraded, is rapidly dying out.

The difficulty of exploration is naturally increased in such a country by the failure of the so-called Government to enforce law and order. Further, in Spanish times many of the old native names were replaced by those of Christian saints. The few that have survived to our days have been supplanted by political catch-words, Progresso, Libertad, and the like. More serious is the damage to these ancient buildings, which the State seems unable to prevent. Mr. Maler tells a curious story which appears to show that certain valuable stelæ were destroyed during an attempt by a Government official to prepare moulds of the sculptures for the Chicago Exhibition. It is quite time that the American Government intervened to preserve these wonderful structures.

FIG. 1.—Photographs at entrance of Tularosa Box Canyon below Delgars.

Taking all these obstacles to archæological inquiry into account, it is only natural that Mr. Maler's survey was little more than a reconnaissance. He had no opportunities for excavation, but was able to procure photographs and moulds of the most important remains. The four great groups of ruins were visited—those at the so-called Altar de Sacrificios and the more important sites, Itsimté-Saclue, Seibal, Cankuen—the order of their occurrence along the course of the river. Of these, the Seibal site seems to be the most promising, though nothing so interesting as the great sacrificial altar, a mass of reddish sandstone 160 cm. in diameter, was discovered here. In the other sites the most remarkable remains are the groups of stelæ or pillars which have survived, while the buildings to which they formed an adjunct are in such a state of decay that without excavation little of their character can be ascertained. The stelæ bear usually the representation of a figure, probably hero, priest, deity, or all combined, with various emblems and accessories, following generally the type characteristic of Central American art. In some cases the figure is seated in European fashion on a sort of throne. In one stela at Seibal he holds in his outstretched right hand a large sawfish lance, and in his left a pouch decorated with elaborate arabesques and loops. In another two personages sit in Turkish style before an altar, at which they are performing some sacred rite. More remarkable is the "tiger-paw man," whose hands and feet are covered with tigers' paws fastened by

FIG. 2.—Cliff-dwellings, west fork of the Gila.

bandages to wrists and ankles. In another sculpture the hideous face of the figure seems to be masked by the flayed skin of a human victim. Indeed, as might have been expected, human sacrifice seems to have played a leading part in the cruel religious rites of this people.

Mr. Maler does not venture an explanation of the symbolism, nor does he speculate on the origin and significance of these sculptures, which cannot be interpreted until the buildings to which they were attached have been fully examined. Meanwhile, he has done good service in collecting drawings, moulds, and photographs of a remarkable series of monuments, which under the present government of the country are in imminent danger of destruction before they can be subjected to careful scientific examination.

## *THE NEW BUILDINGS OF THE UNIVERSITY OF LEEDS.*

THE opening of the new buildings of the University of Leeds by the King, who was accompanied by the Queen, was briefly recorded in NATURE of July 9. A visit on the part of the Sovereign to a modern university, though not a unique occurrence, is sufficiently rare to be regarded, at least by the favoured institution, as an historical event. It is a Royal tribute to learning, cultivated not, as heretofore, in the silent precincts of sombre, mediæval halls, but strenuously pursued within earshot of busy factories and the hum of city life. It is, moreover, a public recognition and encouragement of the aims of a community which has provided from its own resources a centre of active scientific and academic life.

*Historical.*—Although the Leeds School of Medicine, which dates so far back as 1831, represents the oldest branch of the University, it is the Yorkshire College of Science, founded in 1874, which forms its real nucleus, the School of Medicine being incorporated in 1884. The College was then a modest block of buildings near the centre of the town, and began its first year with three professors and one student.

The first important development of the College of Science occurred in 1877, when it took over from the University Extension Committee the teaching of arts subjects, and became the Yorkshire College. In the same year the foundation-stone of the present buildings was laid by the late Dr. Thomson, Archbishop of York.

The Clothworkers' Company, the generosity of which to the technical departments of the college is as conspicuous as it is consistent, undertook the first section of the college buildings by erecting the textile industries and dyeing departments at a cost of 70,000*l.*

In 1887 the Yorkshire College entered the Victoria University as its third constituent college, and thus obtained the privilege of preparing its students for its own degrees.

To pass briefly in review the more recent developments, we must record the building of the Baines wing as a memorial to Sir Edward Baines, which was opened by the Prince and Princess of Wales (their present Majesties) in July, 1885; the building of the leather industries department in 1889 at a cost of 5668*l.*, mainly defrayed by the Skinners' Company; the founding of the agricultural department in 1890; and the building of the library, college hall, and medical school in 1894.

In 1903, when the union of the three constituent colleges of the Victoria University was dissolved and the Yorkshire College became the University of Leeds, the Privy Council, in recommending the grant of a university charter, stipulated that the capital of the institution should be increased.

The council has now succeeded in raising a little more than 100,000*l.*, more than half of which has already been expended in extensions, constituting the new buildings which His Majesty the King, as visitor of the University, opened on July 7.

The new buildings, the design and erection of which have been entrusted to Mr. Paul Waterhouse, comprise the main block extension in College Road for the arts and education departments, the temporary building for physics and chemistry, the mining, fuel, and metallurgical block, the laboratories for electrical engineering, the extension of the mechanical engineering building, certain additions to the textile department, and a central boiler house. The first of them in date of completion is the laboratory for mining, fuel, and metallurgy. The building was erected and equipped mainly from a fund of about 8000*l.* contributed by the Yorkshire Coal Owners. It stands by itself near the main university buildings, and is a simple three-storied red-brick structure. It is divided into two departments, that of mining, which is mainly on the ground floor, being under the supervision of Prof. Thompson, whilst the fuel and metallurgy department, under Prof. Bone, is housed mainly on the first floor.

*The Mining Department.*—This includes a lecture-room capable of seating fifty students, which it shares jointly with the department of fuel and metallurgy; a drawing office, which is equipped with surveying instruments; a general mining laboratory for the study of ore dressing and coal washing, which contains laboratory crushing and sampling machines, small jigs, slime tables, vanning shovel, and gold-washing pans, with the necessary assaying equipment for testing the products. Adjoining is an annexe for larger sized coal-washing and ore-dressing machinery, and includes a stone breaker, Cornish rolls, a stamp battery, jigging screens, &c. There are also fans and galleries for demonstrating the principles of ventilation of coal mines, and a photometric and lamp room for the study of safety-lamps and of different methods of gas-testing as ordinarily employed in collieries.

*The Gas Engineering, Fuel, and Metallurgy Department.*—This includes a large furnace-room, a general laboratory more especially for gas and fuel investigations, a balance and galvanometer room, stores, private laboratory, and a museum with a lecture-room on the top floor. The department represents a somewhat new departure in technical training, for in addition to the usual work connected with the study of metallurgy, it is laid out for the experimental study of different kinds of fuel and for preparing students for the working of gas plant for lighting and heating. In this connection it may be mentioned that the department is receiving financial assistance from the Institute of Gas Engineers in the form of an endowment of 500*l.* a year, which is being raised by the efforts of Sir George Livesey, and a fellowship of 100*l.* a year for research in connection with the gas industry. The furnace-room is equipped for the practical study of the characteristics of metals and alloys. The whole length of the room along one side is furnished with furnaces standing on stone slabs, including a full range of gas crucible furnaces, oil cyclone furnaces, a gas reverberatory furnace, muffle, sagger, and retort furnaces, with blast driven by a Crowell blower. Half the floor space is occupied by machines for testing the mechanical properties of metals and alloys, a rolling mill for reducing ½-inch rods to ¼-inch section, tensile-testing machine, a torsion-testing machine, and a set of electrically driven machines for cutting, grinding, and polishing sections, and preparing them for microscopic examination and photography. Adjoining the furnace-room is a laboratory with a special installation of apparatus for research on gaseous explosions under pressure, a compressing plant for obtaining compressed gases up to 200 atmospheres, and bench for analysis of coal, steel, &c.

The furnace and adjoining balance-room contain a complete installation of recording electrical and optical pyrometers, and the laboratory is also equipped with gas and bomb calorimeters for calorimetric determinations and apparatus for gas analysis. The equipment of these laboratories has been carried out at a cost of about 1000*l.*

*The Electrical Engineering Department.*—This department has been removed from its very cramped quarters in the main block, and now occupies a new and spacious building specially arranged, and standing by itself on the north side of the north quadrangle. It comprises a lecture theatre, drawing office, and photometer room equipped with the latest standards and apparatus for the measurement of the candle-power of electric glow and arc lamps, gas burners, &c.; a transformer room supplied with low- and high-pressure static transformers, rotary and electrolytic rectifiers, and apparatus for investigating efficiency of such plant; an instrument room, equipped with pressure, current and power standards, and a variety of testing apparatus; an electromotor room, with eight types of motors for continuous current and for single, two- and three-phase alternating currents, including a 500-volt 25-B.H.P. tramway motor; a dynamo room with eight pairs of motor-driven generators and rotaries, each having its own switch-panel, and developing from 4 h.p. to 30 h.p. at almost any pressure and periodicity. These sixteen machines are nearly all of the latest types, and comprise series, shunt and compound wound generators, single-phase, two-phase, and three-phase alternators, a double commutator, continuous current rotary, and a polyphase rotary converter; and, finally, an electrical engineering laboratory with all the necessary apparatus for instruction in the principles and practice of the subject.

*Physics Department.*—Prior to 1884, when the present lecture-room and laboratory were erected, the number of students taking practical work was extremely small, and the accommodation provided was regarded at that time as ample. From 1884 to 1898 the number of laboratory students increased eight-fold, and accommodation for them could only be found by annexing and utilising various cellars and underground corridors. In 1898 the Department had about 100 students, and comprised 220 square yards on two different floors, serving for all but electrical work, and 300 square yards of cellars, in which electrical experiments had to be carried on. Subsequently, a dark room of 150 square yards in the form of a corrugated iron building was added for advanced optical work, and another cellar of 200 square yards for elementary physics. The new premises, which consist of a one-storey shed covering the former tennis courts, will add about 1600 square yards, and will be divided into sections for elementary and advanced work. It is anticipated that the space will not only accommodate the present number of students, but will allow of an increase up to 50 per cent. It is impossible, however, that the present structure should have a very long life. Glass-roofed sheds and thin brick walls do not furnish ideal conditions for a physical laboratory, and it is anticipated that as soon as funds allow, a building having some relation to the importance of the subject and the large number of students in attendance will be erected.

*Organic Chemistry Department.*—The history of this department begins with the foundation of a lectureship and its recognition as a separate department in 1891. There was then no special provision for the study of practical organic chemistry. The department was first housed in a private laboratory and furnace-room on the ground floor; but as the number of students increased, additional accommodation had to be found, and a portion of the large lecture theatre was partitioned off, providing bench room for twenty-two students. The new temporary one-storey building, which adjoins the new physical laboratory, will double the present bench space, as well as provide a private laboratory for the professor and a temporary laboratory for occasional classes. As in the case of the Physics Department, it is only lack of funds which prevents suitable provision being made for this branch of practical chemistry.

*Civil and Mechanical Engineering Department.*—This department was founded in 1876, and for eight years was carried on under some difficulties as to space and equipment. In 1884 a special fund was raised by the engineers of the district for the building of a new department, with laboratories, drawing-office, lecture-rooms, &c. The accommodation proved sufficient for some years, but as the number of students increased, it was found necessary to absorb into the department other small rooms of the college, and in 1891 the authorities found themselves compelled to limit the number of students to eighty. The new block is an extension of the 1884 buildings on the north side, and contains a laboratory specially fitted up for hydraulics and one for applied mechanics, as well as an extension of the drawing-office.

This brief history of the university and the account of its new buildings is a record of small beginnings and steady growth. Each department has passed through a similar series of phases, a more or less rapid rise in numbers causing increasing pressure from within, which has led to expansion by various temporary expedients until the department has had to detach itself from the parent building and set up house for itself. There may be now an interval of apparent repose; but there is little doubt that the process will repeat itself. Temporary buildings will have to give place to permanent structures, properly adapted for the purpose which they have to serve, and physics and chemistry, the largest of the departments, will soon have to receive their share of attention. It will only be by constant appeals to the generosity of the public that the university will be able to fulfil the requirements which high teaching efficiency and modern equipment demand, if it is adequately to serve the interests of the city and county in which it is placed.

We have only referred to the work and appliances for ordinary teaching. The pursuit of research is eagerly encouraged, but here again the small sum at the disposal of the council for post-graduate fellowships and maintenance grants greatly reduces that form of assistance which heads of departments naturally look to in carrying out original investigations.

This form of assistance the Treasury has, unfortunately, not yet recommended in allocating funds for research, but its recognition cannot be urged too strongly or too frequently.

J. B. C.

## A CAPE CATALOGUE OF STARS.[1]

THE most recent catalogue of stars emanating from the Cape Observatory contains the places of 1680 stars for the equinox 1900·0, deduced from observations made during the years 1905–6 under the direction of Sir D. Gill. The introduction, which is signed by Mr. S. S. Hough, explains that the stars observed with the old non-reversible transit circle in the above-mentioned years, the places of which are included in this catalogue, are chiefly stars south of declination $-36^\circ$ required by Prof. Boss in connection with the formation of his fundamental catalogue. The catalogue also includes stars the places of which are required in connection with the geodetic survey of South Africa, and stars of which occultations by the moon have been observed.

With regard to the right ascensions, it may be noted that the places of stars employed for the determination of clock-error were those of Newcomb's Fundamental Catalogue. It is also to be noted that the correction has been applied for the observers' personality depending on magnitude. The existence of this kind of personality was first detected by Sir D. Gill in his discussion of the places of the comparison stars used in connection with his determination of the solar parallax by observations of Mars in 1877. It is fit and proper, therefore, that the Cape Observatory should be a pioneer in this direction of refinement, and should include this correction, as a matter of routine, in the ordinary reductions of meridian transits of stars.

The declinations have been reduced with refractions based on the Pulkowa tables and adopted mean latitude of the transit circle, $-33^\circ\ 56'\ 3''{\cdot}50$. The observations have also been corrected for variation of latitude depending on the Chandler polar motion, in accordance with data supplied by Dr. Albrecht. Here again we note the anxious care of the authorities of the Cape Observatory to produce work of the highest excellence and refinement.

The catalogued places of the stars have been reduced by the application of precession alone (based on Newcomb's determination of the precessional constant) from the mean epoch of observation to 1900·0, but the necessary corrections for the inclusion of proper motions are given in a separate column. The adopted values of the latter elements have been taken from Newcomb, Boss, or Auwers.

In view of the uncertainty attaching to the proper motions of stars south of the zenith of the Cape, it is of interest to exhibit the corrections to the places of Prof. Boss's catalogue of 627 standard stars (*Astronomical Journal*, Nos. 531–2), derived from the comparison with the

[1] "Catalogue of 1680 Stars for the Equinox 1900·0 from Observations made at the Royal Observatory, Cape of Good Hope, during the Years 1905–6." Under the direction of Sir David Gill, K.C.B., F.R.S., with Introduction by S. S. Hough, F.R.S. Pp. xii+44. (Edinburgh: Printed for H.M. Stationery Office by Neill and Co., Ltd., Bellevue, 1907.) Price 3s.

places of the Cape catalogue before us, for the stars specified above, when arranged in zones of declination:—

| South decl. | | $\Delta\alpha$ s. | | $\Delta\delta$ " | | No. of stars |
|---|---|---|---|---|---|---|
| 34–46 | ... | −0·004 | ... | +0·33 | ... | 39 |
| 46–56 | ... | −0·008 | .. | +0·42 | ... | 34 |
| 56–66 | ... | +0·009 | ... | +0·45 | ... | 30 |
| 66–80 | ... | −0·049 | ... | +0·44 | ... | 16 |

The discordances in right ascension for the first three zones are not larger than would be anticipated, bearing in mind the fact that Prof. Boss has not corrected his places for personality depending on magnitude. The mean correction for the polar zone is, however, quite uncertain, the mean (without regard to sign) of the individual discordances from the mean value entered above being as much as 0·102s., pointing to the extreme uncertainty with which right ascensions of even so-called "standard" stars situated in this portion of the sky are carried forward for a term of years.

There appears to be a well-marked systematic discordance of about 0″·4 in the declinations. This, however, is not the place in which to inquire into the origin of this discordance, which will doubtless receive due attention at the hands of Prof. Boss.

A melancholy interest attaches to the publication under review. Sir D. Gill, in a short preface, addresses a few words of farewell to the members of the staff of the Cape Observatory, referring to this catalogue as the last that will probably appear in connection with his name. The splendid work performed by Sir D. Gill at the Cape Observatory need not be emphasised here. It must be a satisfaction to him, as well as to astronomers all the world over, that he was able to accomplish another excellent piece of work before the close of his official career, during which he has done so much to enhance the fair fame of British astronomy.

A. M. W. D.

## UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Dr. John Cadman, one of H.M. inspectors of mines, has been appointed to the chair of mining rendered vacant by the resignation of Prof. R. A. S. Redmayne.

GLASGOW.—The University Court has established a lectureship in bacteriology, and appointed Dr. C. H. Browning as the first lecturer. The Court has also established a lectureship in geography, to which an appointment will be made in October.

THE annual meeting of the Midland Agricultural and Dairy College will be held on Monday, July 27, at 3.15 p.m., when the report on the year's work will be presented. The Duke of Portland will address the meeting and present the certificates gained during last session.

To secure the best results, it is highly important that technical colleges should work in close connection with the needs of local industries. A distinguishing characteristic of the prospectus of the day classes at the Heriot-Watt College, Edinburgh, is the excellent system of co-ordinating the more theoretical work of the college with the practical experience gained during apprenticeship. Arrangements have been made with several of the leading firms of engineers in Edinburgh by which students of the college are allowed to begin their apprenticeship at the end of the second winter college session, returning to college the following winter to complete their third winter session. Students holding the college diploma have their term of apprenticeship reduced by a year, and in some cases either reduced premiums are charged to college students or the premiums are entirely dispensed with. The Edinburgh and Leith Corporations' gas commissioners, also, have agreed to allow students who have been three years in the chemistry department of the college to spend four summer months in the laboratories of their gas works, and thus to obtain a thorough knowledge of the analysis of fuels, products of combustion, coal gas, and coal distillation products. A two years' course of instruction in mining, again, has been arranged, which is accepted by the Home Office as equivalent to the two years' underground training required of those who wish to obtain the mine manager's certificate. In connection with the department of technical mycology, an arrangement has been made between the college and the Brewers' Association of Scotland by which brewers' apprentices who have completed satisfactorily an approved course will receive a joint certificate awarded by the association and the college. Students who already hold a university science degree can obtain special post-graduate instruction in several departments of technology. These instances are typical of the successful efforts which are being made in Edinburgh to make technical instruction of real benefit to those employed in industrial pursuits.

ON the occasion of the visit of the King and Queen on July 9 to open the Royal Edward Dock at Avonmouth, an address was presented to their Majesties by the council and senate of the Bristol University College. After detailing the efforts which have been made to provide Bristol with a complete system of education, the address proceeds:—"We humbly trust that your Majesty will regard with satisfaction the provision that has thus been made in our city for education in its various grades, and will look with favour on our hope that our educational system will be completed and crowned by the establishment of a University in Bristol similar to those founded in recent years in other important cities of the realm. The public spirit and generosity lately shown by a member of a well-known Bristol family in promising the sum of one hundred thousand pounds towards the endowment of a Bristol University leads us to anticipate that with the help of other liberal benefactors our city may shortly be in a position to crave of your Majesty the grant of a Royal Charter for the incorporation of this University." During the course of his reply, the King said:—"It is now recognised by the great municipalities and other education authorities of my kingdom that it is their duty to provide facilities for the acquirement of special knowledge, so that young men may be enabled to obtain efficient equipment, both literary and technical, without travelling to distant Universities to obtain it. The generous emulation of rival cities in this respect is necessarily beneficial, for every addition to the practical efficiency and culture of a community, and every stimulus thereby supplied to others, are gains to the whole nation. I will take care that your petition for a grant of a charter for the incorporation of a University in Bristol is referred to a committee of my Privy Council, who will give it careful and sympathetic consideration, and then submit to me their advice." The Society of Merchant Venturers also presented an address in which reference was made to the willingness of the society to maintain a faculty of engineering in the University.

THE Department of Agriculture and Technical Instruction for Ireland has for some years been very active in encouraging the teaching of science both in Irish secondary schools and technical institutes. Technical instruction also, through the efforts of the department, is being given successfully in numerous centres throughout Ireland. Illustrated accounts of the technical work in different districts are published in the Journal of the department from time to time, and afterwards re-published for wide distribution; the latest pamphlet to be issued in this way is a well illustrated description of the facilities for technical instruction in Queenstown, by Mr. George Thompson, the principal of the technical school in that town. The department also does very useful work in providing science teachers in Irish secondary schools with careful guidance as to the best methods of teaching and the most suitable courses of work in science for boys and girls in secondary schools. We have received copies of the revised syllabuses in physics and in physiology and hygiene. The syllabuses, in addition to a general introduction describing the aim and object of the instruction, outline experimental courses of study for each of the four years during which science is taught in the secondary school. During the first two years of their study of science the pupils investigate practically the simple fundamental principles of physics and chemistry, while during the third and fourth years some specialisation is allowed, and the study becomes more intensive. The syllabuses are well worth the careful attention of all teachers of science in secondary schools, whether they are teaching in Ireland or elsewhere. We notice, too, that the department will, in August, 1908, award not more than six industrial scholarships—of the value of 80*l*. each, and renewable for a second and third year—to persons engaged in industries, such as the woollen, linen, leather, and tanning industries. The object of these scholarships is to enable selected persons, who must already have been engaged in one of the higher branches of the industry, to take a full course of instruction in an institution providing special courses of an approved character, with the view of training them for the management of such an industry. Candidates will be required to show that there is a reasonable expectation of their being able to find suitable employment in the industry in Ireland after the termination of their scholarships.

THE installation of Lord Morley of Blackburn as Chancellor of the University of Manchester took place on July 10. Replying to an address presented to him by the Vice-Chancellor, Mr. A. Hopkinson, Lord Morley dealt with the functions of universities. He urged those present not to allow technical teaching, valuable as that science was, to throw into a second place the true object and scope of a University. It is a remarkable and encouraging fact, he said, that there has been no disposition during the last twenty or twenty-five years among the many benefactors of these institutions to limit their benefactions. On the contrary, some of the most remarkable of these benefactions have been for music, for philosophy, for theology, and for literature. This would seem to justify the hope that merely and purely technical teaching will not drive out teaching of the University type. After the installation Lord Morley and Mr. Arthur Balfour were entertained at luncheon. Mr. Balfour, in replying to a toast, said:—"In order to pursue knowledge to the best advantage, knowledge must be pursued for her own sake; and she is more likely to be successfully pursued for her own sake in a great academical house than by any other method or machinery which the wit of man has as yet devised. As knowledge is to be pursued for its own sake, mankind has found its greatest instrument for the better prosecution of knowledge in science. The great advancement of mankind is to be looked for in our ever-increasing knowledge of the secrets of nature—secrets, however, which are not to be unlocked by the men who pursue them for purely material ends, but secrets which are open in their fulness only to men who pursue them in a disinterested spirit. The motive power which is really going to change the external surface of civilisation, which is going to add to the well-being of mankind, which is going to stimulate the imagination of all those who are interested in the universe in which our lot is cast, that lies after all with science. I would rather be known," Mr. Balfour continued, "as having added to the sum of our knowledge of the truth of nature than anything else I can imagine. Unfortunately for me, my opportunities have lain in different directions; but the happiest of men surely are those whom fortune has given time, leisure, the opportunity, and, above all, the genius which enables them to penetrate into the secrets of nature in such a way that, perhaps unknown to themselves, unknown even to the generation in which they are born, something will have been given to mankind which posterity can develop into some great practical discovery on which the felicity of mankind may depend."

## SOCIETIES AND ACADEMIES.

### LONDON.

**Royal Society**, March 12.—"On Reciprocal Innervation in Vaso-motor Reflexes and the Action of Strychnine and of Chloroform thereon." By Dr. W. M. **Bayliss**, F.R.S.

(1) In depressor reflexes there is, along with inhibition of tone in the vaso-constrictor centres, an excitation of vaso-dilator centres. This has been shown in the cases of the submaxillary gland, the penis, the hind-limb, the external ear, and probably the tongue.

(2) Correspondingly, in pressor reflexes, along with excitation of constrictors, there is, in appropriate conditions, inhibition of dilator tone. This is, however, more difficult to demonstrate.

(3) Similarly, in the local, or Lovén, reflexes, there is also both excitation of dilators and inhibition of constrictors.

(4) The action of strychnine is to convert the inhibitory phase of all vascular reflexes into an excitation, so that:—

(5) The depressor nerve produces a rise of blood-pressure under full doses of the alkaloid. It does this by exciting the constrictor centre by the same mechanism which normally inhibits it.

(6) In the "dilator" animal under strychnine, pressor reflexes become depressor, in that inhibition of dilators is converted into excitation.

(7) Various parts (synapses) of the reflex arc are differently sensitive to the alkaloid, the synapse of the pressor fibres with the constrictor centre being the first to show paralysis as the dose is increased.

(8) In the "dilator" animal strychnine causes a fall of blood-pressure on injection by exciting dilator centres. In the normal animal the first dose causes a rise, and subsequent ones a fall of pressure, since the first dose, if not too small, after exciting the vaso-constrictor centre, paralyses the synapses concerned, so that the simultaneous excitation of the dilator centres can now make itself felt.

(9) The excitation of constrictors produced by reversal of inhibition is more resistant to the alkaloid than that produced in the normal way.

(10) Asphyxial blood does not act directly on the efferent constrictor neurones, since it has no action at a stage of strychnine poisoning at which the depressor still excites constriction, by reversal of inhibition.

(11) Chloroform converts pressor into depressor reflexes (in the rabbit) by reversal of excitation of constrictors into inhibition.

(12) This effect of chloroform is not exerted on the efferent neurones directly, but at some point considerably earlier in the reflex arc. This is shown by the fact that asphyxial blood causes rise of pressure when excitation of sensory nerves causes fall.

June 4.—"The Optical Constants of Gypsum at Different Temperatures, and the Mitscherlich Experiment." By Dr. A. E. H. **Tutton**, F.R.S.

The experimental work on selenite now described confirms the author's previously published conclusion, derived from other examples, that the phenomenon of crossed-axial-plane dispersion is due to very low double refraction, combined with close approximation of the intermediate index of refraction to one of the extreme indices, and to the fact that change of wave-length of the light or change of temperature, or both, cause the intermediate index to approach still nearer to the extreme one in question until it becomes identical with it, and eventually to pass it, the relative positions of the two indices thus becoming reversed. The uniaxial rectangular cross and circular rings are produced at the critical point of identity. This critical point is a function of both wave-length and temperature, being a fixed one only for a particular wave-length and specific temperature. The temperature has a maximum for wave-length 573 on the greenish-yellow side of the D lines (589). The optic axial angle has a maximum for the same wave-length 573, for all temperatures below that of the crossing of the optic axes, and a minimum for temperatures superior thereto up to the temperature of decomposition (120°) of selenite. The change of orientation of the median lines (bisectrices of the optic axial acute and obtuse angles) within the symmetry plane, at any specific temperature, also exhibits a critical limit for this greenish-yellow light of wave-length 573, which is thus a very important radiation in connection with the optics of selenite. The range of temperature which includes the production of the uniaxial figure for all colours of the spectrum does not exceed 4°, varying in different crystals from 3°·5 to 4°. The absolute temperatures of crossing for the four crystals investigated varied 9°, the maxima (for wave-length 573) varying from 105°·5 to 114°·5, corrected for conduction of crystal holder.

**Zoological Society**, June 16.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—Photographs and fragments of skin and bone of a mammoth and a rhinoceros discovered in an ozokerite mine at Starunia, Galicia:

Dr. A. Smith **Woodward.** The carcases of these animals appeared to have found their way into an old marsh saturated with petroleum, which had completely preserved them. The photographs and specimens had been received from Dr. George von Kaufmann, who intended to present them to the British Museum.—The lower jaw of a young Canadian beaver in which there was present on each side a small conical tooth anterior to the deciduous premolar: Dr. C. I. Forsyth **Major.** The supernumerary premolar was considered to be a case of atavism.—Drawings made from examples of two species of Castor from the East Runton forest-bed: Dr. Forsyth **Major.** It was remarked that truly forest-bed species were found in association with Pliocene species.—Photographs of Pliocene Bovinæ from specimens in the Florence Museum: Dr. Forsyth **Major.** These unpublished figures showed the great variability of the Pliocene Bovinæ. The exhibitor endorsed Falconer's opinion that these Pliocene Bovinæ were nearly related to the primitive buffaloes from the Siwaliks.—Mammals from the provinces of Chih-li and Shan-si, N. China, collected by Mr. M. P. Anderson, being the tenth of the series of papers on the results of the Duke of Bedford's zoological exploration of eastern Asia: Oldfield **Thomas.** Very little material had hitherto existed from this part of northern China, although a certain number of specimens had been sent to Paris by Père David, and it was therefore of great importance to have a series representing the species he discovered for comparison with mammals from other regions. The present collection consisted of about 100 specimens, belonging to twenty species, of which several are new.—A case of imperfect development in *Echinus esculentus*: J. **Ritchie** and D. C. **McIntosh.**—The minute structure of calcareous sponge-spicules: Prof. E. A. **Minchin** and Dr. D. J. **Reid.** The primary object of this investigation was to demonstrate, by means of photomicrographs, certain structures, the existence of which had been strenuously denied by some of the most competent of previous investigators, namely, the presence, after the spicules had been cautiously decalcified, of a residue in the form of an axial filament which could be stained and rendered evident by certain dyes, in addition to the sheath universally acknowledged to exist. The axial filament was found to be very distinct in the spicules of Clathrinidæ, but much less so in those of Leucosoleniidæ and Heterocœla. Incidentally, the study of the axial filaments led to some interesting conclusions regarding the comparative morphology of the two principal types of spicules, monaxon and triradiate, occurring in calcareous sponges.—*Cyaniris chennellii* of de Niceville: Dr. T. A. **Chapman.** It was shown that this was not a Cyaniris (Celastrina, Tutt), but belonged to a new genus near to Everes, and that a specimen in Colonel Bingham's collection, placed with *chennellii*, was a species almost entitled to be placed in Cyaniris, for which he proposed new generic and specific names. Another specimen of the latter species was in the Tring Museum. It was suggested that de Niceville had both these species together in dealing with *chennellii*, and unfortunately selected as his type the one that was not a Cyaniris. The two forms probably fly together, and are therefore mimetic.—(1) A contribution to knowledge of the batrachian *Rhinoderma darwini*; (2) some notes upon the anatomy of *Chiromys madagascariensis*, with references to other lemurs: F. E. **Beddard.**—*Leucocytozoon musculi*, sp.n., a parasitic protozoon from the blood of white mice: Annie **Porter.** The parasites occur in mononuclear and transitional leucocytes, and free in the plasma. The free trophozoites are gregariniform vermicules, their average size being 10·9 $\mu$ long by 5·1 $\mu$ broad.—Descriptions of African micro-Lepidoptera: E. **Meyrick.** 108 species and eleven genera of Tortricina and Tineina from the African region (especially the Transvaal) were described as new.—A collection of calcareous sponges made by Mr. Cyril Crossland in the Cape Verde Islands: A. G. **Thacker.**

**Royal Microscopical Society,** June 17.—Mr. A. N. Disney in the chair.—*Exhibits.*—A lens for high-power microscopy to obviate the use of the oscillating screen: J. W. **Gordon** and H. Fletcher **Moulton.**—A small, simple microscope by Cary: A. **Skinner.** The instrument was only $4\frac{3}{4}$ inches high. It was provided with a plane mirror and a mechanical stage having movements of 4/10-inch horizontally and $\frac{1}{2}$-inch vertically. Focussing the object was effected by moving the stage by rack and pinion, the teeth of the rack being set obliquely, as in modern microscopes.—Micro-slides illustrating the structural parts of the chick at various stages of its development from about two days to $4\frac{1}{2}$ days: A. **Flatters.**—Stereophotomicrographs: Wm. P. **Dollman.** These were photographs of Alveolina ×6, fungus in eye of horse×350, statoblast of a fresh-water polyzoa from Bombay×350, *Biddulphia antediluviana* from Baltic mud×350.—*Papers.*—Cycloloculina, a new generic type of Foraminifera found on the shore of Selsey Bill: E. **Heron-Allen** and A. **Earland.** The paper was illustrated by a large map, on which the localities where the specimens were collected were pointed out. A number of slides of specimens under microscopes, and lantern-slides were shown upon the screen. Mr. Earland remarked that he believed they would eventually trace the specimens to some Eocene deposit which was not exposed above low-water mark. The source of origin could not be very far away from the place of discovery, for the specimens were too fragile to travel any considerable distance.—Illuminating apparatus for the microscope: J. W. **Gordon.** The light from a Nernst lamp is transmitted through a glass rod, the end of which nearest to the lamp is cut to a plane surface and finely ground; the other end has a polished surface, flat or lenticular in form, according to the user's requirements.—*Corethron criophilum*: E. M. **Nelson.**

**Linnean Society,** June 18.—Dr. D. H. Scott, F.R.S., president, in the chair; afterwards, Dr. A. Smith Woodward, F.R.S., vice-president.—Altitude and distribution of plants in southern Mexico: Dr. Hans **Gadow.**—Reports on the marine biology of the Sudanese Red Sea from collections made by Mr. Cyril Crossland, together with collections made in the Red Sea by Dr. R. Hartmeyer. On the Bryozoa, part i., Cheilostomata: A. W. **Waters.** The author enumerates thirty-nine species of Cheilostomata collected by Mr. Crossland, and twenty-three collected by Dr. Hartmeyer; besides these, eighteen other species are known from the Red Sea, making eighty Cheilostomata in all. The distribution of Red Sea species is in most cases very wide, often extending from the Atlantic to Eastern seas.—The algæ of the Yan Yean reservoir: G. S. **West.**—*Gardenia Thunbergia* and its allies: Dr. **Stapf** and J. **Hutchinson.** These Gardenias, fifteen in number, form the bulk of the section Eu-Gardenia in Africa, and extend over the whole of the continent with the exception of the temperate north. Owing to the instability of certain characters and the scantiness of the material in the older collections, they have not been well discriminated so far, with the result that *Gardenia Thunbergia* came to cover finally half a dozen perfectly distinct species ranging all over Africa, whilst the plant originally described under that name is actually confined to a limited area in South Africa. The distinctive characters of the species admitted—of which six are here described for the first time—are set out in key form, whilst their distribution and synonymy and full descriptions of the new species are given in the second part of the paper. It is also pointed out that the segregation of the "Thunbergia" group from the closely allied Indo-Malayan stock of § Eu-Gardenia must have taken place in pre-Tertiary times.—The marine algæ collected in the Indian Ocean by H.M.S. *Sealark*: A. **Gepp.**—Nudibranchs from the Red Sea, collected by Mr. C. Crossland: Sir Charles **Eliot.**

**Royal Anthropological Institute,** June 23.—Prof. W. Ridgeway, president, in the chair.—The Kurdish tribes of the Ottoman Empire: Mark **Sykes.** The tribes, of which the author distinguished about 323, inhabit that part of Asiatic Turkey between Uruma, in Persia, and Angora, in Asia Minor. Classification is difficult. They may be distinguished as nomadic, semi-sedentary, and sedentary, but any other kind of classification is almost impossible. As to religion, there are to be found among them Sunni Moslems, Shias, Devil worshippers, Pagans, Pantheists, and Christians. Linguistically, they are divided into a variety of dialects, which are said to form two broad divisions, Zaza and Kermanji. Physically, the most extraordinary contrasts are to be found. In Hakkiari they are small, wiry mountaineers; tall, slim horsemen in Irak; those north of Lake Van are clumsy, heavily built, big-boned, and hook-nosed; in north Mesopotamia they are full-bearded, with regular features; while to the north and west of Erzinjian the men are fair-haired and of ruddy complexion. In point of civilisation the contrasts are just as marked.

### Cambridge.

**Philosophical Society**, May 18.—Mr S. Ruhemann, vice-president, in the chair.—Radio-activity of solutions of potassium salts: N. R. **Campbell**. (1) All attempts to observe or to produce any difference in the activity of different samples of the same potassium compound in the same physical state have failed completely. No evidence has been obtained of any such separation of the activity as is to be expected, whatever view may be taken of the source of the activity. (2) The activity of a thick layer of a potassium compound is not accurately proportional to the amount of potassium which it contains. It is probable that the variation from strict proportionality is to be attributed to a difference in different compounds of the values of the ratio of the density of the substance to the absorption coefficient of the rays emitted by it. In the case of solutions, at least, the variations in the value of this ratio are surprisingly large and irregular. The ratio is not necessarily greater for the solution of greater density or greater concentration.—A preliminary note on an effect observed when palladium foil is heated in air at a low pressure: Rev. H. V. **Gill**. Strips of palladium foil were mounted in a glass tube so that they could be heated by means of an electric current. When heated in air at a pressure of about 0·15 mm. first to a dull red and then to a bright white heat, the palladium foil was seen to be surrounded by a purple-blue glow. This glow had all the appearance of a kathode discharge in a vacuum tube. There was no electric field except that due to the current which came from two storage cells to heat the foil. The glow gradually disappeared, and could not be again obtained from a strip which had been already used. This experiment was repeated many times, and with palladium foil obtained from different sources. The cause of this glow is being investigated.—The absorption spectra of some compounds of pyridine (second paper): J. E. **Purvis**. The results indicate that in these isomeric compounds the relative positions and the persistencies of the absorption bands are influenced by the type and the spatial positions of the atoms or groups of atoms introduced into the nucleus.—Further researches in the theory of divergent series and integrals: G. H. **Hardy**.—Some reactions of phenyliodidechloride and iodosobenzene acetate: H. H. **Hodgson**.—Integral forms and their connection with physical equations: R. **Hargreaves**.—The determination of the rate of chemical change by measurement of the gases evolved: F. E. E. **Lamplough**.

### Manchester.

**Literary and Philosophical Society**. May 12.—Prof. H. B. Dixon, F.R.S., president, in the chair.—Spore formation in the genus Chætoceros: Miss Nellie **Snape**. Spined resting spores occur during the late summer; these are set free by the breaking up of the Chætoceros filament and the throwing off of the old shells. Individuals of Chætoceros are also often seen containing a number of small rounded spore-like bodies formed by the contraction of the protoplasm and its aggregation round the chromatophores. The number of these bodies varies considerably, but their size is remarkably constant. It would appear rather probable that these spore-like bodies are really gametes, but confirmatory evidence on this point is at present lacking.—The mummy of Khnumu Nekht in the Manchester Museum: Miss Margaret A. **Murray**. The coffin was found in a rock tomb at Rifeh, near Assiout, in Upper Egypt, and dates from the XIIth Dynasty, or, roughly, about 2500 B.C. That this was a real mummy was shown by the fact that the nails of the hands and feet were carefully bound with threads so as to preserve them in position when the epithelium fell away. This proves the practice of mummifying, which rapidly disappeared on the introduction into Egypt of Christianity, to be more ancient than some have maintained, who give 1600 B.C. as the earliest date of its occurrence. The practice was held by some to be connected with the belief in re-incarnation. On the coffin were inscriptions said to be variants of the Pyramid text. Some of these read as follows:—"Thy mother Nut spreads herself above thee: she causes thee to be as a god without enemies"; "Comes to thee, comes to thee, thy mother Nut"; "To Anubis, Lord of Sepa, may he grant that thou cross heaven, and that thou reach land at the pure places which are in heaven."—Dr. **Cameron** gave an account of the anatomical features of the remains. The bones were remarkably slender. Measurements of the capacity and "indices" of the skull showed that it compared favourably with the average modern European type, whilst the limb bones rather tended towards the Simian character. There were indications that Khnumu Nekht was of lethargic habit, and spent much time in a squatting posture. His height was probably between 5 feet 3 inches and 5 feet 10 inches, and his age between sixty and seventy years. The teeth, with the exception of one, were intact, and only one of them showed any sign of decay, but all were extraordinarily worn, which showed that the food consumed must have been exceedingly gritty.

### Edinburgh.

**Royal Society**, June 22.—Prof. Ewart, F.R.S., vice-president, in the chair.—Equilibrium in the system water, and a pair of enantiomorph solids: Dr. W. W. **Taylor** and Dr. T. **Rettie**. The system investigated was water and the optically active tartar emetics, the systems water with *r* tartar emetic along with *d*- or *l*-tartar emetics being also included to complete the scheme. Series of confirmatory experiments were made with *d*- and *l*-sodium ammonium tartrates and sodium ammonium racemate. In the former case the transition temperature was unknown; it was determined by the solubility and dilatometer methods to be between 60° and 61° C. It was confirmed by crystallisation experiments above and below the transition temperature. The results show that the enantiomorph solids behave as two absolutely distinct phases, any mixture of the two being more soluble than either component alone; and the maximum solubility is possessed by the equimolecular mixture. Owing to the occurrence of labile equilibria, true equilibrium in each system was found to be attained much more slowly than was generally supposed. In some cases 20 days' shaking was found to be necessary.—The electrolytic conductivity of aqueous solutions of lactic acid, and on changes in conductivity accompanying the alcoholic fermentation: Dr. John **Gibson** and Andrew **King**.—An improved thermostat and other apparatus used in conductivity work: Dr. John **Gibson** and G. E. **Gibson**.—Determinations of the conductivity of concentrated solutions of good electrolytes:—(1) hydriodic and hydrobromic acids: Dr. John **Gibson** and Andrew **King**; (2) hydrochloric acid: Dr. John **Gibson** and W. H. **Paterson**; (3) ammonium bromide, lithium bromide, and sodium bromide: Dr. John **Gibson** and Dr. E. B. R. **Prideaux**.—The precipitation of certain chlorides by hydrochloric acid: Dr. John **Gibson** and Dr. R. B. **Denison**. These papers all bore more or less upon a general line of research which has occupied Dr. Gibson's attention for years. The discussion of the facts established was held over for a future communication. The improved thermostat was electrically controlled, the circuit of the incandescent lamps which supplied the heat being interrupted or closed (as the case might be) by an electromagnetic relay controlled by a modification of the usual form of cut-off. By means of this thermostat the temperature could be kept absolutely constant for months at a time.—Andrews's measurements of the compression of carbon dioxide and of mixtures of carbon dioxide and nitrogen: Dr. C. G. **Knott**. This completed a work which was begun by Prof. Tait in 1899 with the view of supplying the true pressures as indicated by the air and hydrogen manometers used by Andrews in his well-known experiments. See a letter by K. Tsuruta, of Tokyo, in NATURE, February 2, 1899, which directed attention to the importance of finding the true pressures instead of those given by Andrews and explicitly referred to by him as only provisional. With the assistance of Dr. Andrews's daughter, Miss M. K. Andrews, the experimental notebooks had been carefully and successfully investigated, and the data obtained from which the true pressures could be calculated.

### PARIS.

**Academy of Sciences**, July 6.—M. Bouchard in the chair.—A fundamental hypothesis implicitly admitted in the classical treatment of astronomy: J. **Boussinesq.** It has been implicitly assumed that the path of any planet with respect to the sun forms a closed trajectory described periodically. The tendency to make the simplest hypothesis consistent with the observed facts is unavoidable; thus the ancient astronomers assumed circular uniform motion for the stars, an assumption which had to be complicated as observations became more exact.—The triboluminescence of racemic compounds: D. **Gernez.** It has been shown by Tschugaeff that whilst with certain optically active bodies both the right- and left-handed constituents are triboluminescent, the racemic compound is not so. The author has filled up some gaps in Tschugaeff's table, and added fresh optically active substances, but is unable to confirm his hypothesis. There seems to be no general relation of cause and effect between triboluminescence of bodies and their symmetrical or unsymmetrical constitution.—The eclipse of the sun of June 28, 1908, at the Observatory of Lyons: Ch. **André.** The results of observations of contacts, chords, and angles of position. The last contact was partially obscured by clouds.—The action of metallic oxides on primary alcohols. The case of oxides undergoing reduction: Paul **Sabatier** and A. **Mailhe.** The simplest case is that of the oxides of antimony and bismuth, which, at 360° C., are reduced to metal, water and aldehyde being the only products. With $HgO$ and $MnO_2$ the oxidation goes further, some carbon dioxide being formed. The reduced metal in these cases shows no catalytic power, but with nickel, cobalt, lead, and copper the catalytic effects of the reduced metal are added to the reducing power of the oxides, and the reaction becomes more complicated. With some metals (iron, cadmium, tin) the oxides also can act catalytically.—The floating population on canals and public health: MM. **Chantemesse** and **Pomès.** The possibility of infection being carried in this way was overlooked in the legislation of 1902. Cases are cited showing how widely infection has been carried by canal boats, and the necessity of suitable prophylactic measures is pointed out.—Some new peculiarities of short-period variable stars: a method of distinguishing their effects from those due to dispersion in a vacuum: Charles **Nordmann.** It is shown that the results obtained by the method of monochromatic images can separate, for a numerous class of variable stars, the two classes of phenomena in question.—The variations of duration of twilight: Ernest **Esclangon.** The visibility of celestial objects, depending as it does on two factors, the apparent brightness of the sky and the transparency of the air, is a faulty method of observation; the photometric state of the sky is more suitable for quantitative study. The great influence of suspended particles in the air is pointed out, and the abnormal twilight of July 1 considered from this point of view.—The partial eclipse of the sun observed at the Observatory of Besançon on June 28, 1908: MM. **Brück, Chofardet,** and **Pernet.**—Observation at the Observatory of Marseilles of the partial eclipse of the sun of June 28, 1908: Henry **Bourget.**—A problem relating to the theory of partial differential equations of the hyperbolic type: A. **Myller.**—A new integrometer: M. **Jacob.** The apparatus described on May 11, 1908, allows the integration of the equation

$$y' = Ay^3 + By^2 + Cy + D,$$

if a particular solution of this equation is known. By slightly modifying the apparatus, the latter restriction is removed.—The useful weight of aëroplanes: Rodolphe **Soreau.**—The use of detectors, sensitive to electric oscillations, based on thermoelectric phenomena: C. **Tissot.**—Researches on ionised gases: A. **Blanc.** The method of measurement used was a modification of the alternating field method of Rutherford, and was applied to the study of mixtures of carbon dioxide and hydrogen, and air and carbon dioxide. The mobility in air of an ion produced in carbon dioxide is the same as if this ion had been directly produced in air, and this is true for ions of both signs.—The influence of temperature on the electromotive force of the cadmium element: R. **Jouaust.** The formula given in 1901 by Jäger and Lindeck for the variation in the electromotive force of the cadmium cell between 0 and 20 for an amalgam containing between 12 and 13 per cent. of cadmium has been confirmed. More recently, Smith has stated that between 10° and 20° C. amalgams of 10 per cent. and 12·5 per cent. show an identical relation; this, however, is now shown not to be true at 0° C., and the anomalies shown by the cells with 10 per cent. amalgam require further investigation.—Interference fringes shown by colour photographs: E. **Rothé.**—A repeating auto-ballistic galvanometer: A. **Guillet.** If successive small impulses are imparted to the ballistic needle at periods corresponding to its vibration period, a large increase of sensibility results. An automatic arrangement for effecting this is described in the present paper.—Dynamos without a collector: C. **Limb.** The application of electrolytic values to dynamos.—The stability of the alternating arc as a function of the atomic weight of the metals forming the electrodes: C. E. **Guye** and A. **Bron.**—The orientation of crystals by the magnetic field. The importance of the optical properties of mixed liquids from the point of view of crystalline symmetry: A. **Cotton** and H. **Mouton.**—The phenomena of Bose and the laws of contact electrification: Édouard **Guillaume.**—The Bose-Guillaume phenomenon and contact electrification: Jean **Perrin.**—A relation between the magnetic and chemical properties of complex iron salts: P. **Pascal.**—The total heats of baryta, witherite, and fused lime: M. **Latschenko.**—The development of negatives in radiography: Maxime **Ménard.** A description of the modification in the details visible in the negative which can be produced by variations in the method of working with the same developing bath.—The influence of the medium on the Brownian movements: Victor **Henri.** A quantitative study by means of a kinematograph microscope of the effects produced by the addition of various amounts of acids and alkalis to the latex of india-rubber. A new iodide of titanium, titanous oxide, $TiI_2$: Ed. **Defacqz** and H. **Copaux.** The new iodide is obtained by the action of mercury vapour upon $TiI_4$ in an atmosphere of hydrogen at a red heat.—The heat of neutralisation of picric acid by various aromatic bases in benzene solution: Léo **Vignon** and M. **Evieux.** Picric acid differs from acetic and benzoic acids in that it forms salts readily with aromatic bases in benzene solution. It furnishes examples of formation of salts in the absence of ionisation.—The direct transformation of borneol into campholic and isocampholic acids: Marcel **Guerbet.** If borneol is heated in sealed tubes at 250° to 280° with recently fused potash it is almost quantitatively converted into the potassium salts of campholic and *iso*campholic acids, hydrogen being evolved.—The preparation of benzoylacetic esters: A. **Wahl.** By the action of sodium upon an ethereal solution of ethyl benzoate, benzoin is produced. Hence, in the condensation of ethyl acetate and benzoate with sodium, three distinct reactions are produced.—Ergosterin and fongosterin: C. **Tanret.**—Study of the *rôle* of yeasts in the aldehydification of alcohol: MM. **Trillat** and **Sauton.**—The influence of formic acid vapours on the growth of *Rhizopus nigricans*: Henri **Coupin.**—The recollection of the tides in *Convoluta Roscoffensis* and its alteration: Louis **Martin.**—The structure of the renal cell: L. **Bruntz.**—The first venous circulation of *Carassius auratus*: P. **Wintrebert.**—Study of the immunising action of chlorinated derivatives of bacilli: MM. **Moussu** and **Goupil.**—The quaternary alluvium of the Loire and Allier: E. **Chaput.**

### New South Wales.

**Linnean Society,** May 27.—Mr. J. H. Maiden, vice-president, in the chair.—The behaviour of *Hyla aurea* to strychnine: Dr. H. G. **Chapman.** The common Australian frog *Hyla aurea* has been noted not infrequently to be much less susceptible to the poisonous alkaloid strychnine than European frogs of the genus Rana. The minimal lethal dose for various species of Rana has been measured by numerous observers, and there seems to be general agreement that it may be said to lie between 2 mg. and 5·5 mg. per kilogram of body-weight. For *Hyla aurea* the minimal lethal dose is 0·1 mg. per gram of body-weight, and is somewhat higher in frogs collected in winter than in those collected in summer, but is unaffected by differences in sex. The receptive substance of the muscles of *Hyla aurea* is sensitive to strychnine, so that the frogs show, with appropriate doses, typical curare paralysis. The prominence of this action produces a characteristic type of poisoning in Hyla.—Notes from the Botanic Gardens, Sydney, No. 13: J. H. **Maiden** and E. **Betche.** The authors described several new species, new varieties, new records for New South Wales, and new localities, and made some remarks on notable plants.—A contribution to our knowledge of Australian Hirudinea. Part i.: E. J. **Goddard.**

### Calcutta.

**Asiatic Society of Bengal,** June 3.—Tibetan charms obtained by Lieut.-Colonel S. H. Godfrey in Ladakh, one for chasing away evil spirits and the other for compelling fortune: Dr. S. C. **Vidyabhusana.** These two charms are printed from wood blocks, and used by people of Ladakh who are entirely ignorant of the meaning of the writing on them. The writing is Sanskrit in Tibetan characters.—A polyglot list of birds in Manchu, Chinese, and Turki: Dr. E. D. **Ross.**—Materials for a flora of the Malay Peninsula, part No. 21: Sir George **King** and J. S. **Gamble.** The part contains the two families which complete the Gamopetalæ, viz. No. 86, Gesneraceæ, and No. 90, Verbenaceæ. A review of the former of these families was published in 1905 by Mr. H. N. Ridley, director of the Singapore Botanic Garden, in the Journal of the Straits Branch of the Royal Asiatic Society, but as the form of that publication was not quite the same as has been used by Sir G. King and his various helpers, Mr. Ridley's work has been revised by Mr. Gamble with the help of Lieut.-Colonel D. Prain, of Kew. The Verbenaceæ have been worked up by Mr. Gamble. Part No. 21 also contains the addenda and corrigenda of the Gamopetalæ and the index to vol. lxxiv.—Note on the peregrine falcon (*Falco peregrinus*): Lieut.-Colonel D. C. **Phillott.**—The use of the abacus in ancient India: E. R. **Kaye.** Tylor, Woepcke, Rodel, Burnell, Bayley, and other writers on Indian mathematics assume that the abacus was in common use in ancient India, but they give no evidence of such use. They, however, on this assumption build up elaborate arguments to prove that our arithmetical notation was invented in India, and incidentally that the Arabs owe their arithmetic to the Hindus. An examination of their statements shows that their assumption is unwarranted, and, indeed, that no evidence at all has yet been given of the use of this instrument in ancient India. This, of course, does not prove that the abacus was not used by the early Hindus, and it is with the idea of eliciting evidence on this point, if it exists, that this paper was read.—Plea for an aquarium in Bengal: Rai Ram Brahma **Sanyal.** The author advocates the establishment of an aquarium at Puri, chiefly for the study of economic questions regarding the fisheries of the Bay of Bengal.—A descriptive list of works on the Madhyamika philosophy: Dr. S. C. **Vidyabhusana.** This paper gives a short account of the Tibetan versions of twenty-seven works on the Madhyamika philosophy, the Sanskrit originals of which, with one exception, appear to have long been lost. The Tibetan versions are included in the well-known collection called the Tangyur, which the writer of the paper examined while residing at the monastery of Labrang, in Sikkim, in June, 1907. They include the works of Arya Nagarjuna, Arya Deva, and Buddha Palita, besides those of the teacher Bhavya, who criticised the contemporaneous systems of Hindu philosophy, viz. the Yoga, Samkhya, Vaisesika, Vedanta, and Mimamsa. These works, which have not been noticed elsewhere, are very important, as they throw a good deal of light on the history of Indian philosophy.—The mechanical, physical, and chemical theories of the ancient Hindus, part i.: Principal B. N. **Seal.** A synoptic view of the mechanical, physical, and chemical theories of the ancient Hindus, based chiefly on the Vyasa Bhashya or Patanjali's Sutras, the Samhita of Charaka, the Bhashya of Prasastapada, the Vartika of Udyotakara, and the Vrihat Samhita of Varaha Mihira, which belonged to the fourth, fifth, and sixth centuries of the Christian era.—Geometrical theory of a plane non-cyclic arc, finite, as well as infinitesimal: Prof. S. **Mukhopadhyaya.**—A memoir on the surgical instruments of the Hindus, with a comparative study of the instruments of Greek, Roman, Arab, and modern European surgeons, part i.: Dr. G. N. **Mukhopadhyaya.** The author describes the surgical instruments of the Hindus, and concludes that knowledge of the kind was considerably more advanced among them than previously held to be.—Rationalisation of algebraical equations: Mahendranath **De.**

## PATENTS AND THE PUBLIC.

*The Patents and Designs Act*, 1907. By James Roberts and H. Fletcher Moulton. Pp. xiv+128. (London: Butterworth and Co., 1907.) Price 4s. net.

IN the preface to this book the authors state that it does not pretend to be a treatise on patent law, but that its object is to give assistance to the reader in the interpretation of the new enactments and to point out their practical effects. The authors have not discussed the wisdom of the many changes in the law introduced by the new Act, nor have they attempted to dogmatise on points which must necessarily, on account of the language employed in framing the new provisions, await judicial decision. They have, however, indicated where these points lie, and have directed attention to both aspects of the questions involved so as to enable persons dealing with patents to appreciate the dangers ahead.

Among the many changes to which the authors direct attention are the important alterations in the jurisdiction and powers of the Comptroller. The jurisdiction of the Comptroller as to the granting of patents has been extended by giving him the power, under section 7, to refuse a patent altogether if he is satisfied that the invention claimed has been wholly and specifically claimed in any specification published before the date of the application for the patent in question. In cases of opposition under the Act of 1883, the Comptroller had power to refuse to grant a patent if the invention had already been patented in this country, and the new Act extends this practice in opposition cases to cases coming under the official search instituted by the Act of 1902. The words "wholly and specifically claimed" would appear to indicate that it is intended to give the Comptroller power to refuse under this provision only patents for those inventions which have been described and claimed in prior specifications in substantially identical terms. This new power of the Comptroller should prove to be of considerable benefit to the i[illegible]al community in that it will tend to prevent the [illegible] of worthless patents, of which there are such a large number in existence.

The jurisdiction of the Comptroller as to the granting of patents has been also extended by enlarging the grounds of opposition before him, for by section 11 any person may give notice of opposition on the ground that the nature of the invention or the manner in which it is to be performed is not sufficiently or fairly described and ascertained in the complete specification. Hitherto it has been the practice that a member of the public who had no special interest was not entitled to oppose the grant of a patent, but the question of what persons are entitled to be heard in opposition now becomes of greater importance, as it is only such persons as are entitled to oppose under this section who are entitled to petition for the revocation of the patent under section 26. The two distinct views which may reasonably be taken of the right to oppose under this section are fairly stated by the authors, but it is not at present clear which view will finally be adopted. This section should result in a desirable improvement of the descriptions contained in specifications, for unless the nature of the invention and the manner in which it is to be performed are sufficiently and fairly described and ascertained in the complete specification, this may be made a ground of opposition to the grant.

Two important changes in the practice of developing an invention are introduced by the new Act. Under section 16, an applicant who has put in two or more provisional specifications for inventions which are cognate or modifications one of the other may file one complete specification in respect of the whole of the applications, so that by this section an applicant may, as the authors state, "file several provisional specifications as improvements occur to him, and in the event of the Comptroller allowing them to be included in one patent, he does not risk invalidity by reason of disconformity." Under section 19 a patent of addition may be applied for in respect of any improvement in or modification of the invention for which an ordinary patent has been applied for. The advantage of introducing patents of addition is that they enable a patentee to develop his invention at less cost than would be incurred by taking out separate patents for each improvement, as no renewal fees are payable in respect of a patent of addition.

The practice on a petition for revocation of a patent has been very much altered by the new Act. Revocation of a patent may be obtained on petition to the Court as hitherto, but, in addition, the Comptroller may now revoke a patent on various grounds. In the first place, under section 26, any person who would have been entitled to oppose the grant of a patent may, within two years of the date of the patent, apply to the Comptroller for an order revoking the patent on any ground on which the grant might have been opposed; so that under this section an opponent may come in to petition for revocation, and thus subject the patentee to the annoyance of what is practically an opposition considerably after the time has expired in which an opposition could have been entered under the old procedure. Secondly, under section 27 any person may apply to the Comptroller for the revocation of a patent on the ground that the patented article or process is manufactured or carried on exclusively or mainly outside the United Kingdom. The authors state that:—

"An attempt was made to attain the object of this clause by section 3 of the Act of 1902, but that section has proved practically a dead letter, partly in consequence of its ambiguity and partly because of the heavy expense it entailed on a petitioner. In the year 1906, out of 14,700 patents issued, 6500 were granted to foreigners; in the case of patents for dyes the proportion was about 95 per cent. In many cases these inventions were worked abroad exclusively, and the patented articles, or substances made by the patented processes, were imported in large quantities into this country, the British patents being used merely for the purpose of closing the market to persons other than the patentee and his licencees."

Such a state of affairs was in direct opposition to the spirit of our patent law, and as the obvious remedy of forfeiture of the patent, on account of the importation, under which the imported articles were made was prohibited by the fifth article of the International Convention, section 27 was introduced to meet the difficulty. By this section, which will come into operation on August 28, the Comptroller will have to consider the application for revocation, and if after inquiry he is satisfied that the allegations contained in it are correct, and unless the patentee proves that the patented article or process is manufactured or carried on to an adequate extent in the United Kingdom, or gives satisfactory reasons why the article or process is not so manufactured or carried on, the Comptroller may make an order revoking the patent either forthwith or after a reasonable interval.

Much has been written lately as to the benefits to this country likely to be produced by this section, and in some cases there has been considerable exaggeration of the probable effects. But although it is almost impossible to state accurately the effects of the section until it is discussed in actual practice, there is no doubt of the fact that foreign inventors are now showing a greater desire than ever before to have their patents worked in the United Kingdom. In and about London, for instance, sites are being acquired for the erection of factories for the manufacture of articles patented by foreign inventors, while in Leicester the manufacture of machinery for making boots and shoes is being largely extended, and a factory has been leased for the manufacture of safety razors. The advertisement pages of the trade journals and of the illustrated official journal of the Patent Office also indicate the anxiety of many foreign inventors to have their patents worked in the United Kingdom in order to avoid revocation.

Perhaps the most interesting case under this section may prove to be the case of the German chemical industries. It is well known, of course, that although the inventor of the original artificial dye was Perkin, the aniline dye trade has been transferred almost entirely to Germany, the proportion of patents in dye cases granted to foreigners being in 1906 about 95 per cent. Most of these patents are under the control of a few large syndicates, and at least one of these syndicates is making active preparation for working their patents in this country. The extent to which this working will be insisted on is, at present, quite problematical, as, under the section, the Comptroller need make no order revoking the patent if the patentee gives satisfactory reasons why the article or process is not manufactured or carried on in this country. What is a satisfactory reason? Is it a satisfactory reason that the article or process can be manufactured or carried on more cheaply abroad? Is it a satisfactory reason to have advertised for someone to work the patent and to have received no offer? These and many other questions at once arise and present difficulties which can, apparently, be settled only in practice.

The authors deal with the many minor changes in the law introduced by the new Act, and, although the comments might with advantage have been more lavish, the book may be recommended as a clear and concise discussion of the new enactments.

## A HISTORY OF GEOGRAPHICAL EVOLUTION.

*Die Entwicklung der Kontinente und Ihrer Lebewelt ein Beitrag zur vergleichenden Erdgeschichte.* By Dr. T. Arlt. Pp. xviii+730. (Leipzig: W. Engelmann, 1907.) Price 20 marks.

THE explanation of the obvious plan in the distribution of oceans and continents has long been one of the ideals of geography. Bacon insisted that one of the main duties of geographers was to solve the riddle of the geographical homologies, and at length a solution has been advanced that has made widespread progress into favour during recent years—the daring and once ridiculed tetrahedral theory of Lowthian Green. That theory, simply stated, is that hard-shelled spheroidal bodies that are contracting owing to internal shrinkage tend to become flattened on four faces; that the spheroid undergoes a tetrahedral deformation as the unshrinkable shell sags down after the contracting interior, and that this shape develops as the body thus most easily gets rid of the excess of surface. The extent of this deformation is limited in a revolving mass, as the effects of rotation oppose the deformation and tend to restore the spheroidal form. Modern developments of the tetrahedral theory attribute to this struggle between tetrahedral collapse and spheroidal recovery an alternate advance and retreat of the sea upon the land, as the ocean basins are alternately deepened and shallowed; and the occurrence of epochs of intense volcanic activity, following long intervals of quiescence, is attributed to disturbances that restore stability to the earth after a period of slow deformation has rendered the crust unstable.

The ultimate test of this theory is its agreement with the records of historical geology, and that test Dr. Arlt applies to it in the large volume of some 730 pages and an atlas of twenty-three plates. The author marshals a very varied array of evidence collected from geography, stratigraphical geology, palæontology, and geodesy. Dr. Arlt shows he has studied an enormous and varied literature, and is capable of handling petrographical, biological, and mathematical evidence.

The book begins with a brief reference to the theory of the permanence of ocean and continent which was much in vogue from 1876 to 1890. If that theory be true, the tetrahedral theory is unnecessary; for one of the astronomical theories which attribute the distribution of the continents to agencies that affected the earth in pre-geological times might be adequate. But, as Prof. G. H. Carpenter has recently remarked, "there can be no doubt that the trend of modern speculation is against the doctrine of the permanence through past ages of the great ocean basins of the present day" ("Scottish National Antarctic Expedition, Report on Scientific Results," vol. v., p. 57); and in accordance with most recent work, Dr. Arlt shortly and emphatically dismisses the theory as inconsistent with the facts. He then proceeds to state the methods of palæogeography They are the petrographic—the study of sedimentary rocks and deep-sea deposits—and the biological—the study of the existing and former distributions of animals and plants.

In the biological section the author deals mostly with the land faunas and floras; for their evidence is naturally the most significant regarding former land connections. But the marine fauna also gives weighty evidence. The writer pointed out in 1891 that the relations of the echinoid faunas of North America and Europe gave convincing evidence of a middle Cainozoic land connection across the Atlantic; and the position then indicated for the North Atlantic shores from the migrations of the sea urchins corresponds to the general position assigned to it by Dr. Arlt from the migrations of land animals. In his statement of the biogeographical evidence, Dr. Arlt follows the method of Blanford's fine address to the Geological Society in 1890. He considers the existing distribution of each group of land organisms in connection with its geological history and with the probable distribution of land and water on the earth during its development. He illustrates the land routes available for migration at successive periods in the history of a group by an ingenious series of diagrams (*e.g.* plate ii.). Dr. Arlt devotes 300 pages to a summary of our knowledge as to the geographical distribution of Cainozoic life. For the existing biological regions he adopts the division into three, and the names he uses suggest the age of the faunas and floras that inhabit them. The Holarctic region he names Kainogæa, on account of the modern character of its life; the Ethiopian and Oriental regions he groups together as Mesogæa; and for the remaining regions, including Australasia, Madagascar, and the Neotropical region, he adopts, with a modified meaning, Dr. Sclater's name, Palæogæa, as the region is characterised by ancient life.

The author then deals similarly with the distribution of Mesozoic and Palæozoic life, and the former continental unions thus proved. He quotes widely from literature, and numerous references show his indebtedness to the works of Lydekker.

The second main division of the work is geological, and here the author is largely dependent upon the work of Suess. He summarises the evidence from the various former continents, including North Atlantis, South Atlantis, Angaraland, Gondwanaland, the larger Oceania and Antarctica. He then describes the seven chief Archæan massifs, the ancient coigns of the earth, which have remained unbroken since the earliest geological times, and have guided the course of the earth-folds that formed the chief fold-mountain lines of the earth.

The section on historical geology summarises the chief geographical incidents and the characters of the life of each of the geological systems, and insists on the periodicity in the dominant phenomena. The author's conclusions, though probably right in the main, perhaps overstate the regularity of the periodicity. For instance, he divides known geological history into six cycles—the Cainozoic-Mesozoic, Upper Palæozoic, Middle Palæozoic (Lower Devonian and Silurian), Lower Palæozoic (Ordovician and Cambrian—the author, however, does not adopt the former term), the Algonkian, and the Urschiefer. Each cycle he represents as beginning with a marine transgression, followed by a period of fold-mountain formation, and then by vast eruptions of basic volcanic rocks, and each cycle closes with a Glacial period. He accepts six Glacial ages, viz. one in the lower and one at the top of the Algonkian, and others in the Upper Ordovician, Lower Devonian, Permian, and Pleistocene. The evidence for these six glaciations is not yet convincing.

Dr. Arlt traces, too, in the last pages of his work the influence of the former land distribution on the distribution of human races. He assigns the original home of mankind to the area north of the Himalaya. As land distribution at the arrival of man was in broad outlines essentially the same as now, the migrations of man, as is shown in the last of Dr. Arlt's admirable series of charts, followed the existing land lines. The woolly-haired races spread from Southern Asia into Africa and Melanesia; the stiff-haired Malays crossed oversea from Malaysia to Madagascar and the islands of the Western Pacific (the author unfortunately includes the Maoris as Malays), and the allied Mongols occupied northern Eurasia and America. The members of the author's last group, including the Indo-Germanic, Semitic and Hamitic peoples, and Dravidians, Veddas and Australians, overran southern Europe and northern Africa, while one section of it passed through the Malay Archipelago to Australia.

Dr. Arlt's work is extensive, comprehensive—the index occupies ninety-eight pages—and ambitious. Probably not one of his readers will agree with it all. The chapters are necessarily of unequal value. Among his classifications of animals, *e.g.*, that of the Echinoderms on his phylogenetic chart of that group, he adopts a now out-of-date system from von Zittel's textbook of 1883. But the work is of great value; it is original, suggestive, and, taken as a whole, we think sound. It is the fullest statement yet issued of the doctrines of a school of geological thought which appears to be making steady progress, and it shows the necessity for the combined study of palæontology, geology, and petrography in discovery of the actual history of the geography of our earth.

J. W. GREGORY.

## BOTANY ON THE VOYAGE OF THE "VALDIVIA."

*Wissenschaftliche Ergebnisse der deutschen Tiefsee-Expedition auf dem Dampfer "Valdivia," 1898–1899.* Edited by Prof. C. Chun. Vol. ii., Part i., No. 2, Beiträge zur Kenntniss der Vegetation der Canarischen Inseln. By H. Schenck. Pp. 180; with 12 plates. Price 45 marks. Vol. ii., Part ii., No. 3. Das Indische Phytoplankton. By G. Karsten. Pp. 326; with 25 plates. Price 70 marks. (Jena: Gustav Fischer, 1907.)

THE second volume of these memoirs has been assigned to the botanical results of the *Valdivia* expedition. The first part deals with insular floras, the second with marine floras, and there will be an account of plants collected in countries visited on the mainland. Dr. H. Schenck is responsible for the account of the Canary Islands, as he was for the previous numbers referring to the islands of Kerguelen, St. Paul, and New Amsterdam; but much of the text and a few of the illustrations are again the work of the late Prof. A. F. W. Schimper, who was botanist to the expedition. The character sketches written by Prof. Schimper bear that particularly vivid impress and breadth of view that characterise "Die Pflanzengeographie." Certainly he has a most fascinating subject, as the flora of the islands is rich in curious endemic plants.

The zones of vegetation as developed on the island of Teneriffe are fairly typical for the group. Schimper distinguishes three regions, basal, montane, and alpine. The basal region is the most extensive; here are found the weird arboreal monarch of the island, *Dracaena Draco*, the dragon's blood tree, showing at first an unbranched stem with tiers of horizontal leaves, but developing later a much-branched system; the candelabra-like *Euphorbia canariensis* and a date palm, *Phoenix Jubae*, the fruits of which provide food for birds but not for man. These are the dominant endemic species, but there are many others, succulent species of Euphorbia, Ceropegia, Echium, &c., and xerophytes characterised by a mass of thin, whip-like branches and narrow leaves, of which *Plocama pendula* furnishes a type. The proportion of endemics in the coastal vegetation is about one-third, a large number being species of Statice.

In the montane region Schimper notes particularly the laurel forest, where *Laurus canariensis*, *Erica arborea*, *Ilex canariensis*, and *Ocotea bullata* hold sway. Great interest attaches to several of these, because they are evidently closely connected with Tertiary fossil forms found in European countries. *Pinus canariensis* gives character to the landscape at 5000 feet, while higher *Spartocytisus supranubius* is almost the sole occupant of the black, stoney slopes. The volume is altogether *un embarras de richesse*, with copious illustrations, some in heliogravure, others interspersed with the text. Not the least pleasing feature is the generous manner in which Dr. Schenck has subordinated his work to that of his former colleague.

The study of phytoplankton is, for obvious reasons, a more exclusive subject, but the results given in the two volumes of text and plates are full of interest. Two earlier accounts treated of the gatherings taken in the Antarctic and Atlantic, while the plankton of the Indian Ocean is here under discussion. It was found that a definite limit to the Antarctic region could be set at Kerguelen Island. As the ship proceeded northwards the character of the plankton changed, species of Ceratium and Peridineæ generally becoming more numerous. Off Sumatra an increase of diatoms and Schizophyceæ connected with the increased food supply furnished evidence of coastal plankton mixed with the oceanic forms. Respecting vertical distribution, it was noted that in tropical waters the mass of plankton exists in the upper six hundred feet, while at twelve hundred feet living forms practically cease. The morphological details at the end of the volume include notes on diatom microspores, the formation of the rays in certain of the Peridineæ, and some life-histories. A final word of commendation must be bestowed on the volume of exceptionally fine drawings that have been skilfully reproduced.

## SOME NEW CHEMICAL BOOKS.

(1) *A Systematic Introduction to Analytical Chemistry.* By A. F. Walden and B. Lambert. Pp. vi+176. (Oxford: J. Thornton and Son, 1908.) Price 3s. 6d.

(2) *Naturlehre für höhere Lehranstalten.* I. Teil. Chemie, Mineralogie, und Geologie. By Dr. F. Dannemann. Pp. viii+225. (Hanover and Leipzig: Hahnsche Buchhandlung, 1908.) Price 2.80 marks.

(3) *Organic Chemistry.* Including certain portions of Physical Chemistry for Medical, Pharmaceutical, and Biological Students. By H. D. Haskins and J. J. R. Macleod. Pp. xi+367. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1907.) Price 8s. 6d. net.

(4) *Stereochemie, die Lehre von der Räumlichen Anordnung der Atome im Molekül.* By Dr. L. Mamlock. Pp. vi+152. (Leipzig: B. G. Teubner, 1907.) Price 5 marks.

(1) ALTHOUGH there is perhaps no branch of chemistry which at the present day is more stagnant than analysis (of the academic as distinguished from the technical kind), there are always to be found teachers whose interest in the subject will prompt them to publish their experiences. With this interest we have the greatest sympathy, for there is no doubt that the skill, neatness, intelligence and patience which analysis demands will always appeal to the chemist. Analysis is, in fact, his handicraft, just as much as the using of a lathe or a planing machine is that of the mechanical engineer, with this difference: that whilst the engineer may employ a mechanic to do his practical work, the chemist must always be his own analyst.

When we approach the question of the place of analysis in chemical teaching, we put the subject at once on a different plane and see it in a different perspective, for as students of chemistry are not all to be professional chemists, we have to consider analysis as merely a part of chemical teaching. There is no doubt that there has been a tendency for the subject to assume an exaggerated value. We inherited the tradition of the Stockholm Laboratory, and continued it because it adapted itself to practical examinations in chemistry. We do not believe any more than the authors "that the neglect of qualitative analysis is either necessary or desirable," but there is a great difference between learning the principles of the process and studying it as a part of the technique of the professional chemist. For the ordinary student there seems no object in discovering and identifying such uncommon combinations as meta- and pyro-phosphoric acid, fluosilicates or perchlorates. The range of practical chemistry has so increased of late that it has become more than ever imperative to restrict the study of one branch if it encroaches on the time which could be given more usefully to another. As to the general character of the book under review, we have failed to discover anything very original in its treatment of the subject, but it seems to be a thoroughly safe and trustworthy guide.

(2) This volume (the first of two parts) is for use in Realschulen and Gymnasien. It is divided into sections. There is one on descriptive and practical chemistry which covers 100 pages, including ten pages on technical processes, one of forty pages on mineralogy, including eight on crystallography. There are about thirteen pages on geology, three pages describe experiments on vegetable physiology, and the last forty pages are devoted to object lessons on topics which range from Scheele's discovery of oxygen to the growth of coral islands. The book is well printed on good paper, illustrated by excellent drawings, and compiled with evident care. It is also, in a sense, a practical manual, the first section being interspersed with a variety of simple chemical experiments. Yet in spite of its attractive appearance it is a satisfaction to think that such a book would find no place in any school in this country. Its defect is diffuseness, especially in the latter sections. We can form a pretty clear notion of the effect of a course of this kind on an average boy or girl. They would have absorbed a number of scientific names, have formed a hurried acquaintance with different kinds of apparatus, remembered several chemical formulæ; they would describe the six crystallographic systems, and talk about sedimentary and igneous rocks; but their knowledge would be a kaleidoscopic assortment of ideas which could produce no sharp and permanent impression, and would do little to stimulate a living interest in the things about them.

Whatever shortcomings our systems of science teaching may possess, we do not set schoolboys and girls, who are old enough to study science seriously, to nibble at a scientific scrap-heap. They may do that as much as they please out of school, and perhaps the more they do it the better; but in school the process with older children must be methodical and thorough, and not superficial and diffuse, and should leave the boy or girl with a solid foundation to build upon.

(3) The authors state in their preface that "it was with the idea of presenting in the simplest manner the facts of organic and physical chemistry which have an essential bearing on medical science that the present work was written." There is no doubt that in the present state of organic chemistry a process of judicious selection for special needs is not only desirable, but imperative. Like the botanist, one has to transplant typical specimens into trim little beds where they can be examined individually without the brain becoming bewildered by an endless and varied flora. Thus the authors have emphasised those facts which have a special relation to physiology and pharmacy, and have suppressed matter which they consider of less importance, and have done it with considerable judgment. Whether they have succeeded as well with the few brief references to physical chemistry is doubtful, the space allotted being altogether inadequate for even an elementary exposition of the subject.

We would direct the authors' attention to the following errors which have been noted in glancing through the book. Amyl and ethyl nitrite are not usually described as "nitro" compounds (p. 162); no distinction is drawn between the metallic derivatives of glycol and glycollic acid, both being described as *glycolates* (pp. 142 and 166); racemic lactic acid is not indicated by "*i*," but by "*r*" (p. 169); *nitrobenzlidene* is wrongly spelt (p. 195); *purine* is not the atomic framework, but the mother-substance of the uric acid group (p. 204); there is a step missing in Traube's synthesis of uric acid (p. 201); and the formula for safrole is wrong (p. 316).

(4) This book is intended for those who are not professed chemists, but are interested in the related sciences of physics and chemistry. It is a clear and concise exposition of the subject, a sort of abridged Werner's "Lehrbuch," and will no doubt fulfil the purpose for which it was compiled. Satisfactory as the book is in many of its essential features, it reveals a curious ignorance on the part of its author of much of the recent work on stereochemistry published in this country. We have noted the following more important omissions. There is no reference to McKenzie's researches on asymmetric synthesis, or to Patterson's work on the activity of substances in solution, or to his recent paper on "Optical Superposition," or to Kipping's synthesis of optically active silicon compounds. A book which ignores, whether by accident or design, contemporary research cannot be regarded as an entirely trustworthy guide. J. B. C.

## OUR BOOK SHELF.

*The Animal Mind. A Text-book of Comparative Psychology.* By Dr. Margaret Floy Washburn. Pp. xi+333. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1908.) Price 7s. net.

This book is the second volume of a series to be devoted to animal psychology, under the title of "The Animal Behaviour Series." The first volume—"The Dancing Mouse," by Dr. Yerkes, recently reviewed in these pages—was an exposition of the different experimental methods applicable to the investigation of the psychology of one particular animal. Miss Washburn's book likewise follows the experimental method, and aims at presenting concisely the facts and principles that have emerged as the result of the application of this method during the last ten or twenty years to the study of different forms of animal behaviour.

Starting with a general statement of the difficulties and limitations inherent in the science of comparative psychology, the author proceeds to give a somewhat brief yet penetrating and concise discussion of the problem of inferring mind from structure and function respectively. Miss Washburn's conclusion is so typical of her general attitude throughout the book that it may well be quoted here:—"We can say neither what amount of resemblance in structure to human beings, nor what speed of learning constitutes a definite mark distinguishing animals with minds from those without minds, unless we are prepared to assert that only animals which learn so fast that they must have memory ideas possess mind at all. And this would conflict with the argument from structure. For example, there is no good experimental evidence that cats possess ideas, yet there is enough analogy between their nervous systems and our own to make it improbable that consciousness, so complex and highly developed in us, is in them wholly lacking."

There follows on this a very full and admirably lucid description of the investigation of sensory discrimination, space perception, and higher forms of consciousness in the various classes and orders of the animal kingdom—methods and results being in every case given in connection with the names of the investigators and references to their works. These references, by the way, nearly five hundred in number, are collected at the end of the book, under the heading "Bibliography," and greatly enhance the value of the book to the intending research student.

Two chapters are devoted to the consideration of the processes of learning in animals. The subject is as difficult as it is important, which perhaps justifies the author's attitude of extreme caution, apparent throughout the discussion. The account is descriptive rather than critical. For example, the conflict between the results of Thorndike and Hobhouse respectively in their experiments on cats and dogs is indeed stated but not discussed. The closing chapters on the memory idea and attention are full of interest, and really come to close quarters with the vexed question of the relation of animal to human intellect.

Psychologists will be unanimous in their gratitude to Miss Washburn for the very thorough way in which she has accomplished her task.

WILLIAM BROWN.

*Natur-Urkunden.* By Georg E. F. Schulz. Heft 1. Vögel. Erste Reihe. Pp. 20, with 20 plates. Heft 2. Planzen. Erste Reihe. Pp. 16, with 20 plates. Heft 3. Planzen. Zweite Reihe. Pp. 16, with 20 plates. Heft 4. Pilze. Erste Reihe. Pp. 16, with 20 plates. (Berlin: Paul Parey, 1908.) Price 1 mark for each part.

VARIOUS books on birds by Messrs. Kearton, and others on natural history, including a miniature series that has attained a wide circulation, have served to indicate how suitably photographs from the life may be utilised to illustrate books on botany and zoology. A very charming series of this kind is now being issued by Messrs. Paul Parey under the title of "Nature Records"; they are being entirely prepared as to photographs and text by Mr. G. E. F. Schulz. The volumes will deal with both branches of natural history. Of the first four, two are devoted to wild plants and a third to fungi. It will be recognised that, owing to their low growing position, size, and tendency to movement, it requires great care and skill to photograph plants as they grow. However, Mr. Schulz is not content to take his photographs under the easiest conditions, but has been at considerable pains to record special phases, such as the open flowers of *Silene noctiflora* and the rain-flecked leaves of *Aira canescens.* Among the illustrations of fungi, one of the best, representing *Boletus scaber,* shows even part of the hymenophore.

Difficult as it must have been to secure these plant photographs, some of the studies of birds in the first part must have required even greater skill and patience. There is a delightful picture of the parent tern holding a small fish while one youngster tries to gobble and the other cries lustily. The turning of the eggs in the nest is shown both for the seagull and the avocet. Altogether the volumes cannot fail to meet with the admiration of all "nature-lovers." Inasmuch as the records are taken at random, the series is intended primarily for the *dilettante,* but the author's notes are full of nature knowledge that may be recommended to teachers of nature-study and others who are not too old to learn. It is to be hoped that the early parts will have a ready sale, as in these circumstances the series will be continued.

*A Pocket Handbook of Minerals.* By G. Montague Butler. Pp. ix+298. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1908.) Price 12*s.* 6*d.* net.

EVERY student of mineralogy knows how difficult it is to acquire facility in identifying minerals off-hand. It is with the view of assisting the student, the miner, and the collector in determining his specimens that this little work has been prepared. It has no pretension to be a manual of mineralogy, even of an elementary character, but it is simply a book for the pocket, to be used as a work of ready reference. For this purpose it seems well adapted. The mineralogist finding an unknown or doubtful mineral may turn to it for assistance, much in the same way that a botanist would use his flora. Chemical and crystallographic characters are deposed from the supreme position which they usually occupy, and attention is directed rather to obvious physical characters, which in some cases appear even trivial, but are yet of diagnostic value. The most characteristic features of a mineral are emphasised by being printed in thick type so as to catch the eye. At the end is a rather ingenious scheme, forming a kind of artificial key for the identification of an unknown species. There is also a glossary, which seems to have been prepared with care.

As the book is likely to be used by the prospector, the commercial element is not ignored, and tables are introduced giving the value of metals, useful minerals, and especially gem-stones. It is notable that space for notes is left here and there in the book, a feature which, though increasing the size of the volume, is likely to be of service in the field; thus a description of moonstone in less than half-a-dozen lines occupies an entire page (p. 136). We have not noticed many printer's errors, but the name of the mineralogist who suggested the scale of hardness was Mohs, not Moh, as printed twice on p. 290.

*La Lutte contre les Microbes.* By Dr. Etienne Burnet. Pp. ix+318. (Paris: Librairie Armand Colin, 1908.) Price 3.50 francs.

IN this book a very readable account is given of certain diseases of microbic origin, of the parasites producing them, modes of transmission, and methods of treatment and prevention. Cancer is first dealt with, the author evidently inclining to the view that this disease is due to a micro-parasite, transmitted perhaps by food and by insect parasities, which we think is probably not the case. The statistical part of this section is a useful summary of data concerning the frequency of the disease, cancer houses and districts, &c. After cancer, tuberculosis, tetanus, sleeping sickness, intestinal infections, and small-pox and vaccinia are dealt with, and with these the author is on less debatable ground, and a good summary of our knowledge of each is given. The volume concludes with a translation of Jenner's researches on the causes and effects of cow-pox.

R. T. HEWLETT.

*The Farm shown to the Children by F. M. B. and A. H. Blaikie.* Described by Foster Meadow. Pp. xii+91. (London and Edinburgh: T. C. and E. C. Jack.) Price 2*s.* 6*d.* net.

THIS attractive little volume contains a great deal of information about farming, expressed in a very simple manner. Its forty-eight coloured pictures are sure to please children greatly, and the book, as a whole, is well calculated to arouse an interest in agricultural pursuits.

## LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

### The Nature of the $\gamma$ and X-Rays.

IN a previous letter to NATURE (January 23, p. 270) I gave a brief description of some experiments made by Dr. Madsen and myself on the properties of the secondary radiation due to $\gamma$ rays. A fuller account is given in the Transactions of the Royal Society of South Australia, 1908, p. 1.

The experiments have been continued, and I hope that the following summary of the results will be of interest:—

(1) When $\gamma$ radiation is diminished in quantity as it passes through matter, $\beta$ radiation appears in its place, moving at the outset in the original direction of the $\gamma$ radiation, and subsequently undergoing scattering in the ordinary manner of $\beta$ rays.

(2) The penetration and therefore the speed of the $\beta$ radiation thus produced increases with the penetration of the $\gamma$ radiation to which it is due.

(3) The speed of the $\beta$ radiation does not depend upon the nature of the atom in which it arises.

(4) In the case of radium at least, the speed of the $\beta$ radiation is nearly equal to, perhaps a little less than, the speed of the normal $\beta$ rays emitted by radium itself.

(5) When very hard $\gamma$ rays traverse matter their absorption and therefore the production of $\beta$ rays are almost independent of the atomic structure of the matter, and a density law follows. Softer rays are affected by atomic structure; they are more absorbed by heavy atoms than by light atoms for equal weights of absorbing screen. The softer the rays, the greater is this effect. Hence arises the difference in character of the logarithmic curves of absorption of different substances; heavy atoms show a rapid initial fall. Hence also when soft $\gamma$ rays are used the emergence radiation from heavy atoms may be greater than from light atoms. And again, the relative extent to which the rays produce secondary radiation from different metals may be modified by passing the rays through screens, as Kleeman has shown. We do not, however, find any true selective absorption such as Kleeman suggests.

(6) If there are any secondary $\gamma$ rays, the ionisation which they produce is negligible compared with that produced by the secondary $\beta$ radiation, at least within a moderate distance of the radiator, say a metre in air.

All these facts can be explained very simply and directly on the neutral-pair theory; indeed, the theory guided us to the verification of most of them.

As regards (1), we have simply to suppose that the negative and positive passing united into an atom are separated if they happen to traverse a very strong field anywhere therein; the negative flies on, and the positive becomes ineffective.

The second property is also an obvious consequence of the hypothesis. The faster the $\gamma$ particle is moving, the greater the initial speed of the negative.

The third is readily explainable: the electric field of the atom is merely the solvent of the bonds that connect the pair. It is not able to affect the speed of the negative set free.

The fourth may be taken to imply that the radio-active atom (say Ra C) ejects electrons at a certain speed, some of which start off in company with a positive counterpart, some without. The former constitute the $\gamma$ rays, the latter the $\beta$.

The fifth would show that there are stronger fields inside heavy atoms than light ones, and that the chance of separation of the pair increases with (*a*) the strength of the field, (*b*) the time taken to cross it.

Turning now to the ether pulse hypothesis, it is convenient to consider it in two different forms, which are irreconcilable with each other.

In the first of these, both the electron and the electron's energy are supposed to be drawn from the atom, the $\gamma$ ray merely pulling the trigger. This theory requires us to accept the extraordinary idea that the primary ray, though it does no more than pull the trigger, determines the direction and velocity of the shot, and it offers no explanation at all of (1) and (4) (see above). We should naturally expect the velocity of the electron to be a function of the properties of the atom from which it is drawn, as in the well-known cases of true radio-activity. Moreover, all the radio-activity of which we have certain knowledge is not to be hurried or stayed by any external agency. It is true that Prof. W. Wien (Göttingen *Nachrichten*, 1907, p. 598) has made a tentative application of a theory of Planck's, and thence derived a formula $v^2\lambda = \text{const.}$, where $v$ is the velocity of the ejected electron, and $\lambda$ the thickness of the pulse. This provides a formula, but it satisfies (2) and (3) only; moreover, it seems to me that the difficulties remain as great as ever, and that the application of Planck's theory must be unjustifiable.

Passing on to the second form of the pulse theory, we now suppose the electron itself to be drawn from the atom, but its energy from the pulse.

I understand that this view is now held by Prof. J. J. Thomson (see Camb. Phil. Soc., vol. xiv., part iv., p. 417), and it is also maintained by Mr. N. R. Campbell ("Modern Electrical Theory"). New works often take some time to reach us here, and I have only just received a copy of this admirable book, but I hope I have understood it sufficiently well to enable me to describe the position correctly.

Since the energy of a pulse, if spread over an ever-widening surface, is utterly insufficient to provide the energy required for the secondary $\beta$ ray, Prof. Thomson and Mr. Campbell suggest that the pulse does not spread, but travels radially from the arrested electron along tubes of force, the latter being considered as things differentiated from the surrounding space. Prof. Thomson speaks of bundles of pulse energy travelling with the speed of light in straight lines. When a kathode particle strikes the anti-kathode, bundles dart away from the point of impact; when these impinge on atoms they drive out the electrons constituting the secondary rays. In this way the energy difficulty is explained, and possibly also the difference between the emergence and the incidence radiations. It must be remembered, however, that this difference may be very large. In the case of carbon under $\gamma$ rays, the one radiation is five or six times the other. Since the secondary $\beta$ ray has the same speed (nearly) as the primary kathode ray which caused the X-ray, it seems to me necessary to suppose that the arrest of the kathode particle must cause one bundle of energy of very small and invariable volume to travel out along one straight tube (and only one) connected to that particle. This causes the ejection of one electron from some atom into which it penetrates, giving all its energy to that electron. Similar arguments apply to $\beta$ and $\gamma$ rays. Surely it requires a very complicated structure of the æther to effect all this. I have too deep a respect for Prof. Thomson's work to say it is not possible to construct a theory on these lines, but I think I may fairly claim that the neutral-pair theory explains all the known properties of the $\gamma$ rays much more simply and completely.

Perhaps I ought to add that the theory, although it may require a detachable positive electron, does not require a free positive electron.

I have scarcely mentioned the X-rays. I am glad to see that Mr. Cooksey (NATURE, April 2, p. 509) has proved the difference between emergence and incidence radiation in their case also. It can now be said, therefore, that all the properties of the $\gamma$ rays as set out in the above summary hold for the X-rays also, *mutatis mutandis*.

University of Adelaide, May 5. W. H. BRAGG.

### Symbols for Physical Quantities.

IT is very desirable to have a notation for the representation of physical quantities in scientific books and periodicals, which shall be the same in all languages.

The subject is under the consideration of the International Electrotechnical Commission with a view to international agreement, and committees in the different countries (in England under the chairmanship of Lord Rayleigh, O.M.)

are discussing this particular subject. They are dealing more especially with symbols for electrical and magnetic quantities, but the system might with advantage be extended to embrace all important quantities in physical science, especially as the subject is receiving the attention of most technical societies with a view to some action being taken in the matter.

There are, however, two great difficulties which arise when we try to fix upon a standard notation.

The first is the difficulty of persuading a number of writers and readers who have become accustomed to a certain symbol for a certain quantity to change it in favour of an equally large number of writers and readers who have become accustomed to another symbol. For instance, in France and Germany the letter "I" commonly represents the strength of an electric current, while in England and America "C" is more commonly used.

In the second place, there are not enough letters in the two or three alphabets at our disposal to give a distinct symbol to each quantity, without resorting to the combination of more than one letter to form a single symbol. There is a great objection to this combination of letters, because the use of subscript letters and numbers is required for distinguishing between particular quantities of the same general kind. If, for instance, C represents current, $C_a$ might conveniently represent armature current, and $C_1$ the current in circuit No. 1. It would therefore not be good to take $C_a$ to represent capacity, or any quantity other than an electric current.

There is, moreover, an objection to using letters at all to represent quantities in a universal notation, because, unless initial letters are used, there is no connection in the mind between the letter and the quantity, and the symbol is difficult to remember. We cannot always use initials, because the initial letters differ in different languages. For instance, in England "R" commonly stands for resistance, while in Germany it is more convenient to use "W" for widerstand. Moreover, the same initial occurs for a great number of different quantites. For instance, "R" might stand for resistance, reluctance, reactance, radius, &c.

One way of avoiding the above difficulties would be to create a number of new symbols which could be printed by means of type like ordinary letters, and which would represent each physical quantity in a distinctive manner.

The question, however, arises as to whether a number of entirely new symbols would be acceptable to writers, readers, and printers alike, and the sub-committee on symbols appointed by the British section of the Commission has requested the writer to place his views publicly before the profession, with the view of obtaining suggestions and criticisms as to the feasibility of such a scheme from as wide a circle as possible.

In choosing a symbol, we would try to make a very simple picture of something that reminds us of the quantity in question. For instance, ⌡ might represent temperature. If we were told that this simple outline of a thermometer represents temperature, we would have no difficulty in remembering it. Similarly, / might represent force, and the various "forces" might be derived from it; for instance, ϟ electromotive force (conventional representation of lighting), and ∩ magnetomotive force.

It is not my purpose here to say what would actually be the best form of symbol for each quantity, but it is not a difficult matter to devise very simple characters which can be written quickly, easily, and with sufficient accuracy, and can at the same time assist the memory to connect them with the quantity for which they stand.

What would the printers say to the new type? The author has taken up this matter with a very large publishing firm, and is assured by their chief expert that 200 or 300 new types would be a small matter to a modern printer, who is already accustomed to deal with many hundreds of different founts, each of which contains from 50 to 120 different symbols. He estimates that a printer in a large way of business has at his command as many as 60,000 distinct types, differing from each other either in letter, size, body, or face. The addition of 200 or 300 more would be a drop in the ocean. The size of the new type could be standardised for most purposes, and it would only be in some special case that another size would be called for.

The setting up of the formulæ with the standard size of type would be simpler than with the present system, in which subscript letters are often unnecessarily introduced. One symbol under the present system sometimes consists of four or five letters.

If it be admitted that the introduction of new symbols is advisable, the question arises, what shall the new symbols represent exactly? Shall the sign ⌡ (temp.) represent temperature in any units, or shall it represent the number of degrees of temperature, measured by some scale agreed upon, and embodied in the definition of the symbol? If the system of units employed be not prescribed, fewer symbols would be required, and the general writer who now says vaguely, "Let T equal the temperature," would find the symbol sufficient for his purpose. But from the reader's point of view there is much to say in favour of a symbol which will embody in its definition a standard system of units. Any formula expressed in such symbols would be completely self-contained, and would be an exact statement of a physical fact. Until the units employed in any formula are known, the formula expresses only half its meaning. Perhaps some slight addition to the symbol, or even to the whole formula, might be used to indicate that the standard system of units is employed. Without that addition, the symbol would have a general meaning. For instance, ⌡ might equal temperature, while ⌡ might indicate the degrees centigrade above the absolute zero. The name of the type might be the name of the physical units which it represents; for instance, for ϟ we might read "volts."

If writers, printers, and readers who have any definite views as to the best method of devising a system of symbols would communicate with the author, they might assist in solving the many difficulties which arise in connection with this matter.

The Cottage, Leicester Road,
Hale, Altrincham.

### Linnæus's Authorities.

I am happily able to throw a little light upon the question raised by Prof. Karl Pearson in Nature of July 16 (p. 247). The citation he quotes is identical with that in the tenth edition of the "Systema Naturæ" (1756), p. 24.

"Bont. jav. 84. t. 84." will be found in Piso, "De Indiæ utriusque re naturali et medica," Amst. 1658. fol. The bastard title following the engraved title-page has towards the bottom this line:—"Iacobi Bontii, Bataviæ in majore Java novæ medici ordinarii, . . . " hence, no doubt, the form employed by Linnæus. This forms the third separately paged part of the volume, and on p. 84 is a woodcut of the "Ourang Outang sive Homo silvestris," &c.

"Kœp. itin. c. 86" is doubtless "Kiöping (Nils Matson) En reesa genom Asia, . . . . &c. Wisingsborgh, 1667. 4to."; I am quoting from Dryander's Catalogue of Banks's Library, vol. i., p. 86.

"Dalin. orat. p. 5." is referred to in Amœn. Acad., vol. vi., p. 74 as "Dalin in oratione Acad. R. Holm. de hac:" &c. I have not verified the actual speech, but it should not be difficult to run it down in the early volumes of the Handlingar.

B. Daydon Jackson.

Linnean Society, Burlington House, W.

### Elliptical Halos.

In Pernter's "Meteorological Optics" the explanation of haloes, based on a consideration of refraction and reflection in ice-crystals, is given at some length. In particular the elliptical halo described by Mr. Cave in Nature of July 16 (p. 247) is shown to be a form depending on the sun's altitude. If the sun is less than 25° above the horizon, the phenomenon appears as two arcs touching the 22° halo at its highest and lowest points. For altitudes greater than 70°, it is indistinguishable from the 22° circular halo.

It would be interesting to know if Mr. Cave observed the transition from the elliptical to the circular form.

E. Gold.

3 Devana Terrace, Cambridge, July 16.

## THE FIXATION OF ATMOSPHERIC NITROGEN AS CYANAMIDE.

In NATURE of August 30, 1906, an article was published describing the Birkeland Eyde process for the fixation of atmospheric nitrogen by electrothermic methods and the conversion of the nitric acid so obtained into calcium nitrate, which is used as a fertiliser in place of Chili saltpetre. Since that date the Birkeland-Eyde works at Notodden, in Norway, have been considerably enlarged, owing to the success which met their initial efforts. The necessity of obtaining large quantities of nitrogen in a form suitable for fertilising purposes does not require to be reiterated again, because the fact that the available sources are being depleted, and the demand for nitrogen for agricultural purposes continually increases, is now universally recognised. This has led many investigators to endeavour to fix atmospheric nitrogen in some other form, which it is hoped will be more economical than that of direct oxidation in the electric arc.

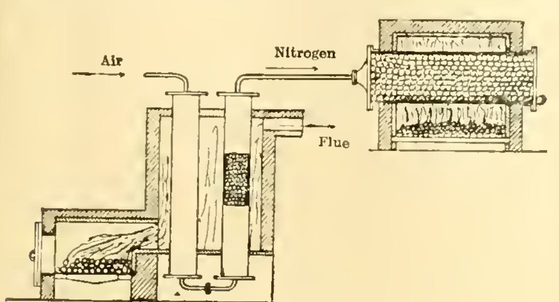

FIG. 1.—Nitrogen Absorption Retort.

The amount of Chili saltpetre exported in 1907 was 1,740,000 tons, and in order to replace this by the fixation of atmospheric nitrogen, it is necessary to employ 280,000 tons of the gas, and this is the amount which, it is calculated, is contained in the atmosphere over every nine acres of the globe. Another method of fixing nitrogen is known, and that is the formation of calcium cyanamide by the heating of calcium carbide in a stream of nitrogen obtained from the atmosphere. The researches which led to the discovery of calcium cyanamide were originally commenced by Drs. Frank and Caro in 1895, when they were endeavouring to produce cyanides by heating a mixture of calcium carbide and sodium carbonate in presence of nitrogen. The results were not very satisfactory, and therefore barium carbide was substituted, and this substance was found to absorb nitrogen with great avidity at between 700° and 800° C. It was intended to treat the barium cyanide with potassium or sodium carbonate, and thus produce the cyanides. On examination of the products produced, however, it was found that not only did barium carbide produce barium cyanide, but also a more complex compound was formed, which upon examination proved to be barium cyanamide according to the equation:—

$$BaC_2 + 2N = BaCN_2 + C.$$

The product obtained in the reaction usually contained 30 per cent. of barium cyanide and 40 per cent. of cyanamide, the remainder consisting of barium oxide and carbon. It was found, however, that the barium cyanamide and barium cyanide could easily be converted into potassium cyanide by melting with potassium carbonate as follows:—

$$Ba(CN)_2 + BaCN_2 + C + 2K_2CO_3 = 4KCN + 2BaCO_3.$$

Experiments were then taken up with calcium carbide, and investigation showed that by altering the conditions it was possible to convert the whole of the calcium carbide into cyanamide according to equation 1. Now when calcium cyanamide is decomposed by means of water, ammonia is produced thus:—

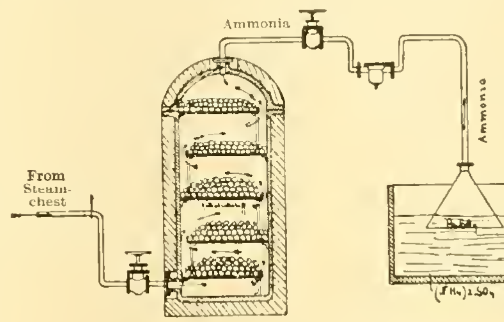

FIG. 3.—Ammonia Producing Apparatus.

$$CaCN_2 + 3H_2O = CaCO_3 + 2(NH_3).$$

It seemed, then, that it might be possible to obtain the ammonia for purposes of fertilisation, that is to say, employ cyanamide directly as a manure, but as the reaction only takes place with water at high temperatures, agricultural authorities were inclined at first to doubt the possibility of employing this product, as it was presumed the ammonia would probably not be liberated by the moisture of the soil. However, experiments showed that the cyanamide actually does decompose in the soil, and that it acts as a source from which plants can obtain the nitrogen which they require for nutriment. The product has therefore been put upon the market under the name of "Nitrolim." Some difficulties, however, were met with, one being that the finished product often contains some quantities of calcium oxide, therefore on exposure to moist atmosphere the nitrolim in-

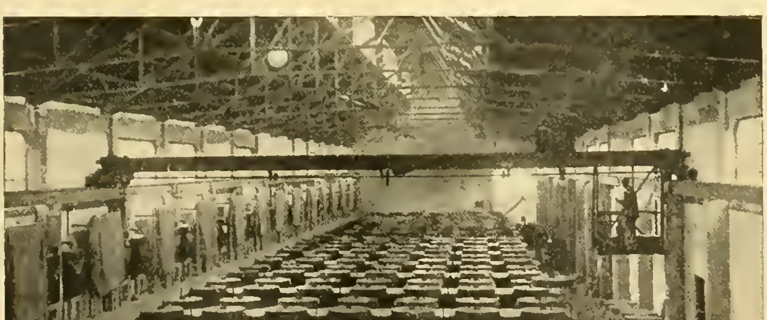

FIG. 2.—Electric Furnaces at Odda for producing Cyanamide.

creased in bulk, which was objectionable for storage purposes, as the jute sacks in which it was contained burst. By, however, taking precautions to line the sacks first of all with double paper, this difficulty was got over, and also by improved methods of manufacture the amount of lime produced was lessened.

As regards the actual part played by cyanamide in the soil various theories have been put forth; *e.g.* it would appear that when brought into contact with the ground the cyanamide is first decomposed through the action of the moisture and also of the carbon dioxide in the soil as follows:—

$$CaCN_2 + H_2O + CO_2 \rightarrow H_2CN_2 + CaCO_3,$$

and the free cyanamide will then, by absorption of water, probably be further decomposed into urea,

$$H_2CN_2 + H_2O \rightarrow CO\begin{matrix}\diagup NH_2 \\ \diagdown NH_2\end{matrix}.$$

Also the decomposition is greatly assisted by the myriads of microbes which are invariably found in cultivated soil.

Experiments have shown that calcium cyanamide is more suitable in some soils than in others, *e.g.* if the soil is in an acid state it is necessary previously to lime it. Such soils are found in high moorland and in sandy places because they are very poor in lime, and when applied to such land, cyanamide, unless lime is first added, is distinctly harmful, but with most other soils it is very satisfactory.

Nitrolim can also be mixed with other fertilisers, such as basic slag, potassium salts or superphosphate, but with this latter particular precautions have to be employed owing to the free phosphoric acid combining with the free lime in the cyanamide. This difficulty, it is stated, has now been got over. One advantage which cyanamide has over Chili saltpetre is that it is less soluble in water, and is therefore not so liable to be washed away in the drains and so lost, consequently the unchanged cyanamide which may have been left in the ground after the first harvest is readily available for the succeeding one.

FIG. 4.—Isere Valley, Nôtre Dame de Briançon.

Cyanamide is manufactured from calcium carbide of the same quality as that which is used for illuminating purposes. The carbide as it comes from the electric furnace is ground up and charged into retorts, which are made of fire-proof material, and are mounted in a furnace similar to the retorts employed for the manufacture of gas. (Fig. 1 shows this arrangement diagrammatically.) The nitrogen is then passed over the carbide, the retort being maintained at a temperature of from 800° to 1000° C. The nitrogen is produced either by the Linde system of fractional distillation of the air or by passing air over heated copper turnings, the resulting copper oxide being reconverted to the metal by passing reducing gases over it. In the Linde process the oxygen which remains after the separation of the nitrogen is a useful bye-product. As soon as the carbide in the retorts is saturated with nitrogen—a fact which becomes evident by the controlling gas meter coming to a standstill—the calcium cyanamide is extracted in the form of a hard cake, and is cooled in vessels from which air is excluded. When cool it is ground into a fine powder, and is ready for use.

During the last year a new electric furnace has been devised for heating the carbide while it is absorbing the nitrogen, and this has given such satisfaction that now all the older retorts are being replaced by the electrically heated ones. The process is cheaper, and the operating costs per furnace are lower, also the life of the retort is practically unlimited, which was not the case with the older retorts (Fig. 2 shows a number of these retorts in position.)

FIG. 5.—Main Buildings at Nôtre Dame de Briançon.

The yield of carbide at most works is about two tons per kilowatt year, and two tons of carbide will absorb practically 500 kilograms of nitrogen in the form of nitrolim. A power of about $2\frac{2}{3}$ h.p. is required per year for fixing each ton of nitrogen, and in addition to this about one-third horse-power is required for the grinding and all other mechanical operations. Consequently, to produce sufficient nitrolim to take the place of all the Chili saltpetre at present consumed annually, plant developing no less than 800,000 h.p. would be required. Not only is nitrolim useful as a fertiliser, but quite a large variety of chemical products have been made by means of it. For instance, by melting it with a flux, a mixture containing 25 per cent. of potassium cyanide, which is found to work quite as efficiently for the extraction of gold and silver as the pure product, is produced. It comes on the market under the name of "Surrogate." Ammonia may be produced very readily from this product, and may be collected pure or used for making salts of ammonia. (Fig. 3 shows diagrammatically the form of plant employed.) Another product is dicyandiamide, which is being used in increasing quantities for the manufacture of organic dyes. Besides which there are urea, thiourea, ferricyanide, and a variety of other products.

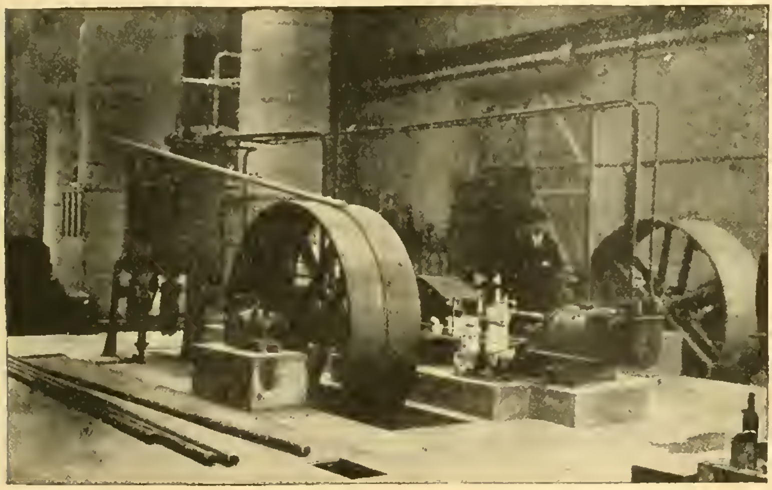

FIG. 6.—Linde Machinery.

As a commentary upon the Birkeland-Eyde process worked at Notodden, it is of interest to notice that the Cyanamide Company at Odda fix about the same quantity of nitrogen as the Birkeland-Eyde; but whereas the former employed about 25,000 kilowatts of power, the energy required by the latter company is between five and six thousand kilowatts. It would thus appear that the actual fixation is cheaper in the form of cyanamide than in that of calcium nitrate. At the end of the present year it is hoped that works having a total output of 45,000 tons of nitrogen will be in operation, and in the course of next year a correspondingly large increase in production of this product is predicted. It should be mentioned that the first plant upon an industrial scale was started about two and a half years ago, at Piano d'Orta, in Central Italy, with a yearly production of about 4000 tons of nitrolim. These works are now being increased to a capacity of 10,000 tons. Other important works are being started in Italy; the power employed is hydro-electric.

Works are being erected in Austria-Hungary, and at the present time a water-power installation, giving at least 50,000 h.p., is being erected at Almissa. In France the Société Française des Produits Azotés has installed works at Nôtre Dame de Briançon (Haute Savoie) having an output of 4000 tons, and these have been in operation for about six months. In Germany, at Westeregeln and Brühl, on the Rhine, 10,000 tons of nitrolim are being annually manufactured. It should be noticed, however, that the works at Brühl do not employ water power, but as the coal in this district is cheap, it is used in place of water power. In the United States the American Cyanamide Company are constructing works on the Canadian side of the Niagara Falls, with a capacity of from five to six thousand tons per annum, which it is hoped to enlarge later on so as to produce 40,000 tons.

The chief British enterprise is the North-Western Cyanamide Company, Ltd., which has erected works at Odda. Figs. 4 and 5 show the Isere Valley, Nôtre Dame de Briançon, and the main buildings of the cyanamide works. Fig. 6 shows the Linde machinery employed there for fractional distillation of the air.

F. M. P.

## THE EDUCATION OF THE BLIND.[1]

THE jubilee year of the Institution for the Blind at Illzach-Mülhausen has been celebrated by the publication of a "Festschrift," which contains addresses and papers by Prof. Kunz and others at the congresses regarding the blind held in Frankfort in 1882, Amsterdam, 1885, Kiel, 1891, Berlin, 1898, Paris, 1900, Breslau, 1901, Halle, 1904, Leipzig, 1905, and in Rome, 1906. There is first an interesting account of the development of the Institution at Illzach since its foundation in 1856. Institutions for the blind were founded in various cities long before this date. Thus, to select from a long list of the chief cities of the world, we find one in Paris in 1784, in Liverpool (the first English institution), 1791, Edinburgh, 1793, London, 1799, Berlin, 1806, St. Petersburg, 1807, Stockholm, 1808, Dublin, 1810, Barcelona, 1820, Munich, 1826, New York, 1831, Bern, 1836, Padua, 1838, and Madrid, 1842.

The home at Illzach was at first small and modest, but it grew rapidly, and now it is one of the best equipped blind asylums. From the first its founders had in view that it was not merely to be a home for the blind, but a school in which all the elements of an ordinary education, and also of a technical education, could be taught. Nothing is more ingenious than the methods now adopted for the education of the blind, more especially by the sense of touch. Reading by raised type, or by a system of raised points so grouped as to represent numerals or letters, arithmetic, grammar, geometry, geography by raised maps, natural history by specimens of plants and animals or by anatomical models, or the outlines of plant and animal forms in bas-relief, music—theoretical, vocal, and instrumental—and gymnastics, and many technical arts are also taught, such as sewing,

[1] Geschichte der Blindenanstalt zu Illzach-Mülhausen i E. Während der ersten fünfzig Jahre ihrer Tätigkeit, ferner deutsche, französische, und italienische Kongressvorträge und Abhandlungen über das Blindenwesen, Prof. M. Kunz, Direktor der Anstalt, 1856–1906. Pp. 346 . Leipzig: Wilhelm Engelmann, 1907.)

knitting, basket-making, mat-making and brush-making. Special maps and even pictures are now made for the blind. There are numerous illustrations of these in the volume. The blind children are taught to take part in plays, some of which are complicated enough to tax the powers of those having vision, and, of course, in music of all kinds, many of the blind attain to remarkable proficiency.

The second part of the work deals with the various congresses. These were largely attended, and papers were read which opened discussions on the best methods of teaching the blind. Each congress had its own speciality. Thus at Kiel, 1891, the subject was the modelling of animal forms; and at Berlin, 1898, it was the teaching of music and grammar. Even comparative grammar was taught to advanced pupils, and those interested in the relationships of languages will find much that is suggestive in the record of the Berlin conference (pp. 130–145). At the Paris conference in 1900, the important question was discussed whether blind children should be taught by blind teachers, and, if so, to what extent? There appear to have been considerable differences of opinion upon this point. The French, Belgians, and Italians made great use of blind teachers, but in Germany and other northern countries the greater part of the teaching was done by those who see, and the blind teachers were only helpers. Prof. Kunz has an important article on this question, and he has arrived substantially at the conclusion that the proportion of seeing to blind teachers should be about two to one. Many blind teachers have, however, attained wonderful skill in imparting knowledge to their unfortunate brethren, and a feeling of sympathy and subtle intuitions, related to personal experience, may to some extent account for their success.

One of the most interesting chapters in the volume is that entitled Zur Blindenphysiologie, das sogenannte "Sinnenvikariat" (p. 186). It might be called the "psycho-physik" of the blind. The results of various experimental inquiries are given, and it is shown that in the blind, taking the average of a large number above puberty, all the other senses are capable of more delicate perceptions than in those who can see. As might be expected, the sense of touch is highly developed. This is of great importance, as it enables the blind to use with accuracy the Braille method of designating letters by various patterns of points, which are sometimes sharp and of varying size, sometimes wedge-shaped, and sometimes the marks consist of thin vertical and horizontal lines, either single or meeting at various angles. An address by Prof. Kuntz at Halle, in 1904, gives much information as to the spread over the world of the methods of teaching the blind. This is followed by an interesting description, with numerous illustrations, of the many forms of type suitable for reading, for arithmetic, and for music, and nothing could show more clearly the delicacy of the sense of touch acquired by the blind during their education than an inspection of these curious patterns. Dr. Javal, the eminent Parisian ophthalmologist, contributes an interesting chapter on some physiological features of the blind.

There is an elaborate paper bearing on the perception of the direction of sound by the blind, and the acuteness with which they perceive the nearness and often the nature of objects by reflection of sound-waves. The whole subject has been investigated with the greatest care. It is interesting to find a translation into modern Greek by Fräulein Irene Lascaridi (a teacher in the Asylum for the Blind in Athens) of Prof. Kunz's paper on the physiology of the blind, *Περὶ τῆς Φυσιολογίας τῶν Τυφλῶν*. Several examples of raised type and maps are shown at the end of the volume. The book is not only worthy as a "Festschrift," as it contains all that can at present be written upon the subject of the education of the blind, but it will be an enduring monument to the zeal, devotion, and learning of Prof. M. Kunz, who has devoted his life to the interests of those who are deprived of one of the most important of the senses.

JOHN G. MCKENDRICK.

## CATALOGUE OF DOUBLE STARS.[1]

PROF. G. W. HOUGH, director of the Dearborn Observatory, while observing with the $18\frac{1}{2}$-inch refractor, discovered 648 double stars. These stars consist of close pairs and of pairs where the companion is very faint; they are, therefore, difficult to measure, and may be regarded as of the same class as those discovered by Prof. Burnham. But whereas the Burnham stars have been fairly well observed and yield a good percentage of binaries, the Hough stars have been very little observed, and they yield few interesting pairs.

Prof. Doolittle, of the Flower Observatory, has done good work in collecting these 648 stars in one catalogue, and arranging this catalogue in a form which leaves nothing to be desired. The stars are not entered according to the Hough number, but in order of right ascension, and the meridian catalogue name is added; but to facilitate reference, a list of the stars is given in order of the Hough number, with the page in the catalogue on which the star appears.

In addition to his own measures, made at the Flower Observatory of the University of Pennsylvania, Prof. Doolittle gives measures by other observers, which unfortunately are few. From the Astronomer Royal's report and from the Greenwich results published in the Monthly Notices of the R.A.S., we gather that the Greenwich observers have been at work on the Hough stars, and it seems a pity that more of these measures could not be included. It may be that Prof. Doolittle experienced difficulties in publication which retarded the appearance of his catalogue. This would make it seem of later date than it really is, and would also explain the phrase in the introduction—"Mr. Burnham's new general catalogue, when it is published," &c. The general catalogue has been with us since August last.

The right ascensions and declinations are given for 1880. This, in a catalogue of 1908, means that the right ascensions are practically $1\frac{1}{2}$ m. wrong to start with, and the declinations sometimes 8′ or 9′ out, thus necessitating the application of precession corrections by everyone using the work, whereas if the places had been given for 1910 they would have been useful for many years.

Prof. Doolittle began systematic work in 1901, and the catalogue he has produced is an important piece of work well carried out, and the printing is very good, the few errors being easily rectified. But owing somewhat to the uninteresting character of the Hough stars, he has had little beyond the actual catalogue itself to repay him for his labour. With the exception of Hough 212, and possibly two others, there is no object in the whole catalogue of any remarkable interest at present; and the paragraph on p. 10 of Prof. Doolittle's introduction must evidently be read in the light of the well-known characteristics of the Hough stars. In this paragraph he gives thirty pairs as being *clearly binary systems in rather rapid motion.*

Astonishment at the large number was increased on an analysis of the thirty. From the notes in the

[1] "Catalogue and Re-measurement of the 648 Double Stars discovered by Prof. G. W. Hough." Publications of the University of Pennsylvania, Astronomical Series, vol. iii., part iii. Pp. 176. (Pennsylvania, 1907.)

body of the work, *i.e.* in Prof. Doolittle's own words, we find these consist of two pairs in which there is no evidence of motion; five pairs in which change is doubtful; five pairs in which some change is probable; seven pairs where the change is less than 1°·0 per annum; six pairs where the change is just over 1°·0 per annum; two pairs where it is approximately 2°·0 per annum; two pairs fairly rapid binaries; one pair, Hough 212, with a period of 5·7 years.

The last five only can be brought under the above phrase.

There are two rather serious errors in identification: Hough 198 should be B.D.+16°.4896, not WB (2)xxiii.195, the declination of which is 42°, not 16°; Hough 507 should be WB(2)iv.151, declination 37°, not WB(2)iv.154, declination 32°.

## NOTES.

We regret to see the announcement of the death on July 20 of Mr. Arthur Lister, F.R.S., distinguished particularly for his researches on the Mycetozoa. Mr. Lister was seventy-eight years of age, and was elected a Fellow of the Royal Society in 1898.

Sir John Banks, first president of the Royal Academy of Medicine, Ireland, and a leading authority on mental diseases, died on July 16 at ninety-seven years of age.

The eighth meeting of the Association of Economic Biologists will be held at Edinburgh on Tuesday, Wednesday, and Thursday, July 28, 29, and 30, under the presidency of Mr. A. E. Shipley, F.R.S., who will deliver a presidential address "On Rats and their Parasites" on July 28.

We learn from the Journal of the Meteorological Society of Japan that the death of H.I.H. Prince Yamashina occurred on May 2 at thirty-one years of age. The late Prince had deep interest in meteorology and allied sciences. On his own account he established the Mount Tsukuba meteorological observatory and two base stations in 1901, and published a series of "Ergebnisse der meteorologischen Beobachtungen auf dem Tsukubasan." He made several valuable researches in meteorology and seismology, and designed a number of excellent instruments.

Dr. Ludwig Mond, F.R.S., has offered to the Reale Accademia dei Lincei a biennial international prize of 400*l.*, to be called the Stanislao Cannizzaro prize, for chemistry and physical chemistry. The amount necessary for providing the prize, together with taxes and expenses, is to be given by the donor in the form of Italian Consols, while the conditions of award have been placed in the hands of the president of the Academy, in consultation with Dr. Mond and Senator Cannizzaro.

The Paris correspondent of the *Times* states that a Society of the Observatories of Mont Blanc has just been regularly constituted, with a board of directors largely chosen from the Academy of Sciences, for the more systematic continuation of the work begun by the late M. Janssen and M. Vallot. The society has decided to place the Vallot and Janssen observatories under the direction of M. Vallot. With this object the latter has given his establishment to the society just formed—a purely scientific association—which appeals for members and funds. The secretary is Comte de La Baume-Pluvinel, 9 Rue de La Baume, Paris.

We are informed that the optical illusion observed by Dr. T. Terada, Tokyo, and described on p. 255 of our last number, has been previously observed and described. In the Proc. Roy. Soc., Edin., 1878–79, there is an account of some experiments on this illusion. Like Dr. Terada, the writer first observed it after looking at moving water, but in his case it was a quickly flowing stream; on afterwards looking at the gravel bank a stream of gravel seemed to flow slowly through it in a direction the opposite of that of the water. A number of experiments are described in the paper referred to on the effect of looking at rotating discs with black and white radii, and moving bands of paper with cross-lines, the eyes being afterwards directed to a mottled surface on which the reverse movements referred to appeared. These spectra were shown to be entirely stopped when a straight line was drawn across the surface.

An international exhibition and congress of the applications of electricity will be held on September 14–20 at Marseilles. The object of the congress is the consideration of the technical, commercial, and administrative problems which have arisen in recent years. These questions will be treated in reports prepared by well-known authorities, and the reports will be submitted to the congress for discussion, and published subsequently. The business of the meeting will be transacted in nine sections dealing with, respectively, the framing of regulations; the construction and protection of electric wiring; technical and commercial workings; lighting and domestic applications; applications to industry, mines, traction, and agriculture; electro-chemistry and electro-metallurgy; telegraphy and telephony; instruction and measurements; and applications to hygiene and medicine. Numerous papers, none of which, we understand, is the work of a British authority, will be discussed in each section. Prof. Maurice Lévy will be the president of the congress. There are four general secretaries, MM. Armagnat, Chaumat, and Dusaugey, and Prof. Zimmern, who may be addressed at 63 Boulevard Haussmann, Paris.

Commander Peary departed on July 17 from Sydney, Nova Scotia, on the *Roosevelt*, on his voyage to the North Pole. A *Times* correspondent reports that Commander Peary has summarised the main features of his programme thus: First, the utilisation of the Smith Sound route, the advantages of which are a land base 100 miles nearer the Pole than is to be found at any other point of the entire periphery of the Arctic Ocean, a long stretch of coast-line upon which to return, and a safe and (to Commander Peary) well-known line of retreat in the event of any mishap to the ship, independently of assistance. Secondly, the selection of a winter base which commands a wider range of the central polar sea and its surrounding coasts than any other base in the Arctic regions. Cape Sheridan is practically equidistant from Crocker Land, from the remaining unknown portion of the north-east coast of Greenland, and from Peary's "Nearest the Pole" of 1906. Thirdly, the use of sledges and Esquimaux dogs. "Man and the Esquimaux dog," Commander Peary observes, "are the only two machines capable of such adjustment as to meet the wide demands and contingencies of Arctic travel. Airships, motor-cars, trained Polar bears, &c., are all premature, except as a means of attracting public attention." Fourthly, the use of the Whale Sound Esquimaux for the rank and file of the sledge party.

The president of the Local Government Board has authorised for the current year the following researches in connection with the annual grant voted by Parliament in aid of scientific investigations concerning the causes and processes of disease:—(1) A further inquiry by Dr. M. H. Gordon into the character and differential tests for the micro-organisms found in the throats of patients suffering from scarlet fever. (2) An investigation of protracted and recurrent infection in diphtheria. This will be undertaken by Dr. Theodore Thomson and Dr. C. J. Thomas. The bacteriological part of the investigation will be undertaken by the Lister Institute. (3) An investigation of protracted and recurrent infection in enteric fever. This will be undertaken by Dr. Theodore Thomson, in conjunction with Dr. Hedingham, of the Lister Institute. (4) Investigations by Dr. W. G. Savage into the presence of paratyphoid bacilli in man, the differentiation of streptococci in goats, and the bacteriological measurement of pollution of milk. (5) A statement of the results of the bacteriological examination of more than 7,000 samples of milk from different parts of the country, made by Prof. Delépine. (6) An investigation into flies as carriers of disease, by Dr. Copeman,, F.R.S., with the co-operation of Prof. Nuttall, F.R.S. (7) An inquiry into the condition of flock beddings, by Dr. Farrer. The bacteriology and biology of bedding (especially in relation to vermin), which will be undertaken in connection with this inquiry, will be superintended by Prof. Nuttall. (8) A statistical inquiry into the social incidence of disease will also be begun, the prevalence of varicose veins and of hernia under different social conditions forming the first subject of inquiry under this head. This will be undertaken by Dr. Basil Cook. Announcements of further investigations for the current year will be made at a later date.

THE Fourth International Fishery Congress will be held under the presidency of Dr. Hermon C. Bumpus at Washington, D.C., U.S.A., on September 22–26, to deliberate on important matters relating to fishing and fish culture, and to submit propositions for the benefit of the fisheries to Governments and to State, provincial, and local authorities. The congress will be organised and conducted in conformity with the decisions for the regulation of the international fishery congresses decreed in Paris in 1900. The membership will consist of Government, State, and provincial representatives, delegates from home and foreign societies, corporations, invited persons, and persons who express a wish to take part in it. In response to invitations from the United States Government, twelve national Governments have signified already their intention to be represented officially, and delegates have been appointed by the governors of many of the States of the United States. Very few nations have indicated formally their inability to participate officially, and the congress promises to be really representative in character. Among the important subjects to be discussed may be mentioned: commercial fisheries; matters affecting fishermen and the fishing population; legislation and regulations relative to fishing, fish culture, pollution of waters, and obstruction of waters; international matters affecting fisheries; aquiculture; acclimatisation; fishways and fish ladders; biological investigation of the waters and their inhabitants; diseases and parasites of fishes, crustaceans, molluscs, and other water animals; and angling and sport fishing. Suitable arrangements will be made for the entertainment and instruction of the members in Washington and at the other places visited, and an opportunity will be given for visits to places of general interest. All communications and inquiries before September 20 should be addressed to Dr. Hugh M. Smith, the secretary-general of the congress, Bureau of Fisheries, Washington, D.C.

THE morphology and physiology of the gephyreans of the family Priapulidæ are discussed by Mr. L. A. Moltschanov in a paper published in the June issue of the Bulletin of the Imperial Academy of St. Petersburg. The author regards the genus Priapuloides as intermediate between Priapulus and Halicryptus.

RICHARD CAREW (1555–1620) forms the subject of the second instalment of "Early British Ornithologists," by Mr. W. H. Mullens, now being published in *British Birds*. In connection with this we may perhaps be permitted to direct attention to the inconvenience of that title as the designation of a serial. In quoting we refer, for instance, to Mullens, *British Birds*, vol. ii., p. 42, while we should in like manner refer to Yarrell, *British Birds*, vol. i., p. 10. Who is to know in such cases whether it is to the serial or to a separate work that the quotation refers?

A SECOND report on the copepod crustaceans of the Irish Atlantic slope, by Mr. G. P. Farran, has just been issued in "Scientific Investigations, Irish Fisheries," for 1906, No. ii. The list given is mainly the result of a number of deep-water tow-nettings taken in 1904–5, and may be regarded in the main as a contribution to our knowledge of the plankton of the zone between 600 and 1000 fathoms. No. viii. of the same issue is devoted to reports concerning the obstacles to the ascent of young eels up the Irish rivers and the illegal capture of the fry.

THE Royal Scottish Museum has issued a general guide-book to the collections, at the price of one penny. Considering that it comprises only 63 pages and includes the artistic, ethnographical, natural history, and technical collections, the notices of each group are necessarily of the briefest. Although the type of the main text is small—too small, we think, for a number of persons who ought to avail themselves of the guide—the "catch-words" are printed in heavy block type well calculated to attract the attention of the reader.

WE are indebted to Mr. L. M. Lambe for a copy of a paper from the first volume of the third series of the Transactions of the Royal Society of Canada on the remains of a new type of crocodile from the Cretaceous formation of the Judith river. This crocodile, for which the barbarous name *Leidyosuchus canadensis* is suggested, is a broad-nosed form recalling Diplocynodon, but with the splenial included in the short mandibular symphysis, as in some of the Goniopholididæ. Possibly it may be a direct descendant of the latter—an idea supported by the fact that several members of the Judith river fauna present a Jurassic *facies*.

THE ninetieth volume of the *Zeitschrift für wissenschaftliche Zoologie* is published in a single issue of 677 pages, with 43 plates, of which several are coloured. All the eighteen papers are devoted to invertebrates. Among these, special reference may be made to one by Mr. F. Blochmann on the taxonomy and geographical distribution of brachiopods. The paper is illustrated with a large map, in colour, showing the distribution of Liothyrina, a genus most numerously represented in the neighbourhood of the Gulf of Mexico on the one side of the Atlantic, and the Spanish and north-west African coast, together with the Mediterranean, on the other. This distribution seems to confirm the theory of the existence until comparatively recently of a belt of shallow water across the mid-Atlantic. Further, the distribution of this and other genera indicates, in the author's opinion, the existence during Tertiary times of a communication between the Atlantic and the Indian Ocean by way of the isthmus of Suez.

THE results of a number of experiments with regard to the inheritance of colour and the head-crest in canaries undertaken at the Carnegie Institution of Washington are recorded by Mr. C. B. Davenport in publication No. 95 of that body, the report being illustrated with three coloured plates. After referring in some detail to the introduction and cult of the canary as a cage-bird, the author observes that in some respects this species, owing to the comparatively short time it has been under the influence of domestication, is better adapted for investigations of this nature than animals which have been longer subject to human influence. As regards colour, it appears that the domesticated yellow breeds are derived from the original "green" breed by the loss of the black, and that it consequently carries a mottling factor which leads to the production of mottled hybrids when crossing takes place with a pigmented canary or a finch. Although such hybrids do not display a fixed pattern, the degree of their mottling is heritable. Further, the principle of localisation of the unit of complex plumage-colour must be recognised, as is exemplified by the restriction of a red patch to the sides of the face in hybrid canary-goldfinches.

ON the occasion of succeeding to the presidency of the Royal Microscopical Society for the second time, Lord Avebury delivered an address on seeds, with special reference to British plants. The president confined himself to a synopsis of the forms occurring in the British dicotyledonous orders and indicated the biological significance of the various devices met with. The paper is printed in the June number of the society's journal.

FROM Messrs. Gallenkamp and Co., London, a new catalogue of museum jars and window aquarium apparatus has been received. It also contains an illustrated list of Smedley's models. The models of Palæozoic seeds and cones, which are on view in the Hall of Science at the Franco-British Exhibition, have met with the universal approbation of botanists; the models of cryptogamic plants, flowers and seeds, and of invertebrates are less generally known. They are all modelled in hard wax on a rigid foundation.

THE editorial article in the June number of *Tropical Life* deals with the arrangements made for insurance against gales, hurricanes, and earthquakes as applicable to Jamaica and other West Indian islands. These permit of the insurance of such crops as limes, cocoa, and cocoanut-trees. Cotton can be specially insured against damage during the hurricane months July to October. In the same journal Mr. F. T. Crawley discusses the value of manures for lands planted with sugar-canes. With reference to the experience of planters in the Hawaiian islands, it is stated that fertilisers containing ammonia, phosphoric acid and potash are found to lead to an increased proportion of sucrose.

HAVING for twenty years pursued the study of the resinous substances found in plants, Dr. A. Tschirch laid before the Chemical Society of Switzerland, in response to its invitation, a paper treating of the chemistry and biology of plant secretions, with special reference to the resins. The author classifies the resinous substances according to the various products that are associated with the pure resin, and distinguishes *tannol resine, resinol resine,* and *harzsaure*, also such extraneous substances as ethereal oils, gums, &c. With reference to their systematic value, it is observed that while the orders Dipterocarpaceæ, Burseraceæ and others are characterised by definite groups of resins, other resins occur in plants quite unrelated. But it is suggested that for distinguishing between certain resin-producing species, chemical tests based on the secretions might be devised. The lecture has been published in pamphlet form.

THE results of an expedition in the Atlas Mountains of Morocco, made by M. Louis Gentil in 1906–7, are given in *La Géographie* for March. From the data obtained, a valuable map has been drawn up, indicating the main geological features of the High Atlas Mountains from the west coast to the region of Demnat. In an article accompanying the map, M. Gentil discusses the various difficulties encountered in obtaining accurate observations, and emphasises the utility of geological methods in mountain exploration. Information has been obtained of the hitherto little-known regions of Ounila, Anr'mer, Sous, and Siroua, the characteristic geological structure of the last being especially noticed. In an orographical sketch of Morocco, the regions of the High Atlas, Middle Atlas, and Anti-Atlas are distinguished, and the main features shown on a map.

MR. W. H. WHEELER has prepared a paper on the physical characteristics, tides, currents, and fisheries of the North Sea (J. D. Potter, 145 Minories). In the first section an account is given of the pre-Glacial condition of the North Sea, the main features being a deep fiord in the north branching out of the Atlantic, a large estuary south of the Wash, and an isthmus joining England to the Continent. In the post-Glacial period the mouth of the fiord between Durham and Yorkshire became blocked up, sandbanks were formed, and the channel which now forms the Strait of Dover was scooped out. This section of the paper includes also a description of the Dogger Bank, and illustrations of the depression of the land on the east coast of England and in the Low Countries. The making of new land by the deposit of glacial drift covered by alluvium is discussed, examples being drawn from the coasts of Belgium and Holland. The opposite effect of erosion is observed along the English coasts. An account is given of the Orkney and Shetland Islands, and the east coasts of Scotland and England are described in detail. The progress of the tidal wave in the North Sea is traced, velocities and range of the tides being given, with a table showing the effect of winds on the tides. As the result of experiments made by the Fishery Board of Scotland, the general drift of the surface currents in the North Sea was shown to be southerly down the coasts of England and Scotland, then south-east round the Dogger Bank, and, finally, east-north-east to the Skager-rack. Statistics of the fishing industry are given in the section dealing with this subject.

THE first application of the Kimberley method of diamond washing to the concentration of alluvial tin is described by Mr. H. D. Griffiths in the *Mining Journal* of July 11. The new method has been adopted at Kuils River tin mines, Cape Colony, and has given such exceptional results as regards efficiency and economy that the sluicing methods formerly in use on the property have now been discarded.

THE British Fire Prevention Committee has issued a red book (No. 127) on fire tests with fire extinguishers. The series of tests with the "Diamond" dry powder extinguisher showed that hand powder fire extinguishers, as a class, if applied with skill, can often be usefully employed in the incipient stages of small fires. The various tests undertaken with petrol point to the conclusion that, with a volatile liquid of this nature giving off a highly inflammable vapour, the powder extinguisher is only efficient when the area of the fire is small or narrow. The efficiency of powder extinguishers depends materially on the closeness of range, the position of the operator's shoulder, and on a certain knack or dexterity in handling the appliance. The action of powder extinguishers would appear to be largely mechanical.

We have received from the Deutschen Gesellschaft zur Bekämpfung des Strassenstaubes a pamphlet of thirty-five pages, in which Colonel Layriz has compiled from the scattered notes in technical journals a report on the methods at present in use to obviate the dust nuisance on roads. The data collected tend to show that efficacious methods are now available for obviating the formation of dust in densely populated cities and in the vicinity of summer resorts, but that the unavoidable cost renders it impossible to apply such methods, except by degrees, so as to make country high-roads free from dust.

The June number of the Journal of the Franklin Institute is of special interest to metallurgists. Mr. E. A. Custer has a copiously illustrated article describing the casting of pipes in permanent moulds that the hottest iron attainable from the cupola does not destroy. The method is one deserving careful attention, for it has long been the dream of every foundryman whose trade requires a large number of duplicate castings to make such castings in moulds that would not merely survive the process, but would also produce castings that would be marketable and be easily machined. Mr. G. B. Heckel reviews the methods in use for protecting iron and steel against corrosion, and Mr. H. P. Cochrane discusses engineering practice as applied to the handling of fuel at power stations.

Numerous attempts have been made to obtain ammonia from peat, but the difficulties of dealing with a substance which often contains 90 per cent. of water have hitherto proved insuperable, and none of the methods has survived the experimental stage. We have received an account of the Woltereck process, stated by the inventor to have overcome successfully all these difficulties. The peat is slowly decomposed at a regulated temperature by means of a blast of air charged with water vapour, and forms "paraffin tars," acetic acid, and ammonia. These pass successively through a scrubber to remove tar, an alkali tower containing a hot solution of caustic soda or milk of lime to absorb the acetic acid, and finally through an acid tower, where the ammonia is taken up by sulphuric acid. The tar on distillation yields a wax said to be worth 4*l.* a ton; the acetate is to be utilised for preparing either acetic acid or acetone. The ash of the peat is a saleable manure, and contains potash, lime, and phosphoric acid. It is estimated that the cost of producing the sulphate of ammonia will not be more than 5*l.* 8*s.* per ton, and, as the present market price is 12*l.*, a considerable profit is anticipated.

The officiating director-general of observatories (Mr. J. H. Field) has issued a memorandum, dated June 9, on the meteorological conditions prevailing in the Indian monsoon region before the advance of the south-west monsoon of 1908, with an estimate of the probable distribution of the monsoon rainfall. Account is taken, as usual, of the recent conditions over a wide area, including parts of Australia, Africa, Siberia, and South America, and all the available data have been analysed by the method developed by Dr. Walker and described by him in his forecast for last year. The result indicates, *inter alia*, that the total rainfall for the whole of India during the period from June to September will probably be nearly normal or in slight defect.

We have received part ii., vol. xx., of the Memoirs of the Indian Meteorological Department, containing kite observations made by Mr. J. H. Field at Belgaum (Bombay Presidency) during the pre-monsoon and monsoon periods in 1906, in continuation of those begun at Karachi in 1905 (published in part i.). One series was made in May, in which month the normal weather is dry and hot; the records, which are diagrammatically shown, indicated no marked increase in wind velocity up to 1300 metres, the maximum height reached. Temperature gradients were strong, by day always considerably above the adiabatic rate for unsaturated air. Comparatively humid air extended on different days to a height of 600–1100 metres; above it exceedingly dry air was met with. The other series was made in August and September, when the weather was comparatively cool, with frequent rain, especially in September. The wind velocity was, on the whole, nearly uniform up to the maximum height reached, 2500 metres. The temperature gradients were considerably smaller than in May and, except near the surface, always below the adiabatic rate. The upper limit of humid air had risen by about 1000 metres since May.

With reference to the article on recent developments in electric lamps which appeared in our issue of June 25, we are informed by the General Electric Co. that the statement to the effect that tungsten lamps for high voltages, 200 and above, have not yet been commercially introduced is not correct, as they have had these lamps on the market since the commencement of April. This firm is now in a position to deliver Osram and Wolfram lamps up to 260 volts pressure in 50 and 100 candle-power sizes and lamps for 100 to 130 volts in 25, 30, 50, and 100 candle-power sizes. In addition to this, 25-volt lamps are made for 10, 16, and 25 candle-power, and there is a large demand for this type of lamp for private plants and for alternating-current circuits where advantage can be taken of the possibility of transforming down the voltage. The company sends us two very well arranged catalogues setting out the advantages and possibilities of these lamps.

Vol. v. of Contributions from the Jefferson Physical Laboratory of Harvard University consists of reprints of ten papers by the staff and students which appeared in the Proceedings of the American Academy, the *Physical Review*, &c., during the year 1907. Of those not already noticed in these pages may be mentioned a paper by Mr. G. W. Pierce on "Crystal Rectifiers for Electric Currents and Electric Oscillations," part i., in which the author follows up and explains the fact recently discovered by General Dunwoody that a crystalline mass of carborundum between two electrodes will act as a receiver for electric waves when used either with or without a cell in series with it. This property is shown to be due to carborundum not following Ohm's law, but conducting better for high than for low voltages. It thus falls into line with other detectors of electric waves investigated by Profs. Braun and Strientz. The author is not yet prepared to advance any theory as to the cause of the phenomenon, but considers that there is sufficient evidence to show that it is not of thermoelectric origin.

Mercury has usually been regarded as completely insoluble in water and other solvents. It has, however, a definite vapour pressure, although a very low one at ordinary temperatures, and since no gas is completely insoluble in water, it appeared not improbable that this vapour should prove to be slightly soluble in water. This question is dealt with by Mr. A. Christoff in the current number of the *Zeitschrift für physikalische Chemie* (June

30), the experiments described being conceived with much ingenuity. The reducing action of mercury upon a solution of gold chloride was relied upon for detecting the extremely minute amounts of mercury involved, great care being taken to eliminate disturbing influences. The solvent action of water, benzene, nitrobenzene, and alcohol on mercury is clearly proved, and it was also shown that the effects observed could not be attributed to the formation of an oxide or hydroxide of mercury.

THE *Bio-Chemical Journal* for June (iii., No. 5) is mainly occupied with papers by Prof. P. W. Latham on the synthesis of protein. Taking the results of Schutzenberger, obtained by the hydrolytic decomposition of egg-albumin with baryta, the author analyses them and attempts to reconstruct a formula for albumin.

A THIRD edition of "Determination of Radicles in Carbon Compounds," by Profs. H. Meyer and J. Bishop Tingle, has been published by Messrs. John Wiley and Sons, of New York. Messrs. Chapman and Hall, Ltd., publish the book in this country at the price of 5*s*. 6*d*. net. The new matter, running to fifty-five pages, has been placed at the end of the volume in the form of an appendix, and copious cross-references have been provided.

WE have received a copy of a new periodical devoted to scientific subjects, and entitled the *Scientific Monthly*, an illustrated journal of science. There are contributions dealing with electrical, astronomical, chemical, and microscopical subjects, and numerous notes on scientific questions of current interest. The articles are of a general informative character and are illustrated. The magazine, the price of which is 3*d*., is published by Mr. Arthur N. Kemp, 26 Shaftesbury Avenue, London.

WE have received from Mr. Bernard Quaritch, of Grafton Street, New Bond Street, London, W., copies of two of his July catalogues of books. One deals with Oriental history, languages, and literature, and includes works on Oriental art and natural history; the other gives particulars of a large number of books printed during the fifteenth and sixteenth centuries, and is the first part of an illustrated catalogue to be completed in about three parts. The first part, now issued, contains some sixty facsimiles, and comprises examples of xylography in the Low Countries and Italy, and typography in Germany.

## OUR ASTRONOMICAL COLUMN.

THE LICK OBSERVATORY ECLIPSE EXPEDITION, JANUARY, 1908.—A very interesting account of the work done, and the preliminary results obtained, by the Lick Observatory-Crocker eclipse expedition to Flint Island, written by Dr. Sebastian Albrecht, appears in No. 3, vol. ii., of the Journal of the Royal Astronomical Society of Canada (pp. 115–131, May–June).

After explaining the importance of the several items in the programme prepared, and describing the various instruments, Dr. Albrecht gives an illustrated description of the eclipse-camp site, and tells of the difficulties overcome in transporting and setting up the several instruments. Errors in the ephemeris-positions of the moon led to totality commencing 27 secs. earlier than predicted, and the observed times of beginning and ending of the total phase were 9h. 22m. 20s. and 9h. 26m. 12s. G.M.T.

The equipment included a coronagraph of 40-ft. focal length, pointed directly at the eclipsed sun, and intended to photograph the details of the inner corona, a shorter instrument for photographing the coronal extensions, several spectrographs, including one with quartz lenses and prisms, two sets of four cameras for seeking any intra-mercurial planet that may exist, polarigraphs, a photometer, and Prof. Abbot's bolometric apparatus.

The photographs taken with the 40-ft. camera show about thirty streamers extending to a distance of more than one solar diameter, and about half that number extending to 1½ diameters; excellent negatives, eight in number, were obtained with the smaller coronagraph. Four good negatives, on which the linear dispersion is such that from λ 3700 to λ 5300 is thirteen inches, were obtained with the large moving-plate spectrograph, and on the one taken at the end of totality there are hundreds of bright lines, the study of which should afford a wealth of information concerning the structure and composition of the sun's higher atmosphere. From one of the smaller-scale spectrograms the wave-length of the green corona line has been determined as 5301·4. Both on these and on the spectrograms obtained with the quartz spectrograph, the shifting of the great intensity of the continuous spectrum towards the red indicates the lower temperature of the corona as compared with that of the photosphere. About twenty-five sharp lines are shown on the coronal spectrograms taken with the quartz instrument, two of which appear to be new. Dr. Perrine's examination of the photographs taken leads to the conclusion that no intra-mercurial planet of sufficient magnitude to account for the Mercury perturbation anomalies exists. Two of the photographs illustrating Dr. Albrecht's article are of the corona.

THE APPROACHING RETURN OF HALLEY'S COMET.—*Popular Astronomy* for May contains an article of general interest on Halley's comet, written by Prof. H. C. Wilson. After describing the comet's appearance at various returns since 1066, the writer compares the approximate elements, reduced to the equinox of 1910, of the orbit at the recorded apparitions from 451 A.D. onwards, and shows that those for 1910 indicate similar conditions to those obtaining in 1066, when the comet was an object of remarkable grandeur. At present the comet appears to be just beyond the orbit of Jupiter, which it should traverse about March 1, 1909, and may possibly be discovered photographically during the coming winter.

THE ORBIT OF ALGOL.—No. 5, vol. i., of the Publications of the Allegheny Observatory is devoted to a discussion of the orbit of Algol, based on observations made in 1906 and 1907 with the Mellon spectrograph; the measurable portion of the spectra extends from λ 3927 to λ 4750, and is 21 mm. in length. In this region eight lines, due respectively to Ca, He, H, Si, and Mg were selected for measurement by Dr. Schlesinger, and were measured by him and Dr. Curtiss independently, adjusted wave-lengths being employed by the latter observer. An apparent change of velocity (about −10 km.) between the observations of 1906 and those of 1907 may be due, possibly, to a change of camera lens, but it is not impossible that it is a real change in the star such as was suspected by Belopolsky. The elements and the light-curve obtained by each observer are given, and the results indicate that the light minimum lags about one and a half or two hours behind the time demanded by the velocity determinations.

THE PATH OF THE MINOR PLANET (279) THULE.—An exhaustive mathematical discussion of the orbit of the minor planet (279) Thule, by Dr. A. Wedemeyer, occupies the fifty-six pages of No. 2, vol. xxxi., of the *Archiv der deutschen Seewarte*. The special perturbations are determined by Oppolzer's method and tabulated, and the corrections derived are applied for each observed opposition of the planet from 1888 to 1906.

AN AMATEUR'S MERIDIAN INSTRUMENT.—In the July number of the *Bulletin de la Société astronomique de France* M. E. Soulié describes a simple and inexpensive apparatus which enables amateur observers to determine the meridian with very fair exactitude. It consists of a flat plate of heavy material, so supported that it hangs vertically like a plumb-line. Using the plane of this sheet to direct the line of sight, the plate is oriented to Polaris some minutes before ζ Ursæ Majoris, or δ Cassiopeiæ, crosses the sight-line. By fine adjustments, the instant when Polaris and one of these stars, preferably the latter, are in the plane of the plate together is noted, and then the plate is made to follow Polaris for exactly six minutes. At the end of this interval it is in the meridian, and may afterwards be used to observe transits or to determine local noon, &c.

## GEOLOGICAL WORK IN THE UNITED STATES.

THE work of the Geological Survey of the United States is in many regions also geographical. Bulletin No. 307 (1906), by Henry Gannett, is thus a useful "Manual

FIG. 1.—Weathering of Madison (Carboniferous) Limestone, Tongue River Canyon, Bighorn Mountains.

of Topographic Methods," reviewing in its eighty-six pages "the most approved methods of surveying as applied to the production of topographic maps." Those of us who have used the American maps on the scale of 1 : 62,500 may have wondered at the selection of this figure in place of our 1 : 63,360, or 1 inch to one mile. It is here clear, however, that the American scale is a convenient deduction from 1 : 250,000, which is employed for the maps of large areas, and which furnishes a scale of practically four miles to an inch. The thick Bulletin No. 299, by Mr. Jas. McCormick, is a second edition of the "Geographic Dictionary of Alaska," and includes 9300 names, as against 6300 published in 1902, numbers that afford "a rough indication of Alaskan growth."

Mr. N. H. Darton's "Geology of the Bighorn Mountains" (Professional Paper No. 51, 1906) is a fascinating description, very handsomely illustrated, of a region in Wyoming that has come into notice as a summer resort. There are few areas more calculated to convert the ordinary man into a keen stratigraphical geologist. Huge sections can be read off on the mountain-sides, and Cambrian, Ordovician, Carboniferous, Triassic, Jurassic, and Cretaceous deposits are represented. The Cretaceous system closes with fresh-water stages some 9000 feet thick, containing coal-seams in the upper layers, which correspond with the type of strata usually known as Laramie. Prof. R. D. Salisbury (pp. 71–90) describes the glacial geology, largely from material gathered by Messrs. Blackwelder and Bastin. Two Glacial epochs are traceable, and diminutive glaciers belonging to the later one still remain in the great chain of pre-Cambrian granite, rising 12,000 feet above the sea (see Plates xxix., xxxvi., &c.). It is claimed that glacial erosion has deepened some of the valleys by at least 700 feet. A glacial and a geological map accompany the memoir, in a pocket at the end, in accordance with the convenient plan now adopted by the United States Survey.

West of the Bighorn Mountains stretches the Bighorn Basin, on an average 5000 feet above the sea. Its geology and water-supply have been described by Mr. C. A. Fisher (Professional Paper No. 53, 1906). The basin is formed by a broad synclinal of the older strata, and its floor is occupied by Laramie beds, unconformably covered by the Eocene Wasatch clays and sandstones, as is well shown in Plate x. The ranges on the west divide this basin from the Yellowstone Park, and hot springs and geyser-deposits occur within the area now described.
