We have received from the author, Mr. P. H. Grimshaw, a copy of a paper from the July number of the *Annals of Scottish Natural History* on the species of insects frequenting Scotch grouse-moors. The list was compiled in connection with an investigation of the food of young grouse, undertaken at the instance of the Grouse Disease Committee, and it was considered that its publication might be of interest from a faunistic point of view. Species known to be eaten by grouse-chicken are denoted by asterisks.

In concluding an article on chromosomes and heredity, published in the August number of the *American Naturalist*, Prof. T. H. Morgan states, in a guarded manner, that some progress has been made in the interpretation of the mechanism by which sex is determined in the organism. He considers it certain "that we have discovered in the microscopic study of the germ cells a mechanism that is connected in some way with sex determination; and I have tried to show, also, that this mechanism accords precisely with that the experimental results seem to call for. The old view that sex is determined by external conditions is entirely disproven, and we have discovered an internal mechanism by means of which the equality of the sexes where equality exists is attained. We see how the results are automatically reached even if we cannot entirely understand the details of the process."

In reference to the recent article on "Wild Plants on Waste Land in London" (August 11, p. 184), a correspondent suggests that various seeds may have been brought to the ground in the nose-bags and hay trusses of horses employed during the demolition of the buildings or passing along the neighbouring streets. Many of the plants on the waste ground near the Strand are common weeds of arable land.

Much interest attaches to two palæobotanical papers by Dr. E. C. Jeffrey that have been published in the Proceedings of the Boston Society of Natural History (vol. xxxix., Nos. 9 and 10). In the first the author describes a petrified stem taken from the remains of a Triassic forest in Arizona, that presents several novel features. The wood structure resembles that of living representatives of the Araucarineæ, but the plant produced short shoots that persisted and elongated with the growth of the stem. The leaf traces, on the contrary, did not, as in present-day genera, persist in the secondary wood. The author regards the persistent short shoots as primitive, and therefore indicating the antiquity of the two coniferous groups of Abietineæ and Araucarineæ in which these characters occur. The second paper deals with fossil remains of a conifer, collected in Massachusetts in the Lower Cretaceous days, in the shape of two short shoots similar to, but distinct from, the brachyblasts of Pinus, and referred to the genus Prepinus previously proposed by the author.

A popular account of the date gardens of the Jerid at the northern fringe of the Sahara Desert is contributed by Dr. T. H. Kearney to the American *National Geographic Magazine* (July). The author's journey was undertaken with the object of obtaining palms for the date orchards established by the United States National Department of Agriculture in Arizona and California. The two largest oases in the Jerid district comprise about 6000 acres each. The ownership is much divided, as individual holdings range from a few square rods to several acres. More than a hundred distinct varieties are grown, differing in shape, colour, and flavour. The variety exported to Europe strikes the mean between the hard and very soft kinds, and is characterised by its translucent flesh and keeping quality. The method of propagation is by offshoots that arise from the base of the palm; these, when dipped in clay and bound with layers of leaf-stalk fibre, will travel safely any distance.

The Board of Agriculture and Fisheries reminds growers of potatoes that it is their duty under the Destructive Insects and Pests Order of 1910 to report to the Board all outbreaks of wart disease, otherwise known as black scab of potatoes, cauliflower disease, "fungus," &c., in counties in which no officer has as yet been appointed by the local authority to receive reports. The penalty for neglecting to report disease is 10*l*. The presence of disease should be again reported this year, notwithstanding the fact that it may have existed and been reported last year. A leaflet describing the disease may be obtained on application to the Secretary, Board of Agriculture and Fisheries, 4 Whitehall Place. Letters so addressed need not be stamped.

The West Indian Bulletin (No. 3, vol. x.) contains an article by Mr. Ballou on legislation in the West Indies for the control of pests and diseases of imported plants. Such control has been exercised since 1884, and was considerably developed in 1898, when the Imperial Department of Agriculture was organised. The text of the various laws and proclamations is given, and certain modifications are suggested. It appears that legislation has been distinctly beneficial. Messrs. Bancroft and South briefly describe the fungi which have from time to time proved injurious to cultivated crops in the West Indies. The account is brought up to date, only a few minor unidentified forms being omitted. A note is added containing a summary of the diseases, probably caused by bacteria, which have not yet been fully investigated.

From the Agricultural and Forestry Department of the Nyasaland Protectorate we have received a Bulletin, by Mr. McCall, on bacterial blight in cotton caused by *Bact. malvacearum*, by far the worst enemy of Egyptian cotton cultivators in Nyasaland, having reduced the output of several estates by at least 60 per cent. in the past season. The disease first appears on the leaves, causing them to shed; then the bacteria get into the branches, and soon the flowers and bolls die. No method of control is yet known. Mr. Purves deals with tree-planting in the highlands of the country. In general, the natural timber consists of small slow-growing hard-woods and shrubs. There is an increasing demand for building timber and firewood, and it seems likely that plantations may be profitable. A number of suitable trees are recommended.

We have received from the Agricultural Institute at Pusa copies of several of their recent publications. The *Agricultural Journal of India*, which is intended as much for the intelligent lay reader as for the professed agriculturist, contains an article on the outbreak of blister-blight (*Exobasidium vexans*, Massee) on tea in the Darjeeling district in 1908 and 1909, which caused a considerable amount of damage. In the first instance the leaves are attacked, then the disease spreads to the leaf stalks and the young green stems, where the damage is more serious, although less conspicuous. The disease is not new, and has been known for more than forty years in the Brahmaputra valley in Upper Assam, but not elsewhere. The districts are widely separated, yet the disease has not appeared in intervening places. A memoir is issued by Mr. Annett on the cause of the colour of black cotton soil. He finds several per cent. of titaniferous magnetite, and also a certain proportion of humus, both contributing to the colour. Mr. Howard issues a report on his fruit experiments. Of the numerous interesting results one may be noted: the effect of grass growing round the tree was apparently fully as injurious as in the Woburn experiments. Tillage of orchards, however, is not an unmixed advantage, as it exposes the soil to considerable washing in the rainy season. A system of embanking combined with monsoon leguminous cover crops seems to be the best means of preventing this loss. Dr. Butler describes the wilt-disease of pigeon pea, which he finds is brought about by *Fusarium udum*, n.sp.

The U.S. Weather Bureau has issued its useful meteorological charts of the North Atlantic and North Pacific Oceans for September, and of the South Atlantic and South Pacific for the season September–November, 1910. The North Atlantic chart contains an account of the violent West India hurricane of September 16–21 last, with synoptic charts showing the existing weather conditions at Greenwich noon over the North Atlantic and Gulf of Mexico during that period. On September 16 the storm was south-west of Jamaica, moving north-westward, and warnings of its approach were issued to various ports. It continued its north-westerly direction, reaching the Gulf ports on September 20, where exceptional severity was experienced, thence curving northwards and moving up the Mississippi Valley. About half the coal fleet anchored along the banks of that river were sunk, but the remainder were saved as a direct result of the action taken on the advice of the Weather Bureau. Arrangements have been made by the Bureau to obtain during the present hurricane season (July to November) wireless storm telegrams from vessels in the Gulf of Mexico and all West Indian waters.

IN connection with the production of undamped electrical oscillations of high frequency by the arc and condenser method, Messrs. M. Kimura and K. Yamamoto, of the Kyoto University, have carried out a series of determinations of the effects of atmospheres of various vapours on the volt-ampere "characteristic curves" of the carbon-copper arc. The carbon electrode was solid, and was used as the kathode. The copper anode was water-cooled. The curves obtained are all of the usual form, which suggests a rectangular hyperbola, and show that the vapours tried stand in the following order of relative efficiency:—hydrogen, hydrogen mixed with benzene, methyl alcohol, methyl and ethyl alcohols mixed, ethyl alcohol, air, the volts absorbed for a given current being highest for hydrogen. The complete paper is contained in part iv. of the second volume of the Memoirs of the College of Science and Engineering of Kyoto University, just to hand.

THE following figures for the solubility of ether in water are given by Mr. Y. Osaka in the Memoirs of the College of Science at Kyoto, and will be of interest to people who are constantly making use of this solvent:—

Temperature	0°	5°	10	15°	20°	25°	30°	
Solubility (Osaka)	13·13	11·18	9·55	8·22	7·08	6·13	5·39	gr. per 100 gr. water.
Solubility (Seidell)	13·12	11·4	9·5	8·2	6·95	6·05	5·4	gr. per 100 gr. water.

PROF. BONE and Dr. H. F. Coward have replied, in the Journal of the Chemical Society, to the criticisms by Berthelot and others of their work on the production of methane by the direct union of hydrogen with carbon. In their most recent experiments they have obtained yields of 95·8, 95·6, and 91 per cent. of that theoretically obtainable from the weight of carbon used. The carbon used was particularly pure, containing not more than 0·06 per cent. of hydrogen, or 0·06 per cent. of ash. The gas produced (at 1150°) contained only a trace of carbon monoxide, never exceeding 0·03 per cent., and the amount of nitrogen was also very small.

IT is seldom now that one firm is entrusted with the order for as many as ten vessels for any navy, and the successful completion of such an order by Messrs. Yarrow and Co. for the Brazilian Government forms the subject of an article in *Engineering* for August 19. The ten torpedo-boat destroyers are all of one design, an important advantage both from the tactical point of view and also from the standpoint of management by Brazilian officers and crews. They partake generally of the British "river" class, in which were embodied greater strength and other qualities to enable the vessels to maintain their speed in a heavy sea. The guaranteed speed of 27 knots has been easily exceeded by every ship. The length between perpendiculars is 240 feet, and the displacement is 650 tons. The ratio of length to beam is 10·2 to 1. Each vessel has two sets of four-cylinder triple-expansion engines, balanced on the Yarrow-Schlick-Tweedy system, and supplied with steam from two double-ended Yarrow boilers. The greatest power developed on an official trial was 8877 indicated horse-power, in the case of the *Parana*. The coal-consumption trials showed that at 14 knots speed the radius of action was 3690 nautical miles.

Engineering for August 19 directs attention to the important and continuous increase in Germany's imports of British coal—from 1899 to 1909 the increase is more than 115 per cent. The figures are 4,873,555 tons in 1899 to 10,498,118 tons in 1909. In no place, perhaps, has British coal to a more marked extent encroached upon German coal than in Berlin. In 1890 British coal consumption in Berlin amounted to 105,894 tons, or 7·53 per cent.; last year the respective figures were 946,102 tons, and 39·88 per cent. The total consumption in Berlin in the two years was respectively 1,406,961 tons and 2,372,310 tons. Coinciding with this increase in British coal consumption is a notable decrease in the consumption of coal from Silesia, and it is from this quarter also that complaints are loudest. Fears are openly expressed that British coal is in a fair way of, lastingly and fully, securing the Berlin market unless proper precautions are taken soon and with the greatest possible energy. The increase in import of British coal to Berlin is to a great extent owing to the growing consumption of British gas-coal at the Berlin gas-works.

MANY ingenious pieces of apparatus for illustrating the principles and laws of heat are described and illustrated in a new catalogue (List 56) just issued by Messrs. A. Gallenkamp and Co., Ltd. The aim of the makers has been to produce at a moderate price instruments which can be used continuously by students without getting out of order, and will yield accurate results. A noteworthy feature is the inclusion of a number of new devices which have been described in text-books or periodicals, or before scientific societies. Teachers of physics will find the catalogue of service in the selection of experiments for the lecture-room and laboratory.

OUR ASTRONOMICAL COLUMN.

THE PERSEID METEORIC SHOWER.—Observations of this phenomenon have been received by Mr. Denning from twelve stations, and he informs us that the results are fairly satisfactory. Clouds, it is true, greatly interfered with watching on the important nights of August 11 and 12, but August 10 was clear.

The character of the display seems to have been of an average character. Meteors were not strikingly abundant, but there were enough to make the event exciting and to attract the interest of the general public. In Norfolk one observer was very successful, and relates that he counted twenty-one meteors in eight minutes between 1h. 16m. and 1h. 24m. on the morning of August 12, and estimated that they were falling at the rate of about 250 per hour! Other observers give the number as much less, but testify as to the brilliancy of some of the individual meteors.

Mr. C. L. Brook, of Meltham, saw splendid Perseids on August 8, 11h. $26\frac{1}{2}$m., and on August 10, 12h. $5\frac{1}{2}$m., with paths from $319°+68°$ to $279°+50°$ and $7\frac{1}{2}°+41\frac{1}{2}°$ to $350°+25°$ respectively. Mr. W. H. Steavenson, at Cheltenham, recorded the latter as moving from $90°+58°$ to $120°+48°$, and saw another magnificent meteor at 13h. 11m., twice as bright as Venus, shooting from $120°+48°$ to $135°+40°$. Others, comparable with Jupiter, followed at 13h. 18m. and 13h. 30m. The fireball of 12h. $5\frac{1}{2}$m. fell from a height of 81 to 51 miles over the eastern region of Yorkshire. Its length of path was 45 miles, and velocity about 31 miles per second. It was a true Perseid, with radiant at about $45+56$, but the exact place is not defined, as at Meetham Mr. Brook saw the meteor moving westwards, while at Cheltenham Mr. Steavenson observed it travelling to east.

Miss Warner, at Bristol, saw a number of meteors on August 10, the finest being a Perseid equal to Venus at 10h. 25m. It was, however, very low in the east, passing under Andromeda and Pegasus. Mr. D. E. Packer, of Birmingham, saw 200 meteors in watches of twenty-one hours between July 31 and August 14. There were thirty of the apparent brightness of Jupiter and twenty equal to Saturn.

Mr. W. Johnson, of Lastingham, witnessed a fine meteoric display on August 12. During the evening there were many brilliant meteors, including two of quite exceptional lustre. The display seemed at its best between 11 and 12 p.m.; clouds prevented observations after midnight.

METCALF'S COMET, 1910*b*.—Numerous observations of the comet discovered by the Rev. J. H. Metcalf on August 9 are recorded in No. 4434 of the *Astronomische Nachrichten*.

The magnitudes given for the whole object range from 9·0 to 11·0, and show no marked increase or decrease with the date. While some observers report a stellar nucleus, others say that there is no definite nucleus, but there is a central condensation in the nebulosity forming the head. A short tail is reported by the majority of observers, M. Guillaume, using the equatorial *coudé* of the Lyons Observatory, with a power of 360, giving the length on August 11 as about 1·5′, and the direction as towards E.

From observations made on August 11, 13, and 15, Dr. Kobold has calculated parabolic elements and an ephemeris, the former giving the time of perihelion as August 30·018 (Berlin M.T.). The later part of the ephemeris is given below:—

Ephemeris for 12h. (M.T. Berlin).

1910	α h. m.	δ ° ′	Mag.
August 24	15 46·6	+16 15·0	
,, 25	15 45·4	+16 18·8	10·7
,, 26	15 44·2	+16 22·4	
,, 27	15 43·1	+16 25·9	
,, 28	15 42·1	+16 29·2	
,, 29	15 41·0	+16 32·3	10·9

Owing to the short arc yet observed, the elements are, of course, somewhat uncertain. From this ephemeris we see that the comet is now moving very slowly in a direction slightly N. of W. through the constellation Serpens.

PHOTOGRAPHS OF DANIEL'S COMET, 1907*d*.—The advantages to be secured from widespread cooperation, especially in the study of the physical features of comets, are well illustrated in a paper by Prof. Barnard which appears in No. 194, vol. xlix., of the Proceedings of the American Philosophical Society. There Prof. Barnard publishes twenty-five plate reproductions of photographs secured by him, with the 3·4 and 10-inch Bruce portrait lenses, during the period July 11 to September 8.

The physical changes depicted from day to day are very remarkable; but Prof. Barnard shows, by comparing his plates with series taken at Lick and Juvisy, that much shorter periods produced such great changes that some of the features became recognisable with difficulty. The time difference in the case of the Lick photographs is, generally, about two hours, for the Juvisy plates about six hours, yet even in the comparison between Yerkes and Lick there are very distinct changes shown. In several cases it is shown that a detached portion of the tail, although receding from the head, was still moving sunwards in the path followed by the comet.

PRECESSION AND THE SOLAR MOTION.—In No. 614 of the *Astronomical Journal* Prof. Boss publishes the results of an investigation of the proper motions of more than 5000 stars, uniformly distributed over the whole sky, and deduces therefrom the position of the solar apex and corrections to Newcomb's values for precessions and for the equinox of 1874. For the position of the apex he derives, for 1875·0, R.A. $=270·52° \pm 1·08°$ to $\pm 1·53°$, dec. $= +34·28° \pm 0·90°$ to $\pm 1·28°$. Other solutions, for selections of stars, such as those of different magnitudes or large proper motions, are obtained, but they show no sensible modifications of these values.

For the velocity of the sun in space Prof. Boss finds 24 km. per second as a useful constant to adopt for the present, and is of the opinion that the value (19·9 km.) determined from spectroscopic observations is open to objections inherent to that method.

Further, he finds that his results strongly support the hypothesis of the random motions of the stars, an hypothesis which is directly opposed to the several ideas of definite "star drifts" which have been published in recent years.

CALCIUM VAPOUR IN THE SUN.—No. 1, vol. xxxii., of the *Astrophysical Journal* contains a paper, by Mr. C. E. St. John, which is full of important results concerning the distribution and the circulation of calcium vapour in the solar atmosphere. The research was undertaken in order to provide data for the better interpretation of spectroheliograms in so far as they reveal the disposition and inter-relation of the various solar layers. In 1872 Young observed the reversal of the H and K lines in disturbed regions, in 1883 Lockyer photographed them, and in 1892 Hale and Deslandres noted the reversals distributed over the entire disc.

With the splendid apparatus available at Mount Wilson, Mr. St. John has measured the various parts of the K line (K_1, K_2, and K_3), and, referring these measures to Fabry and Buisson standards, has determined the apparent displacement at various points on the disc, thus deriving data which indicate the conditions, altitudes, &c., under which the emitting vapours exist.

Among other results, he finds that the vapours producing the K_3 (absorption) line show a descending motion of 1·14 km. per sec., while the vapours producing the K_2 (bright) line have, generally, an ascending motion of 1·97 km. per sec. A comparison of the angular velocities obtained points to the vapour-producing K_3 being at a greater elevation than the hydrogen which produces the Hα line. A comparison of the wave-lengths of K_2 and K_3 at, and away from, the limb indicates that these intermediate and higher levels of the sun's calcium atmosphere are not greatly disturbed by currents parallel to the solar surface.

From measurements of the widths of K_3 and H_3, and reasoning from their behaviour in the calcium arc spectrum, it appears that the quantity of calcium vapour in the upper levels must be extremely small, while, from similar considerations of the K_2 and H_2 lines, the emitting vapours would be relatively thick and dense. In approximate figures, the 5000 km. depth of the solar envelopes above the photosphere is divided into 1500 km. for the upper (absorbing) atmosphere and 3000 km. for the emitting layer, leaving 700 km. for the layer which emits the bright chromospheric radiations. A curious result is that the K line persists for some 500 or 600 km. above the level at which the H line ceases to show.

On determining the wave-lengths of H_3 and K_3, a difference of 34·810 A. was found, which differs by 0·010 A. from the value derived from Rowland's tables; this discrepancy is probably caused by an error of that amount in Rowland's wave-length for H.

Mr. St. John's paper takes up forty-seven pages of the journal, and there are other important results which are too numerous for full discussion in these columns.

OBSERVATIONS OF THE MOTION OF THE UPPER AIR.[1]

THE two publications before us evidence the progress which is being made in different ways in our knowledge of the upper currents of the atmosphere. Dr. Figee, invalided home owing to the trying climate of Java, has taken the opportunity of discussing the observations (286) of the height of clouds, made at Batavia, 7° S., 107° E., in 1896–7, and later observations of cloud-velocity. The results for *height* agree generally with the values obtained in the same period at Manila, 14° N., 121° E. The following table gives the heights in km., the mean values for Paris and Potsdam being added for comparison:—

Cloud	Ci.	Ci.S.	Ci.Cu.	A.Cu.	Cu.
Batavia	11·5	10·6	6·3	5·4	1·74
Manila	10·9	11·4	6·6	5·3	1·7
Paris and Potsdam	8·7	7·6	5·7	3·3	1·5

The *motion* of the higher clouds shows different features at the two places. In both the seasons, November–April, May–October, the drift is towards the south-west at Batavia, a result corroborated by the recent work of Van Bemmelen, while at Manila it is towards the south-west in the latter season, but nearly north in the former. The value of the results in Dr. Figee's paper can be rightly appreciated only when they come to be utilised in preparing an atlas of monthly charts showing the main features of the circulation at the cirrus-level, an atlas which is much needed at present.

The second paper is a discussion of fifty-one pilot-balloon

[1] (1) Royal Magnetical and Meteorological Observatory at Batavia: Report on Cloud-Observations at Batavia made during the International Cloud-year 1896–1897 and subsequent years. By Dr. S. Figee. Appendix ii. to vol. xxx. of the "Observations." Pp. 32. (Utrecht: Kemink and Sons, 1910.)

(2) "Velocità e Direzione delle Correnti Aeree alle diverse Altitudini Determinate a Mezzo dei Palloni-Sonde e Piloti." By Dr. G. Pericle. Pp. 55—126; 5 plates. (Milana: U. Hoepli, 1910.)

ascents made at the Geophysical Observatory, Pavia, during 1908. The balloons were observed to heights exceeding 10 km. in six cases, and exceeding 5 km. in thirty-one additional cases. The ascents were made generally during comparatively calm weather, so that the results cannot be taken as representative of average conditions, a restriction applying, of course, to all pilot-balloon observations.

The values of the observed wind are collected in a convenient table, which is accompanied by a brief description of the general pressure distribution on the days of the ascents, and by diagrams showing the paths of the balloons and the wind at all heights for each ascent. An outstanding feature of the results is the large proportion of cases, thirty-two out of forty-four, in which the wind above 3 km. has a northerly component, compared with three cases in which an extensive southerly current was found. This agrees with the cloud observations at Perpignan and Pola, and is markedly different from those at Paris and Berlin.

Dr. Pericle finds that the wind usually veers with increasing height up to 2 km., veers as often as it backs from 2 to 5 km., and usually backs above 5 km. A sudden increase in the velocity of the wind was observed in thirty-one cases at heights between 2 and 4 km., and this was accompanied generally, but not invariably, by a change in direction. The average change is from 5·2 m.p.s. below the level of the discontinuity to 9·4 m.p.s. above it. The wind veered in passing upwards in thirteen cases, backed in thirteen cases, and did not change in five cases. The "backing" is usually larger than the "veering," the average value being 29° for the former and 18° for the latter. These results confirm the temperature observations in indicating the intermediate layer from 2 to 5 km. as the region where the more immediate causes of remarkable meteorological phenomena are to be sought.

E. GOLD.

FURTHER RESULTS OF THE JESUP NORTH PACIFIC EXPEDITION.[1]

FORCE of circumstances has prevented Prof. F. Boas from giving to science a complete monograph of the Kwakiutl, but he has given a further instalment in the publications of the Jesup North Pacific Expedition, which, so far as it goes, together with his study of the sociology of these interesting Indians (Report U.S. Nat. Mus. for 1895 [1897]), practically supersedes the reports published by the British Association. The present memoir deals with the industries of the Kwakiutl, but the author acknowledges the "many gaps and imperfections," which he has endeavoured to supply by correspondence; even so, we have an important contribution on the technology of a representative tribe of the north-west coast, a district in which the natives have developed a culture which differs markedly from that of other American Indians.

FIG. 1.—Kwakiutl Village at Newettee, Vancouver Island.

The two key-notes from the material side of this culture are the cedar tree and the salmon. The former is utilised for a large number of purposes, and as the wood splits easily large planks are readily made; hence we have a peculiar type of house construction. Also, the manufacture of chests and boxes is very characteristic; boxes are made by bending a board, a kerf having been made where the corners are to come; the two ends are then sewn together. In the late summer enormous numbers of salmon migrate up the rivers, thus affording food which, with proper preparation, can be stored for future consumption. Fishing is carried on by means of traps, nets, hooks, and with the spear. In some cases, also, combinations of fish-weirs and nets are used, or fish are speared or hooked in pounds

[1] "The Jesup North Pacific Expedition." Mem. Am. Mus. Nat. Hist., N.Y. Vol. v., pt. ii. "The Kwakiutl of Vancouver Island." By Franz Boas. Pp. 301–522 (plates xxvii–lii)+ix. Vol viii., pt. i. "Chukchee Mythology." By Waldemar Bogoras (*loc. cit.*). Pp. 197. Vol. ix. pt. i. "The Yukaghir and the Yukaghirized Tungus." By Waldemar Jochelson (*loc. cit.*). Pp. 133; 1 map. (Leiden: E. J. Brill, 1909–10.)

connected with traps; many of these are described by the author.

In this favoured wooded region berries are abundant, and there are numerous land mammals and birds. The principal method of hunting the former is by means of traps; bow and arrow and spear are not used extensively for this purpose. Birds are generally snared or shot with arrows.

Fig. 2.—Kwakiutl Mask representing Whale and Thunder-Bird. Length 172 cm.

The peculiar socio-religious beliefs and practices of the Kwakiutl, together with their skill in working wood, have led to the decoration of the majority of their domestic tools and appliances with human and animal forms and motives. House posts are often decorated with human and animal forms, and human effigies are frequently carved; but their fancy runs riot in the masks which are employed on ceremonial occasions; these often have movable jaws, and are well carved and brilliantly painted; numerous plain and coloured illustrations of these are given, one of which is shown in Fig. 2.

Prof. Boas has "spared no trouble to collect descriptions of customs and beliefs in the language of the Indian, because in these the points that seem important to him are emphasised, and the almost unavoidable distortion contained in the descriptions given by the casual visitor and student is eliminated." He goes on to say he has for many years advocated a more extended application of this method in our studies of the American aborigines. Other field workers might with advantage adopt this suggestion, which has, however, been more or less systematically employed by previous investigators. In this particular instance, Prof. Boas has given a presentation of the culture as it appears to the Indian himself. These accounts by the Indians of their technical processes afford very interesting reading from various points of view, and it was a happy idea to publish them in full, but, as so many Kwakiutl texts have already been published, it seems hardly worth while to have gone to the expense of printing so many of the native texts in full in addition to the translations.

Dr. W. Bogoras gives us forty-seven Chukchee myths and tales, ten incantations, and several songs, proverbs, riddles, &c., the native text being given in many instances. The pronunciation of the women differs from that of the men; they generally use *s* instead of *c* and *r*, and *ss* instead of *rk* and *ch*; also contracted forms of words are never used by them. They are not unable to pronounce these letters, and in tales, when quoting a man's words, they use the male pronuciation; but in ordinary conversation the male pronunciation is considered unbecoming in a woman. The tales give a valuable insight into native life and thought, and, on the whole, appear to be very similar to those current among the tribes living on the north-west coast of America, but no comparisons are made or general conclusions drawn in the present memoir.

Of great interest and value is the first part of Dr. W. Jochelson's monograph on the Yukaghirs, a tribe now on the verge of complete physical and ethnic extinction. The whole area between the rivers Lena and Kolyma, and between the Arctic Sea and the Verkhoyansk Range, may be considered as the ancient boundary of the Yukaghir tribe. Probably Finnish tribes were formerly the neighbours of the Yukaghir west of the Lena, as the Yakut and Tungus appear to have come there in comparatively recent times, but the original home of the Samoyed tribes was evidently in the Sayan Mountains, whence they were driven northwards by the Turko-Tatar peoples; in their new abode they had to wage long wars with the Finnish tribes. Chukchee formerly inhabited the tundra between the mouths of the Alaseya and Kolyma rivers; when the Russians came they moved east, and only about sixty years ago one division crossed the Kolyma and spread west as far as the Yerchen (long. 150° E.). Now the Yukaghir are confined to the north and north-west of their ancient area.

The term Yukaghir is probably of Tungus origin; the people call themselves Odul, which means "strong," "powerful." A sufficiently full account is given of the physical characters of the people, accompanied by numerous excellent photographs of types. There is an admirable account of their physiological characteristics, and their nervous diseases are treated in detail, the description of arctic hysteria being the best we have seen. Two principal forms of arctic hysteria may be distinguished; one has little to distinguish it from fits of hysteria in civilised countries. The fits occur mostly in grown-up girls or young women, while in the young males they are principally due to the influence of religious imagination; they are observed in the nervously strained youths who are inclined to become shamans. The characteristic feature of this type is that the patient continues to sing a long time,

Fig. 3.—A Man of the Yukaghir Tribe

enunciating in the song the wishes of the spirit that tortures him or her. The other form is more strange and complicated, the first symptom being extreme impressionableness and a feeling of fright or timidity. At the least knock, shout, or unexpected noise, the patient shudders or falls backward, and the fright usually evokes the most obscene words or phrases. Another phase is akin to hypnotic aural suggestion; the visional auto-suggestion is also well known among other races, for example, the *latah* of the Malay peoples. Persons who are past thirty or forty years of age, and chiefly women, are subject to this second form of arctic hysteria.

The chapter on family life is of especial importance; a careful account is given of relationship terms and the ideas of kinship; the system is essentially classificatory, with some suggestive modifications, the information here given being more detailed than is usually the case with even professed ethnologists. A review of the facts pertaining to marriages shows that, just as in the period of courtship, there are two distinct tendencies, one towards loose sexual relations, and the other towards idealising constancy and mutual faithfulness. So, also, in marriage, there is a striving towards exogamy and an inclination towards consanguineous marriages, which, it seems, were common in former times. Both the Yakut (who in general practise very strict exogamy) and the Yukaghir observe that children born from consanguineous marriages are generally unhealthy. Dr. Jochelson has not only given us a detailed account of a vanishing people, but he alludes to problems that will interest the student of comparative ethnology.

A. C. HADDON.

INTERNATIONAL CONGRESS OF ANATOMISTS AT BRUSSELS.

THE second quinquennial Congress of Anatomists was held at Brussels on August 7–11. The societies participating in it were the Anatomische Gesellschaft of Germany, the Association des Anatomistes of France, the American Association of Anatomists, the Anatomical Society of Great Britain and Ireland, and the Unione Zoologica of Italy; there was an attendance of about one hundred members. Among the representatives from the various countries and associations were Waldeyer and Von Bardeleben, Nicolas and Laguesse, Minot and Piersol, Romiti, and Arthur Thomson, Paterson and Dixon.

Meetings for the reading and discussion of papers were held in the forenoons in the physics classroom of the university, and demonstrations were given in the afternoon in the anatomical department in the Parc Leopold. About fifty communications were read, of which the majority dealt with embryological or histological subjects; many of the papers were of great interest and importance.

Among the papers presented by members from Germany, Poll gave an important communication dealing with spermatogeneris and oogenesis in hybrids. Using material derived mainly from hybrid pheasants, he demonstrated that spermatogenesis in them never went beyond the primary stage, or to the production of fully formed sperms. Braus gave a communication and demonstration upon the distribution of motor nerve fibres to the muscle segments in the lateral fin of the skate, and showed that each muscle segment in it received an innervation from a number of spinal nerves, and he also demonstrated the contraction of from 5–8 muscle segments upon stimulation of a single spinal nerve.

Neumayer showed a beautiful series of models illustrating the development of the skeleton of the head in Bdellostoma St. L., and Fetzer showed a model and sections of a very early human embryo closely resembling the ovum of Peters. In it the fixation and the histological structure of the trophoblast were particularly well seen.

Lenhossek gave a communication on the nerve-cells of the ciliary and otic ganglia in man, and showed some very fine specimens of them. Several communications from members of the German and American societies dealt with the development of the blood cells, Maximow giving a communication upon the development in Selachians and Amphibians, Frau Wera Dantschakoff that in Reptiles, and Minot upon the nomenclature and morphology of blood cells in general. He appealed for a more rational and scientific terminology than at present exists, and for the abolition of terms such as "normoblasts."

The papers from French anatomists included one from Lams, accompanied by a demonstration of beautiful specimens on the fertilisation and early changes in the ovum of the guinea-pig, which gave rise to an interesting discussion upon the *rôle* of the tail segment of the entering spermatozoon, in which Brachet and Van der Stricht took part. Dubreuil showed the development of the lamellæ in the upper end of the femur, and the relation which they present to the entering vessels. Several communications from members of this society dealt with the presence and character of Mitochondria in various tissue cells.

Huntingdon and McClure, of the American Society, dealt with the development of the lymphatic system, and demonstrated a loosening of the intima of the early veins, by which lymph channels could take origin within the lumen, outside the intima.

Lee gave a communication upon the implantation of the ovum in various North American rodents, and Huber demonstrated some fine corrosion preparations, illustrating the morphology of the renal tubules and vessels in vertebrates.

Of the British and Irish Society, Hill (London) demonstrated, by a fine series of photographs, the growth and maturation of the marsupial ovum as illustrated by Dasyurus. Berry (Melbourne) gave a communication upon Tasmanian crania; Evatt (Winnipeg) advanced a new view of the homologies of the urethra and vagina in the sexes; Arthur Thomson and Whitnall (Oxford) dealt with the anatomy of the angle of the iris and a ligament acting as a check to the action of the levator palpebræ superioris; and Waterston (London) gave a communication upon the shape of the human stomach and the action of formalin. A paper from Cameron (London) was read, upon the development of the anterior commissure and adjacent parts.

Most of these papers will probably be published at an early date, and hence no description of them need be given here.

On the last day of the congress an important step was taken in the appointment of an international committee to consider the question of a uniform embryological nomenclature, on the model of the Basel anatomical nomenclature for general anatomy. A committee of representatives from each country represented at the congress was appointed, with power to co-opt additional members, and with Prof. Mall, of Baltimore, as general secretary.

The members of the congress were entertained at a municipal reception in the magnificent Hotel de Ville, and they also appreciated greatly a demonstration given by Dollo of the great collection of fossil Iguanodons in the Natural History Museum.

BRITISH MARINE ZOOLOGY.

THE Bureau of British Marine Zoology has been established under the directorship of Mr. S. Pace, late director of the Millport Marine Biological Station. The objects of the bureau, we learn from the prospectus before us, are twofold:—(1) to compile a bibliography of all works dealing with the biology of the European seas, and (2) to establish a marine biological station of a movable character with adequate staff, but relatively simple and inexpensive equipment, to work at faunistic problems at one or two points on the coast, with no reference to any question of their possible economic importance.

It is intended that the bibliography should be issued in a large number of parts each year, and that the issue of each part should follow the papers referred to in it at the shortest possible interval. From the specimen pages of such an issue submitted to us, we gather that the papers are classified both under the author's name and according to subject-matter, and they are accompanied by very brief synopses of their contents, the brevity of which is increased by the use of the numerous abbreviations employed. Such a bibliography should be of very considerable value to workers at marine biology. Whilst, of course, it cannot compare with such periodicals as the *Zoological Record* or the *Zoologisches Jahresbericht*, it will anticipate the appearance of these by many months.

With respect, however, to the second project for which the bureau has been established, viz. to carry on an exhaustive faunistic survey of the marine life at one or more points on our coasts, a point of cardinal importance is at once raised. We have at present about half a dozen "stations" for the study of marine biology. There is hardly one of these which receives anything like adequate support. The largest of them, the Marine Biological Association's station at Plymouth, is faced with a serious deficit, and is forced to contemplate the curtailment of its operations. The amount of sympathy and support which the cause of "pure" science can evoke in Great Britain is, unfortunately, very small. We should therefore regret very much to see another "station" started, especially as the staff at Plymouth have carried out just such a faunistic survey of the coast near Plymouth as Mr. Pace desiderates.

Mr. Pace believes that the intrusion of the economic motive "must arrest, if it does not entirely hinder, scientific research." If the zoological schools of this country would concentrate on supporting one station, economic work might be dispensed with, and we might have a purely scientific biological station like Wood's Hole in America. But this goal is far off. Each new zoological school seems to desire its own station, and since the "stations" must look outside the ranks of professional zoologists for support, this support must be attracted by the promise either to devote part of the energies of the staff to economic problems, as the council of the Plymouth station have done, or to undertake the dissemination of popular knowledge of natural history, as the council of the Millport station has done. After all, the foundations of our knowledge of natural history were laid by the splendid amateurs of the last generation, of whom the founder of the Millport station was one. A great service to science would be accomplished if we could resuscitate this race.

We agree with Mr. Pace that it would be an admirable thing if marine biological research in this country could be organised; but it seems to us that the first step in this direction would be the whole-hearted support of the Marine Biological Association, which was founded for this purpose, and this association, if adequately financed, could provide a steamer which would serve the purpose of faunistic investigation better than the movable laboratory which Mr. Pace desires. Mr. Pace's scheme is an admirable one for starting investigation in a new country—it was that adopted by Canada for seven years; but in Canada it has been given up, and a permanent station on the model of Plymouth has been substituted for it.

E. W. MacBride.

INHERITANCE IN THE DOMESTIC FOWL.[1]

In the conditions under which they work, students of genetics enjoy exceptional advantages in America, where the munificence of private benefactors or the enterprise of various States has already led to the creation of several institutions specially endowed for this line of research; and from time to time the record of their work may appear in the form of a sumptuous publication issued by the Carnegie Institution of Washington. Dr. Davenport is already known for his investigations on heredity in poultry, and the present volume forms a continuation of the account of his researches to which a volume in the same series was devoted in 1906.

The memoir deals mainly with characters which, at any rate in some cases, are remarkable for the considerable grading that is found among the offspring of the various crosses. To this category belong the feathering on the shanks and the extra toe, both normally found in certain breeds of fowl. It has been recognised for some years that the inheritance of polydactylism in poultry often exhibits irregularities as compared with that of other characters where the mode of transmission is of a simple Mendelian nature. There are cases where the polydactyl condition may behave as a dominant to the normal in the ordinary way, but there are also cases where a bird with normal feet, bred from a polydactyl strain, may transmit the polydactyl condition to some of its offspring, *i.e.* where the individual does not exhibit the extra toe, though breeding tests show that the factor or factors for it must be carried by some of its germ-cells. The dominance of such a character as exhibited by the zygote may range from completeness down to *nil.* Nevertheless, some of the F_2 birds are without the extra toe, and are incapable of transmitting it; in other words, some of the germ-cells of the F_1 birds are completely free from the element, whatever it may be, to which the extra toe is due.

Hitherto it has not been possible to express this case more precisely, and though Davenport's results confirm our previous knowledge, he has been unable to construct a definite factorial scheme to cover the facts. He concludes that in polydactylism, as also in other cases, such as rumplessness and the feathered shank, dominance varies quantitatively, and that the degree of dominance is inheritable; but, of course, this does not help us in understanding what these varying degrees of dominance are due to. It may be that further work will make this more clear, or it may be that the heredity of these meristic characters differs from that of other characters in some way that has not yet been perceived. For the present, we can only confess to ignorance.

An account is given of crosses between either Houdan or Polish and single combs, and an attempt is made to explain the results on the supposition that two comb factors are concerned. Here again the irregularities between normal expectation and observation are attributed to quantitative variation in the degree of dominance. Experiments with fowls' combs have hitherto given such well-defined results that it seems not impossible that the complexities encountered by the author are due to the fact that he is dealing with more than two comb factors in this particular cross. The author's statement that many forms of comb appear in the F_2 generation is probably not without significance.

A chapter is devoted to the inheritance of the high and widely open type of nostril found in the low-combed Polish and Houdan breeds. From an elaborate system of grading his data, the author concludes that the widely open condition is dominant to the more usual narrow form of nostril, and that the intermediate grades are the result of imperfection of dominance, though here again no suggestion is given of the cause of this imperfection. There is little doubt that this character of wide nostril is largely dependent upon the size of the comb, and we cannot help feeling that the treatment of the question would have been more satisfactory had the nostril and comb characters been worked out in relation to one another.

The inheritance of crest Davenport considers a somewhat more complex case than it was originally thought to be, and he suggests that its nature depends certainly upon two, and possibly upon more than two, factors.

A short chapter is devoted to the results of breeding from a wingless cock. When crossed with normal birds the offspring were all normal, and some of these bred together again produced nothing but normals. Davenport suggests that winglessness is dominant to the normal condition, that the wingless cock was heterozygous, and that dominance in subsequent generations was imperfect. It may be pointed out that the facts accord equally well with the view that the abnormality was a purely somatic one, and was not reflected in the germ-cells of this wingless bird.

A number of experiments were made on plumage colour, largely with the view of elucidating the nature of buff and of black, and the author has seen his way to express his results in simple terms. Perhaps one of the most interesting results is the appearance of a definite proportion of white birds in the F_2 generation from a cross between black and buff Cochins. The author is, however, less happy in his discussion of the inheritance of blue, and his attempt to make the colour-inhibiting factor of the white Leghorn partly responsible has led to an account that is inconsistent with itself.

The memoir concludes with a general discussion on topics connected with heredity.

[1] "Inheritance of Characteristics in Domestic Fowl." By C. B. Davenport. Publication No. 121. Pp. 100; 12 plates. (Washington: Carnegie Institution, 1909.)

AGRICULTURE AND ALLIED SCIENCES.[1]

The number of agricultural and horticultural publications has reached somewhat alarming proportions during the last few years, but there is always room for really good works; and in this category must be placed the Journal of the South-eastern Agricultural College, Wye, Kent, No. 18 of which is under notice. This publication

[1] "The Journal of the South-eastern Agricultural College, Wye, Kent." No. 18. Pp. 443. (London and Ashford: Headley Bros., 1909.) Price 6s.; Residents in Kent and Surrey, 3s.

deserves to be more widely known, for as a compendium of all that is latest and best in agricultural research it is far in advance of most of its compeers. The book is divided into parts dealing with the farm, chemical analysis, zoology, botany, veterinary work, and general notes. Where so much is good it is difficult to do more than merely direct attention to some of the most striking portions of the book. A masterful article on the financial aspect of sheep-washing will well repay perusal, and the splendid series of plates illustrative of sheep-shearing are so lucid as to be self-explanatory.

The report on zoology deals mainly with entomology, and is illustrated very fully by many striking plates, one of which is of especial interest, showing as it does female

Photo. *F. Edenden.*

FIG. 1.—Female March Moths: The lower one laying her egg-band beneath one of the Lackey Moth (× 4). From the Journal of the South-eastern Agricultural College.

March moths laying their eggs in proximity to the egg-band of a lackey moth. That insidious pest *Tylenchus devastatrix* receives attention, and further notes are promised for the next report. A very interesting article on the British Culicidæ concludes one of the most fascinating portions of the book.

In addition to the general analytical work, the analytical report deals, for the most part, with soya-bean cake and meal. Economic mycology and experiments on hops form the chief items in the botanical report. It is interesting to note that the good work carried on at Wye in dealing with American gooseberry mildew, apple "scab," and "black scab" of potatoes, is being continued. The notes on the making and application of Bordeaux mixture, with notes on Bordeaux injury, illustrated by no fewer than twenty-three plates, will be greatly appreciated by fruit-growers. Two plates showing the right and wrong kinds of spray for Bordeaux mixture are interesting. In addition to the American gooseberry mildew, the somewhat neglected but no less prevalent Sclerotinia (Botrytis), "die back," of the same plant is described.

In the previous issue of the journal attention was directed to the importance of the male plant in the growing out of hops, and it appears that the advice tendered in the article in question has borne good fruit, and that several Kentish hop-growers have obtained good results by retaining, or even planting, male hops. The veterinary report, always interesting, is especially so in this issue on account of the announcement of the termination of a long series of "struck sheep" experiments, and the probable discovery of a preventive treatment.

FIG. 2.—Diseased Gooseberry Branch, showing the Botrytis fructification at × and elsewhere. From the Journal of the South-eastern Agricultural College.

The general notes consist of a summary of the college events of the year, and will appeal to all old students. To those who desire to keep abreast of the times in matters agricultural the journal is indispensable. C. A. E.

THE BICENTENARY OF THOMAS SIMPSON.

ON August 20 occurred the bicentenary of the birth of Thomas Simpson, who may be regarded as one of the last of the English school of mathematicians of the eighteenth century. Newton, Halley, the Gregories, Muston, Demoivre, Brook Taylor, Maclaurin, had all passed away before Simpson reached middle age, and the study of mathematics in England was entering upon that period of stagnation which left us without a single mathematician in any way comparable with the great writers on the Continent.

Simpson was the son of a Leicestershire weaver, and was born at Market Bosworth, August 20, 1710. He was brought up as a weaver, and the little learning he obtained as a boy was gained in spite of many disadvantages and obstacles. Indeed, the opposition he received from his father at last drove him from home, and he went to Nuneaton, where, at about the age of twenty, he married his landlady, a widow of fifty.

His acquaintance with mathematics began at the age of twenty-four with "Cocker's Arithmetic," the study of which he combined with that of astrology, his tutor being a fortune-telling pedlar. Simpson's astrology, however, brought him more trouble than credit, and on the charge of frightening a girl into fits by "raising the devil" he had to leave the district. He spent some time at Derby, and in 1735–6 he went to London, worked as a weaver in Spitalfields, and taught mathematics in his spare time. A year or two afterwards, with the sole assistance of Edmund Stone's translation of L'Hôpital's "Analyse des Infiniments Petits," Simpson wrote "A New Treatise on Fluxions," which was considered a notable contribution to the literature of that comparatively new subject. Other publications followed, his pupils increased, and he gained a considerable reputation.

In 1743, through the influence of William Jones, the mathematician, Simpson obtained a post as professor of mathematics at the Royal Military Academy, Woolwich, and two years later he was elected a Fellow of the Royal Society, having already been made a member of the Academy of Sciences, Stockholm. After holding his post at Woolwich for eight years he was seized with illness, caused, it was thought, by overwork. Advised to try his native air, he journeyed to Bosworth in February, 1761, and died there on May 14, in the fifty-first year of his age. He was buried in the churchyard of Sutton Cheney, a parish a short distance from Market Bosworth, where in 1790 the Leicestershire antiquarian John Throsby placed a tablet over his grave. Simpson had one son, who became a captain in the Royal Artillery, and one daughter. His wife survived him many years, received a pension from the Crown, and died in 1782 at the great age of 102.

EDGAR C. SMITH.

ELECTRICAL AND OTHER PROPERTIES OF SAND.[1]

THIS material, which flows so freely through my fingers and may be poured in the manner of a liquid from one vessel to another, is common sand. Specimens from various parts of the world are here exhibited; there are sands from the Sahara Desert, from New Zealand, France, Scotland, and several parts of England. There are also bottles of the coloured sands from Alum Bay, in the Isle of Wight, and Redhill. It may be pointed out at once that this coloration is merely due to the presence of an adherent layer of oxides or hydroxide of iron, for even varieties which appear under the microscope to contain little or no coloured particles generally have a trace of iron clinging to the grains.

For instance, a small quantity of white sand from Charlton, having been wetted with strong sulphuric acid before the lecture, will yield on the addition of water a solution containing iron. A few drops of ferrocyanide of potassium give a strong blue characteristic precipitate.

FIG. 1.

Further, the so-called black iron sand from New Zealand consists almost entirely of magnetite. If some of it is poured out upon a sheet of paper and brought near to a powerful magnet, you see that the grains fly eagerly to the poles and form large clusters there. This powder, on account of the regularity of its grains, their highly magnetic character and freedom from dust, is particularly useful in the laboratory for tracing lines of magnetic force. It is interesting to compare this with the black oolitic sand from Compton Bay, in the Isle of Wight, for that is a silicate of iron, and therefore non-magnetic.

I wish now to direct your attention to some of the phenomena connected with sand in large quantities, such as are met with upon wide stretches or drifts.

Blown sand, having been stopped by hedges and grass, gradually accumulates to a mound (Fig. 1)—in some cases with serious consequences. Dr. Vaughan Cornish, who has made a special study of this subject, has clearly proved,

[1] Discourse delivered at the Royal Institution on Friday, February 11, by Mr. Charles E. S. Phillips.

however, that the formation of a sand dune is very frequently due to wind eddies. The second photograph was, in fact, taken by him in Egypt, and depicts the steady, irresistible march of millions of tons of sand, encroaching upon and slowly burying casuarina trees (Fig. 2).

To come nearer home, the seriousness of problems arising out of this state of things may be illustrated by two photographs obtained recently at Southport, in Lancashire. In the first one (Fig. 3), the back garden of a newly built house is nearly buried beneath the enormous hill, which will probably soon cover the whole property. The second (Fig. 4) shows that the familiar appearance of a sandy beach at low water, with regular lines of ripples, may be produced by the direct action of the wind, and, incidentally, the utter futility of constructing an esplanade in such a neighbourhood. All these phenomena depend, in some measure, upon the size, weight, and shape of the sand grains themselves.

FIG. 2.

Silica, a substance which occurs in numerous impure forms, and constitutes a large portion of the rock masses known to geologists, is also to be found in a pure state as crystalline quartz. Here is an actual specimen about 18 inches long, which, together with the beautiful group of quartz crystals by its side, known as amethysts (and tinted, probably, by a trace of organic matter), are the property of this institution. Sand, therefore, being the result of rock disintegration, assisted by the grinding action due to the motion of wind or water, varies in composition in different localities.

The next slides are photomicrographs taken with a low-power objective. They represent some grains of sand found at Charlton and the Isle of Eigg respectively (Figs. 5 and 6). The former are seen to consist of minute silica particles of very irregular form, whereas the larger grains of the Eigg sand are remarkable for their smoothness. It is owing to this fact that the latter possess a peculiar property, to be referred to later.

Owing to the Sahara Desert having once formed the bed of a vast sea, it is, of course, found to be rich in marine deposit.

The damage which sand is capable of doing has been already referred to. It must not be forgotten, however, that its utility in the arts and crafts is of the utmost importance. The Egyptians are reputed to have been the first to find a wide use for it. They were probably the earliest glass-workers in the world. By the time glass-making was begun in England, viz. about 1611, the Romans and Venetians had so far mastered the art of blending sand with other substances that almost all the technical difficulties had already been overcome.

Now the melting point of silica being about 3000° C., it cannot be worked in an ordinary furnace. In glass-making the sand is therefore heated with a salt of one or more of the alkaline group of metals, preferably with sodium carbonate. At a moderate temperature sodium silicate is formed, and if this be subsequently heated in the presence of either lead oxide or borax, the melting point of the mass is still further reduced. Here is a white-hot crucible containing sand so treated and melted. You see the glass pours out like treacle, and sets rapidly into a transparent slab upon a hot brass plate.

Many useful applications, besides providing us with windows and glass-ware, have been found for sand, such as the decorating of hard surfaces by means of an impinging stream of its particles, scouring and cleaning, preventing slip on the roads, and so on. By no means the least important of these is its employment in war as a protection against bullets: a thickness of 20 inches of dry sand is proof against the modern rifle.

Now a mass of sand grains moving down a slope, by a motion consisting of rolling and sliding, meets with great opposition, due to friction. The grains thus come into close contact with the surface, and a considerable charge of electricity may readily be obtained by the simple device of allowing them to impinge upon a suitable substance.

A stream of sand flowing from the base of this reservoir B (Fig. 7) strikes upon an oblique sheet of tin T, which is attached to an insulating pillar N. An electrostatic voltmeter connected with the metal plate serves to measure the electrical potential. You see that in a moment the tin becomes charged to 3000 volts. The needle, however, soon falls back. Something has changed. The plate has, in fact, become dulled and pitted where the sand struck it. A fresh part reproduces the high potential. Filter paper is far more serviceable, and so is a wooden surface. One may rapidly obtain a potential of 6000 volts if the sand fall upon paper or wood, and this can be maintained for a considerable time. If the reading of the voltmeter diminishes, a fresh portion of the surface offered to the sand stream immediately brings it to its original value as before. The greater efficiency of paper (preferably filter paper) as compared with a metal sheet in producing the electrification, appears to arise in the following way.

A fine layer of dust soon becomes firmly imbedded in the metallic surface, so that further sand falling does not come into contact with the metal itself. On the other hand, it is probable that these particles cut through the fibres of the paper, and thus free themselves. I need hardly point out that the filter papers used should not be specially dried. Pieces which have been left about in a room for a few hours absorb sufficient moisture to ensure the right degree of conductivity.

The sign of the charge is always positive, in spite of the fact that a rod of silica rubbed upon the paper electrifies it negatively. In 1843 Faraday had noticed this curious reversal, and briefly refers to it in his experimental researches. Even if the actual silica rod be broken up into pieces, say as large as an orange-pip, and allowed to fall upon the paper held obliquely, the sign of the electrification is still positive. Further experiments have shown, however, that the sign of the electricity caused by friction against glass or silica depends upon the form of the rubbed surface. For instance, a strip of paper stroked by the smooth side of a tube of either substance becomes negatively electrified, whereas if the sharp edges of the end graze the paper, the sign of the electrification of the latter is positive. Now sand consists of sharply angular particles of silica, and even the comparatively large pieces obtained by crushing the tube, as previously described, have razor-like jagged edges. We should therefore expect, from the result of the experiments just mentioned, that when either sand grains or even large silica chips fall upon paper they will electrify it positively—and this is what actually occurs. Why an edge of glass should give an opposite charge to that produced by a flat surface when rubbed, say, with paper, is a question of great interest and difficulty. But that this is the explanation of the strange electrical behaviour of practically all powders appears certain.

The sand grains themselves become, of course, negatively electrified after striking the paper, so that this is often a convenient method of obtaining a high potential of either sign. Further, a stream of sand falling upon a metal plate will give a comparatively low potential, say 600 volts, for an indefinite period, in spite of pitting, and a tolerably steady value may be obtained by catching the grains upon a second disc (previously dulled by a sand-blast) connected with the apparatus required to be constantly electrified. As the charge increases upon this, a point is reached when some of the impinging sand particles become deviated by repulsion, so as to completely miss it. If the potential falls below the critical value, a reverse action takes place, and the plate rapidly charges up.

Turning for a moment to the question of the electrification produced in sand by the friction between the grains, experiments upon this point may be conveniently made by catching the particles, which roll down the surface of a sand cone, upon a small wet insulated table. Any electrification of the latter may then be detected in the usual manner. If the grains are all of the same nature, we should not expect to find other than slight irregular charges. The friction between particles differing in composition would give more definite results. Thus white sand racing over iron sand might be expected to show a charge; but experiment gave only a feeble electrification. I mention this because it is of interest in connection with the atmospheric electrical phenomena which often accompany sand storms in hot climates. Even if the wind electrified the surface of the sand over which it blows, the charge would probably leak instantly to earth, for in common with all powders it readily absorbs moisture into the interstices between the grains. When making electrical experiments with this material, it is therefore essential to have it well warmed.

There is still much useful work to be done in studying the electrical conditions in the neighbourhood of wide stretches of warm sand swept by dry wind. Owing to lack of data, it is difficult to form an opinion as to the part which this substance plays in the remarkable electrical phenomena sometimes witnessed during a storm.

I spoke of allowing sand to run down itself. Here is a cell made by separating two glass plates, 14 inches square, by strips of wood along the bottom and top edges. The sides are open. Through a hole in the upper distance strip sand pours from a funnel, and builds itself into a beautifully symmetrical conic section. Presently the base will so far widen that any further increase shoots the

FIG. 3.

sand off through the open ends of the cell. When this point is reached the cone can no longer grow. A supply of white sand is then poured in, and seen to run down the sloping sides without carrying any of the coloured particles with it. The base has spread out proportionately as the cone increased in height, so that the angle which the sides make with the horizontal shall be 35°. If the sand be wet or damp, this law no longer holds. The addition of sufficient water materially diminishes the friction between the grains.

It is often observed when walking along the sea-shore, upon sand left wet by the receding tide, that for a moment the foot, on touching the ground, is surrounded by a comparatively dry area. This appearance is quickly followed, however, by one which indicates that the sand has gathered moisture, for on lifting the foot—which has by now probably sunk a little below the surface—the excess of water is particularly noticeable. In order to explain

Fig. 4.

this we must have recourse to some ingenious experiments made a few years ago by Prof. Osborne Reynolds. He pointed out that a number of particles, whether spheres or irregular grains, may fit together in such a way that the size of the spaces enclosed by them is either a maximum or minimum. Figs. 8 and 9 show a sectional view of a collection of spheres, arranged in what Prof. Reynolds calls abnormal and normal piling respectively. It is evident that the spaces between the spheres are far less in the second than in the first case. Now here is an elastic bag tied upon one end of a glass tube. The arrangement is partly filled with sand and coloured water—the latter standing 2 inches in the tube, so as to serve as an index. If the bag is now tapped, all the particles in it become normally piled. We have seen that any departure from this arrangement will enlarge the spaces between them. It is no longer surprising to notice, therefore, when the bag is pinched and the grains are thus made to ride up on one another, that the liquid in the tube, instead of rising, actually sinks.

Returning to the effect observed upon the sea-shore, we see that the pressure of the foot disturbs the arrangement of the sand-particles from one of normal piling to one in which the interstices between the grains become larger. Since these spaces were originally full of water (held up by capillarity), they are now no longer filled, and we obtain a comparatively dry area. Water is rapidly drawn in from all sides, however, by the partial vacuum formed in the interstices, and the internal friction diminishes. The sand feels insecure. On withdrawing the foot normal piling is resumed, the excess of water producing a puddle, until it slowly percolates away whence it came.

This brings me to the subject of quicksands.

A certain amount of unnecessary mystery seems to surround this matter. I hasten to point out that the grains of quicksands appear to be in no way extraordinary. Nevertheless, the fact remains that sand in certain localities upon the coast readily gives way under a load. Instances are recorded where a cart driven over a wet shore has rapidly disappeared below the surface. The general opinion seems to be that this is due to a soft underlying layer of clay or mud, which no doubt in some instances is the true explanation. Mr. Carus-Wilson, who is an expert in these matters, pointed out to me recently, however, that another factor may be the imprisoning of gas between the grains, due to decomposition of organic matter. Experiment certainly supports this view, for you see that one of these beakers of wet sand easily sustains a weight which sinks down in the other. Yet both appear similar. The sand in the second beaker, however, was mixed when dry with a powder capable of effervescing if wetted. In the neighbourhood of dangerous bogs, in Ireland especially, it is evident that a quantity of gas is imprisoned in the mud.

It must also be borne in mind that any surface in so good a contact with wet sand that the air is excluded will be held fast by atmospheric pressure; and further, that an object so situated, and tilted this way and that, will rapidly become embedded and swallowed up. It is by this simple process that the celebrated Goodwin Sands have claimed so many victims. A large percentage of the vessels stranded upon them, however, float safely off on the rising tide, but now and then one is caught and doomed. In the past they have been responsible for many a shipping tragedy; and there is a pathetic interest attaching to the fact that ribs and other remains of ships, long lost and forgotten, sometimes reappear for a time above the surface. Since the advent of steam, it is happily a rare occurrence for a vessel to be lost upon a sandbank.

In 1849 boring operations were carried out on the Goodwins by the engineering staff of Trinity House. The Deputy Master and Brethren, whose generous offer of assistance on all matters relating to this subject I gratefully acknowledge, have kindly lent a model made at the time, which shows the nature of the sand found at increasing depths. Solid chalk was reached at 80 feet below the surface.

Let us now turn to some experiments upon the flow of sand through a tube. This long glass barrel is filled and ready. I free the nozzle, and collect the powder which flows out during ten seconds. The quantity so obtained is placed in one pan of a balance. When the height of sand in the tube has fallen to only a few inches above the outlet, I repeat the operation, placing the second amount collected in the opposite one. You see that the pans again stand level. It is therefore clear that the sand pours out at the same rate, irrespective of its height in the tube.

The question now is, how has the "head" been so completely destroyed? This may be answered by a further experiment.

A glass cell 2 feet high, 14 inches wide, and $\frac{1}{2}$ inch deep, is closed in at the sides only (Fig. 10). A movable section of a cone O, made of wood and imitating one of sand, is pushed up through the lower opening. Resting upon this, and fitting its sloping sides, is a strip of felt D. If the wood section be lowered (as shown in the figure), the felt, resembling an inverted V, remains wedged between the glass back and front of the cell. A very small force, however, will dislodge it.

Suppose we replace the wood model and hold it in position by a strut S. Regarding this as a section of a sand cone, we see that its entire weight would be carried upon the base of the cell. Sand is now poured in from the centre of the top opening, and rests upon the sloping felt. The point to notice is that it supports its own weight. When the particles are interlocked it resembles the span of an arch, for if I now remove the wood section the sand remains in position. When more is added, and the cell is nearly filled, the net weight is considerable, yet the felt bridge is not deformed in the least. Further, a wooden plunger P, fitting the top opening, and carrying heavy weights, may be inserted without increasing the pressure upon the felt.

Since the angle which the slope of a dry sand-cone makes with the horizontal is 35°, the height, h, to which the particles will build in a tube of radius r, so that the base of the cone corresponds to the diameter of the tube, is $h=r\tan 35°$. If we consider an element of the section just referred to, it is evident that a vertical downward force applied to the top of the sand becomes resolved in two directions, making an angle of 55° with the vertical. Now, applying the well-known formula for a symmetrical triangular frame loaded at its apex, we have

$$H=\frac{Wl}{4h} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

where H is the horizontal thrust, W the load, l the span, and h the height.

Regarding the cell as the section of a tube, $l=2r$ and $h=r\tan 35°$. Therefore, substituting these values in (1), we have

$$H=\frac{W}{2\tan 35°}=\frac{W}{1\cdot 4}.$$

The ratio of the force applied vertically to that of the lateral thrust is thus equal to twice the tangent of the angle which the slope of a cone makes with the horizontal, viz. 1·4.

For instance, if the vertical force due to a weight placed on the sand is 100 lb., the lateral pressure will amount to about 71 lb. A piston resting upon a column of sand only a few diameters high, contained in a strong tube closed at its lower end by merely a thin membrane, is capable, therefore, of sustaining very heavy loads.

In order to demonstrate this on a moderate scale, I have arranged a sort of gallows, through the projecting arm of which a flanged brass tube is inserted vertically. This tube is 0·5 inch in diameter, and closed at its lower extremity with a piece of cigarette paper held in position by an indiarubber band. A small quantity of sand is tipped into the tube from above—enough to fill it to a height of 3 inches. The column within will therefore measure 6 diameters. The tube is then well tapped to ensure normal piling of the grains, and a loosely fitting iron plunger is inserted so as to rest upon the sand. Attached to the plunger is a cross-piece carrying a ring at each end, which may be grasped with the hands. My assistant (who weighs about 11 stone) thus suspends himself safely, his weight being supported by the small sand column. If the piece of cigarette paper is now removed, he is let down with an unpleasant jerk.

Some idea of the close arrangement of the particles may be gathered by noticing that a long column of sand,

FIG. 5.

FIG. 6.

moving downward within such a tube, will produce a vacuum above it sufficient to lift water to a height of about 6 feet. (Experimentally shown.)

These experiments upon loaded sand columns clearly prove, therefore, how it is that the "head" is destroyed, and explain why the powder issues from an orifice at a uniform rate.

Lord Rayleigh applied this principle to a very interesting device, which he used here some years ago, for the purpose of slowly rotating a smoked disc. A weight stood upon a sand column contained in a glass tube. Its downward motion as the column lowered, due to escape of powder from a nozzle at the end, served to operate a train of wheels. The question arises, however, as to whether such a motion is quite uniform. In other words, does the sand move regularly in the tube? Experiments

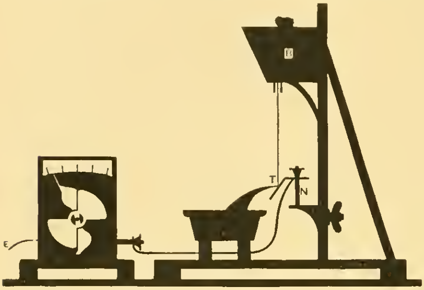

Fig. 7.

indicate that it is very difficult to obtain an absolutely uniform motion by this means. Friction appears to be the controlling factor. A tube, oiled upon its inner surface, is now filled. On freeing the nozzle, you see that the sand moves out by slow regular jerks. Certain curious rattling sounds, emitted occasionally by the column descending in a glass tube, also drew attention to the intermittent motion of the grains.

It seemed reasonable to hope, therefore, that this might be made sufficiently rapid and regular to give rise to a musical note.

Now many strange noises have been heard in the neighbourhood of large sand masses when surface layers have been disturbed by someone walking over them; and there are curious shrieking sands—rarely met with upon the coast.

Thanks to the great kindness of Mr. Carus-Wilson, whose work in this direction is so well known, I am able to exhibit a remarkable specimen of sand from the Isle of Eigg, in the Hebrides. When a plunger strikes down upon the grains contained in a suitable cup, you hear a

Fig. 8.—Abnormal Piling.

Fig. 9.—Normal Piling.

piercing musical sound. Mr. Carus-Wilson attributes this to the friction between the particles, the effect being produced in much the same manner as that which results from gently rubbing an agate style upon glass. He has discovered musical sand in Poole Harbour, as well as at other places.

The essential conditions for the production of this sound are:—

(1) That the grains be nearly of the same size and rounded.

(2) That they be clean and free from adherent fine dust.

(3) That the vessel in which they are struck have sloping sides, and be made of a suitable material.

But to return to the question of obtaining musical sounds from ordinary sand.

There stands, fixed to the wall, a large glass-fronted section of a tube. It is filled with alternate bands of white and black sand, the latter being about one-sixth as deep as the former. An outlet is provided at the bottom. This arrangement enables the motion of the different portions of the sand column to be observed while the powder issues from the orifice.

On freeing the nozzle, we see that the centre of the lowest black band immediately falls, and that, as the sand continues to escape, successive bands become similarly deformed. It is clear that the grains from the central part of the column are moving rapidly downward, and, since no eddies can form in the remainder, the whole becomes divided into a core of moving particles and a large surrounding mass of dead sand (Fig. 11).

The diminished density of the axial region releases the lateral pressure upon the sides of the tube, and the upper part of the column suddenly slips until the grains again pack and seize as before.

Now if sand of a suitable fineness be slowly passed in this manner through a glass tube of correct dimensions, a musical note may be produced.

The tube should be about 1 inch in diameter, and filled with sand resembling that found in the Charlton pits. The length of the one now ready is 3 feet. When the flow begins, a curious rattling sound is heard, which finally changes to a distinct musical note. It may be varied slightly, say to the extent of a whole tone or so, by gripping a part of the tube while the sand pours out. The two upper dark bands (Fig. 11) have not become deformed, except slightly at their ends, owing to friction between the sand and tube. It is essential for the production of musical sounds that the ratio of the length of a column to its diameter be such that the upper portion moves downward without central deformation. In order to explain the cause of the sound, we must therefore consider the motion of this more or less compact body of particles.

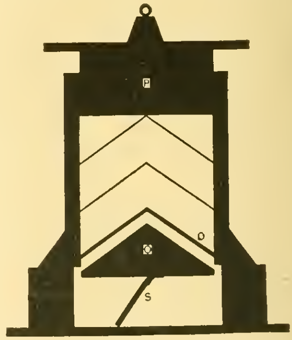

Fig. 10

Now, if the lower half of the tube be filled with mercury and the rest with well-packed sand, the regular lowering of the liquid causes the granular piston apparently to stretch until its extension is about 2 per cent. of its original length. It is not until that point is reached that the upper layers begin to move downward. The particles, however, are no longer normally piled. A further slight movement of the lower layers causes the upper ones to follow and to overrun a little (owing to their momentum). Therefore, even if the mercury is adjusted to pour out uniformly from the orifice, the upper part of the sand column moves downward with an intermittent motion, analogous, in fact, to that of a weight drawn over a rough surface by an elastic string. It is also clear that, within wide limits, the motion of the upper layers may be independent of, or completely out of phase with, that of the lower ones, and still produce a musical note.

The glass wall of the tube is thrown into violent vibration by the intermittent rise and fall of the lateral pressure upon it, so that damping the barrel raises the pitch of the note. The greater part of the sound is due, however, to the direct action of the sand column upon the air above it, for even a tight wrapping of tape but slightly affects its

THURSDAY, SEPTEMBER 1, 1910.

COLOUR-VISION.

Colour-Blindness and Colour-Perception. By Dr. F. W. Edridge-Green. Second edition. Pp. xii + 322. International Scientific Series. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1909.) Price 5s.

DR. EDRIDGE-GREEN has been engaged for more than twenty years in advocating opinions about colour-blindness which he has not the gift of stating with extreme lucidity, which most people find it by no means easy to understand, and it is therefore somewhat difficult either to accept or to refute. The general basis on which the opinions rest appears to be his conception of something called by him a "psycho-physical unit," by which he appears to mean the limit, in any individual, of the power to perceive actual difference between two things closely resembling one another, as, for example, between two similar colours, or between two masses of the same substance that are of nearly the same magnitude. There are, no doubt, great personal differences of this kind, differences which may be partly congenital and partly the results of training; but it does not appear to us that the prefix "psycho," whatever it may mean, bears any intelligible relation to them. The differences are differences of the acuteness of sense-perception, and, if we regard simple sense-perception, colour-perception, for example, as "psychical," we must postulate the activity of a "psyche" in the humblest fly which is guided to the nectary of a flower by the colour of the corolla.

We do not know whether Dr. Edridge-Green is prepared for such an extension of the domain of "psychology," and may leave him to settle the question with the professors of that branch of speculation, but we may admit that the condition known as "colour-blindness" may fairly be said to consist of an inability to respond by accurate sense-perception to the impact of light-waves of certain amplitudes, and of a consequent liability either to ignore them completely or to confound them with waves of other amplitudes. It is at least highly probable that minute differences of this kind are extremely common, and Lord Rayleigh long ago showed that some persons, whose colour-sense could only be described as normal, nevertheless differed from others in respect of the precise admixtures of light from different portions of the spectrum, more especially in respect of the admixtures of red and green, which they were prepared to accept as a perfect "match" for a test-spot given as a standard.

It is probable that such terms as "red-blind" or "green-blind" might be extended not only to the six classes (hexachromic, pentachromic, &c.), described by Dr. Edridge-Green, but to a much larger number; and, by the way, we do not know on what ground our author regards the normal-sighted as "hexachromic" only, and so apparently excludes from the spectrum, as they see it, the seventh distinct colour, indigo, which was described by Newton, and has commonly been accepted by later observers. The limitations of our space forbid us to follow these questions into detail, and the chief practical importance of colour-blindness depends upon the fact that a liability to make mistakes about colour-signals involves dangers to life and property on railways and in navigation.

As regards protection against these dangers, we do not see that Dr. Edridge-Green has furnished us with any increased security, or, indeed, that any better security is needed than is obtained from Holmgren's wool test, when this is employed in the precise manner directed by its originator, whose very definite instructions are too often departed from. The elaborate lanterns and slides described by Dr. Edridge-Green are in all essential respects identical with many of the tests used by the Royal Society's committee; and, if we may admit that they afford means of distinguishing one case of colour-blindness from another of a slightly different type, we cannot admit that they are calculated to afford any increased security to the industries in which the power to distinguish promptly between different signal colours is required.

A HISTORY OF BIOLOGICAL THEORIES.

Geschichte der biologischen Theorien. By Dr. Em. Rádl. II. Teil. Geschichte der Entwicklungstheorien in der Biologie des XIX. Jahrhunderts. Pp. x + 604. (Leipzig: W. Engelmann, 1909.) Price 16 marks.

THE author of this scholarly work attaches great importance to the cultivation of the historical sense among biologists, believing that progress is impeded because there is relatively little of it, and one of the aims of his book is to stimulate a study of the history of the science. To this end it is admirably adapted. It is learned, but at the same time wisely selective; it is at once appreciative and critical; and it is written in a fresh, interesting way. We had the pleasure of welcoming the first volume, published four years ago, which dealt with ancient history, and we would congratulate the author again on the success with which he has accomplished a very difficult task in dealing with what has occurred in biology, or in biological ætiology, since the end of the eighteenth century. It seems to us, indeed, that the author has added to his strength since he completed the first part of his great work.

There are forty-one chapters in the book, and we may note some of the titles to suggest the range of discussion:—Lamarck and Cuvier, idealistic morphology, embryology before Darwin, the cell-theory, physiology before Darwin, transition from Naturphilosophie to modern science, origin of Darwinism, Darwin, Wallace, reception of Darwin's theory, influence of Darwinism, Haeckel, spontaneous generation, anthropology, Darwinian morphology and embryology, geographical distribution, palæontology, natural selection, heredity, psychology, Lamarckism, species, reproduction, crossing, developmental mechanics, Driesch, decline of Darwinism, the history of science.

What the author aims at is a historical appreciation of the significance of the various stages in the development of ætiology, and this involves a critical judgment

 K

of the contributions made by the succession of workers. He seeks to show how one step is related to others, often beyond the boundaries of biology. There is, for example, a very interesting passage in which he maintains that Darwin projected upon nature the contemporary ideal of the English state, his theory being, in fact, "a sociology of Nature." In parts Rádl's book shows an interpretative insight, which reminds us of Merz's "History of Intellectual Development in the Nineteenth Century," which is great praise; in other parts we think that he is quite unsound—notably in his curiously non-evolutionary contention that Darwinism is dead. Nor do we think that he is uniformly fair and accurate in his treatment of Darwinism, *e.g.*, in a sentence like this:—"Die Theorie Darwins, welche jeden Glauben an die Gesetzmässigkeit der organischen Welt vernichtete, und alles Geschehen für eine Häufung von Zufällen hielt, konnte zwar für kurze zeit die Welt blenden."

It is unsatisfactory to do no more than record dissent from Dr. Rádl's pronouncement that Darwinism is discredited, but the matter cannot be argued out in a few sentences. We might refer him, however, to some weighty considerations set forth in the fifth chapter of Sir Ray Lankester's "Science from an Easy Chair," which is entitled "Darwin's Theory Unshaken."

As we lay down the big book, our dominant impressions are that it is stimulating and even provocative, that it shows an extraordinary acquaintance with the literature, that it expresses a sometimes surprising appreciation of the importance of thinkers outside the ordinary schools (Samuel Butler, for instance), and that it carries one on with an undeniable swing, though it passes our understanding to discover the meaning of the detailed arrangement of the chapters.

SCIENCE IN SCHOOL.

Broad Lines in Science Teaching. Edited by F. Hodson, with an introduction by Prof. M. E. Sadler. Pp. xxxvi+267. (London: Christophers, n.d.) Price 5*s.* net.

IN the curricula of English schools a place, sometimes an important place, has been allotted to "science." The result has been to kindle intellectual interest in certain boys to whom the other work of the class-room made no appeal, as well as to direct the interests of the more studious to a wider field of intellectual exploration. Even more important has been the influence of the science-masters, who, having no well-worn groove of tradition along which to travel with the minimum of effort, have brought scientific method to the investigation of methods of teaching. Nevertheless, to many observers the effects of science teaching have been disappointing. Such critics demand that the average youth shall acquire the scientific way of looking at things. This is a very much larger demand than was realised in the early days, and it is the special aim of the book before us to present a broad view of the work which is involved in any sound curriculum which can make boys and girls of secondary-school age the possessors of that which science has to give.

The volume contains a number (not strictly a series) of essays by writers who desire that the methods of science teaching should be built upon a fundamental study of the right relation of the growing mind towards new knowledge, new dexterities, new perceptions of duty. We may at once congratulate the editor on the *personnel* of the contributors and on the manner in which he and they have justified the title of the work. Prof. Sadler contributes an introduction, which is also somewhat in the nature of a review, and emphasises the necessity of first-hand study of nature. The place of science in the curriculum, its position in Germany, and the utility of examinations are discussed by the editor and Mr. Badley. Biological subjects receive a goodly share of attention in articles contributed by Miss von Wyss, Mr. Oswald Latter, and Miss Ravenhill. The chapter on geography is written by Mr. J. N. Stephenson, and is full of useful and sound criticism—obviously the work of an experienced and shrewd teacher. The relation of school work to the spiritual side of the pupil is discussed by the headmaster of Bedales and Miss Sanders, and in a measure by Prof. Powicke in his chapter on "Science in the Teaching of History." It is impossible within the limits of a short review to deal with these; the mention of them will serve to show the breadth of the editor's objective. Consideration is also given to the preliminary training of those who are to become farmers, housewives, engineers. In the last-mentioned case the writer considers the administrative and economic difficulties, but so rapidly are changes taking place in the organisation of educational courses for boys leaving school between the ages of fourteen and seventeen that no demerit attaches to the essays in which these aspects are omitted, as is usually the case in this volume.

Physics, chemistry, mathematics, are dealt with in the short space of forty to fifty pages. It would have been an improvement if more space had been given to these branches, even if this had involved the loss of the chapter on laboratory planning, which is not quite on the "broad lines" of the rest of the book. Teachers of chemistry should certainly read Dr. T. P. Nunn's essay on "The Place of Hypotheses in Science Teaching"; those who wish to train their pupils in the habit of independent thinking about phenomena and theories cannot fail to gain help from this searching probe into the tissues of our chemical belief.

The general impression produced by this book is encouraging. Especially marked is the thoroughness with which correlation between branches of the curriculum is made the basal plan of the educational structure. Correlation has ceased to be a word merely (blessed or the reverse), or at best a number of adventitious links between subjects mainly pursued apart; it is fast becoming an influence pervading the more progressive common-rooms and giving unity—but not monotony—to aims and methods in adjoining class-rooms. The subject of the chemistry-master is not primarily chemistry but boy. The writers of "Broad Lines" realise this. They also realise the claims of practical application to health, morals, and livelihood, and seek to imbue school work and school life with the research habit and attitude of mind.

The volume is pleasant to read and handle; our main regret is that the essays are not twice their present length. We hope that this most opportune book will be widely read.

CLASSIC WALL-PAINTING.

Greek and Roman Methods of Painting: Some Comments on the Statements made by Pliny and Vitruvius about Wall and Panel Painting. By Dr. A. P. Laurie. Pp. vi+124. (Cambridge: University Press, 1910.) Price 2*s*. 6*d*. net.

Dr. Laurie, who is principal of the Heriot-Watt College at Edinburgh, has devoted much time and considerable ingenuity to the study of the materials and methods of painting. Many of his results are recorded in the Journal of the Royal Society of Arts and in other periodicals. But in the little book now before us we possess, in a detached and accessible form, an account of Dr. Laurie's latest studies on fresco- and wax-painting as described by Pliny and Vitruvius and practised in classic times. As the volume is not supplied with a table of contents, and is not divided into chapters, it may be well, in the present notice, to describe, in the order followed by the author, the several topics which he discusses.

The book opens with a review of the conditions under which the inquiry into ancient painting methods should be conducted. Then we pass on to the consideration of the pigments, both natural and artificial, which were available for use in early days. Dr. Laurie's list and his observations on several of the items which it comprises are of considerable interest. The murex purple, lately ascertained to be a dibromindigotin, and Egyptian blue, which was investigated by the late Dr. W. H. Russell, are important constituents of the ancient palette. A madder pigment was also in use, as well as indigo.

Primitive vehicles are next discussed, size, gum, milk, white and yolk of egg being included in the series of available mediums. Both bitumen and turpentines, or liquid resins and balsams, were known, but neither drying oils nor spirit varnishes. Beeswax played an important part as a painting vehicle; our author's studies and experiments confirm the modern view as to the process of encaustic painting as described by Pliny and illustrated by the wax portraits brought from the Hawara cemetery in the Fayum by Prof. Flinders Petrie. The doubts once expressed by Eastlake and other authorities as to the feasibility of painting with melted coloured waxes may now be regarded as not warranted. In some places the wax was mixed with a liquid resinous body, such as Venice turpentine; this mixture was more easy to manipulate than wax alone, but acquired greater hardness in the course of time.

Wax-painting was, however, not the ancient process in use for the decoration of walls; this was painting on wet or wetted lime-plaster with pigments mixed with water, or possibly on occasion with glue or size. Such fresco-painting is discussed by Dr. Laurie at some length. The process is not precisely that of the fourteenth century and the Italian Renaissance, the *buon fresco* of the historians of art. There are no joins or seams in the ground, and the painting could not have been completed on the freshly spread plaster while its surface was in the best state to receive and incorporate the paint. The surface must have been wetted with water admixed with a little slaked lime from time to time, while later applications of colours must have contained milk of lime. Such a process approaches closely to that known as *fresco secco*, and can be traced back to a much earlier date than can the true *buon fresco*.

We must not linger over the technical questions connected with fresco-painting as discussed by Dr. Laurie, but may now pass on to consider his criticism of the views as to old mural painting advocated by Herr Ernst Berger, in his "Maltechnik des Alterthums." These views are shown to be untenable, deriving no support either from the chemical examination of ancient examples, from modern experimental trials, or from the careful study of the language used by Pliny and by Vitruvius. The method imagined by Herr Berger was allied to the modern *stucco lustro*, and involved the use of an emulsion of beeswax, oil, and soda or potash; our author shows (pp. 107–9) that there is no valid evidence in favour of the use of this dangerous and ineffective mixture.

Dr. Laurie will, we hope, pursue his interesting and illuminating inquiries into the materials and methods of ancient painting, and of modern painting also; but in his next book will he not give us, besides such an adequate index as appears in the present work, a table of contents? This will involve the arrangement of his material in chapters or sections, which will prove more easy to study or to consult than an unbroken discussion occupying no less than 112 pages.

A. H. C.

OUR BOOK SHELF.

A Monograph of the Foraminifera of the North Pacific Ocean. Part i., Astrorhizidæ and Lituolidæ. By J. A. Cushman. Pp. xiv+134. United States National Museum Bulletin 71. (Washington: Government Printing Office, 1910.)

This is the first instalment of a work on the foraminiferal fauna of the North Pacific. It embodies the results of Brady, in the *Challenger* report, in so far as concerns this area, and of Goës, Flint, Rhumbler, Bagg, and others, and presents the outcome of the author's own investigations. These are based on the examination of material dredged by the United States s.s. *Albatross*, *Nero*, and *Alert*, parts of which have been already used in the reports of Goës, Flint, and Bagg.

In many cases the author extends the range of previously known species, and several are regarded as new. New generic names are given to divisions of recognised genera, particularly of the Lituolids Haplophragmium and Trochammina. Of wider interest is the author's identification of *Ammodiscus tenuis* as the megalospheric form of *A. incertus*, under which name the microscopic form has been described.

Each species is illustrated, and the figures are in most cases quite sufficient.

(1) *A First Year's Course of Inorganic Chemistry.* By G. F. Hood. Pp. iv+107. (London: Rivingtons, 1910.) Price 1s. 6d.

(2) *A Manual of Elementary Practical Chemistry for Use in the Laboratory.* By P. W. Oscroft and R. P. Shea. Pp. viii+134. (London: Rivingtons, 1910.) Price 2s.

THESE two little volumes are for use in schools, and are intended to serve as an introduction to chemistry. Oscroft and Shea's manual carries the subject to the stage of equivalent weight estimations and simple gravimetric and volumetric analysis, whilst Hood's book, which is a first year's course, stops short of this point. Both books contain descriptions of a series of easy quantitative experiments on loss and gain in weight, as well as a detailed account of a variety of thoroughly instructive preparations.

There is nothing in either that strikes one as very new or original in conception or arrangement; but, on the other hand, there is nothing to which objection can be taken, and both volumes may be recommended without reservation. It might be well in a future issue to give the actual results of the quantitative experiments so that both teacher and student might form some idea of the accuracy attainable. In conclusion, we question to what extent it is permissible to adapt a classical discovery to the intelligence of a schoolboy; for it may be doubted if either Berthollet, Gay-Lussac, or Davy ever thought of chlorine as "murium dioxide" (Hood, p. 51). J. B. C.

Catalogue of the Books, Manuscripts, Maps, and Drawings in the British Museum (Natural History). Vol. iii. (L–O). Pp. iv+1039–1494. (London: British Museum (Natural History), 1910.) Price 20s.

THE long interval which has elapsed since the publication of the second volume of this catalogue (see NATURE, August 25, 1904)—which followed the first (*ibid.*, October 22, 1903) in reasonable time—is explained in the preface as due to other library work. Apparently the earlier sheets of this volume were completed and printed off before 1907, as we find no title associated with the name of Sir E. Ray Lankester, while the latest of his works referred to bears the date of 1906. In this connection it may be noted that in some cases the full Christian names of authors, as in the case of Sir E. R. Lankester and Sir R. Owen, are repeated in each entry, whereas in other instances, as in the case of Sir Charles Lyell, these are reduced to the initials after the first entry. Apparently the compiler was compelled to follow the order adopted in the library catalogue at Bloomsbury, which will probably account for the sundering of such names as Loennbohm (p. 1163) and Lönnberg (p. 1175). Like its predecessors, this volume contains valuable bibliographical information, and it is to be hoped that we shall have the pleasure of welcoming the fourth volume at an early date. R. L.

The Calendar of Garden Operations. New and enlarged edition. By members of the staff of the *Gardener's Chronicle.* Pp. vi+175. (London: *Gardeners' Chronicle*, Ltd., 1910.) Price 6d. net.

THIS is a new edition of a work prepared originally by Sir Joseph Paxton, and published in 1842. It is a concise and practical manual from which possessors of small gardens in country or town may obtain much useful advice and guidance. Chapters have been added on the cultivation of trees and shrubs in towns, and on the principles of intensive culture or French gardening. In its enlarged form the continued success of the book is ensured.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Separating Power of a Telescope.

CAN an observer inform me what are the proper telescopic powers, and apertures or sizes of glasses, required to see stars which are apart from each other the following distances, and of different magnitudes?

(1)	... $0''$ to $1''$	(5)	... $8''$ to $12''$
(2)	... 1 to 2	(6)	... 12 to 16
(3)	... 2 to 4	(7)	... 16 to 24
(4)	... 4 to 8	(8)	... 24 to 32

Gore made a table showing the magnitude of the faintest star visible in any telescope in his "Stellar Heavens," but I would like to see if anybody can make a table out from *experience and ordinary practical observation* in the case of double and multiple stars. Where the glare of one star interferes with the definition of another star, I am inclined to think a larger aperture is needed in the case of doubles and multiples than in singles, and where the stars are very close. If a table could be made out for reference by students it would be useful.

Grimscar, Huddersfield. J. W. SCHOLES.

THE questions proposed cannot be answered quite so definitely as Mr. Scholes would appear to think. To begin, we must have a clear idea of what is meant by the separating power of a telescope. Put in a theoretical form, it means: Given two points of light (stars) a certain angular distance apart, what is the size objective which will just give two distinct images in the focus? For practical purposes, this is answered by the formula

$$\text{Separating power} = \frac{4''\cdot 56}{a}$$

where a is the aperture of the object-glass in inches.

This can easily be remembered; or, if it is preferred, a table can readily be formed, thus:—

Size of O.G. Inches	Separating power
1	$4''\cdot56$
4	1·4
8	0·57
28	0·17
36	0·13

A second of arc in the focus of the 28-inch Greenwich refractor is 0·00103 inch. Let it be clearly understood that this table gives the theoretical size of object-glass to obtain *separate points in focus.*

If the points are not separated in the focus, no amount of magnifying power will afterwards separate them.

This does not imply that the unaided eye, looking at the focal images in the telescope, can detect duplicity. The points to be thus seen must subtend at the eye an angle of at least $60''$. It is here that the eye-piece comes in, for, given two separated points, we can magnify the separation until the eye can not only detect, but can see it sufficiently to enable micrometric measures to be made.

Hence we use eye-pieces magnifying 2, 3, 4, 5 times, and so on.

These eye-pieces bring up the total magnifying power, which is quoted as the power used. It is stated in textbooks that a power of 50 or 60 per inch aperture is the practical limit; but it is readily seen, however, that the power used is dependent on several conditions:—

(1) Size of object-glass.
(2) Quality of object-glass.
(3) Condition of the atmosphere.
(4) Personality of the observer.
(5) Subject observed.

The questions asked refer especially to double-star work, and confining ourselves to this simplifies matters.

If we allow 50 per inch aperture, we should expect to find observers with the

36-inch Lick, using a power of ...	1800
28-inch Greenwich ,, ,, ...	1400
18½-inch Dearborn ,, ,, ...	950
8-inch (Maw) ,, ,, ...	400
6-inch (Solà) ,, ,, ...	300

Atmospheric conditions affect the large glasses much more than the smaller, for we find in actual practice that the Lick observers prefer powers of 1000 and 1500; the Greenwich observers prefer 670 and 1120; Hough, with the 18½-inch, used generally a power 390, and less frequently 925.

Maw uses powers of about 300 and 400 on both his 6-inch and 8-inch, while Solà uses 350 on his 6-inch.

When an observer is quite used to his instrument and his eye-pieces, he develops a preference for one particular eye-piece under most all conditions.

One element, as yet not mentioned, has naturally a great influence in the choice of an object-glass, viz. the range of visibility, or the ability to show faint objects. The above remarks apply to pairs the components of which are fairly equal; but, in general, distant companions are very faint.

The light-grasping power of a telescope depends on the surface or diameter squared of the object-glass. A good 1-inch object-glass should show a ninth-magnitude star, and one star is said to be a magnitude fainter than another when its light is 2·5 times less.

Consequently, the aperture must be $\sqrt{2{\cdot}5}$ greater to show it. Roughly, $\sqrt{2{\cdot}5}=1{\cdot}6$, and hence if 1 inch shows a ninth magnitude $1\times1{\cdot}6$, or a 1·6-inch shows a tenth magnitude, or generally

Star magnitude	9	10	11	12	13	14
Aperture in inches	1·0	1·6	2·5	4·0	6·3	10·0

Of course, this table is not to be taken too seriously, as it is governed by much the same conditions as already mentioned for separating power. Bear in mind Burnham's words: "An object-glass of 6 inches one night will show the companion to Sirius perfectly; on the next night, just as good in every respect, so far as one can tell with the unaided eye, the largest telescope in the world will show no more trace of the small star than if it had been blotted out of existence."

I hope, with a little twisting and adaptation, the foregoing remarks may be made to answer the fundamental principles underlying the apparently easy questions.

Mr. Scholes is quite right as to the glare, and the larger aperture by increasing the separation, and by making the apparent discs smaller, does make observation easier.

T. LEWIS.

Colour-vision.

As one who was responsible for the testing for colour-vision of several thousands of drivers and firemen, I should like to refer to the method of testing by means of different coloured skeins of wool.

The usual method is to take a particular skein of wool and request the person who is being tested to select in succession the three or more skeins which mostly resemble it. In some cases I found that men who were clearly colour-blind succeeded in passing such a test satisfactorily.

It must be remembered that a colour-blind person has been accustomed to consider his capacity for appreciating colour differences in the light of other people's statements. It thus comes about that they learn to consider differences, which are really colour differences to those whose sight is normal, as being partly due to intensity of light, texture, or other considerations. They are aware, of course, that they cannot always detect differences of colour in the ready way that others can, but they also feel that they can often see differences much more quickly than can others. With the colour-blind, therefore, the capacity for matching or naming colours becomes more and more perfect the greater their experience becomes of the objects to be compared. Now, in the case of the wool test, the different coloured skeins are certainly in many cases of different texture, coarseness, or gloss. The skeins are also frequently numbered. With a little careful study of the wools with which the tests are carried out, it may be quite possible for a colour-blind man to get through the tests satisfactorily unless great care is exercised.

I found the following to be a ready method of detecting colour-blindness. The wool skeins were arranged in the order of their brightness, the white skein being at one end and the black at the other. It is, of course, somewhat difficult to estimate the comparative brightness of a red and a yellow object. I found, however, that with a little practice and care this could be done satisfactorily. If a person whose vision is normal be asked to pick out the darkest skeins, he will at once pick the black one and afterwards those next to it. On the other hand, a colour-blind person will probably pick the black skein first and then the reds or greens, the darker shades being selected first. A test of this kind is most striking. In one case, a man who had got through the ordinary tests with some hesitation selected all the reds before the dark greys, neutral tints, greens, &c., although some of the reds were much brighter colours than the greens.

The better plan is to take a number of different coloured skeins of wool and ask the person who is being tested to arrange them in their order of brightness. A markedly colour-blind person cannot do this properly.

R. M. DEELEY.

Melbourne House, Osmaston Road, Derby.

LAKE EDWARD, RUWENZORI, AND THE UGANDA-CONGO FRONTIER.

THE argument lately arrived at by the representatives of Great Britain and the Congo has affected the settlement of a troublesome boundary dispute, in which the competence of any diplomacy to deal with a geographical question in a scientific manner has not shown itself in a particularly favourable light.

The original agreement, the *fons et origo* of all the subsequent mischief, was signed at Brussels on May 9, 1894. By this it was enacted:—

"That the sphere of influence of the Independent Congo State shall be limited to the north of the German sphere in East Africa by a frontier following the thirtieth meridian east of Greenwich up to its intersection by the watershed between the Nile and the Congo, and thence following this watershed in a northerly and north-westerly direction."

At the time this agreement was made the 30th meridian was shown on the maps as dividing Lake Edward into two approximately equal parts, and as passing to the west of the whole Ruwenzori range. It is, however, a commonplace among geographers and surveyors that a determination of longitude in an unsurveyed country is liable to large errors, and that a meridian line is, of all possible boundaries, the worst that can be selected. In this case the actual event proved that the selection of this line had resulted in the maximum of inconvenience and loss. The true position of the meridian was found to be about half a degree east of its position as assumed in 1894, and a strict interpretation of the letter of the treaty would have involved our retirement from Lake Edward and from practically the whole of the Ruwenzori district. Such a contingency was obviously intolerable, and the only practicable course was to arrive at some sort of compromise which should, as far as possible, minimise our loss. The commissioners entrusted with the recent negotiations arrived at what perhaps was the best solution available at this date, and by surrendering to the Congo the whole of the north shore of Lake Albert, they regained the eastern half of Lake Edward, and about half Ruwenzori. The net result of the whole transaction is therefore that we lose all the country lying between Lake Albert and the Congo-Nile watershed and the western half of the Ruwenzori range.

From the geographical point of view the great error that was committed was the definition of a frontier by a meridian line, and what makes the error the more regrettable is that this unscientific boundary was a gratuitous importation, which was substituted for the perfectly precise and scientific frontier laid down in the original act constituting the Congo State. This frontier was the watershed line dividing the Congo basin from the surrounding river basins, of all natural geographical frontiers the most satisfactory.

It was defined, with ideal precision, in the "Berlin Act" of February 26, 1885, in the following words:—

"All the regions forming the basin of the Congo and its outlets. This basin is bounded by the watersheds (or mountain ridges) of the adjacent basins, namely, in particular, those of the Niari, the Ogowé, the Schari and the Nile on the north. . . . It therefore comprises all the regions watered by the Congo and its affluents."

Apart therefore from the actual method of frontier definition, we cannot avoid the conclusion that to have allowed the Congo State to acquire claims to any territory outside the actual Congo basin was a surrender of our clear rights. We may remind those of our readers who have not got a map in front of them that both the Lakes Albert and Edward and the Semliki river, which connects the two, lie wholly within the Nile basin.

Our knowledge of the interior of Africa has so progressed since 1894 that there is no locality where a mistake, at all comparable in magnitude, could be made at the present time. We may further be permitted to hope that the spirit in which our great departments of State approach this and similar questions has undergone such a change in the last few years that a total setting aside of all expert opinion, on which alone the agreement of 1894 is explicable, is no longer probable. E. H. H.

WILLIAM JAMES.

THE announcement of the death, at the comparatively early age of sixty-eight, of William James, emeritus professor of philosophy in Harvard University, will have been received with regret by an unusually wide circle of readers of philosophic literature, and with deep sorrow by an unusually large circle of friends, who knew from experience how much greater was the charm of his personality than the charm even of his writings. But few even of his friends can have suspected under what physical disabilities were produced the utterances of which the sunny geniality, irrepressible vitality, coruscating vividness, and brave optimism, unstained by any shadow of insincerity or cowardice in facing the ills of life, so deeply fascinated them, or realised that they were listening to a martyr to a grave cardiac affection, whose life for the last ten years had hung by a thread.

This is not the place for an estimate of James's achievements as a philosopher, but it will not be amiss to signalise the intimacy of his relations to science. It is not often that a philosopher of the first rank has had the good fortune to receive a scientific education or the literary genius to gain by losing a literary education. But William James is a shining example of how stimulus and freshness may be imparted even to philosophic subjects by one who is allowed to approach the real problems direct, and without wandering through a thick fog of historic errors. Originally trained for the medical profession, he became interested in "pure" science; accompanied Agassiz on an expedition to Brazil; was appointed to teach anatomy at Harvard; proceeded to the teaching of physiology; approached psychology from the physiological side; became a peerless master in the art of psychological description; applied his psychology with revolutionising and revivifying effect to the study of religion, superstition, logic, and to that chamber of horrors for unsolved puzzles which is called metaphysics; and, finally, before he could formulate his conclusions, was taken from the world he had studied so variously and with such eager human sympathy. But at heart perhaps his attitude towards life always remained psychological. He was more interested in discovering and describing facts than in dogmatising and system-building with them, and almost as disregardful of formality as of technicality and pedantry.

To scientific psychology his services are admittedly immense. His work on "The Principles of Psychology" (1890) at once became a classic, and is likely to remain so. He found the science entangled in metaphysical obscurities and based on false descriptions. He insisted that it should be made a natural science, descriptive, and, wherever possible, experimental, and described its facts anew. His fundamental innovation was to perceive that the "facts" of consciousness form a continuous flow and *not* a succession or series of separate facts, as, since Hume, psychologists and their metaphysical opponents had alike assumed. The consequence was that the problem of *synthesis* disappeared, and that the function of scientific knowing became the *analysis* of a continuum. When the meaning of this has been fully grasped, it will be seen that a number of metaphysical puzzles (*e.g.* about "the one" and "the many") answer themselves.

But James also saw that if psychology was to progress further on the road to an exact science, it must not be only descriptive, but must devise applications of its theories sufficiently precise to discriminate between alternative interpretations by their differential values. This probably was one of the main motives that led him to make the great generalisation of scientific method which is known as pragmatism, though he also conceived it in another aspect as an extension to psychology and logic of the biological conception of survival and the Darwinian principle of selection. Of pragmatism he was practically the founder, though he took a hint and the name (which is a bad one) from his friend C. S. Peirce, and it was to the explanation and advocacy of this method that the last dozen years of his life were devoted. The controversy which was thereby started is still unfinished, and, indeed, is only just beginning to bear fruit.

But it is a psychological curiosity how few of the many who denounced James as a dangerous revolutionary perceived that the doctrine that the meaning of an assertion depends on the value of its consequences enunciated merely the scientific postulate that all assertions must be *tested*, and that any doctrine which could not be applied to any problem was unmeaning. One can only suppose that this philosophic generalisation of scientific practice was propounded to persons who, as a matter of psychological fact, were not in the habit of subjecting their pet convictions to any test, and therefore aroused so great an emotional disturbance that the actual doctrine was hardly attended to. A similar reception was accorded to James's account of the will and the right to believe. James, after pointing out that, as a matter of psychological fact, there existed a strong bias in men to believe what they desired, had restricted the right to believe to cases where a choice between a number of intellectually possible alternatives was practically necessitated, and asserted that in such cases the empirical consequences of the belief, favourable or otherwise, formed the test of its truth. Whereupon he was, in spite of repeated disclaimers, universally credited by his critics with exhorting men to believe whatever they pleased without regard to the consequences!

But all the world over the old dies hard, and the new has to struggle into birth so slowly that it is adult by the time it comes out, and the pioneers have to rough it. Logic will be the last science to submit to the sway of Darwinism, but there is no doubt that in the end it, too, will yield to the pragmatist followers of William James.

In addition to writing a large number of articles and reviews which have never been republished, James was the author of the following substantive works:—"The Principles of Psychology" (1890), the "Text-book of Psychology" (1892), "The Will to Believe" (1896), the Ingersoll lecture on "Human Immortality" (1898), "Talks to Teachers" (1899), probably the easiest and most delightful introduction to psychology extant, the "Varieties of Religious Experience" (1902), "Pragmatism" (1907), "A Pluralistic Universe" (1909), and "The Meaning of Truth" (1909).

DR. LOUIS OLIVIER.

DR. LOUIS OLIVIER, whose death we announced last week, was one of the best-known men of science in France, and had many friends also in Great Britain. He was only fifty-six years of age, and that the scientific world should have been deprived of his influence and activities when years of further work were anticipated has caused widespread regret.

For most of the following particulars of his career we are indebted to M. Louis Brunet. Louis Olivier was born at Elbeuf on June 29, 1854. He studied at the Museum of the Sorbonne, and obtained the degree of doctor of science in 1881, with a thesis entitled "L'appareil tegumentaire des racines," which was awarded the Bordin prize of the Paris Academy of Sciences. Entering Pasteur's laboratory, he carried on bacteriological work, which led to some valuable results, such as the reduction of sulphates by micro-organisms, and, in collaboration with M. Ch. Richet, the existence of various bacteria in the lympth and blood of healthy fishes. In 1888 he went to Havre as director of the municipal laboratory there, and to form a course in bacteriology for medical men.

But the work for which Dr. Olivier deserves the lasting gratitude of the scientific world was the foundation of the *Revue générale des Sciences pures et appliquées* in 1890. When making arrangements for the establishment of that journal, Dr. Olivier was kind enough to state that he desired it to have much the same scope and character as NATURE. Possessed of vast knowledge of men and matters in all departments of science, he was able to exercise sound judgment upon the numerous contributions submitted to him, and was successful in securing authoritative collaborators, not only in France, but also in other countries, to deal with subjects of wide interest and prime importance. During numerous visits to England, he obtained the active support of many men of science here, and they mourn his loss as that of a friend as well as of an editor.

At the outset, the *Revue générale des Sciences* was recognised as a substantial addition to the periodical literature of science. The outlook was wide, the contributors men of distinguished eminence and sound knowledge, and the subjects important; and the journal has maintained this character throughout its existence. As an example of the breadth of view, we may mention that arrangements were made by Dr. Olivier for special reports to be supplied to his journal of the meetings of the Royal Society of London and of other leading scientific societies in Europe. So far as we are aware, no other journal abroad gives such attention to the progress of science in Great Britain as is still devoted to it by the *Revue générale des Sciences.*

In 1897 Dr. Olivier established a series of cruises which have enabled many of his countrymen to visit various places, with guides well acquainted with the aspects of scientific interest presented by them. Among the countries to which he thus introduced many travellers are Spitsbergen, the Canary Islands, Scotland, Egypt, and the Caucasus.

Though Dr. Olivier was not a member of the Paris Academy of Sciences, Prof. Bouchard, who presided at the meeting of the academy on August 16, expressed sorrow at his death, and this testimony to the esteem in which he was held was put on record in the *Comptes rendus.* This exceptional mark of honour shows the high regard in which Dr. Olivier was held in France, and we are sure that in our own country there is real regret that one whose life has been of such great service should have passed into silence while actively engaged in his work for the extension of scientific knowledge.

NOTES.

IN accordance with previous announcements, arrangements have been made to hold the autumn meeting of the Iron and Steel Institute at Buxton, on Monday to Friday, September 26–30. The following are among the subjects of papers to be brought before the meeting:—Electric steel refining, D. F. Campbell; manganese in cast iron and the volume changes during cooling, H. I. Coe; sulphurous acid as a metallographic etching medium, E. Colver-Glauert and S. Hilpert; the theory of hardening carbon steels, C. A. Edwards; the influence of silicon on pure cast iron, A. Hague and T. Turner; the preparation of magnetic oxides of iron from aqueous solutions, S. Hilpert; the utilisation of electric power in the iron and steel industry, J. Elink Schuurman; some experiments on fatigue of metals, J. H. Smith.

AT the autumn meeting of the Institute of Metals, which is to take place in Glasgow on September 21–23, the following papers will probably be read:—The heat treatment of brass: experiments on 70:30 alloy, Messrs. G. D. Bengough and O. F. Hudson; some common defects occurring in alloys, Dr. C. H. Desch; shrinkage of the antimony-lead alloys, and of the aluminium-zinc alloys, during and after solidification, Mr. D. Ewen; the effect of silver, bismuth, and aluminium upon the mechanical properties of "tough-pitch" copper containing arsenic, Mr. F. Johnson; metallography as an aid to the brass founder, Mr. H. S. Primrose; magnetic alloys formed from non-magnetic materials, Mr. A. D. Ross.

A HITHERTO unknown region in New Guinea, near the central mountain range in Netherlands territory and west of the Fly River, has been visited by a Dutch explorer, Dr. H. A. Lorentz, who has published an account of the inhabitants. These, unlike the people found further west by the English expedition under Captain Rawling, are not pigmies, and most of Dr. Lorentz's description shows that they are not very far removed from the typical dwellers in the Fly River region. They wore no clothes, and lived in small huts about ten feet from the ground, as do some of the people of the Fly delta. As usual among the western Papuans, they used the bow and arrow, and had stone axes, the common weapon of all Papuans, until the advent of the white man. Mutilation was practised. The women cut off the middle finger of the left hand, the men removed the upper portion of one ear. This tribe was found to smoke and grow tobacco, which is not used on the coast of

Netherlands New Guinea, though used in the valley of the Fly River, and in the central district of British New Guinea, whence it has spread along the coast. The discovery of its use and culture among these mountaineers suggests that the custom was introduced into New Guinea from the north. Dr. Lorentz suggests intercourse with the northern coast, as the mountaineers wore large sea-shells as breast ornaments. No accurate information was obtainable, as intercourse was carried on only by signs.

MR. J. HEWITT, assistant for lower vertebrates in the Transvaal Museum, and formerly curator of the Sarawak Museum, has been appointed director of the Albany Museum, Grahamstown, South Africa, in succession to Dr. S. Schonland, who has resigned owing to pressure of other work. The herbarium is still under the care of Dr. Schonland.

A REUTER telegram from Spezia announces the death, on August 28, of Prof. Paolo Mantegazza. From a short notice in the *Times*, we learn that Prof. Mantegazza was born at Monza on October 31, 1831. After having studied at Milan and at Pisa he devoted himself to the study of medicine, and took his degree as doctor of medicine at Pavia. He early acquired a reputation, which increased steadily until he came to be regarded as one of the most learned physicians and the first hygienist of Italy. His method of exposition was easy, brilliant, and attractive, and did much to popularise the teaching of medical science. His devotion to his profession, however, did not prevent him from taking an active part in public affairs. A member of the Consiglio Superiore di Sanità, Mantegazza was also professor of general and experimental pathology in the University of Pavia, whence he proceeded to teach anthropology in the Istituto di Studii Superiori in Florence, in which city he founded the first anthropological and ethnographical museum ever established in Italy. In November, 1876, he was included by Royal decree amongst the Senators of the Kingdom.

DURING the past month sixteen advanced students and researchers have been at work at the Port Erin Biological Station. The Oceanography course conducted by Prof. Herdman, with Dr. Dakin and Dr. Roaf, during the first half of August was attended by eight, and consisted partly of lectures and laboratory work in the Biological Station and partly of work at sea. One day was spent in fish-trawling on board the Lancashire Sea-fisheries steamer, and other occasions in plankton work and dredging from the s.y. *Ladybird*. The contemplated addition of a new research wing at the back of the present building has now been decided on, and the work will be commenced in a few days. This new building will provide an addition to the library and a large experimental-tank room and two smaller research rooms with large tanks for physiological and other experimental work on the ground floor, and a series of eight separate research rooms, each with two windows, on the upper floor. The whole will be completed in time for use during next Easter vacation. The addition is made necessary by the increase in the number of students and research workers at the Port Erin Biological Station. A circular letter stating that 350*l.* would be required to build the new wing was issued by Prof. Herdman in May last, and since then the sum of about 250*l.* has been raised. It is hoped that the balance will soon be found; and in the faith that the work of the laboratory justifies the extension, the building is to be commenced.

THE eleventh annual meeting of the Astronomical and Astrophysical Society was held at the Harvard College Observatory, August 17–19. The programme included about fifty papers, and the meeting was well attended, among those present being many astronomers and physicists, who have gone to the United States in order to attend this meeting and that of the International Solar Union at Pasadena.

THE subject of the celebrated skull discovered at Galley Hill, Kent, in 1888, and now in the possession of Dr. F. Corner, formed the subject of a full-dress debate before the Anthropological Society of Paris, of which a report is included in the last issue of its *Bulletins et Mémoires*. The character of this skull has been discussed by many British anthropologists. Mr. E. T. Newton attributed it to the race known as that of Néanderthal; and this view was more or less accepted by M. Paul Raymond, while it was questioned by authorities such as MM. Fraipont, Hervé, and A. de Mortillet. The result of the debate was thus inconclusive. But, on the whole, the doubts of Prof. Boyd Dawkins and the late Sir John Evans, the latter expressing surprise at the discovery of an entire cranium in the diluvium, will suggest an attitude of caution in arriving at any definite conclusion on the age and racial affinities of this remarkable specimen.

THE forty-fourth volume (Series 3, vol. v.) of the *Journal of Anatomy and Physiology* is completed by the number published in July last. The papers which it contains nearly all refer to the human subject, and are therefore of interest more particularly to medical men. We may direct special attention to an elaborate account of the development of the larynx by Mr. J. E. Frazer, which illustrates very well the important part now played by wax model reconstruction in the study of human embryology.

IN the August number of the *Zoologist* Colonel C. E. Shepherd gives the results of investigations in regard to the relative sizes of the otoliths in various species and groups of bony fishes. Among the catfishes, it is noteworthy that while in the fresh-water *Synodontis schal* all these bones are very small, in the marine *Ælurichthys gronovii* one of them is very large. This suggests a difference between deep- and shallow-water fishes in this respect, but the idea is negatived by the fact that deep- and shallow-water members of the Berychidæ have otoliths of nearly similar relative size. All flat fishes likewise agree in the large size of these bones, so that in both instances adherence to a constant family type overrides adaptation in this matter. More promise seems to be afforded by the idea that the size of the otoliths may vary in proportion to the degree of development of visual power, long rectal ocular muscles, which indicate a quickly mobile eye, being correlated in the Scombridæ in most cases with small otoliths. In the Gadidæ, on the other hand, the eye-muscles are short, indicating an eye with little mobile power, while the otoliths are large. Although his investigations show that such a correlation holds good in the case of a large number of the species examined, Colonel Shepherd remarks that it cannot yet be regarded as proved that quickness of sight among fishes is compensated for by dullness of hearing, or that acute hearing accompanies an increase in the size of the otoliths. It is added that in sharks and rays the otoliths are represented by "ear-dust," although why this should be so is at present a mystery.

CONSIDERABLE interest attaches to a paper by Dr. Einar Lönnberg published in vol. vii., No. 2, of *Arkiv för Zoologi*, in which it is shown that the hinder teeth of very young white whales (*Delphinapterus leucas*) constantly display a more or less distinctly tricuspid character, as was suggested by Mr. True would prove to be the case. In certain respects the white whale is known to be a primitive type, and this is now further emphasised by its tooth-structure. The teeth of the species are, however, in some ways distinctly specialised, so that they could not have given rise to those of typical dolphins. Consequently, the author is of opinion that the white whale should be separated from the Delphinidæ as a distinct family (Delphinapteridæ), and also that each of these families should be regarded as divergent branches from a common ancestral type.

WE have to acknowledge the receipt of a copy of the report of the Otago University Museum for 1909–10, which is illustrated with a view of the building showing the new wing built for the reception of the library and pictures recently presented by Dr. Hocken.

THE natural features of the Australian Grampians, a mountain range accessible from Stawell, in Victoria, forms the subject of a note by Mr. A. G. Campbell in the *Victorian Naturalist* (vol. xxvii., No. 2). The sandstone hills are the habitat of several rare plants, including the singular little *Candollea sobolifera*; here, too, the native heath, *Epacris impressa*, luxuriates in a magnificent and long-flowering season. The cliff faces are veritable rock-gardens of Epacrids and Grevilleas, while the foot-slopes are favourable to the growth of orchids. *Caleya major* and *C. minor* are two rare orchids found by the author.

THE two "Master's lectures" on the adaptation of the plant to the plant, delivered by Mr. A. D. Hall before the Fellows of the Royal Horticultural Society, are published in the journal of the society (vol. xxxvi., part i.). Perhaps the most instructive lessons are based on the reading of crop-distribution maps, from which the author deduces the primary importance of the mechanical composition of the soil. Following these articles, the journal contains, amongst the contributions, a paper by Mr. C. C. Hurst on the application of Mendel's laws of heredity to horticulture, an account by Miss E. Armitage of cultivation by the peasants in Madeira, and notes on insect pests in the West Indies by Mr. R. Newstead. Mr. Hurst quotes from recent experiments by Cambridge workers in connection with the elucidation of the complicated colours of the snapdragon and variation in sweet peas, and discusses the origin of "albino" orchids, which can be explained upon the assumption of two complementary colour factors.

BULLETIN 419 of the United States Geological Survey contains a collection of analyses of rocks and minerals made in the laboratory of the Survey during the years 1880–1908. It is compiled by Dr. F. W. Clarke, chief chemist, who has also furnished an interesting introduction. This is the third collection issued by the U.S. Geological Survey, and will be of great use to petrologists in general. The analyses are 2420 in number, half of these belonging to igneous and crystalline rocks, and in all the later ones a large number of constituents are separately estimated. The analyses not included in the last edition (Bulletin 228) are mostly those of igneous rocks from the western States, and there are also numerous analyses of minerals isolated from crystalline rocks. An innovation which we regret is the use of a smaller type, presumably with the object of saving space.

THE summary of the weather issued by the Meteorological Office for the week ending August 27 shows that the rainfall for the period was exceptionally heavy in nearly all parts of the country. Falls of an inch or more within twenty-four hours are noted as having occurred over a wide area: on August 23 in various parts of England and Wales, on August 25 in Scotland and at Waterford, and on August 26 at Stonyhurst. The largest measurements were 2·38 inches at Crieff on August 24 and 1·69 inches on August 25, 2·2 inches at Stornoway and 1·60 inches at Stonyhurst on August 26. At Crieff the total for the week was 5·89 inches, the three days, Tuesday to Thursday, giving 5·19 inches, of which 3·50 inches fell in twenty-three hours. The succeeding days were also very wet in many parts of the country, and at Bath the aggregate for the two days, August 28 and 29, amounted to 2·57 inches, which is nearly equal to the average aggregate fall for August.

THE report of the Meteorological Committee for the year ended March 31 shows that the business of the year was exceptionally important. Arrangements for new premises at South Kensington claimed much attention; these will include space for a museum and better accommodation for the library, which now contains some 21,500 books and pamphlets, and is rapidly increasing, in addition to which space is required for a very large number of valuable documents from ships and land stations. The negotiations relating to the control of the observatories at Kew and Eskdalemuir resulted in making the committee responsible for the whole of the work, except the verification of instruments, aided by the scientific advice of a committee appointed by the Royal Society (see NATURE, June 23). Important changes have been made in some of the periodical publications of the office, *e.g.* the daily weather report includes important telegrams from Funchal, Madeira, and for the new year the ordinary forecasts for twenty-four hours have been extended when conditions are regarded as favourable. Weekly editions of the monthly North Atlantic charts are now issued showing the weather conditions over that ocean up to the day prior to that of publication. The director points out that these promise to be of considerable use to the forecast branch of the office. Wireless reports from the Royal Navy are found to be of much value, and those from the Atlantic liners have improved; in the course of the year, 4388 reports were received from the latter, and 42 per cent. arrived within twenty-four hours of the time of observation. The percentage of success (complete and partial) of the forecasts issued at 8h. 30m. p.m. for the whole of the British Islands in 1909 was 93, the highest on record, but the percentage of complete success, although higher than the mean for the last ten years, was lower than in 1906; the success or otherwise depends to some extent on the character of the weather, as shown more particularly by the harvest forecasts. Investigation of the upper air was actively continued, and the results were published, as before, in the Weekly Weather Report.

AN editorial note in the August number of the *Illuminating Engineer* of New York directs attention to the movement now on foot to educate the employees of American lighting companies through the medium of the American Gas Institute and the National Commercial Gas Association, in much the same way as some of the larger electrical firms have afforded facilities to their employees. According to the editor, it is felt that the time to sneer at "book larnin'" is now past, and the "self-made" practical man, while continuing "to worship his maker," must do it "secretly in his closet." On the other hand, when the college-trained man thinks he "knows it all," he "has no further mission in this world, and should be translated to some other sphere." To the man who is interested in every detail, whether scientific or commercial, of the business, each item of knowledge is of positive value, and the more he has the better it is for himself and his employer.

ALTHOUGH the use of "invar" wire with a very small coefficient of expansion in the measurements of the base lines of geodetic surveys has rendered an accurate knowledge of the temperature of the wire of less importance than it formerly was, it is still necessary if an accuracy of one part in a million is desired to know that temperature to within 1° C. In general, the temperature of the air, determined by means of a swinging thermometer, has been taken as identical with that of the wire; but Mr. B. F. E. Keeling, in a communication to the July number of the *Cairo Scientific Journal*, shows that, under field conditions, the wire temperature is about 2° C. higher than the air temperature owing to the absorption of sunlight at the surface of the wire. His method consists in substituting for the invar wire two wires of copper and constantan of the same diameter as the invar wire soldered together, so as to constitute a thermocouple, and connected to a galvanometer. The temperature of the junction exposed under field conditions is then determined from the galvanometer deflections.

THE *Builder* for August 27 comments on the facilities provided at the Brussels Exhibition for the beginning and rapid spread of fire. The liberal employment of canvas and other textile fabrics as structural and decorative materials doubtless served to render the sections affected by the disastrous fire even more than usually vulnerable. Apart from this characteristic, there is no reason for believing the average exhibition to be much safer from fire than that which has paid so heavy a price for attempted economy. No exhibition within recent times has been better conceived from the structural point of view than the Paris Exposition of 1900, where numerous important buildings were constructed entirely in reinforced concrete so as to afford safe accommodation for artistic, historical, and other treasures beyond all price. The example thus set is one that should always be followed, regardless of cost. We must break finally with the traditional flimsy structure of wood, canvas, and plaster. Steel is quite permissible if inexpensively sheathed in fire-protective casing, and is essential in roof construction. But timber wall panels, interior partitions, floors, roof framing, and roof covering must be given up. Expanded metal, wire netting, and steel lathing can easily be stretched between the main stanchions as the basis for incombustible walls and partitions formed of cement, mortar, or fire-resisting plaster.

FOR nearly four years past, the firm of Westinghouse, Church, Kerr and Co. has had in hand an investigation of the rust-preventing properties of protective coatings for structural steel. The *Engineering Magazine* for August contains a brief account of the results in the form of a paper read by Mr. C. M. Chapman before the American Society for Testing Materials. More than 500 coatings were tested, each paint being applied to two mild steel plates of about No. 16 gauge, 2 inches wide and 6 inches long. One plate was given one coat and the other two coats. After drying, the plates were fastened to boards with galvanised iron tacks, and exposed on the roof at an angle of 45 degrees, facing south. On the day the plates were exposed, scratch marks were made with a sharp instrument across two opposite corners of each plate, leaving bright metal exposed, so that rusting started immediately along these lines. At regular intervals each plate was examined, and a record made of its condition. The one quality which was being sought was protection against rust. The tabulated results show that with one coating the red leads take first place, both for one year's and two years' exposure. With two coatings and one year's exposure the white leads take best place; with two years' exposure the red leads are best. Red-lead primers, zinc oxides, iron oxides, carbons, and graphites also come out very good in these tests.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN SEPTEMBER:—

Sept. 1. 8h. 3m. Venus in conjunction with Moon. (Venus 4° 26′ S.)
14. 6h. 5m. to 7h. 23m. Moon occults ω Sagittarii. (Mag. 4·8.)
,, 7h. 56m. to 9h. 15m. Moon occults A Sagittarii. (Mag. 4·9.)
15. Saturn. Major axis of outer ring = 45·36″, minor axis = 13·94″.
17. 12h. 36m. Minimum of Algol (β Persei).
20. 9h. 25m. Minimum of Algol (β Persei).
21. 11h. 30m. Saturn in conjunction with Moon (Saturn 1° 31′ S.)
23. 10h. 31m. Sun enters Libra. Autumn commences.
23. 13h. 43m. to 14h. 5m. Moon occults κ' Tauri. (Mag. 4·1.)
23. 14h. 13m. to 14h. 59m. Moon occults v' Tauri. (Mag. 4·2.)

THE PARIS OBSERVATORY.—M. Baillaud's report of the Paris Observatory, for 1909, opens with a fitting tribute to the memory of MM. Fraissinet and Paul Gautier, and then proceeds to give an account of each department of the work and its labours during the year. Among other things, he mentions that the "cercle méridien du Jardin" has been completely overhauled and made perfect, while the programme has been greatly modified; the instrument is now being employed to observe fundamental stars, and will eventually undertake observations for the large catalogue proposed at the last meeting of the Paris Conference.

When not in use for spectroscopic work, the large *coudé* equatorial was employed by MM. Puiseux and Le Morvan for photographing the moon and planets; 218 images of Jupiter were secured between February and May, and later in the year more than 1200 images of Mars were secured.

A reproduction of the spectrum of Arcturus, original size, shows how effective are the new arrangements for employing the large *coudé* for stellar spectroscopy; the definition is magnificent, and the length of the spectrum between λ 4100 and λ 4800 is 15·4 cm.

The small equatorial *coudé* was employed by Dr. Nordmann in his photometric determination of stellar temperatures, and, with M. Salet, he has undertaken the observation of 300 stars of various spectral types.

OBSERVATIONS OF COMET 1910*a*.—In No. 4433 of the *Astronomische Nachrichten* Dr. Karl Bohlin publishes an excellent photograph and two drawings of the great comet, 1910*a*, as observed at Stockholm on January 28. The photograph shows the main tail 18° long, cleft at its extremity. The two drawings show enlarged views in the neighbourhood of the head, and in the second the head appears to stand out from the general plane in the form of a half moon.

THE SUN'S VELOCITY THROUGH SPACE.—In No. 1, vol. xxxii., of the *Astrophysical Journal* Profs. Frost and Kapteyn discuss the value of the sun's velocity through space as derived from the radial velocity of Orion stars. The reasons for employing this class of stars are fully discussed, and the stars considered were taken from within a moderate distance of the apex, or the antapex; for the former, the position $\alpha = 269{\cdot}7°$, $\delta = +30{\cdot}8°$ (1875·0), was taken, and the fact is elucidated that the Orion stars are, as a rule, at a great distance from the sun. This fact may account for the result that the velocity now determined is some 2 km. per sec. greater than that found by Hough and Halm, who employed many stars relatively near to our system; tentatively, it is suggested that these proximate stars appear to participate to some extent in the sun's motion through space.

A remarkable feature of the results is that the solar velocity, relatively to the stars near the apex, is some 10 km. per sec. less than the velocity relative to those near the antapex, separate solutions giving −18·38 km. and −28·38 km. respectively. It is suggested that this difference may be due to the stars near each point, or near both, belonging to the two great star streams. The mean value given as the definitive result of the paper is $v = -23·3$ km. per sec.

As further results, it was found that the average radial velocity of the stars, independent of the sun's motion, is −6·3 km. per sec., and that the average parallax of the sixty-one stars employed is 0·00924″.

PARALLAX OF FOURTH-TYPE STARS.—The question of the absorption of light in interstellar space led Prof. Kapteyn to look for classes of stars of which the probable distances are very great; such stars would best indicate any existing absorption. The fact that the proper motions of fourth- and fifth-type stars are, so far as is known, insensible, suggested that such stars would have extremely small parallaxes; therefore Prof. Kapteyn calculated the probable average parallax for some 120 stars of this type from data determined by Mr. Nörlund at Copenhagen.

The result is striking, for the average parallax of these fourth-type stars is found to be extremely small, 0·0007″, and does not exceed the probable error. Taking a previous result for the selective absorption in space, the quantity (photographic—visual magnitude) must amount, for these stars, to at least half a magnitude; it may be much greater. Therefore, to be satisfactory, any interpretation of the spectra of these stars cannot neglect the effect of the possible light-absorption in space.

For comparison, Prof. Kapteyn computed the probable average parallaxes of other types and for Orion stars of magnitude 5·0; he found the value 0·0068″ ± 0·0004″, which agrees satisfactorily with the value 0·0064″ determined, by an absolutely different method, in the discussion of the sun's velocity published by him, in collaboration with Prof. Frost, in the same number of the *Astrophysical Journal* (No. 1, vol. xxxii.).

THE MAXIMUM OF MIRA IN 1909.—Two papers dealing with the maximum of Mira in 1909 are published in No. 4434 of the *Astronomische Nachrichten*. In the former Prof. Nijland discusses his observations at Utrecht, which covered the period July 20, 1909, to March 3, and finds that a maximum, of magnitude 3·1, took place on September 7, 1909. This agrees with Guthnick's ephemeris, and gives a period, since last maximum, of 336 days.

In the second paper Mr. Ichinohe discusses the observations made by him at the Tokio Observatory during approximately the same period. According to him, the maximum took place on September 3, nearly four days before the predicted epoch, and the magnitude was 3·2.

THE STUDY OF DOUBLE STARS FOR AMATEURS.—Possessors of small instruments desiring to take up a useful study will find an interesting article by Mr. G. F. Chambers in the August number of *Knowledge and Scientific News*. This is the first of a series of articles on double stars, and in it Mr. Chambers discusses the question as to what constitutes a double star, and also pays attention to the question of coloured doubles.

METCALF'S COMET, 1910*b*.—Further observations of, and a continuation of the ephemeris for, Metcalf's comet are published in No. 4435 of the *Astronomische Nachrichten*; the following is an extract from the ephemeris:—

Ephemeris 12h. M.T. Berlin.

THE ROYAL PHOTOGRAPHIC SOCIETY'S EXHIBITION.

AS the New Gallery is now used for other than exhibition purposes, the Royal Photographic Society have had to return to the Gallery of the Royal Society of Painters in Water Colour, 5A Pall Mall East, and hold their exhibition earlier than usual. It is now open, and closes on September 16. The trade and professional sections have had to be omitted for want of room, and the number of exhibits in the other sections considerably reduced. The diminution in the number of exhibits may cause disappointment to many who had prepared work for the occasion; but it is not an unmixed misfortune to the visitor, for it seems to have led to a general raising of the standard of quality. The pictorial section has a certain measure of scientific interest, as the method of production of almost all the prints is stated in the catalogue. They indicate, therefore, in an intelligible way the possibilities of the various processes, and at the same time a purchaser knows what he is buying. The proportion of bromides seems to be unduly large, and to indicate that many prefer ease of production to an unassailable permanency. There are two notable oil prints in colour, a still-life subject by MM. Séeberger Frères, and "Carmencita" by Messrs. Tilney and Corke; but such work is on the very borderland of photography.

In the colour-transparency section, the large majority of the exhibits are autochromes. Some of these are of a very high standard of excellence. Mr. J. C. Warburg's "Court of Honour, Ivory and Azure," and "Grey Hound Inn, Corfe," and Mr. Ellis Kelsey's "Beachy Head, Reflections," show how truly it is possible to reproduce the effects of neutral and sober colours. The few transparencies by the Dioptichrome Dufay Process are chiefly of the garish colour type, and do not serve to indicate the characteristics or possibilities of these plates. The application of colour photography to natural history and scientific purposes is illustrated by several transparencies, and several photomicrographs of polarised light effects show how well such slides can represent the actual appearances. A set of nine slides of mineral sections in polarised light by Mr. E. J. Garwood, made by the Sanger Shepherd colour process, by the side of the autochromes of similar subjects, demonstrates the superior brilliancy of the Sanger Shepherd plates, and that this process, although more trouble to work than the other, still holds its own.

In the natural history section, those exhibitors whose work we expect to see year by year continue to contribute. Mr. Douglas English shows the black ratton, the probable type of the old English *black* rat, and the "plague" rat of the East. Mr. William Farren shows five photographs of the "whiskered tern" (taken in Spain), three showing various phases of wing elevation in the act of alighting. When Miss Turner and Mr. E. J. Bedford exhibit rows of birds, each in the same row in a similar attitude and sometimes a strange attitude, we should like to know whether the birds were alive or dead when photographed. And this question might perhaps be asked with regard to some other exhibits. Among the entomological subjects, special note may perhaps be made of Mr. Hugh Main's series of thirteen photographs of the metamorphoses of the glow-worm in natural size, and Mr. P. J. Barrand's "queen wasp" in the attitude assumed during hybernation (×6).

The photomicrographs include many notable works. Dr. G. H. Rodman's series of fourteen photographs illustrating the life-history and structure of the stick insects, all low magnifications (×3 to ×14) except the complete insects, which are half size, and Mr. J. T. Holder's low magnifications of the twelve excellent sections, prepared, we believe, by himself, showing the eyes and adjacent parts of various living creatures, deserve especial mention. Dr. Max Poser's diatoms are, of course, good, but the interest of them would be much increased if the optical conditions under which they were photographed were stated. The only apparent advantage of the enormous magnification of nine thousand diameters of the *Pleurosigma angulatum* seems to be that all that is to be seen can be seen from the other side of the room. His bacilli with flagellæ (×1000) and his trypanosome (×3000) are fine examples.

A reproduction of the latter, which is almost equal to the original, is given in the catalogue.

Among several interesting radiographs, Dr. C. Thurstan Holland exhibits one of an "Adult male chest, through all the clothing, taken with a Snook Transformer. Instantaneous exposure." Dr. H. Ronen, Dr. W. J. S. Lockyer, and Stonyhurst College contribute astronomical and spectroscopical photographs. There are two or three excellent telephotographs, and a single exhibit of photomechanical work.

THE BRITISH ASSOCIATION AT SHEFFIELD.

WRITING on the eve of the meeting, there is every prospect that the Sheffield meeting of the association will be a successful one, and a certainty that, with an improvement in the weather conditions, it will be an enjoyable one. A considerable amount of private hospitality is being dispensed, but, even so, late arrivals will have some difficulty in finding accommodation. Local interest is considerable, and all classes are combining to give a welcome worthy of the city. One special feature will be the opportunity afforded to members to inspect the operations connected with armour and armament, all the firms engaged in naval shipbuilding opening their works to large parties. Members should be, however, careful to apply for tickets immediately on arrival, as some are open only on the Thursday. The technical instruction and investigations in iron and steel metallurgy carried on in the University have been of very material assistance in enabling Sheffield to maintain its leading position as the centre of high-class steel production, and the University is arranging to run its furnaces and special plants on afternoons at the close of the sectional meetings. Amongst the most interesting may be mentioned the crucible house, the Kjellin electric melting furnace, the electric hardening furnace, and the new form of the Siemens' acid open-hearth furnace. Interest will also be taken in the exhibition of Dr. Sorby's original micro-sections.

The Sheffield Musical Union is giving a concert to the association on the Saturday evening, under the conductorship of Dr. Coward. This is an innovation which will enable members to hear the famed Sheffield Choir, the programme including, besides part-songs, choral selections from the "Messiah" and the "Golden Legend."

In consonance with the growing fancy in England for ceremonial, the local committee have arranged for a procession on Sunday of representatives of the association, the Town Council, and the University from the Town Hall to the Parish Church, where the Archbishop of York is to preach the official sermon.

On Tuesday the University will hold a congregation to confer honorary degrees on leading representatives of the association. The recipients are to be:—The President (Dr. Bonney), the Lord Mayor (Earl Fitzwilliam, chairman of the local committee), Mr. W. H. Bateson, Sir W. Crookes, Mr. Francis Darwin, Sir A. Geikie, Prof. Hobson, Sir J. Jonas, Sir Norman Lockyer, Sir O. Lodge, Principal Miers, Sir W. Ramsay, Prof. Rhys Davies, Prof. Sherrington, Mr. J. E. Stead, Sir J. J. Thomson, and Sir W. White. Later the same evening the Chancellor of the University (the Duke of Norfolk, E.M., K.G.) will hold a reception. In connection with this an attempt is being made to arrange a scientific exhibition, more especially in relation to papers read before the various sections. It is hoped thereby to encourage this method of illustrating papers and at the same time to render them available to a wider circle of members. Simultaneously with the reception at the University, the Lord Mayor is receiving local guests at the Art Gallery; and the Weston Park, between it and the University, is to be the scene of an evening garden-party, with a military tattoo and torchlight procession.

Inaugural Address by the Rev. Prof. T. G. Bonney, Sc.D., LL.D., F.R.S., President of the Association.

Thirty-one years have passed since the British Association met in Sheffield, and the interval has been marked by exceptional progress. A town has become a city, the head of its municipality a Lord Mayor; its area has been enlarged by more than one-fifth; its population has increased from about 280,000 to 479,000. Communication has been facilitated by the construction of nearly thirty-eight miles of electric tramways for home service and of new railways, including alternative routes to Manchester and London. The supplies of electricity, gas, and water have more than kept pace with the wants of the city. The first was just being attempted in 1879; the second has now twenty-three times as many consumers as in those days; the story[1] of the third has been told by one who knows it well, so that it is enough for me to say your water supply cannot be surpassed for quantity and quality by any in the kingdom. Nor has Sheffield fallen behind other cities in its public buildings. In 1897 your handsome Town Hall was opened by the late Queen Victoria; the new Post Office, appropriately built and adorned with material from almost local sources, was inaugurated less than two months ago. The Mappin Art Gallery commemorates the munificence of those whose name it bears, and fosters that love of the beautiful which Ruskin sought to awaken by his generous gifts. Last, but not least, Sheffield has shown that it could not rest satisfied until its citizens could ascend from their own doors to the highest rung of the educational ladder. Firth College, named after its generous founder, was born in the year of our last visit; in 1897 it received a charter as the University College of Sheffield, and in the spring of 1905 was created a University, shortly after which its fine new buildings were opened by the late King; and last year its library, the generous gift of Dr. Edgar Allen, was inaugurated by his successor, when Prince of Wales. I must not now dwell on the great work which awaits this and other new universities. It is for them to prove that, so far from abstract thought being antagonistic to practical work, or scientific research to the labour of the factory or foundry, the one and the other can harmoniously cooperate in the advance of knowledge and the progress of civilisation.

You often permit your President on these occasions to speak of a subject in which he takes a special interest, and I prefer thus trespassing on your kindness to attempting a general review of recent progress in science. I do not, however, propose, as you might naturally expect, to discuss some branch of petrology; though for this no place could be more appropriate than Sheffield, since it was the birthplace and the lifelong home of Henry Clifton Sorby, who may truly be called the father of that science. This title he won when, a little more than sixty years ago, he began to study the structure and mineral composition of rocks by examining thin sections of them under the microscope.[2] A rare combination of a singularly versatile and active intellect with accurate thought and sound judgment, shrewd in nature, as became a Yorkshireman, yet gentle, kindly, and unselfish, he was one whom his friends loved and of whom this city may well be proud. Sorby's name will be kept alive among you by the Professorship of Geology which he has endowed in your University; but, as the funds will not be available for some time, and as that science is so intimately connected with metallurgy, coal-mining, and engineering, I venture to express a hope that some of your wealthier citizens will provide for the temporary deficiency, and thus worthily commemorate one so distinguished.

But to return. I have not selected petrology as my subject, partly because I think that the great attention which its more minute details have of late received has tended to limit rather than to broaden our views, while

1 "History and Description of Sheffield Water Works." W. Terrey, 1908.

2 His subsequent investigations into the microscopic structure of steel and other alloys of iron, in the manufacture of which your city holds a foremost place, have been extended by Mr. J. E. Stead and others, and they, besides being of great value to industrial progress, have thrown important sidelights on more than one dark place in petrology.

for a survey of our present position it is enough to refer to the suggestive and comprehensive volume published last year by Mr. A. Harker;[1] partly, also, because the discussion of any branch of petrology would involve so many technicalities that I fear it would be found tedious by a large majority of my audience. So I have preferred to discuss some questions relating to the effects of ice which had engaged my attention a dozen years before I attempted the study of rock slices. As much of my petrological work has been connected with mountain districts, it has been possible for me to carry on the latter without neglecting the former, and my study of ice-work gradually led me from the highlands into the lowlands.[2] I purpose, then, to ask your attention this evening to some aspects of the glacial history of Western Europe.

At no very distant geological epoch the climate in the northern part of the earth was much colder than it is at present. So it was also in the southern; but whether the two were contemporaneous is less certain. Still more doubtful are the extent and the work of the ice which was a consequence, and the origin of certain deposits on some northern lowlands, including those of our own islands, namely, whether they are the direct leavings of glaciers or were laid down beneath the sea by floating shore-ice and bergs. Much light will be thrown on this complex problem by endeavouring to ascertain what snow and ice have done in some region which, during the Glacial Epoch, was never submerged, and none better can be found for this purpose than the European Alps.

At the present day one school of geologists, which of late years has rapidly increased in number, claims for glaciers a very large share in the sculpture of that chain, asserting that they have not only scooped out the marginal lakes, as Sir A. Ramsay maintained full half a century ago, but have also quarried lofty cliffs, excavated great cirques, and deepened parts of the larger Alpine valleys by something like two thousand feet. The other school, while admitting that a glacier, in special circumstances, may hollow out a tarn or small lake and modify the features of rock scenery, declares that its action is abrasive rather than erosive, and that the sculpture of ridges, crags, and valleys was mainly accomplished in pre-Glacial times by running water and the ordinary atmospheric agencies.

In all controversies, as time goes on, hypotheses are apt to masquerade as facts, so that I shall endeavour this evening to disentangle the two, and direct attention to those which may be safely used in drawing a conclusion.

In certain mountain regions, especially those where strong limestones, granites, and other massive rocks are dominant, the valleys are often trench-like, with precipitous sides, having cirques or corries at their heads, and with rather wide and gently sloping floors, which occasionally descend in steps, the distance between these increasing with that from the watershed. Glaciers have unquestionably occupied many of these valleys, but of late years they have been supposed to have taken a large share in excavating them. In order to appreciate their action, we must imagine the glens to be filled up and the district restored to its former condition of a more or less undulating upland. As the mean temperature[3] declined, snow would begin to accumulate in inequalities on the upper slopes. This, by melting and freezing, would soften and corrode the underlying material, which would then be removed by rain and wind, gravitation and avalanche. In course of time the hollow thus formed would assume more and more the outlines of a corrie or a cirque by eating into the hillside. With an increasing diameter it would be occupied, as the temperature fell, first by a permanent snowfield, then by the *névé* of a glacier. Another process now becomes important, that called "sapping." While ordinary glacier-scour tends, as we are told, to produce "sweeping curves and eventually a graded slope," "sapping" produces "benches and cliffs, its action being horizontal and backwards," and often dominant over scour. The author of this hypothesis[4] convinced himself of its truth in the Sierra Nevada by descending a *bergschrund* 150 feet in

[1] "The Natural History of Igneous Rocks," 1909.

[2] May I add that hereafter a statement of facts without mention of an authority means that I am speaking from personal knowledge.

[3] In the remainder of this address "temperature" is to be understood as mean temperature. The Fahrenheit scale is used.

[4] W. D. Johnson, *Science*, N.S., ix. (1899), pp. 106, 112.

depth, which opened out, as is so common, beneath the walls of a cirque. Beginning in the *névé*, it ultimately reached the cliff, so that for the last 30 feet the bold investigator found rock on the one hand and ice on the other. The former was traversed by fracture planes, and was in all stages of displacement and dislodgment; some blocks having fallen to the bottom, others bridging the narrow chasm, and others frozen into the *névé*. Clear ice had formed in the fissures of the cliff; it hung down in great stalactites; it had accumulated in stalagmitic masses on the floor. Beneath the *névé* the temperature would be uniform, so its action would be protective, except where it set up another kind of erosion, presently to be noticed; but in the chasm, we are informed, there would be, at any rate for a considerable part of the year, a daily alternation of freezing and thawing. Thus the cliff would be rapidly undermined and be carried back into the mountain slope, so that before long the glacier would nestle in a shelter of its own making. Farther down the valley the moving ice would become more effective than subglacial streams in deepening its bed; but since the *névé*-flow is almost imperceptible near the head, another agency must be invoked, that of "plucking." The ice grips, like a forceps, any loose or projecting fragment in its rocky bed, wrenches that from its place, and carries it away. The extraction of one tooth weakens the hold of its neighbours, and thus the glen is deepened by "plucking," while it is carried back by "sapping." Streams from melting snows on the slopes above the amphitheatre might have been expected to cooperate vigorously in making it, but of them little account seems to be taken, and we are even told that in some cases the winds probably prevented snow from resting on the rounded surface between two cirque-heads.[1] As these receded, only a narrow neck would be left between them, which would be ultimately cut down into a gap or "col." Thus a region of deep valleys with precipitous sides and heads, of sharp ridges, and of more or less isolated peaks, is substituted for a rather monotonous, if lofty, highland.

The hypothesis is ingenious, but some students of Alpine scenery think more proof desirable before they can accept it as an axiom. For instance, continuous observations are necessary to justify the assumption of diurnal variations of temperature sufficient to produce any sensible effect on rock at the bottom of a narrow chasm nearly fifty yards deep and almost enclosed by ice. Here the conditions would more probably resemble those in a *glacière*, or natural ice cave. In one of these, during the summer, curtains and festoons of ice depend from the walls; from them and from the roof water drips slowly, to be frozen into stalagmitic mounds on the floor, which is itself sometimes a thick bed of ice. On this the quantity of fallen rock débris is not greater than is usual in a cave, nor are the walls notably shattered, even though a gap some four yards deep may separate them from the ice. The floors of cirques, from which the *névé* has vanished, cannot as a rule be examined, because they are masked by débris which is brought down by the numerous cascades, little and big, which seam their walls; but glimpses of them may sometimes be obtained in the smaller corries (which would be cirques if they could), and these show no signs of either "sapping" or "plucking," but some little of abrasion by moving ice. Cirques and corries also not infrequently occur on the sides as well as at the heads of valleys, such, for instance, as the two in the *massif* of the Uri Rothstock on the way to the Surenen Pass and the Fer à Cheval above Sixt. The Lago di Ritom lies between the mouth of a hanging valley and a well-defined step, and just above that is the Lago di Cadagno in a large, steep-walled corrie, which opens laterally into the Val Piora, as that of the Lago di Tremorgio does into the southern side of the Val Bedretto. Cirques may also be found where glaciers have had a comparatively brief existence, as the Creux des Vents on the Jura; or have never been formed, as on the slopes of Salina, one of the Lipari Islands, or in the limestone desert of Lower Egypt.[2] I have seen a miniature stepped valley carved by a rainstorm on a slope of Hampstead Heath; a cirque, about a yard in height and breadth, similarly excavated in the

[1] This does not appear to have occurred in the Alps.

[2] A. J. Jukes-Browne, *Geol. Mag.*, 1877, p. 477.

vertical wall of a gravel pit; and a corrie, measured by feet instead of furlongs, at the foot of one of the Binns near Burntisland, or, on a much reduced scale, in a bank of earth. On all these the same agent, plunging water, has left its marks—runlets of rain for the smaller, streams for the larger; convergent at first, perhaps, by accident, afterwards inevitably combined as the hollow widened and deepened. Each of the great cirques is still a "land of streams," and they are kept permanent for the greater part of the year by beds of snow on the ledges above its walls.

The "sapping and plucking" process presents another difficulty—the steps already mentioned in the floors of valleys. These are supposed to indicate stages at which the excavating glacier transferred its operations to a higher level. But, if so, the outermost one must be the oldest, or the glacier must have been first formed in the lowest part of the incipient valley. Yet, with a falling temperature, the reverse would happen, for otherwise the snow must act as a protective mantle to the mature pre-glacial surface almost down to its base. However much age might have smoothed away youthful angularities, it would be strange if no receptacles had been left higher up to initiate the process; and even if sapping had only modified the form of an older valley, it could not have cut the steps unless it had begun its work on the lowest one. Thus, in the case of the Creux de Champ, if we hesitate to assume that the sapping process began at the mouth of the valley of the Grande Eau above Aigle, we must suppose it to have started somewhere near Ormont Dessus and to have excavated that gigantic hollow, the floor of which lies full 6000 feet below the culminating crags of the Diablerets.

But even if "sapping and plucking" were assigned a comparatively unimportant position in the cutting out of cirques and corries, it might still be maintained that the glaciers of the Ice Age had greatly deepened the valleys of mountain regions. That view is adopted by Profs. Penck and Brückner in their work on the glaciation of the Alps,[1] the value of which even those who cannot accept some of their conclusions will thankfully admit. On one point all parties agree—that a valley cut by a fairly rapid stream in a durable rock is **V**-like in section. With an increase of speed the walls become more vertical; with a diminution the valley widens and has a flatter bed, over which the river, as the base-line is approached, may at last meander. Lateral streams will plough into the slopes, and may be numerous enough to convert them into alternating ridges and furrows. If a valley has been excavated in thick horizontal beds of rock varying in hardness, such as limestones and shales, its sides exhibit a succession of terrace walls and shelving banks, while a marked dip and other dominant structures produce their own modifications. It is also agreed that a valley excavated or greatly enlarged by a glacier should be **U**-like in section. But an Alpine valley, especially as we approach its head, very commonly takes the following form. For some hundreds of feet up from the torrent it is a distinct **V**; above this the slopes becomes less rapid, changing, say, from 45° to not more than 30°, and that rather suddenly. Still higher comes a region of stone-strewn upland valleys and rugged crags, terminating in ridges and peaks of splintered rock, projecting from a mantle of ice and snow. The **V**-like part is often from 800 to 1000 feet in depth, and the above-named authors maintain that this, with perhaps as much of the more open trough above, was excavated during the Glacial Epoch. Thus the floor of any one of these valleys prior to the Ice Age must often have been at least 1800 feet above its present level.[2] As a rough estimate, we may fix the deepening of one of the larger Pennine valleys, tributary to the Rhone, to have been, during the Ice Age, at least 1600 feet in their lower parts. Most of them are now hanging valleys, the stream issuing, on the level of the main river, from a deep gorge. Their tributaries are rather variable in form, the larger, as a rule, being more or less **V**-shaped; the shorter, and especially the smaller, corresponding more with the upper part of the larger valleys, but their lips generally are less deeply notched. Whatever may have been the cause, this rapid change in slope must indicate a corresponding change of action in the erosive agent. Here and there the apex of the **V** may be slightly flattened, but any approach to a real **U** is extremely rare. The retention of the more open form in many small, elevated recesses, from which at the present day but little water descends, suggests that where one of them soon became buried under snow,[1] but was insignificant as a feeder of a glacier, erosion has been for ages almost at a standstill.

The **V**-like lower portion in the section of one of the principal valleys, which is all that some other observers have claimed for the work of a glacier, cannot be ascribed to subsequent modification by water, because ice-worn rock can be seen in many places, not only high up its sides, but also down to within a yard or two of the present torrent.

Thus valley after valley in the Alps seems to leave no escape from the following dilemma: Either a valley cut by a glacier does not differ in form from one made by running water, or one which has been excavated by the latter, if subsequently occupied, is but superficially modified by ice. This, as we can repeatedly see in the higher Alpine valleys, has not succeeded in obliterating the physical features due to the ordinary processes of erosion. Even where its effects are most striking, as in the Spitallamm below the Grimsel Hospice, it has not wholly effaced those features; and wherever a glacier in a recent retreat has exposed a rock surface, that demonstrates its inefficiency as a plough. The evidence of such cases has been pronounced inadmissible, on the ground that the glaciers of the Alps have now degenerated into senile impotence; but in valley beds over which they passed when in the full tide of their strength, the flanks show remnants of rocky ridges only partly smoothed away, and rough rock exists on the "lee-sides" of ice-worn mounds which no imaginary plucking can explain. The ice seems to have flowed over rather than to have plunged into the obstacles in its path, and even the huge steps of limestone exposed by the last retreat of the Unter Grindelwald Glacier have suffered little more than a rounding off of their angles, though that glacier must have passed over them when in fullest development, for it seems impossible to explain these by any process of sapping.

The comparatively level trough, which so often forms the uppermost part of one of the great passes across the watershed of the Alps, can hardly be explained without admitting that in each case the original watershed has been destroyed by the more rapid recession of the head of the southern valley, and this work bears every sign of having been accomplished in pre-Glacial times. Sapping and plucking must have operated on a gigantic scale to separate the Viso from the Cottian watershed, to isolate the huge pyramid of the Matterhorn, with its western spur, or to make, by the recession of the Val Macugnaga, that great gap between the Strahlhorn and Monte Rosa. Some sceptics even go so far as to doubt whether the dominant forms of a non-glaciated region differ very materially from those of one which has been half buried in snowfields and glaciers. To my eyes, the general outlines of the mountains about the Lake of Gennesaret and the northern part of the Dead Sea recalled those around the Lake of Annecy and on the south-eastern shore of Leman. The sandstone crags, which rise here and there like ruined castles from the lower plateau of the Saxon Switzerland, resembled in outlines, though on a smaller scale, some of the Dolomites in the Southern Tyrol. The Lofoten Islands illustrate a half-drowned mountain range from which the glaciers have disappeared. Those were born among splintered peaks and ridges, which, though less lofty, rival in form the Aiguilles of Chamonix, and the valleys become more and more ice-worn as they descend, until the coast is fringed with skerries every one of which is a *roche moutonnée*. The *névé* in each of these valleys has been comparatively ineffective; the ice has gathered strength with the growth of the glacier. As can be seen from photographs, the scenery of the heart of the

[1] "Die Alpen in Eiszeitalter," 1900.

[2] The amount varies in different valleys; for instance, it was fully 2880 feet at Amsteg on the Reuss, just over 2000 feet at Brieg in the Rhone Valley, about 1000 feet at Guttanen in the Aare Valley, about 1550 feet above Zermatt, and 1100 feet above Saas Grund.

[1] My own studies of mountain districts have led me to infer that on slopes of low grade the action of snow is preservative rather than destructive. That conclusion was confirmed by Prof. Garwood in a communication to the Royal Geographical Society on June 20 of the present year.

Caucasus or of the Himalayas differs in scale rather than in kind from that of the Alps. Thus the amount of abrasion varies, other things being equal, with the latitude. The grinding away of ridges and spurs, the smoothing of the walls of troughs,[1] is greater in Norway than in the Alps; it is still greater in Greenland than in Norway, and it is greatest of all in the Antarctic, according to the reports of the expeditions led by Scott and Shackleton. But even in Polar regions, under the most favourable conditions, the dominant outlines of the mountains, as shown in the numerous photographs taken by both parties, and in Dr. Wilson's admirable drawings, differ in degree rather than in kind from those of mid-European ranges. It has been asserted that the parallel sides of the larger Alpine valleys—such as the Rhone above Martigny, the Lütschine near Lauterbrunnen, and the Val Bedretto below Airolo—prove that they have been made by the ice-plough rather than by running water; but in the first I am unable to discern more than the normal effects of a rather rapid river which has followed a trough of comparatively soft rocks; in the second, only the cliffs marking the channel cut by a similar stream through massive limestones—cliffs like those which elsewhere rise up the mountain flanks far above the levels reached by glaciers; while in the third I have failed to discover, after repeated examination, anything abnormal.

Many lake basins have been ascribed to the erosive action of glaciers. Since the late Sir A. Ramsay advanced this hypothesis, numbers of lakes in various countries have been carefully investigated and the results published, the most recent of which is the splendid work on the Scottish lochs by Sir J. Murray and Mr. L. Pullar.[2] A contribution to science of the highest value, it has also a deeply pathetic interest, for it is a father's memorial to a much-loved son, F. P. Pullar, who, after taking a most active part in beginning the investigation, lost his life while saving others from drowning. As the time at my command is limited, and many are acquainted with the literature of the subject, I may be excused from saying more than that even these latest researches have not driven me from the position which I have maintained from the first, namely, that while many tarns in corries and lakelets in other favourable situations are probably due to excavation by ice, as in the mountainous districts of Britain, in Scandinavia, or in the higher parts of the Alps, the difficulty of invoking this agency increases with the size of the basin—as, for example, in the case of Loch Maree or the Lake of Annecy—until it becomes insuperable. Even if Glas Llyn and Llyn Llydaw were the work of a glacier, the rock basins of Gennesaret and the Dead Sea, still more those of the great lakes in North America and in Central Africa, must be assigned to other causes.

I pass on, therefore, to mention another difficulty in this hypothesis—that the Alpine valleys were greatly deepened during the Glacial Epoch—which has not yet, I think, received sufficient attention. From three to four hundred thousand years have elapsed, according to Penck and Brückner, since the first great advance of the Alpine ice. One of the latest estimates of the thickness of the several geological formations assigns 4000 feet[3] to the Pleistocene and Recent, 13,000 to the Pliocene, and 14,000 to the Miocene. If we assume the times of deposit to be proportional to the thickness, and adopt the larger figure for the first-named period, the duration of the Pliocene would be 1,300,000 years, and of the Miocene 1,400,000 years. To estimate the total vertical thickness of rock which has been removed from the Alps by denudation is far from easy, but I think 14,000 feet would be a liberal allowance, of which about one-seventh is assigned to the Ice Age. But during that age, according to a curve given by Penck and Brückner, the temperature was below its present amount for rather less than half (0·47) the time. Hence it follows that, since the sculpture of the Alps must have begun at least as far back as the Miocene period, one-seventh of the work has been done by ice in not quite one-fifteenth of the time, or its action must be very potent. Such data as are at our command make it probable that

[1] If one may judge from photographs, the smoothing of the flanks of a valley is unusually conspicuous in Milton Sound, New Zealand.

[2] "Bathymetrical Survey of the Scottish Freshwater Lochs." Sir J. Murray and Mr. L. Pullar, 1910.

[3] I have doubts whether this is not too great.

a Norway glacier at the present day lowers its basin by only about 80 millimetres in 1000 years; a Greenland glacier may remove some 421 millimetres in the same time, while the Vatnajökul in Iceland attains to 647 millimetres. If Alpine glaciers had been as effective as the last-named, they would not have removed, during their 188,000 years of occupation of the Alpine valleys, more than 121·6 metres, or just over 397 feet; and as this is not half the amount demanded by the more moderate advocates of erosion, we must either ascribe an abnormal activity to the vanished Alpine glaciers, or admit that water was much more effective as an excavator.

We must not forget that glaciers cannot have been important agents in the sculpture of the Alps during more than part of Pleistocene times. That sculpture probably began in the Oligocene period; for rather early in the next one the great masses of conglomerate, called *Nagelfluh*, show that powerful rivers had already carved for themselves valleys corresponding generally with, and nearly as deep as, those still in existence. Temperature during much of the Miocene period was not less than 12° F. above its present average. This would place the snow-line at about 12,000 feet.[1] In that case, if we assume the altitudes unchanged, not a snowfield would be left between the Simplon and the Maloja, the glaciers of the Pennines would shrivel into insignificance, Monte Rosa would exchange its drapery of ice for little more than a tippet of frozen snow. As the temperature fell, the white robes would steal down the mountain-sides, the glaciers grow, the torrents be swollen during all the warmer months, and the work of sculpture increase in activity. Yet with a temperature even 6° higher than it now is, as it might well be at the beginning of the Pliocene period, the snow-line would be at 10,000 feet; numbers of glaciers would have disappeared, and those around the Jungfrau and the Finster Aarhorn would be hardly more important than they now are in the Western Oberland.

But denudation would begin so soon as the ground rose above the sea. Water, which cannot run off the sand exposed by the retreating tide without carving a miniature system of valleys, would never leave the nascent range intact. The Miocene Alps, even before a patch of snow could remain through the summer months, would be carved into glens and valleys Towards the end of that period the Alps were affected by a new set of movements, which produced their most marked effects in the northern zone from the Inn to the Durance. The Oberland rose to greater importance; Mont Blanc attained its primacy; the *massif* of Dauphiné was probably developed. That, and still more the falling temperature, would increase the snowfields, glaciers, and torrents. The first would be, in the main, protective; the second, locally abrasive; the third, for the greater part of their course, erosive. No sooner had the drainage system been developed on both sides of the Alps than the valleys on the Italian side (unless we assume a very different distribution of rainfall) would work backwards more rapidly than those on the northern. Cases of trespass, such as that recorded by the long level trough on the north side of the Maloja Kulm and the precipitous descent on the southern, would become frequent. In the interglacial episodes—three in number, according to Penck and Brückner, and occupying rather more than half the epoch—the snow and ice would dwindle to something like its present amount, so that the water would resume its work. Thus I think it far more probable that the **V**-like portions of the Alpine valleys were in the main excavated during Pliocene ages, their upper and more open parts being largely the results of Miocene and yet earlier sculpture.

During the great advances of the ice, four in number, according to Penck and Brückner,[2] when the Rhone glacier covered the lowlands of Vaud and Geneva, welling on one occasion over the gaps in the Jura, and leaving its erratics in the neighbourhood of Lyons, it ought to have given

[1] I take the fall of temperature for a rise in altitude as 1° F. for 300 feet or, when the differences in the latter are large, 3° per 1000 feet. These estimates will, I think, be sufficiently accurate. The figures given by Hann (see for a discussion of the question, Report of Brit. Assoc., 1909, p. 93) work out to 1° F. for each 318 feet of ascent (up to about 10,000 feet).

[2] On the exact number I have not had the opportunity of forming an opinion.

signs of its erosive no less than of its transporting power. But what are the facts? In these lowlands we can see where the ice has passed over the Molasse (a Miocene sandstone); but here, instead of having crushed, torn, and uprooted the comparatively soft rock, it has produced hardly any effect. The huge glacier from the Linth Valley crept for not a few miles over a floor of stratified gravels, on which, some eight miles below Zurich, one of its moraines, formed during the last retreat, can be seen resting, without having produced more than a slight superficial disturbance. We are asked to credit glaciers with the erosion of deep valleys and the excavation of great lakes, and yet, wherever we pass from hypotheses to facts, we find them to have been singularly inefficient workmen!

I have dwelt at considerable, some may think undue, length on the Alps, because we are sure that this region from before the close of the Miocene period has been above sea-level. It accordingly demonstrates what effects ice can produce when working on land.

In America also, to which I must now make only a passing reference, great ice-sheets formerly existed: one occupying the district west of the Rocky Mountains, another spreading from that on the north-west of Hudson's Bay, and a third from the Laurentian hill-country. These two became confluent, and their united ice-flow covered the region of the Great Lakes, halting near the eastern coast a little south of New York, but in Ohio, Indiana, and Illinois occasionally leaving moraines only a little north of the 39th parallel of latitude.[1] Of these relics my first-hand knowledge is very small, but the admirably illustrated reports and other writings of American geologists[2] indicate that, if we make due allowance for the differences in environment, the tills and associated deposits on their continent are similar in character to those of the Alps.[3]

In our own country and in corresponding parts of Northern Europe we must take into account the possible cooperation of the sea. In these, however, geologists agree that, for at least a portion of the Ice Age, glaciers occupied the mountain districts. Here ice-worn rocks, moraines and perched blocks, tarns in corries, and perhaps lakelets in valleys, demonstrate the former presence of a mantle of snow and ice. Glaciers radiated outwards from more than one focus in Ireland, Scotland, the English Lake District, and Wales, and trespassed, at the time of their greatest development, upon the adjacent lowlands. They are generally believed to have advanced and retreated more than once, and their movements have been correlated by Prof. J. Geikie with those already mentioned in the Alps. Into that very difficult question I must not enter; for my present purpose it is enough to say that in early Pleistocene times glaciers undoubtedly existed in the mountain districts of Britain, and even formed piedmont ice-sheets on the lowlands. On the west side of England, smoothed and striated rocks have been observed near Liverpool, which can hardly be due to the movements of shore-ice, and at Little Crosby a considerable surface has been cleared from the overlying Boulder Clay by the exertions of the late Mr. T. M. Reade and his son, Mr. A. Lyell Reade. But, so far as I am aware, rocks thus affected have not yet been discovered in the Wirral peninsula. On the eastern side of England similar markings have been found down to the coast of Durham, but a more southern extension of land ice cannot be taken for granted. In this direction, however, so far as the tidal valley of the Thames, and in corresponding parts of the central and western lowlands, certain deposits occur which, though to a great extent of glacial origin, are in many respects different from those left by land ice in the Alpine regions and in Northern America.

They present us with problems the nature of which may be inferred from a brief statement of the facts. On the Norfolk coast we find the glacial drifts resting, sometimes on the chalk, sometimes on strata of very late Pliocene or early Pleistocene age. The latter show that in their time the strand-line must have oscillated slightly on either side of its present level. The earliest of the glacial deposits, called the Cromer Till and Contorted Drift, presents its most remarkable development in the cliffs on either side of that town. Here it consists of Boulder Clays and alternating beds of sand and clay; the first-named, two or three in number, somewhat limited in extent, and rather lenticular in form, are slightly sandy clays, full of pieces of chalk, flint, and other kinds of rock, some of the last having travelled from long distances. Yet more remarkable are the huge erratics of chalk, in the neighbourhood of which the sands and clays exhibit extraordinary contortions. Like the beds of till, they have not been found very far inland, for there the group appears as a whole to be represented by a stony loam, resembling a mixture of the sandy and clayey material, and this is restricted to a zone some twenty miles wide, bordering the coast of Norfolk and Suffolk, not extending south of the latter county, but being probably represented to the north of the Humber. Above these is a group of false-bedded sands and gravels, variable in thickness and character—the Mid-glacial Sands of Searles V. Wood and F. W. Harmer. They extend over a wider area, and may be traced, according to some geologists, nearly to the western side of England, rising in that direction to a greater height above sea-level. But as it is impossible to prove that all isolated patches of these materials are identical in age, we can only be certain that some of them are older than the next deposit, a Boulder Clay, which extends over a large part of the lowlands in the Eastern Counties. This has a general resemblance to the Cromer Till, but its matrix is rather more clayey and is variable in colour. In and north of Yorkshire, as well as on the seaward side of the Lincolnshire wolds, it is generally brownish or purplish, but on their western side, and as far as the clay goes to the south, it is some shade of grey. Near to these wolds, in mid-Norfolk, and on the northern margin of Suffolk, it has a whitish tint, owing to the abundance of comminuted chalk. To the south and west of this area it is dark, from the similar presence of Kimeridge Clay. Yet further west it assumes an intermediate colour by having drawn upon the Oxford Clay. This Boulder Clay, whether the chalky or the purple, in which partings of sand sometimes occur, must once have covered, according to Mr. F. W. Harmer, an area about ten thousand square miles in extent. It spreads like a coverlet over the pre-glacial irregularities of the surface. It caps the hills, attaining sometimes an elevation of fully 500 feet above sea-level;[1] it fills up valleys,[2] sometimes partly, sometimes wholly, the original floors of which occasionally lie more than 100 feet below the same level. This Boulder Clay, often with an underlying sand or gravel, extends to the south as far as the neighbourhood of Muswell Hill and Finchley; hence its margin runs westward through Buckinghamshire, and then, bending northwards, passes to the west of Coventry. On this side of the Pennine Chain the matrix of the Boulder Clay is again reddish, being mainly derived from the sands and marls of the Trias; pieces of chalk and flint are rare (no doubt coming from Antrim), though other rocks are often plentiful enough. Some authorities are of opinion that the drift in most parts of Lancashire and Cheshire is separable, as on the eastern coasts, into a lower and an upper Boulder Clay, with intervening gravelly sands, but others think that the association of the first and third is lenticular rather than successive. Here also the lower clay cannot be traced very far inland, eastward or southward; the others have a wider extension, but they reach a greater elevation above sea-level than on the eastern side

[1] Some of the glacial drifts on the eastern side of the continent, as we shall find, may have been deposited in the sea.

[2] See the "Reports of the United States Geological Survey" (from vol iii. onwards), *Journal of Geology*, *American Journal of Science*, and local publications too numerous to mention. Among these the studies in Greenland by Prof. Chamberlin are especially valuable for the light they throw on the movement of large glaciers and the transport of débris in the lower part of the ice

[3] Here, however, we cannot always be so sure of the absence of the sea.

[1] Not far from Royston it is found at a height of 525 feet above O.D. *See* F. W. Harmer, "Pleistocene Period in the Eastern Counties," p. 115.

[2] At Old North Road Station, on a tributary of the Cam, the Boulder Clay was pierced to a depth of 180 feet, and at Impington it goes to 60 feet below sea level Near Hitchin, a hidden valley, traced for seven or eight miles, was proved to a depth of 68 feet below O.D., and one near Newport in Essex, to 140 feet. Depths were also found of 120 feet at West Horseheath in Suffolk, of 120 feet on low ground two miles S.W. of Sandy in Bedfordshire, of from 100 to 160 feet below the sea at Fossdyke, Long Sutton, and Boston, and at Glemsford in the valley of the Stour, 477 feet of drift was passed through before reaching the chalk. *See* F. W. Harmer, Quart. Journ. Geol. Soc., lxiii. (1907), p. 404.

of England. The sand is inconstant in thickness, being sometimes hardly represented, sometimes as much as 200 feet. The upper clay runs on its more eastern side up to the chalky Boulder Clay, and extends on the south at least into Worcestershire. On the western side it merges with the upper member of the drifts radiating from the mountains of North Wales, which often exhibit a similar tripartite division, while (as we learn from the officers of the Geological Survey) Boulder Clays and gravelly sands, which it must suffice to mention, extend from the highlands of South Wales for a considerable distance to the south-east and south. Boulder Clay has not been recognised in Devon or Cornwall, though occasional erratics are found which seem to demand some form of ice-transport. A limited deposit, however, of that clay, containing boulders now and then more than a yard in diameter, occurs near Selsey Bill on the Sussex coast, which most geologists consider to have been formed by floating rather than by land ice.

Marine shells are not very infrequent in the lower clays of East Anglia and Yorkshire, but are commonly broken. The well-known Bridlington Crag is the most conspicuous instance, but this is explained by many geologists as an erratic—a piece of an ancient North Sea bed caught up and transported, like the other molluscs, by an advancing ice-sheet. They also claim a derivative origin for the organic contents of the overlying sands and gravels, but some authorities consider the majority to be contemporaneous. Near the western coast of England, shells in much the same state of preservation as those on the present shore are far from rare in the lower clay, where they are associated with numerous striated stones, often closely resembling those which have travelled beneath a glacier, both from the Lake District and the less distant Trias. Shells are also found in the overlying sands up the valleys of the Dee and Severn, at occasional localities, even as far inland as Bridgnorth, the heights of the deposits varying from about 120 feet to more than 500 feet above the sea-level. If we also take account of the upper Boulder Clay, where it can be distinguished, the list of marine molluscs, ostracods, and foraminifers from these western drifts is a rather long one.[1]

Marine shells, however, on the western side of England are not restricted to the lowlands. Three instances, all occurring more than 1000 feet above sea-level, claim more than a passing mention. At Macclesfield, almost thirty miles in a straight line from the head of the estuary of the Mersey, Boulder Clays associated with stratified gravels and sands have been described by several observers.[2] The clay stops at about 1000 feet, but the sands and gravels go on to nearly 1300 feet, while isolated erratics are found up to about 100 feet higher. Sea shells, some of which are in good condition, have been obtained at various elevations, the highest being about 1200 feet above sea-level. About forty-eight species of molluscs have been recognised, and the fauna, with a few exceptions, more Arctic in character and now found at a greater depth, is one which at the present day lives in a temperate climate at a depth of a few fathoms.

The shell-bearing gravels at Gloppa, near Oswestry, which are about thirty miles from the head of the Dee estuary, were carefully described in 1892 by Mr. A. C. Nicholson. He has enumerated fully sixty species, of which, however, many are rare. As his collection[3] shows, the bivalves are generally broken, but a fair number of the univalves are tolerably perfect. The deposit itself consists of alternating seams of sand and gravel, the one generally about an inch in thickness, the other varying from a few inches to a foot. The difference in the amount of rounding shown by the stones is a noteworthy feature. They are not seldom striated; some have come from Scotland, others from the Lake District, but the majority from Wales, the last being the more angular. Here and there a block, sometimes exceeding a foot in diameter, and usually from the last-named country, has been dropped among the smaller material, most of which ranges in diameter from half an inch to an inch and a half. The beds in one or two places show contortions; but, as a rule, though slightly wavy and with a gentle dip rather to the west of south, they are uniformly deposited. In this respect, and in the unequal wearing of the materials, the Gloppa deposit differs from most gravels that I have seen. Its situation also is peculiar. It is on the flattened top of a rocky spur from higher hills, which falls rather steeply to the Shropshire lowland on the eastern side, and on the more western is defined by a small valley, which enlarges gradually as it descends towards the Severn. If the country were gradually depressed for nearly 1200 feet, this upland would become, first a promontory, then an island, and finally a shoal.

The third instance, on Moel Tryfaen in Carnarvonshire, was carefully investigated and described by a Committee of this Association[1] about ten years ago. The shells occur in an irregularly stratified sand and gravel, resting on slate, and overlain by a Boulder Clay, no great distance from, and a few dozen feet below, the rocky summit of the hill, being about 1300 feet above the level of the sea and at least five miles from its margin. About fifty-five species of molluscs and twenty-three of foraminifers have been identified. According to the late Dr. J. Gwyn Jeffreys,[2] the majority of the molluscs are littoral in habit, the rest such as live in from ten to twenty fathoms of water. Most of the erratics have been derived from the Welsh mountains, but some rocks from Anglesey have also been obtained, and a few pebbles of Lake District and Scotch rocks. If the sea were about 1300 feet above its present level, Moel Tryfaen would become a small rocky island, open to the storms from the west and north, and nearly a mile and a half away from the nearest land.

I must pass more rapidly over Ireland. The signs of vanished glaciers—ice-worn rocks and characteristic Boulder Clays—are numerous, and may be traced in places down to the sea-level, but the principal outflow of the ice, according to some competent observers, was from a comparatively low district, extending diagonally across the island from the south of Lough Neagh to north of Galway Bay. Glaciers, however, must have first begun to form in the mountains on the northern and southern side of this zone, and we should have expected that, whatever might happen on the lowlands, they would continue to assert themselves. In no other part of the British Islands are eskers, which some geologists think were formed when a glacier reached the sea, so strikingly developed. Here also an upper and a lower Boulder Clay, the former being the more sparsely distributed, are often divided by a widespread group of sands and gravels, which locally, as in Great Britain, contains, sometimes abundantly, shells and other marine organisms; more than twenty species of molluscs, with foraminifers, a barnacle, and perforations of annelids, having been described. These are found in Counties Dublin and Wicklow, at various altitudes,[3] from a little above sea-level to a height of 1300 feet.

Not the least perplexing of the glacial phenomena in the British Isles is the distribution of erratics, which has been already mentioned in passing. On the Norfolk coast, masses of chalk, often thousands of cubic feet in volume, occur in the lowest member of the glacial series, with occasional great blocks of sand and gravel, which must have once been frozen. But these, or at any rate the larger of them, have no doubt been derived from the immediate neighbourhood. Huge erratics also occasionally occur in the upper Boulder Clay—sometimes of chalk, as at Roslyn Hill near Ely, and at Ridlington in Rutland, of Jurassic limestone, near Great Ponton, to the south of Grantham, and of Lower Kimeridge Clay near Biggleswade.[4] These also probably have not travelled more than a few miles. But others of smaller size have often made much longer journeys. The Boulder Clays of eastern England are full of pieces of rock, commonly ranging from about half an inch to a foot in diameter. Among these are samples of the Carboniferous, Jurassic, and Cretaceous rocks of Yorkshire and the adjacent counties,

the Red Chalk from either Hunstanton, Speeton, or some part of the Lincolnshire wolds being found as far south as the northern heights of London. Even the chalk and flint, the former of which, especially in the Upper Boulder Clay, commonly occurs in well-worn pebbles, are frequently not the local, but the northern varieties. And with these are mingled specimens from yet more distant sources—Cheviot porphyrites, South Scotch basalts, even some of the crystalline rocks of the Highlands. Whatever was the transporting agent, its general direction was southerly, with a slight deflection towards the east in the last-named cases.

But the path of these erratics has been crossed by two streams, one coming from the west, the other from the east. On the western side of the Pennine watershed the Shap granite rises at Wasdale Crag to a height of about 1600 feet above sea-level. Boulders from it have descended the Eden valley to beyond Penrith; they have travelled in the opposite direction almost to Lancaster,[1] and a large number of them have actually made their way near the line of the Lake District watershed, across the upper valley of the Eden, and over the high pass of Stainmoor Forest,[2] whence they descended into Upper Teesdale. Subsequently the stream seems to have bifurcated, one part passing straight out to the present sea-bed, by way of the lower course of the Tees, to be afterwards driven back on to the Yorkshire coast. The other part crossed the low watershed between the Tees and the Ouse, descended the Vale of York, and spread widely over the plain.[3] Shap boulders by some means penetrated into the valleys tributary to the Ouse on its west bank, and they have been observed as far to the south-east as Royston, near Barnsley. It is noteworthy that Lake District rocks have been occasionally recorded from Airedale and even the neighbourhood of Colne, though the granite from Shap has not been found there. The other stream started from Scandinavia. Erratics, some of which must have come from the north-western side of the Christiania Fjord, occur on or near the coast from Essex to Yorkshire, and occasionally even as far north as Aberdeen, while they have been traced from the East Anglian coast to near Ware, Hitchin, and Bedford.[4] It may be important to notice that these Scandinavian erratics are often water-worn, like those dispersed over Denmark and parts of northern Germany.

On the western side of England the course of erratics is not less remarkable. Boulders from south-western Scotland, especially from the Kirkcudbright district, both water-worn and angular, are scattered over the lowlands as far south as Wolverhampton, Bridgnorth, and Church Stretton. They may be traced along the border of North Wales, occurring, as has been said, though generally small, up to about 1300 feet on Moel Tryfaen, 1100 feet at Gloppa, and more than that height on the hills east of Macclesfield. Boulders from the Lake District are scattered over much the same area and attain the same elevation, but extend, as might be expected, rather farther to the east in Lancashire. They also have been found on the eastern side of the Pennine watershed, perhaps the most remarkable instances being in the dales of the Derbyshire Derwent and on the adjacent hills as much as 1400 feet above the sea-level.[5] A third remarkable stream of erratics from the neighbourhood of the Arenig mountains extends from near the estuary of the Dee right across the paths of the two streams from the north, its eastern border passing near Rugeley, Birmingham, and Bromsgrove. They also range high, occurring almost 900 feet above sea-level on Romsley Hill, north of the Clents, and being common at Gloppa. Boulders also from the basalt mass of Rowley Regis have travelled in some cases between four and five miles, and in directions ranging from rather west of south to north-east; and, though the mass hardly rises above the 700-feet contour line, one lies with an Arenig boulder on Romsley Hill. From Charnwood

1 A pebble of it is said to have been identified at Moel Tryfaen.

2 The lowest part of the gap is about 1400 feet. A little to the south is another gap about 200 feet lower, but none of the boulders seem to have taken that route.

3 A boulder was even found above Grosmont in the Eske valley, 345 feet above sea-level.

4 R. H. Rastall and J. Romanes, Quart. Journ. Geol. Soc., lxv. (1909), p. 246.

5 Communication from Dr. H. Arnold-Bemrose.

Forest, the crags of which range up to about 850 feet above sea-level, boulders have started which have been traced over an area to the south and west to a distance of more than twenty miles.

Such, then, are the facts which call for an interpretation. More than one has been proposed; but it will be well, before discussing them, to arrive at some idea of the climate of these islands during the colder part of the Glacial Epoch. Unless that were associated with very great changes in the distribution of sea and land in northern and north-western Europe, we may assume that neither the relative position of the isotherms nor the distribution of precipitation would be very materially altered. A general fall of temperature in the northern hemisphere might so weaken the warmer ocean current from the south-west that our coasts might be approached by a cold one from the opposite direction.[1] But though these changes might diminish the difference between the temperatures of London and Leipzig, they would not make the former colder than the latter. At the present day the snow-line in the Alps on either side of the Upper Rhone Valley is not far from 8000 feet above sea-level, and this corresponds with a temperature of about 30°. Glaciers, however, are not generally formed until about 1000 feet higher, where the temperature is approximately 27°. Penck and Brückner place this line during the coldest part of the Ice Age at about 4000 feet.[2] In that case the temperature of the Swiss lowland would be some 15° lower than now, or near the freezing point.[3] If this fall were general, it would bring back the small glaciers on the Gran Sasso d'Italia and Monte Rotondo in Corsica; perhaps also among the higher parts of the Vosges and Schwarzwald.[4] In our own country it would give a temperature of about 35° at Carnarvon and 23° on the top of Snowdon, of 32° at Fort William and 17·5° on the top of Ben Nevis. If, in addition to this, the land were 600 feet higher than now (as it probably was, at any rate in the beginning of the Glacial Epoch), there would be a further drop of 2°, so that glaciers would form in the corries of Snowdon, and the region round Ben Nevis might resemble the Oetzthal Alps at the present day. This change of itself would be insufficient, and any larger drop in the ocean-level would have to be continental in its effects, since we cannot assume a local upheaval of much more than the above amount without seriously interfering with the river system of North Central Europe. But these changes, especially the former, might indirectly diminish the abnormal warmth of winter on our north-western coasts.[5] It is difficult to estimate the effect of this. If it did no more than place Carnarvon on the isotherm of Berlin (now lower by 2°), that would hardly bring a glacier from the Snowdonian region down to the sea. At the present time London is about 18° warmer than a place in the same latitude near the Labrador coast or the mouth of the Amur River, but the removal of that difference would involve greater changes in the distribution of sea and land than seems possible at an epoch, comparatively speaking, so recent. I am doubtful whether we can attribute to changed currents a reduction in British temperatures of so much as 11°; but, if we did, this would amount to 28° from all causes, and give a temperature of 20° to 22° at sea-level in England during the coldest part of the Glacial Epoch.[6] That is now

1 Facts relating to this subject will be found in "Climate and Time," by J. Croll, ch. ii. and iii. (1875). Of course the air currents would also be affected, and perhaps diminish precipitation as the latitude increased.

2 *Loc. cit.*, p. 586, *et seq.* They say the snow-line, which would mean that the temperature was only 12° lower than now; but as possibly this line might then more nearly correspond with that of glacier formation, I will provisionally accept the higher figures, especially since Corsica, the Apennines, and some other localities in Europe, seem to require a reduction of rather more than 12°.

3 It would be 32·5° at Zurich, 31·6° at Bern, 34·1° at Geneva, about 39·0° on the plain of Piedmont, and 36·0° at Lyons.

4 See for particulars the author's "Ice Work" (International Scientific Series), p. 237.

5 For much valuable information on these questions see a paper on Climate of the Pleistocene Epoch (F. W. Harmer, Quart. Journ. Geol. Soc., lvii. 1901, p. 405).

6 The present temperature in Ireland over the zone (from S. of Belfast to N. of Galway Bay) which is supposed to have formed the divide of the central snowfield may be given as from 49° to 50°, nearly the same as at the sea-level in Carnarvonshire. Thus, though the district is less mountainous than Wales, it would not need a greater reduction, for the snowfall would probably be rather larger. But this reduction could hardly be less than 20°, for the glaciers would have to form nearly at the present sea-level.

found, roughly speaking, in Spitsbergen, which, since its mountains rise to much the same height, should give us a general idea of the condition of Britain in the olden time.

What would then be the state of Scandinavia? Its present temperature ranges on the west coast from about 45° in the south to 35° in the north.[1] But this region must now be very much, possibly 1800 feet, lower than it was in pre-Glacial, perhaps also in part of Glacial, times.[2] If we added 5° for this to the original 15°, and allowed so much as 18° for the diversion of the warm current, the temperature of Scandinavia would range from 7° to −3°, approximately that of Greenland northwards from Upernivik. But since the difference at the present day between Cape Farewell and Christiania (the one in an abnormally cold region, the other in one correspondingly warm) is only 7°, that allowance seems much too large, while without it Scandinavia would correspond in temperature with some part of that country from south of Upernivik to north of Frederikshaab.[3] But if Christiania were not colder than Jakobshavn is now, or Britain than Spitsbergen, we are precluded from comparisons with the coasts of Baffin Bay or Victoria Land.

Thus the ice-sheet from Scandinavia would probably be much greater than those generated in Britain. It would, however, find an obstacle to progress westwards which cannot be ignored. If the bed of the North Sea became dry land, owing to a general rise of 600 feet, that would still be separated from Norway by a deep channel extending from the Christiania Fjord round the coast northward. Even then this would be everywhere more than another 600 feet deep, and almost as wide as the Strait of Dover.[4] The ice must cross this and afterwards be forced for more than 300 miles up a slope, which, though gentle, would be in vertical height at least 600 feet. The task, if accomplished by thrust from behind, would be a heavy one, and, so far as I know, without a parallel at the present day; if the viscosity of the ice enabled it to flow, as has lately been urged,[5] we must be cautious in appealing to the great Antarctic barrier, because we now learn that more than half of it is only consolidated snow.[6] Moreover, if the ice floated across that channel, the thickness of the boulder-bearing layers would be diminished by melting (as in Ross's Barrier), and the more viscous the material the greater the tendency for these to be left behind by the overflow of the cleaner upper layers. If, however, the whole region became dry land, the Scandinavian glaciers would descend into a broad valley, considerably more than 1200 feet deep, which would afford them an easy path to the Arctic Ocean, so that only a lateral overflow, inconsiderable in volume, could spread itself over the western plateau.[7] An attempt to escape this difficulty has been made by assuming the existence of an independent centre of distribution for ice and boulders near the middle of the North Sea bed[8] (which would demand rather exceptional conditions of temperature and precipitation); but in such case either the Scandinavian ice would be fended off from England, or the boulders, prior to its advance, must have been dropped by floating ice on the neighbouring sea-floor.

If, then, our own country were but little better than Spitsbergen as a producer of ice, and Scandinavia only surpassed southern Greenland in having a rather heavier snowfall, what interpretation may we give to the glacial phenomena of Britain? Three have been proposed. One asserts that throughout the Glacial Epoch the British Isles generally stood at a higher level, so that the ice which almost buried them flowed out on to the beds of the North and Irish Seas. The Boulder Clays represent its moraines. The stratified sands and gravels were deposited in lakes formed by the rivers, which were dammed up by ice-sheets.[1] A second interpretation recognises the presence of glaciers in the mountain regions, but maintains that the land, at the outset rather above its present level, gradually sank beneath the sea, until the depth of water over the eastern coast of England was fully 500 feet, and over the western nearly 1400 feet, from which depression it slowly recovered. By any such submergence Great Britain and Ireland would be broken up into a cluster of hilly islands, between which the tide from an extended Atlantic would sweep eastwards twice a day, its currents running strong through the narrower sounds, while movements in the reverse direction at the ebb would be much less vigorous. The third interpretation, in some respects intermediate, was first advanced by the late Prof. Carvill Lewis, who held that the peculiar Boulder Clays and associated sands (such as those of East Anglia), which, as was then thought, were not found more than about 450 feet above the present sea-level, had been deposited in a great fresh-water lake, held up by the ice-sheets already mentioned and by an isthmus, which at that time occupied the place of the Strait of Dover. Thus these deposits, though indirectly due to land-ice, were actually fluviatile or lacustrine. But this interpretation need not detain us, though the former existence of such lakes is still maintained, on a small scale in Britain, on a much larger one in North America, because, as was pointed out when it was first advanced, it fails to explain the numerous erratic blocks and shell-bearing sands which occur far above the margin of the hypothetical lake.

Each of the other two hypotheses involves grave difficulties. That of great confluent ice-sheets creeping over the British lowlands demands, as has been intimated, climatal conditions which are scarcely possible, and makes it hard to explain the sands and gravels, sometimes with regular alternate bedding, but more generally indicative of strong current action, which occur at various elevations to more than 1300 feet above sea-level, and seem too widespread to have been formed either beneath an ice-sheet or in lakes held up by one, for the latter, if of any size, would speedily check the velocity of influent streams. Also the mixture and crossing of boulders, which we have described, are inexplicable without the most extraordinary oscillations in the size of the contributing glaciers. To suppose that the Scandinavian ice reached to Bedfordshire and Herts, and then retired in favour of north British glaciers, or *vice versâ*, assumes an amount of variation which, so far as I am aware, is without a parallel elsewhere. So also the mixture of boulders from South Scotland, the Lake District, and North Wales, which lie, especially in parts of Staffordshire and Shropshire, as if dropped upon the surface, far exceeds what may reasonably be attributed to variations amplified by lateral spreading of mountain glaciers on reaching a lowland, while the frequent presence of shells in the drifts, dozens of miles away from the present coast, implies a rather improbable scooping up of the sea-bed without much injury to such fragile objects. The ice also must have been curiously inconstant in its operations. It is supposed in one place to have glided gently over its bed, in another to have gripped and torn out huge masses of rock.[2] Both actions may be possible in a mountain region, but it is very difficult to understand how they could occur in a lowland or plain. Besides this, we can only account for some singular aberrations of boulders, such as Shap granite well above Grosmont in Eskdale, or the Scandinavian rhomb-porphyry above Lockwood,[3] near Huddersfield, by assuming a flexibility in the lobes of an ice-sheet which it is hard to match at

[1] It is 44·42° at Bergen, 38·48° at Bodo, 35·42° at Hammerfest, 41·36° at Christiania and Stockholm.

[2] For particulars see *Geol. Mag.*, 1899, p. 97 (W. H. Hudleston) and p. 282 (T. G. Bonney).

[3] Christiania and Cape Farewell (Greenland) are nearly on the same latitude.

[4] For details see *Geol. Mag.*, 1899, pp. 97 and 282.

[6] E. Shackleton, "The Heart of the Antarctic," ii., p. 277.

[7] It has indeed been affirmed (Brögger, *Om de senglaciale og postglaciale nivaforandringer i Kristianiafeltet*, p. 682) that at the time of the great ice-sheet of Europe the sea-bottom must have been uplifted at least 8500 feet higher than at present. This may be a ready explanation of the occurrence of certain dead shells in deep water, but, unless extremely local, it would revolutionise the drainage system of Central Europe.

[8] *Geol. Mag.*, 1901, pp. 142, 187, 284, 332.

[1] See Warren Upham, Monogr. U.S. Geol. Survey, xxv. (1896). This explanation commends itself to the majority of British geologists as an explanation of the noted parallel roads of Glenroy, but it is premature to speak of it as "conclusively shown" (Quart. Journ. Geol. Soc., lviii. (1902) p. 473) until a fundamental difficulty which it presents has been discussed and removed.

[2] That this has occurred at Cromer is a very dubious hypothesis (see *Geol. Mag.*, 1905, pp. 397, 524). The curious relations of the drift and chalk in the islands of Möen and Rügen are sometimes supposed to prove the same action. Knowing both well, I have no hesitation in saying that the chalk there is, as a rule, as much *in situ* as it is in the Isle of Wight.

[3] About half-way across England and 810 feet above sea-level. P. F. Kendall, Quart. Journ. Geol. Soc., lvii. (1902), p. 498.

the present time. Again, the Boulder Clay of the eastern counties is crowded, as we have described, with pebbles of chalk, which generally are not of local origin, but have come from north of the Wash. Whether from the bed of a river or from a sea-beach, they are certainly water-worn. But if pre-Glacial, the supply would be quickly exhausted, so that they would usually be confined to the lower part of the clay. As it is, though perhaps they run larger here, they abound throughout. The so-called moraines near York (supposed to have been left by a glacier retreating up that vale), those in the neighbourhood of Flamborough Head and of Sheringham (regarded as relics of the North Sea ice-sheet), do not, in my opinion, show any important difference in outline from ordinary hills of sands and gravels, and their materials are wholly unlike those of any indubitable moraines that I have either seen or studied in photographs. It may be said that the British glaciers passed over very different rocks from the Alpine; but the Swiss molasse ought to have supplied abundant sand, and the older interglacial gravels quantities of pebbles; yet the differences between the morainic materials on the flank of the Jura or near the town of Geneva and those close to the foot of the Alps are varietal rather than specific.

Some authorities, however, attribute such magnitude to the ice-sheets radiating from Scandinavia that they depict them, at the time of maximum extension, as not only traversing the North Sea bed and trespassing upon the coast of England, but also radiating southward to overwhelm Denmark and Holland, to invade northern Germany and Poland, to obliterate Hanover, Berlin, and Warsaw, and to stop but little short of Dresden and Cracow, while burying Russia on the east to within no great distance of the Volga and on the south to the neighbourhood of Kief. Their presence, however, so far as I can ascertain, is inferred from evidence[1] very similar to that which we have discussed in the British lowlands. That Scandinavia was at one time almost wholly buried beneath snow and ice is indubitable; it is equally so that at the outset the land stood above its present level, and that during the later stages of the Glacial Epoch parts, at any rate of southern Norway, had sunk down to a maximum depth of 800 feet. In Germany, however, erratics are scattered over its plain and stranded on the slopes of the Harz and Riesengebirge up to about 1400 feet above sea-level. The glacial drifts of the lowlands sometimes contain dislodged masses of neighbouring rocks like those at Cromer, and we read of other indications of ice action. I must, however, observe that since the glacial deposits of Möen, Warnemünde, and Rügen often present not only close resemblances to those of our eastern counties, but also very similar difficulties, it is not permissible to quote the one in support of the other, seeing that the origin of each is equally dubious. Given a sufficient "head" of ice in northern regions, it might be possible to transfer the remains of organisms from the bed of the Irish Sea to Moel Tryfaen, Macclesfield, and Gloppa; but at the last-named, if not at the others, we must assume the existence of steadily alternating currents in the lakes in order to explain the corresponding bedding of the deposit. This, however, is not the only difficulty. The "Irish Sea glacier" is supposed to have been composed of streams from Ireland, south-west Scotland, and the Lake District, of which the second furnished the dominant contingent, the first-named not producing any direct effect on the western coast of Great Britain, and the third being made to feel its inferiority and "shouldered in upon the mainland." But even if this ever happened, ought not the Welsh ice to have joined issue with the invaders a good many miles to the north of its own coast?[2] Welsh boulders, at any rate, are common near the summit of Moel Tryfaen, and I have no hesitation in saying that the pebbles of riebeckite-rock, far from rare in its drifts, come from Mynydd Mawr, hardly half a league to the E.S.E., and not from Ailsa Craig.[1]

[1] A valuable summary of it is given in "The Great Ice Age," J. Geikie, ch. xxix., xxx. (1894)

[2] From Moel Tryfaen to the nearest point of Scotland is well over a hundred miles, and it is a few less than this distance from Gloppa to the Lake District. In order to allow the Irish Sea ice-sheet to reach the top of Moel Tryfaen the glacier productive power of Snowdonia has been minimised (Wright, "Man and the Glacial Epoch," pp. 171, 172). But the difference between that and the Arenig region is not great enough to make the one incompetent to protect its own borderland while the other could send an ice-sheet which could almost cover the Clent Hills and reach the neighbourhood of Birmingham. Anglesey also, if we suppose a slight elevation and a temperature of 29° at the sea-level, would become a centre of ice-distribution and an advance guard to North Wales.

As such frequent appeal is made to the superior volume of the ice-sheet which poured from the northern hills over the bed of the Irish Sea, I will compare in more detail the ice-producing capacities of the several districts. The present temperature of West-Central Scotland may be taken as 47°, its surface as averaging about 2500 feet, rising occasionally to nearly 4000 feet above sea-level. In the western part of the Southern Uplands the temperature is a degree higher, and the average for altitude at most not above 1500 feet. In the Lake District and the Northern Pennines the temperature is increased by another degree, and the heights are, for the one 1800 feet with a maximum of 3162 feet, for the other 1200 feet and 2892 feet. In North Wales the temperature is 50°, the average height perhaps 2000 feet, and the culminating point 3571 feet. For the purpose of comparing the ice-producing powers of these districts, we may bring them to one temperature by adding 300 feet to the height for each degree below that of the Welsh region. This would raise the average elevation of Central and Southern Scotland to 3400 feet and 2100 feet respectively, for the Lake District and Northern Pennines to 2100 feet and 1500 feet. We may picture to ourselves what this would mean, if the snow-line were at the sea-level in North Wales, by imagining 8000 feet added to its height and comparing it with the Alps. North Wales would then resemble a part of that chain which had an average height of about 10,000 feet above sea-level, and culminated in a peak of 11,571 feet; the Lake District would hardly differ from it; the Northern Pennines would be like a range of about 9000 feet, its highest peak being 11,192 feet. Southern Scotland would be much the same in average height as the first and second, and would rise, though rarely, to above 11,000 feet; the average in Central Scotland would be about 11,400 feet, and the maximum about 13,000 feet. Thus North Wales, the Lake District, and the Southern Uplands would differ little in ice-productive power, while Central Scotland would distinctly exceed them, but not more than the group around the Finsteraarhorn does that giving birth to the Rhone glacier. In one respect, however, all these districts would differ from the Alps—that, at 8000 feet, the surface, instead of being furrowed with valleys, small and great, would be a gently shelving plateau, which would favour the formation of piedmont glaciers. Still, unless we assume the present distribution of rainfall to be completely altered (for which I do not know any reason), the relative magnitudes of the ice coming from these centres (whether separate glaciers or confluent sheets) could differ but little. Scotch ice would not appreciably "shoulder inland" that from the Lake District, nor would the Welsh ice be imprisoned within its own valleys.

During the last few years, however, the lake-hypothesis of Carvill Lewis has been revived under a rather different form by some English advocates of land-ice. For instance, the former presence of ice-dammed lakes is supposed to be indicated in the upper parts of the Cleveland Hills by certain overflow channels. I may be allowed to observe that, though this view is the outcome of much acute observation and reasoning,[2] it is wholly dependent upon the ice-barriers already mentioned, and that if they dissolve before the dry light of sceptical criticism, the lakes will "leave not a rack behind." I must also confess that, to my eyes, the so-called "overflow channels" much more closely resemble the remnants of ancient valley-systems, formed by only moderately rapid rivers, which have been isolated by the trespass of younger and more energetic streams, and they suggest that the main features of this picturesque upland were developed before rather than after the beginning of the Glacial Epoch. I think that even "Lake Pickering," though it has become an accepted fact with several geologists of high repute, can be more simply explained as a two-branched "valley of

[1] The boulders of picrite near Porth Nobla, from Llanerchymedd, though they have travelled southward, have moved much to the west.

[2] P. F. Kendall, Quart. Journ. Geol. Soc., lviii. (1902), 471.

strike," formed on the Kimeridge Clay, the eastern arm of which was beheaded, even in pre-Glacial times, by the sea.[1] As to Lake Oxford,[2] I must confess myself still more sceptical. Some changes, no doubt, have occurred in later Glacial and post-Glacial times; valleys have been here raised by deposit, there deepened sometimes by as much as 100 feet; the courses of lowland rivers may occasionally have been altered; but I doubt whether, since those times began, either ice-sheet or lake has ever concealed the site of that university city.

The submergence hypothesis assumes that, at the beginning of the Glacial Epoch, our islands stood rather above their present level, and during it gradually subsided, on the west to a greater extent than on the east, until at last the movement was reversed, and they returned nearly to their former position. During most of this time glaciers came down to the sea from the more mountainous islands, and in winter an ice-foot formed upon the shore. This, on becoming detached, carried away boulders, beach pebbles, and finer detritus. Great quantities of the last also were swept by swollen streams into the estuaries and spread over the sea-bed by coast currents, settling down especially in the quiet depths of submerged valleys. Shore-ice in Arctic regions, as Colonel H. W. Feilden[3] has described, can striate stones and even the rock beneath it, and is able, on a subsiding area, gradually to push boulders up to a higher level. In fact, the state of the British region in those ages would not have been unlike that still existing near the coasts of the Barents and Kara Seas. Over the submerged region southward, and in some cases more or less eastward, currents would be prevalent, though changes of wind[4] would often affect the drift of the floating ice-rafts. But though the submergence hypothesis is obviously free from the serious difficulties which have been indicated in discussing the other one, gives a simple explanation of the presence of marine organisms, and accords with what can be proved to have occurred in Norway, Waigatz Island, Novaia Zemlya, on the Lower St. Lawrence, in Grinnell Land, and elsewhere,[5] it undoubtedly involves others. One of them—the absence of shore terraces, caves, or other sea marks—is perhaps hardly so grave as it is often thought to be. It may be met by the remark that unless the Glacial Age lasted for a very long time and the movements were interrupted by well-marked pauses, we could not expect to find any such record. In regard also to another objection, the rather rare and sporadic occurrence of marine shells, the answer would be that, on the Norway coast, where the ice-worn rock has certainly been submerged, sea-shells are far from common, and occur sporadically in the raised deltaic deposits of the fjords.[6] An advocate of this view might also complain, not without justice, that, if he cited an inland terrace, it was promptly dismissed as the product of an ice-dammed lake, and his frequent instances of marine shells in stratified drifts were declared to have been transported from the sea by the lobe of an ice-sheet; even if they have been carried across the path of the Arenig ice, more than forty miles as the crow flies, from the Irish Sea up the Valley of the Severn, or forced some 1300 feet up Moel Tryfaen.[7] The difficulty in the latter case, he would observe, is not met by saying the ice-sheet would be able to climb that hill "given there were a sufficient head behind it."[1] That ice can be driven uphill has long been known, but the existence of the "sufficient head" must be demonstrated, not assumed. There may be "no logical halting-place between an uplift of ten or twenty feet to surmount a *roche moutonnée* and an equally gradual elevation to the height of Moel Tryfaen," yet there is a common-sense limitation even to a destructive *sorites*. The argument, in fact, is more specious than valid, until we are told approximately how thick the northern ice must be to produce the requisite pressure, and whether such an accumulation would be possible. The advocates of land ice admit that, before it had covered more than a few leagues on its southward journey, its thickness was less than 2000 feet, and we are not entitled, as I have endeavoured to show, to pile up ice indefinitely on either our British highlands or the adjacent sea-bed. The same reason also forbids us largely to augment the thickness of the latter by the snowfall on its surface, as happens to Antarctic barrier ice. Even if the thickness of the ice-cap over the Dumfries and Kirkcudbright hills had been about 2500 feet, that, with every allowance for viscosity, would hardly give us a head sufficient to force a layer of ice from the level of the sea-bed to a height of nearly 1400 feet above it, and at a distance of more than 100 miles.

Neither can we obtain much support from the instance in Spitsbergen, described by Profs. Garwood and Gregory, where the Ivory Glacier, after crossing the bed of a valley, had transported marine shells and drift from the floor (little above sea-level) to a height of about 400 feet on the opposite slope. Here the valley was narrow, and the glacier had descended from an inland ice-reservoir, much of which was at least 2800 feet above the sea, and rose occasionally more than a thousand feet higher.[2]

But other difficulties are far more grave. The thickness of the chalky Boulder Clay alone, as has been stated, not unfrequently exceeds 100 feet, and, though often much less, may have been reduced by denudation. This is an enormous amount to have been transported and distributed by floating ice. The materials, also, are not much more easily accounted for by this than by the other hypothesis. A continuous supply of well-worn chalk pebbles might indeed be kept up from a gradually rising or sinking beach, but it is difficult to see how, until the land had subsided for at least 200 feet, the chalky Boulder Clay could be deposited in some of the East Anglian valleys or on the Leicestershire hills. That depression, however, would seriously diminish the area of exposed chalk in Lincolnshire and Yorkshire, and the double of it would almost drown that rock. Again, the East Anglian Boulder Clay, as we have said, frequently abounds in fragments and finer detritus from the Kimeridge and Oxford Clays. But a large part of their outcrop would disappear before the former submergence was completed. Yet the materials of the Boulder Clay, though changing as it is traced across the country, more especially from east to west, seem to vary little in a vertical direction. The instances, also, of the transportation of boulders and smaller stones to higher levels, sometimes large in amount, as in the transference of "brockram" from outcrops near the bed of the Eden valley to the level of Stainmoor Gap, seem to be too numerous to be readily explained by the uplifting action of shore-ice in a subsiding area. Such a process is possible, but we should anticipate it would be rather exceptional.

Submergence also readily accounts for the above-named sands and gravels, but not quite so easily for their occurrence at such very different levels. On the eastern side of England gravelly sands may be found beneath the chalky Boulder Clay well below sea-level to three or four hundred feet above it. Again, since, on the submergence hypothesis, the Lower Boulder Clay about the estuaries of the Dee and the Mersey must represent a deposit from piedmont ice in a shallow sea, the mid-glacial sand (sometimes not very clearly marked in this part) ought not to be more than forty or fifty feet above the present Ordnance datum. But at Manchester it reaches more than 200 feet, while near Heywood it is at least 425 feet. In other

[6] If, as seems probable, the temperature was changing rather rapidly the old fauna would be pauperised and the new one make its way but slowly into the British fjords.

[7] Critics of the submergence hypothesis seem to find a difficulty in admitting downward and upward movements, amounting sometimes to nearly 1,400 feet during Pleistocene Ages; but in the northern part of America the upheaval, at any rate, has amounted to about 1,000 feet, while on the western coast, beneath the lofty summit of Mount St. Elias, marine shells of existing species have been obtained some 5,000 feet above sea level. It is also admitted that in several places the pre-glacial surface of the land was much above its present level On the Red River, whatever be the explanation, foraminifers, radiolarians, and sponge spicules have been found at 700 feet above sea-level, and near Victoria, on the Saskatchewan, even up to about 1,900 feet.

[2] Quart. Journ. Geol. Soc., liv. (1898), p. 205. Earlier observations of some upthrust of materials by a glacier are noted on p. 219.

words, the sands and gravels, presumably (often certainly) mid-glacial, mantle, like the Upper Boulder Clay, over great irregularities of the surface, and are sometimes found, as already stated, up to more than 1200 feet. Either of these deposits may have followed the sea-line upwards or downwards, but that explanation would almost compel us to suppose that the sand was deposited during the submergence and the upper clay during the emergence, so that, with the former material, the higher in position is the newer in time, and with the latter the reverse. We must not, however, forget that in the island of Rügen we find more than one example of a stratified gravelly sand between two beds of Boulder Clay (containing Scandinavian erratics) which present some resemblance to the Boulder Clays of eastern England, while certain glacial deposits at Warnemünde, on the Baltic coast, sometimes remind us of the Contorted Drift of Norfolk.

Towards the close of the Glacial Epoch, the deposition of the Boulder Clay ceased[1] and its denudation began. On the low plateaux of the Eastern Counties it is often succeeded by coarse gravels, largely composed of flint, more or less water-worn. These occasionally include small intercalations of Boulder Clay, have evidently been derived from it, and indicate movement by fairly strong currents. Similar gravels are found overlying the Boulder Clay in other parts of England, sometimes at greater heights above sea-level. Occasionally the two are intimately related. For instance, a pit on the broad, almost level, top of the Gogmagog Hills, about 200 feet above sea-level and four miles south of Cambridge, shows a current-bedded sand and gravel, overlain by a Boulder Clay, obviously rearranged, while other pits in the immediate neighbourhood expose varieties and mixtures of one or the other material. But, as true Boulder Clay occurs in the valley below, these gravels must have been deposited, and that by rather strong currents, on a hill-top—a thing which seems impossible under anything like the existing conditions; and, even if the lowland were buried beneath ice full 200 feet in thickness, which made the hill-top into the bed of a lake, it is difficult to understand how the waters of that could be in rapid motion. Rearranged Boulder Clays also occur on the slopes of valleys[2] which may be explained, with perhaps some of the curious sections near Sudbury, by the slipping of materials from a higher position. But at Old Oswestry gravels with indications of ice action are found at the foot of the hills almost 700 feet below those of Gloppa.

Often the plateau gravels are followed at a lower level by terrace gravels,[3] which descend towards the existing rivers, and suggest that valleys have been sometimes deepened, sometimes only re-excavated. The latter gravels are obviously deposited by rivers larger and stronger than those which now wind their way seawards, but it is difficult to explain the former gravels by any fluviatile action, whether the water from a melting ice-sheet ran over the land or into a lake, held up by some temporary barrier. But the sorting action of currents in a slowly shallowing sea would be quite competent to account for them, so they afford an indirect support to the hypothesis of submergence. It is, however, generally admitted that there have been oscillations both of level and of climate since any Boulder Clay was deposited in the districts south of the Humber and the Ribble. The passing of the Great Ice Age was not sudden, and glaciers may have lingered in our mountain regions when Palæolithic man hunted the mammoth in the valley of the Thames or frequented the caves of Devon and Mendip. But of these times of transition, before written history became possible, and of sundry interesting topics connected with the Ice Age itself —of its cause, date, and duration, whether it was persistent or interrupted by warmer episodes, and, if so, by what number, of how often it had already recurred in the history of the earth—I must, for obvious reasons, refrain from speaking, and content myself with having endeavoured to place before you the facts of which, in my opinion, we must take account in reconstructing the physical geography of Western Europe, and especially of our own country, during the Age of Ice.

[1] Probably deposits of a distinctly glacial origin (such as those near Hessle in Yorkshire) continued in the northern districts, but on these we need not linger

[2] For instance, at Stanningfield in the valley of the Lark.

[3] These contain the instruments worked by palæolithic (Acheulean) man who, in this country at any rate, is later than the chalky boulder clay.

Not unnaturally you will expect a decision in favour of one or the other litigant after this long summing up. But I can only say that, in regard to the British Isles, the difficulties in either hypothesis appear so great that, while I consider those in the "land-ice" hypothesis to be the more serious, I cannot as yet declare the other one to be satisfactorily established, and think we shall be wiser in working on in the hope of clearing up some of the perplexities. I may add that, for these purposes, regions like the northern coasts of Russia and Siberia appear to me more promising than those in closer proximity to the North or South Magnetic Poles. This may seem a "lame and impotent conclusion" to so long a disquisition, but there are stages in the development of a scientific idea when the best service we can do it is by attempting to separate facts from fancies, by demanding that difficulties should be frankly faced instead of being severely ignored, by insisting that the giving of a name cannot convert the imaginary into the real, and by remembering that if hypotheses yet on their trial are treated as axioms, the result will often bring disaster, like building a tower on a foundation of sand. To scrutinise, rather than to advocate any hypothesis, has been my aim throughout this address, and, if my efforts have been to some extent successful, I trust to be forgiven, though I may have trespassed on your patience and disappointed a legitimate expectation.

SECTION A.

MATHEMATICAL AND PHYSICAL SCIENCE.

OPENING ADDRESS BY PROF. E. W. HOBSON, Sc.D., F.R.S., PRESIDENT OF THE SECTION.

SINCE the last meeting of our Association one of the most illustrious of the British workers in science during the nineteenth century has been removed from us by the death of Sir William Huggins. In the middle of the last century Sir William Huggins commenced that pioneer work of examination of the spectra of the stars which has ensured for him enduring fame in connection with the foundation of the science of Astrophysics. The exigencies of his work of analysis of the stellar spectra led him to undertake a minute examination of the spectra of the elements with a view to the determination of as many lines as possible. To the spectroscope he later added the photographic film as an instrument of research in his studies of the heavenly bodies. In 1864 Sir William Huggins made the important observation that many of the nebulæ have spectra which consist of bright lines, and two years later he observed, in the case of a new star, both bright and dark lines in the same spectrum. In 1868 his penetrating and alert mind made him the first to perceive that the Doppler principle could be applied to the determination of the velocities of stars in the line of sight, and he at once set about the application of the method. His life-work, in a domain of absorbing interest, was rewarded by a rich harvest of discovery, obtained as the result of most patient and minute investigations. The "Atlas of Representative Stellar Spectra," published in the names of himself and Lady Huggins, remains as a monumental record of their joint labours.

The names of the great departments of science, Mathematics, Physics, Astronomy, Meteorology, which are associated with Section A, are a sufficient indication of the vast range of investigation which comes under the purview of our Section. An opinion has been strongly expressed in some quarters that the time has come for the erection of a separate Section for Astronomy and Meteorology, in order that fuller opportunities may be afforded than hitherto for the discussion of matters of special interest to those devoted to these departments of Science. I do not share this view. I believe that, whilst the customary division into sub-sections gives reasonable facilities for the treatment of questions interesting solely to specialists in the various branches with which our Section is concerned, a policy of disruption would be injurious to the wider interests of science. The close association of the older Astronomy with Mathematics, and of the newer Astronomy with Physics, form strong presumptions against the change that has been suggested. Meteorology, so far as it goes beyond the purely empirical region, is, and must always remain, a branch of Physics. No doubt the more technical problems which arise in connection with these subjects, though of great importance to specialists, are often of little or no interest to workers in cognate departments. It appears to me, however, that it is unwise, in view of the general objects of the British Association, to give too much prominence in the meetings to the more technical aspects of the various departments of science. Ample opportunities for the full discussion of all the detailed problems, the solution of which forms a great and necessary part of the work of those who are advancing science in its various branches, are afforded by the special Societies which make those branches their exclusive concern. The British Association will, in my view, be performing its functions most efficiently if it gives much prominence to those aspects of each branch of science which are of interest to a public at least in some degree larger than the circle of specialists concerned with the particular branch. To afford an opportunity to workers in any one department of obtaining some knowledge of what is going on in other departments, to stimulate by means of personal intercourse with workers on other lines the sense of solidarity of men of science, to do something to counteract that tendency to narrowness of view which is a danger arising from increasing specialisation, are functions the due performance of which may do much to further that supreme object, the advancement of science, for which the British Association exists.

I propose to address to you a few remarks, necessarily fragmentary and incomplete, upon the scope and tendencies of modern Mathematics. Not to transgress against the canon I have laid down, I shall endeavour to make my treatment of the subject as little technical as possible.

Probably no other department of knowledge plays a larger part outside its own narrower domain than Mathematics. Some of its more elementary conceptions and methods have become part of the common heritage of our civilisation, interwoven in the everyday life of the people. Perhaps the greatest labour-saving invention that the world has seen belongs to the formal side of Mathematics; I allude to our system of numerical notation. This system, which, when scrutinised, affords the simplest illustration of the importance of Mathematical form, has become so much an indispensable part of our mental furniture that some effort is required to realise that an apparently so obvious idea embodies a great invention, one to which the Greeks, with their unsurpassed capacity for abstract thinking, never attained. An attempt to do a multiplication sum in Roman numerals is perhaps the readiest road to an appreciation of the advantages of this great invention. In a large group of sciences, the formal element, the common language, so to speak, is supplied by Mathematics; the range of the application of mathematical methods and symbolism is ever increasing. Without taking too literally the celebrated dictum of the great philosopher Kant, that the amount of real science to be found in any special subject is the amount of Mathematics contained therein, it must be admitted that each branch of science which is concerned with natural phenomena, when it has reached a certain stage of development, becomes accessible to, and has need of, mathematical methods and language; this stage has, for example, been reached in our time by parts of the science of Chemistry. Even Biology and Economics have begun to require mathematical methods, at least on their statistical side. As a science emerges from the stages in which it consists solely of more or less systematised descriptions of the phenomena with which it is concerned in their more superficial aspect; when the intensive magnitudes discerned in the phenomena become representable as extensive magnitudes, then is the beginning of the application of mathematical modes of thought; at a still later stage, when the phenomena become accessible to dynamical treatment, Mathematics is applicable to the subject to a still greater extent.

Mathematics shares with the closely allied subject of Astronomy the honour of being the oldest of the sciences. When we consider that it embodies, in an abstract form, some of the more obvious, and yet fundamental, aspects of our experience of the external world, this is not altogether surprising. The comparatively high degree of development which, as recent historical discoveries have disclosed, it had attained amongst the Babylonians more than five thousand years B.C., may well astonish us. These times must have been preceded by still earlier ages, in which the mental evolution of man led him to the use of the tally, and of simple modes of measurement, long before the notions of number and of magnitude appeared in an explicit form.

I have said that Mathematics is the oldest of the sciences; a glance at its more recent history will show that it has the energy of perpetual youth. The output of contributions to the advance of the science during the last century and more has been so enormous that it is difficult to say whether pride in the greatness of achievement in his subject, or despair at his inability to cope with the multiplicity of its detailed developments, should be the dominant feeling of the mathematician. Few people outside the small circle of mathematical specialists have any idea of the vast growth of mathematical literature. The Royal Society Catalogue contains a list of nearly thirty-nine thousand papers on subjects of Pure Mathematics alone, which have appeared in seven hundred serials during the nineteenth century. This represents only a portion of the total output, the very large number of treatises, dissertations, and monographs published during the century being omitted. During the first decade of the twentieth century this activity has proceeded at an accelerated rate. Mathematical contributions to Mechanics, Physics, and Astronomy would greatly swell the total. A notion of the range of the literature relating, not only to Pure Mathematics, but also to all branches of science to which mathematical methods have been applied, will be best obtained by an examination of that monumental work, the "Encyclopädie der mathematischen Wissenschaften"—when it is completed.

The concepts of the pure mathematician, no less than those of the physicist, had their origin in physical experience analysed and clarified by the reflective activities of the human mind; but the two sets of concepts stand on different planes in regard to the degree of abstraction which is necessary in their formation. Those of the mathematician are more remote from actual unanalysed precepts than are those of the physicist, having undergone in their formation a more complete idealisation and removal of elements inessential in regard to the purposes for which they are constructed. This difference in the planes of thought frequently gives rise to a certain misunderstanding between the mathematician and the physicist, due in the case of either to an inadequate appreciation of the point of view of the other. On the one hand it is frequently and truly said of particular mathematicians that they are lacking in the physical instinct, and on the other hand a certain lack of sympathy is frequently manifested on the part of physicists for the aims and ideals of the mathematician. The habits of mind and the ideals of the mathematician and of the physicist cannot be of an identical character. The concepts of the mathematician necessarily lack, in their pure form, just that element of concreteness which is an essential condition of the success of the physicist, but which to the mathematician would often only obscure those aspects of things which it is his province to study. The abstract mathematical standard of exactitude is one of which the physicist can make no direct use. The calculations in Mathematics are directed towards ideal precision; those in Physics consist of approximations within assigned limits of error. The physicist can, for example, make no direct use of such an object as an irrational number; in any given case a properly chosen rational number approximating to the irrational one is sufficient for his purpose. Such a notion as continuity, as it occurs in Mathematics, is, in its purity, unknown to the physicist, who can make use only of sensible continuity. The physical counterpart of mathematical discontinuity is very rapid change through a thin layer of transition, or during a very short time. Much of the skill of the true mathematical physicist and of the mathematical astronomer consists in the power of adapting methods and results carried out on an exact mathematical basis to obtain approximations sufficient for the purposes of physical measurement. It might perhaps be thought that a scheme of Mathematics on a frankly approximative basis would be sufficient for all the practical purposes of application in Physics, Engineering Science, and Astronomy, and no doubt it would be possible to develop, to some extent at least, a species of Mathematics on these lines. Such a system would, however, involve an intolerable awkwardness and prolixity in the statement of results, especially in view of the fact that the degrees of approximation necessary for various purposes are very different, and thus that unassigned grades of approximation would have to be provided for. Moreover, the mathematician working on these lines would be cut off from his chief sources of inspiration, the ideals of exactitude and logical rigour, as well as from one of his most indispensable guides to discovery, symmetry, and permanence of mathematical form. The history of the actual movements of mathematical thought through the centuries shows that these ideals are the very life-blood of the science, and warrants the conclusion that a constant striving towards their attainment is an absolutely essential condition of vigorous growth. These ideals have their roots in irresistible impulses and deep-seated needs of the human mind, manifested in its efforts to introduce intelligibility into certain great domains of the world of thought.

There exists a widespread impression among physicists, engineers, and other men of science that the effect of recent developments of Pure Mathematics, by making it more abstract than formerly, has been to remove it further from the order of ideas of those who are primarily concerned with the physical world. The prejudice that Pure Mathematics has its sole *raison d'être* in its function of providing useful tools for application in the physical sciences, a prejudice which did much to retard the due development of Pure Mathematics in this country during the nineteenth century, is by no means extinct. It is not infrequently said that the present devotion of many mathematicians to the interminable discussion of purely abstract questions relating to modern developments of the notions of number and function, and to theories of algebraic form, serves only the purpose of deflecting them from their proper work into paths which lead nowhere. It is considered that mathematicians are apt to occupy themselves too exclusively with ideas too remote from the physical order in which Mathematics had its origin, and in which it should still find its proper applications. A direct answer to the question *cui bono?* when it is raised in respect of a department of study such as Pure Mathematics, seldom carries conviction, in default of a standard of values common to those who ask and to those who answer the question. To appreciate the importance of a sphere of mental activity different from our own always requires some effort of the sympathetic imagination, some recognition of the fact that the absolute value of interests and ideals of a particular class may be much greater than the value which our own mentality inclines us to attach to them. If a defence is needed of the expenditure of time and energy on the abstract problems of Pure Mathematics, that defence must be of a cumulative character. The fact that abstract mathematical thinking is one of the normal forms of activity of the human mind, a fact which the general history of thought fully establishes, will appeal to some minds as a ground of decisive weight. A great department of thought must have its own inner life, however transcendent may be the importance of its relations to the outside. No department of science, least of all one requiring so high a degree of mental concentration as Mathematics, can be developed entirely, or even mainly, with a view to applications outside its own range. The increased complexity and specialisation of all branches of knowledge makes it true in the present, however it may have been in former times, that important advances in such a department as Mathematics can be expected only from men who are interested in the subject for its own sake, and who, whilst keeping an open mind for suggestions from outside, allow their thought to range freely in those lines of advance which are indicated by the present state of their subject, untrammelled by any preoccupation as to applications to other departments of science. Even with a view to applications, if Mathematics is to be adequately equipped for the purpose of coping with the intricate problems which will be presented to it in the future by Physics, Chemistry, and other branches of physical science, many of these problems probably of a character which we cannot at present forecast, it is essential that Mathematics should be allowed to develop itself freely on its own lines. Even if much of our present mathematical theorising turns out to be useless for external purposes, it is wiser, for a well-known reason, to allow the wheat and the tares to grow together. It would be easy to establish in detail that many of the applications which have been actually made of Mathematics were wholly unforeseen by those who first developed the methods and ideas on which they rest. Recently, the more refined mathematical methods which have been applied to gravitational Astronomy by Delaunay, G. W. Hill, Poincaré, E. W. Brown, and others, have thrown much light on questions relating to the solar system, and have much increased the accuracy of our knowledge of the motions of the moon and the planets. Who knows what weapons forged by the theories of functions, of differential equations, or of groups, may be required when the time comes for such an empirical law as Mendeléeff's periodic law of the elements to receive its dynamical explanation by means of an analysis of the detailed possibilities of relatively stable types of motion, the general schematic character of which will have been indicated by the physicist? It is undoubtedly true that the cleft between Pure Mathematics and Physical Science is at the present time wider than formerly. That is, however, a result of the natural development, on their own lines, of both subjects. In the classical period of the eighteenth century, the time of Lagrange and Laplace, the nature of the physical investigations, consisting largely of the detailed working out of problems of gravitational Astronomy in accordance with Newton's law, was such that the passage was easy from the concrete problems to the corresponding abstract mathematical ones. Later on, mathematical physicists were much occupied with problems which lent themselves readily to treatment by means of continuous analysis. In our own time the effect of recent developments of Physics has been to present problems of molecular and sub-molecular Mechanics to which continuous analysis is not at least directly applicable, and can only be made applicable by a process of averaging the effects of great swarms of discrete entities. The speculative and incomplete character of our conceptions of the structure of the objects of investigation has made the applications of Dynamics to their detailed elucidation tentative and partial. The generalised dynamical scheme developed by Lagrange and Hamilton, with its power of dealing with systems, the detailed structure of which is partially unknown, has, however, proved a powerful weapon of attack, and affords a striking instance of the deep-rooted significance of mathematical form. The wonderful and perhaps unprecedentedly rapid discoveries in Physics which have been made in the last two decades have given rise to many questions which are as yet hardly sufficiently definite in form to be ripe for mathematical treatment, a necessary condition of which treatment consists in a certain kind of precision in the data of the problems to be solved.

The difficulty of obtaining an adequate notion of the general scope and aims of Mathematics, or even of special branches of it, is perhaps greater than in the case of any other science. Many persons, even such as have made a serious and prolonged study of the subject, feel the difficulty of seeing the wood for trees. The severe demands made upon students by the labour of acquiring a difficult technique largely accounts for this; but teachers might do much to facilitate the attainment of a wider outlook by directing the attention of their students to the more general and less technical aspects of the various parts of the subject, and especially by the introduction into the courses of instruction of more of the historical element than has hitherto been usual.

All attempts to characterise the domain of Mathematics by means of a formal definition which shall not only be complete, but which shall also rigidly mark off that domain from the adjacent provinces of Formal Logic on the one side and of Physical Science on the other side, are almost certain to meet with but doubtful success: such success as they may attain will probably be only transient, in view of the power which the science has always shown of constantly extending its borders in unforeseen directions. Such definitions, many of which have been advanced, are apt to err by excess or defect, and often contain distinct traces of the personal predilections of those who formulate them. There was a time when it would have been a tolerably sufficient description of Pure Mathematics to say that its subject-matter consisted of magnitude and geometrical form. Such a description of it would be wholly inadequate at the present day. Some of the most important branches of modern Mathematics, such as the theory of groups, and Universal Algebra, are concerned, in their abstract forms, neither with magnitude nor with number, nor with geometrical form. That great modern development, Projective Geometry, has been so formulated as to be independent of all metric considerations. Indeed, the tendency of mathematicians under the influence of the movement known as the Arithmetisation of Analysis, a movement which has become a dominant one in the last few decades, is to banish altogether the notion of measurable quantity as a conception necessary to Pure Mathematics, Number, in the extended meaning it has attained, taking its place. Measurement is regarded as one of the applications, but as no part of the basis, of mathematical analysis. Perhaps the least inadequate description of the general scope of modern Pure Mathematics—I will not call it a definition—would be to say that it deals with *form*, in a very general sense of the term; this would include algebraic form, geometrical form, functional relationship, the relations of order in any ordered set of entities such as numbers, and the analysis of the peculiarities of form of groups of operations. A strong tendency is manifested in many of the recent definitions to break down the line of demarcation which was formerly supposed to separate Mathematics from formal logic; the rise and development of symbolic logic has no doubt emphasised this tendency. Thus Mathematics has been described by the eminent American mathematician and logician B. Pierce as "the Science which draws necessary conclusions," a pretty complete identification of Mathematics with logical procedure in general. A definition which appears to identify all Mathematics with the Mengenlehre, or Theory of Aggregates, has been given by E. Papperitz: "The subject-matter of Pure Mathematics consists of the relations that can be established between any objects of thought when we regard those objects as contained in an ordered manifold; the law of order of this manifold must be subject to our choice." The form of definition which illustrates most strikingly the tendencies of the modern school of logistic is one given by Mr. Bertrand Russell. I reproduce it here, in order to show how wide is the chasm between the modes of expression of adherents of this school and those of mathematicians under the influence of the ordinary traditions of the science. Mr. Russell writes:[1] "Pure Mathematics is the class of all propositions of the form 'p implies q,' where p and q are propositions containing one or more variables, the same in the two propositions, and neither p nor q contains any constants except logical constants. And logical constants are all notions definable in terms of the following: Implication, the relation of a term to a class of which it is a member, the notion of *such that*, the notion of relation, and such further notions as may be involved in the general notion of propositions of the above form. In addition to these, Mathematics *uses* a notion which is not a constituent of the propositions which it considers—namely, the notion of truth."

The belief is very general amongst instructed persons that the truths of Mathematics have absolute certainty, or at least that there appertains to them the highest degree of certainty of which the human mind is capable. It is thought that a valid mathematical theorem is necessarily of such a character as to compel belief in any mind capable of following the steps of the demonstration. Any considerations tending to weaken this belief would be disconcerting, and would cause some degree of astonishment. At the risk of this, I must here mention two facts which are of considerable importance as regards an estimation of the precise character of mathematical knowledge. In the first place, it is a fact that frequently, and at various times, differences of opinion have existed among mathematicians, giving rise to controversies as to the validity of whole lines of reasoning, and affecting the results of such reasoning; a considerable amount of difference of opinion of this character exists among mathematicians at the present time. In the second place, the accepted standard of rigour, that is, the standard of what is deemed necessary to constitute a valid demonstration, has undergone change in the course of time. Much of the reasoning which was formerly regarded as satisfactory and irrefutable is now regarded as insufficient to establish the results which it was employed to demonstrate. It has even been shown that results which were once supposed to have been fully established by demonstrations are, in point of fact, affected with error. I propose here to explain in general terms how these phenomena are possible.

In every subject of study, if one probes deep enough, there are found to be points in which that subject comes in contact with general philosophy, and where differences of philosophical view will have a greater or less influence on the attitude of the mind towards the principles of the particular subject. This is not surprising when we reflect that there is but one universe of thought, that no department of knowledge can be absolutely isolated, and that metaphysical and psychological implications are a necessary element in all the activities of the mind. A particular department, such as Mathematics, is compelled to set up a more or less artificial frontier, which marks it off from general philosophy. This frontier consists of a set of regulative ideas in the form of indefinables and axioms, partly ontological assumptions, and partly postulations of a logical character. To go behind these, to attempt to analyse their nature and origin, and to justify their validity, is to go outside the special department and to touch on the domains of the metaphysician and the psychologist. Whether they are regarded as possessing apodictic certainty or as purely hypothetical in character, these ideas represent the data or premises of the science, and the whole of its edifice is dependent upon them. They serve as the foundation on which all is built, as well as the frontier on the side of philosophy and psychology. A set of data ideally perfect in respect of precision and permanence is unattainable—or at least has not yet been attained; and the adjustment of frontiers is one of the most frequent causes of strife. As a matter of fact, variations of opinion have at various times arisen within the ranks of the mathematicians as to the nature, scope, and proper formulation of the principles which form the foundations of the science, and the views of mathematicians in this regard have always necessarily been largely affected by the conscious or unconscious attitude of particular minds towards questions of general philosophy. It is in this region, I think, that the source is to be found of those remarkable differences of opinion amongst mathematicians which have come into prominence at various times, and have given rise to much controversy as to fundamentals. Since the time of Newton and Leibnitz there has been almost unceasing discussion as to the proper foundations for the so-called infinitesimal calculus. More recently, questions relating to the foundations of geometry and rational mechanics have much occupied the attention of mathematicians. The very great change which has taken place during the last half-century in the dominant view of the foundations of mathematical analysis—a change which has exercised a great influence extending through the whole detailed treatment of that subject—although critical in its origin, has been constructive in its results. The Mengenlehre, or theory of aggregates, had its origin in the critical study of the foundations of analysis, but has already become a great constructive scheme, is indispensable as a method in the investigations of analysis, provides the language requisite for the statement in precise form of analytical theorems of a general character, and, moreover, has already found important applications in geometry. In connection with the Mengenlehre, there has arisen a controversy amongst mathematicians which is at the present time far from having reached a decisive issue. The exact point at issue is one which may be described as a matter of mathematical ontology; it turns upon the question of

[1] "Principles of Mathematics," p. 1.

what constitutes a valid definition of a mathematical object. The school known as mathematical "idealists" admit, as valid objects of mathematical discussion, entities which the rival "empiricist" school regard as non-existent for mathematical thought, because insufficiently defined. It is clear that the idealist may build whole superstructures on a foundation which the empiricist regards as made of sand, and this is what has actually happened in some of the recent developments of what has come to be known as Cantorism. The difference of view of these rival schools, depending as it does on deep-seated differences of philosophical outlook, is thought by some to be essentially irreconcilable. This controversy was due to the fact that certain processes of reasoning, of very considerable plausibility, which had been employed by G. Cantor, the founder of the Mengenlehre, had led to results which contained flat contradictions. The efforts made to remove these contradictions, and to trace their source, led to the discussion, disclosing much difference of opinion, of the proper definitions and principles on which the subject should be based.

The proposition $7+5=12$, taken as typical of the propositions expressing the results of the elementary operations of arithmetic, has since the time of Kant given rise to very voluminous discussion amongst philosophers in relation to the precise meaning and implication of the operation and the terms. It will, however, be maintained, probably by the majority of mankind, that the theorem retains its validity as stating a practically certain and useful fact, whatever view philosophers may choose to take of its precise nature—as, for example, whether it represents, in the language of Kant, a synthetic or an analytic judgment. It may, I think, be admitted that there is much cogency in this view; and, were Mathematics concerned with the elementary operations of arithmetic alone, it could fairly be held that the mathematician, like the practical man of the world, might without much risk shut his eyes and ears to the discussions of the philosophers on such points. The exactitude of such a proposition, in a sufficiently definite sense for practical purposes, is empirically verifiable by sensuous intuition, whatever meaning the metaphysician may attach to it. But Mathematics cannot be built up from the operations of elementary arithmetic without the introduction of further conceptual elements. Except in certain very simple cases, no process of measurement, such as the determination of an area or a volume, can be carried out with exactitude by a finite number of applications of the operations of arithmetic. The result to be obtained appears in the form of a limit, corresponding to an interminable sequence of arithmetical operations. The notion of "limit," in the definite form given to it by Cauchy and his followers, together with the closely related theory of the arithmetic continuum, and the notions of continuity and functionality, lie at the very heart of modern analysis. Essentially bound up with this central doctrine of limits is the concept of a non-finite set of entities, a concept which is not directly derivable from sensuous intuition, but which is, nevertheless, a necessary postulation in mathematical analysis. The conception of the infinite, in some form, is thus indispensable in Mathematics; and this conception requires precise characterisation by a scheme of exact definitions, prior to all the processes of deduction required in obtaining the detailed results of analysis. The formulation of this precise scheme gives an opening to differences of philosophical opinion which has led to a variety of views as to the proper character of those definitions which involve the concept of the infinite. Here is the point of divergence of opinion among mathematicians to which I have alluded above. Under what conditions is a non-finite aggregate of entities a properly defined object of mathematical thought, of such a character that no contradictions will arise in the theories based upon it? That is the question to which varying answers have been offered by different mathematical thinkers. No one answer of a completely general character has as yet met with universal acceptance. Physical intuition offers no answer to such a question; it is one which abstract thought alone can settle. It cannot be altogether avoided, because, without the notion of the infinite, at least in connection with the central conception of the "limit," mathematical analysis as a coherent body of thought falls to the ground.

Both in geometry and in analysis our standard of what constitutes a rigorous demonstration has in the course of the nineteenth century undergone an almost revolutionary change. That oldest text-book of science in the world, "Euclid's Elements of Geometry," has been popularly held for centuries to be the very model of deductive logical demonstration. Criticism has, however, largely invalidated this view. It appears that, at a large number of points, assumptions not included in the preliminary axioms and postulates are made use of. The fact that these assumptions usually escape notice is due to their nature and origin. Derived as they are from our spatial intuition, their very self-evidence has allowed them to be ignored, although their truth is not more obvious empirically than that of other assumptions derived from the same source which are included in the axioms and postulates explicitly stated as part of the foundation of Euclid's treatment of the subject. The method of superimposition, employed by Euclid with obvious reluctance, but forming an essential part of his treatment of geometry, is, when regarded from his point of view, open to most serious objections as regards its logical coherence. In analysis, as in geometry, the older methods of treatment consisted of processes of deduction eked out by the more or less surreptitious introduction, at numerous points in the subject, of assumptions only justifiable by spatial intuition. The result of this deviation from the purely deductive method was more disastrous in the case of analysis than in geometry, because it led to much actual error in the theory. For example, it was held until comparatively recently that a continuous function necessarily possesses a differential coefficient, on the ground that a curve always has a tangent. This we now know to be quite erroneous, when any reasonable definition of continuity is employed. The first step in the discovery of this error was made when it occurred to Ampère that the existence of the differential coefficient could only be asserted as a theorem requiring proof, and he himself published an attempt at such proof. The erroneous character of the former belief on this matter was most strikingly exhibited when Weierstrass produced a function which is everywhere continuous, but which nowhere possesses a differential coefficient; such functions can now be constructed *ad libitum*. It is not too much to say that no one of the general theorems of analysis is true without the introduction of limitations and conditions which were entirely unknown to the discoverers of those theorems. It has been the task of mathematicians under the lead of such men as Cauchy, Riemann, Weierstrass, and G. Cantor, to carry out the work of reconstruction of mathematical analysis, to render explicit all the limitations of the truth of the general theorems, and to lay down the conditions of validity of the ordinary analytical operations. Physicists and others often maintain that this modern extreme precision amounts to an unnecessary and pedantic purism, because in all practical applications of Mathematics only such functions are of importance as exclude the remoter possibilities contemplated by theorists. Such objections leave the true mathematician unmoved; to him it is an intolerable defect that, in an order of ideas in which absolute exactitude is the guiding ideal, statements should be made and processes employed, both of which are subject to unexpressed qualifications, as conditions of their truth or validity. The pure mathematician has developed a specialised conscience, extremely sensitive as regards sins against logical precision. The physicist, with his conscience hardened in this respect by the rough-and-tumble work of investigating the physical world, is apt to regard the more tender organ of the mathematician with that feeling of impatience, not unmingled with contempt, which the man of the world manifests for what he considers to be over-scrupulosity and unpracticality.

It is true that we cannot conceive how such a science as Mathematics could have come into existence apart from physical experience. But it is also true that physical precepts, as given directly in unanalysed experience, are wholly unfitted to form the basis of an exact science. Moreover, physical intuition fails altogether to afford any trustworthy guidance in connection with the concept of the infinite, which, as we have seen, is in some form indispensable in the formation of a coherent system of mathematical analysis. The hasty and uncritical extension to the region of the infinite, of results which are true and often obvious in the region of the finite, has been a fruitful source of error in the past, and remains as a pitfall for the unwary student in the present. The notions derived from physical intuition must be transformed into a scheme of exact definitions and axioms before they are available for the mathematician, the necessary precision being contributed by the mind itself. A very remarkable fact in connection with this process of refinement of the rough data of experience is that it contains an element of arbitrariness, so that the result of the process is not necessarily unique. The most striking example of this want of uniqueness in the conceptual scheme so obtained is the case of geometry, in which it has been shown to be possible to set up various sets of axioms, each set self-consistent, but inconsistent with any other of the sets, and yet such that each set of axioms, at least under suitable limitations, leads to results consistent with our perception of actual space-relations. Allusion is here made, in particular, to the well-known geometries of Lobatchewsky and of Riemann, which differ from the geometry of Euclid in respect of the axiom of parallels, in place of which axioms inconsistent with that of Euclid and with one another are substituted. It is a matter of demonstration that any inconsistency which might be supposed to exist in the scheme known as hyperbolic geometry, or in that known as elliptic geometry, would necessarily entail the existence of a corresponding inconsistency in Euclid's set of axioms. The three geometries therefore, from the logical point of view, are completely on a par with one another. An interesting mathematical result is that all efforts to prove Euclid's axiom of parallels, *i.e.* to deduce it from his other axioms, are doomed to necessary failure; this is of importance in view of the many efforts that have been made to obtain the proof referred to. When the question is raised which of these geometries is the true one, the kind of answer that will be given depends a good deal on the view taken of the relation of conceptual schemes in general to actual experience. It is maintained by M. Poincaré, for example, that the question which is the true scheme has no meaning; that it is, in fact, entirely a matter of convention and convenience which of these geometries is actually employed in connection with spatial measurements. To decide between them by a crucial test is impossible, because our space perceptions are not sufficiently exact in the mathematical sense to enable us to decide between the various axioms of parallels. Whatever views are taken as to the difficult questions that arise in this connection, the contemplation and study of schemes of geometry wider than that of Euclid, and some of them including Euclid's geometry as a special case, is of great interest, not only from the purely mathematical point of view, but also in relation to the general theory of knowledge, in that, owing to the results of this study, some change is necessitated in the views which have been held by philosophers as to what is known as Kant's space-problem.

The school of thought which has most emphasised the purely logical aspect of Mathematics is that which is represented in this country by Mr. Bertrand Russell and Dr. Whitehead, and which has distinguished adherents both in Europe and in America. The ideal of this school is a presentation of the whole of Mathematics as a deductive scheme in which are employed a certain limited number of indefinables and unprovable axioms, by means of a procedure in which all possibility of the illicit intrusion of extraneous elements into the deduction is excluded by the employment of a symbolism in which each symbol expresses a certain logical relation. This school receives its inspiration from a peculiar form of philosophic realism which, in its revolt from idealism, produces in the adherents of the school a strong tendency to ignore altogether the psychological implications in the movements of mathematical thought. This is carried so far that in their writings no explicit recognition is made of any psychological factors in the selection of the indefinables and in the formulation of the axioms upon which the whole structure of Mathematics is to be based. The actually worked-out part of their scheme has as yet reached only the mere fringe of modern Mathematics as a great detailed body of doctrine; but to any objection to the method on the ground of the prolixity of the treatment which would be necessary to carry it out far enough to enable it to embrace the various branches of Mathematics in all the wealth of their present development, it would probably be replied that the main point of interest is to establish in principle the possibility only of subsuming Pure Mathematics under a scheme of logistic. It is quite impossible for me here to attempt to discuss, even in outline, the tenets of this school, or even to deal with the interesting question of the possibility of setting up a final system of definables and axioms which shall suffice for all present and future developments of Mathematics.

I am very far from wishing to minimise the high philosophic interest of the attempt made by the Peano-Russell school to exhibit Mathematics as a scheme of deductive logic. I have myself emphasised above the necessity and importance of fitting the results of mathematical research in their final form into a framework of deduction for the purpose of ensuring the complete precision and the verification of the various mathematical theories. At the same time, it must be recognised that the purely deductive method is wholly inadequate as an instrument of research. Whatever view may be held as regards the place of psychological implications in a completed body of mathematical doctrine, in research the psychological factor is of paramount importance. The slightest acquaintance with the history of Mathematics establishes the fact that discoveries have seldom, or never, been made by purely deductive processes. The results are thrown into a purely deductive form after, and often long after, their discovery. In many cases the purely deductive form, in the full sense, is quite modern. The possession of a body of indefinables, axioms, or postulates, and symbols denoting logical relation, would, taken by itself, be wholly insufficient for the development of a mathematical theory. With these alone the mathematician would be unable to move a step. In face of an unlimited number of possible combinations, a principle of selection of such as are of interest, a purposive element, and a perceptive faculty are essential for the development of anything new. In the process of discovery, the chains in a sequence of logical deduction do not at first arise in their final order in the mind of the mathematical discoverer. He divines the results before they are established; he has an intuitive grasp of the general line of a demonstration long before he has filled in the details. A developed theory, or even a demonstration of a single theorem, is no more identical with a mere complex of syllogisms than a melody is identical with the mere sum of the musical notes employed in its composition. In each case the whole is something more than merely the sum of its parts; it has a unity of its own, and that unity must be, in some measure at least, discerned by its creator before the parts fall completely into their places. Logic is, so to speak, the grammar of Mathematics; but a knowledge of the rules of grammar and the letters of the alphabet would not be sufficient equipment to enable a man to write a book. There is much room for individuality in the modes of mathematical discovery. Some great mathematicians have employed largely images derived from spatial intuition as a guide to their results; others appear wholly to have discarded such aids, and were led by a fine feeling for algebraic and other species of mathematical form. A certain tentative process is common, in which, by the aid of results known or obtained in special cases, generalisations are perceived and afterwards established, which take up into themselves all the special cases so employed. Most mathematicians leave some traces, in the final presentation of their work, of the scaffolding they have employed in building their edifices, some much more than others.

The difference between a mathematical theory in the making and as a finished product is, perhaps, most strikingly illustrated by the case of geometry, as presented in its most approved modern shape. It is not too much to say that geometry, reduced to a purely deductive form—as presented, for example, by Hilbert, or by some of the modern Italian school—has no necessary connection with space. The words "point," "line," "plane" are employed to denote any entities whatever which satisfy certain prescribed conditions of relationship. Various premises are postulated that would appear to be of a perfectly arbitrary nature, if we did not know how they had been suggested. In that division of the subject known as metric geometry, for example, axioms of congruency are assumed which, by their purely abstract character, avoid the very real difficulties that arise in this regard in reducing perceptual space-relations of measurements to a purely conceptual form. Such schemes, triumphs of constructive thought at its highest and most abstract level as they are, could never have been constructed apart from the space-perceptions that suggested them, although the concepts of spatial origin are transformed almost out of recognition. But what I want to direct attention to here is that, apart from the basis of this geometry, mathematicians would never have been able to find their way through the details of the deductions without having continual recourse to the guidance given them by spatial intuition. If one attempts to follow one of the demonstrations of a particular theorem in the work of writers of this school, one would find it quite impossible to retain the steps of the process long enough to master the whole, without the aid of the very spatial suggestions which have been abstracted. This is perhaps sufficiently warranted by the fact that writers of this school find it necessary to provide their readers with figures, in order to avoid complete bewilderment in following the demonstrations, although the processes, being purely logical deductions from premises of the nature I have described, deal only with entities which have no necessary similarity to anything indicated by the figures.

A most interesting account has been written by one of the greatest mathematicians of our time, M. Henri Poincaré, of the way in which he was led to some of his most important mathematical discoveries.[1] He describes the process of discovery as consisting of three stages: the first of these consists of a long effort of concentrated attention upon the problem in hand in all its bearings; during the second stage he is not consciously occupied with the subject at all, but at some quite unexpected moment the central idea which enables him to surmount the difficulties, the nature of which he had made clear to himself during the first stage, flashes suddenly into his consciousness. The third stage consists of the work of carrying out in detail and reducing to a connected form the results to which he is led by the light of his central idea; this stage, like the first, is one requiring conscious effort. This is, I think, clearly not a description of a purely deductive process; it is assuredly more interesting to the psychologist than to the logician. We have here the account of a complex of mental processes in which it is certain that the reduction to a scheme of precise logical deduction is the latest stage. After all, a mathematician is a human being, not a logic-engine. Who that has studied the works of such men as Euler, Lagrange, Cauchy, Riemann, Sophus Lie, and Weierstrass, can doubt that a great mathematician is a great artist? The faculties possessed by such men, varying greatly in kind and degree with the individual, are analogous to those requisite for constructive art. Not every great mathematician possesses in a specially high degree that critical faculty which finds its employment in the perfection of form, in conformity with the ideal of logical completeness; but every great mathematician possesses the rarer faculty of constructive imagination.

The actual evolution of mathematical theories proceeds by a process of induction strictly analogous to the method of induction employed in building up the physical sciences; observation, comparison, classification, trial, and generalisation are essential in both cases. Not only are special results, obtained independently of one another, frequently seen to be really included in some generalisation, but branches of the subject which have been developed quite independently of one another are sometimes found to have connections which enable them to be synthesised in one single body of doctrine. The essential nature of mathematical thought manifests itself in the discernment of fundamental identity in the mathematical aspects of what are superficially very different domains. A striking example of this species of immanent identity of mathematical form was exhibited by the discovery of that distinguished mathematician, our General Secretary, Major Macmahon, that all possible Latin squares are capable of enumeration by the consideration of certain differential operators. Here we have a case in which an enumeration, which appears to be not amenable to direct treatment, can actually be carried out in a simple manner when the underlying identity of the operation is recognised with that involved in certain operations due to differential operators, the calculus of which belongs superficially to a wholly different region of thought from that relating to Latin squares. The modern abstract theory of groups affords a very important illustration of this point; all sets of operations, whatever be their concrete character, which have the same group, are from the point of view of the abstract theory identical, and an analysis of the properties of the abstract group gives results which are applicable to all the actual sets of operations, however diverse their character, which are dominated by the one group. The characteristic feature of any special geometrical scheme is known when the group of transformations which leave unaltered certain relations of figures has been assigned. Two schemes in which the space elements may be quite different have this fundamental identity, provided they have the same group; every special theorem is then capable of interpretation as a property of figures either in the one or in the other geometry. The mathematical physicist is familiar with the fact that a single mathematical theory is often capable of interpretation in relation to a variety of physical phenomena. In some instances a mathematical formulation, as in some fashion representing observed facts, has survived the physical theory it was originally devised to represent. In the case of electromagnetic and optical theory, there appears to be reason for trusting the equations, even when the proper physical interpretation of some of the vectors appearing in them is a matter of uncertainty and gives rise to much difference of opinion; another instance of the fundamental nature of mathematical form.

One of the most general mathematical conceptions is that of functional relationship, or "functionality." Starting originally from simple cases such as a function represented by a power of a variable, this conception has, under the pressure of the needs of expanding mathematical theories, gradually attained the completeness of generality which it possesses at the present time. The opinion appears to be gaining ground that this very general conception of functionality, born on mathematical ground, is destined to supersede the narrower notion of causation, traditional in connection with the natural sciences. As an abstract formulation of the idea of determination in its most general sense, the notion of functionality includes and transcends the more special notion of causation as a one-sided determination of future phenomena by means of present conditions; it can be used to express the fact of the subsumption under a general law of past, present, and future alike, in a sequence of phenomena. From this point of view the remark of Huxley that Mathematics "knows nothing of causation" could only be taken to express the whole truth, if by the term "causation" is understood "efficient causation." The latter notion has, however, in recent times been to an increasing extent regarded as just as irrelevant in the natural sciences as it is in Mathematics; the idea of thorough-going determinancy, in accordance with formal law, being thought to be alone significant in either domain.

The observations I have made in the present address have, in the main, had reference to Mathematics as a living and growing science related to and permeating other great departments of knowledge. The small remaining space at my disposal I propose to devote to a few words about some matters connected with the teaching of the more elementary parts of Mathematics. Of late years a new spirit has come over the mathematical teaching in many of our institutions, due in no small measure to the reforming zeal of our General Treasurer, Prof. John Perry. The changes that have been made followed a recognition of the fact that the abstract mode of treatment of the subject that had been traditional was not only wholly unsuitable as a training for physicists and engineers, but was also to a large extent a failure in relation to general education, because it neglected to bring out clearly the bearing of the subject on the concrete side of things. With the general principle that a much less abstract mode of treatment than was

[1] See the "Revue du Mois," 1908.

formerly customary is desirable for a variety of reasons, I am in complete accord. It is a sound educational principle that instruction should begin with the concrete side, and should only gradually introduce the more general and abstract aspects of the subject; an abstract treatment on a purely logical basis being reserved only for that highest and latest stage which will be reached only by a small minority of students. At the same time I think there are some serious dangers connected with the movement towards making the teaching of Mathematics more practical than formerly, and I do not think that, in making the recent changes in the modes of teaching, these dangers have always been successfully avoided.

Geometry and mechanics are both subjects with two sides: on the one side, the observational, they are physical sciences; on the other side, the abstract and deductive, they are branches of Pure Mathematics. The older traditional treatment of these subjects has been of a mixed character, in which deduction and induction occurred side by side throughout, but far too much stress was laid upon the deductive side, especially in the earlier stages of instruction. It is the proportion of the two elements in the mixture that has been altered by the changed methods of instruction of the newer school of teachers. In the earliest teaching of the subjects they should, I believe, be treated wholly as observational studies. At a later stage a mixed treatment must be employed, observation and deduction going hand in hand, more stress being, however, laid on the observational side than was formerly customary. This mixed treatment leaves much opening for variety of method; its character must depend to a large extent on the age and general mental development of the pupils; it should allow free scope for the individual methods of various teachers as suggested to those teachers by experience. Attempts to fix too rigidly any particular order of treatment of these subjects are much to be deprecated, and, unfortunately, such attempts are now being made. To have escaped from the thraldom of Euclid will avail little if the study of geometry in all the schools is to fall under the domination of some other rigidly prescribed scheme.

There are at the present time some signs of reaction against the recent movement of reform in the teaching of geometry. It is found that the lack of a regular order in the sequence of propositions increases the difficulty of the examiner in appraising the performance of the candidates, and in standardising the results of examinations. That this is true may well be believed, and it was indeed foreseen by many of those who took part in bringing about the dethronement of Euclid as a text-book. From the point of view of the examiner it is without doubt an enormous simplification if all the students have learned the subject in the same order, and have studied the same text-book. but, admitting this fact, ought decisive weight to be allowed to it? I am decidedly of opinion that it ought not. I think the convenience of the examiner, and even precision in the results of examinations, ought unhesitatingly to be sacrificed when they are in conflict—as I believe they are in this case—with the vastly more important interests of education. Of the many evils which our examination system has inflicted upon us, the central one has consisted in forcing our school and university teaching into moulds determined not by the true interests of education, but by the mechanical exigencies of the examination syllabus. The examiner has thus exercised a potent influence in discouraging initiative and individuality of method on the part of the teacher; he has robbed the teacher of that freedom which is essential for any high degree of efficiency. An objection of a different character to the newer modes of teaching geometry has been frequently made of late. It is said that the students are induced to accept and reproduce, as proofs of theorems, arguments which are not really proofs, and thus that the logical training which should be imparted by a study of geometry is vitiated. If this objection really implies a demand for a purely deductive treatment of the subject, I think some of those who raise it hardly realise all that would be involved in the complete satisfaction of their requirement. I have already remarked that Euclid's treatment of the subject is not rigorous as regards logic. Owing to the recent exploration of the foundations of geometry we possess at the present time tolerably satisfactory methods of purely deductive treatment of the subject; in regard to mechanics, notwithstanding the valuable work of Mach, Herz, and others, this is not yet the case. But, in the schemes of purely deductive geometry, the systems of axioms and postulates are far from being of a very simple character; their real nature, and the necessity for many of them, can only be appreciated at a much later stage in mathematical education than the one of which I am speaking. A purely logical treatment is the highest stage in the training of the mathematician, and is wholly unsuitable—and, indeed, quite impossible—in those stages beyond which the great majority of students never pass. It can then, in the case of all students, except a few advanced ones in the universities, only be a question of degree how far the purely logical factor in the proofs of propositions shall be modified by the introduction of elements derived from observation or spatial intuition. If the freedom of teaching which I have advocated be allowed, it will be open to those teachers who find it advisable in the interests of their students to emphasise the logical side of their teaching to do so; and it is certainly of value in all cases to direct the attention of students to those points in a proof where the intuitional element enters. I draw, then, the conclusion that a mixed treatment of geometry, as of mechanics, must prevail in the future, as it has done in the past, but that the proportion of the observational or intuitional factor to the logical one must vary in accordance with the needs and intellectual attainments of the students, and that a large measure of freedom of judgment in this regard should be left to the teacher.

The great and increasing importance of a knowledge of the differential and integral calculus for students of engineering and other branches of physical science has led to the publication during the last few years of a considerable number of text-books on this subject intended for the use of such students. Some of these text-books are excellent, and their authors, by a skilful insistence on the principles of the subject, have done their utmost to guard against the very real dangers which attend attempts to adapt such a subject to the practical needs of engineers and others. It is quite true that a great mass of detail which has gradually come to form part—often much too large a part—of the material of the student of Mathematics, may with great advantage be ignored by those whose main study is to be engineering science or physics. Yet it cannot be too strongly insisted on that a firm grasp of the principles, as distinct from the mere processes of calculation, is essential if Mathematics is to be a tool really useful to the engineer and the physicist. There is a danger, which experience has shown to be only too real, that such students may learn to regard Mathematics as consisting merely of formulæ and of rules which provide the means of performing the numerical computations necessary for solving certain categories of problems which occur in the practical sciences. Apart from the deplorable effect, on the educational side, of degrading Mathematics to this level, the practical effect of reducing it to a number of rule-of-thumb processes can only be to make those who learn it in so unintelligent a manner incapable of applying mathematical methods to any practical problem in which the data differ even slightly from those in the model problems which they have studied. Only a firm grasp of the principles will give the necessary freedom in handling the methods of Mathematics required for the various practical problems in the solution of which they are essential.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A MERCHANT VENTURERS' research scholarship of the value of 50*l*., tenable for one year in the faculty of engineering of the University of Bristol, which is provided and maintained in the Merchant Venturers' Technical College, has been awarded to Mr. Harold Heaton Emsley.

The Child, a new monthly journal devoted to child welfare, will appear in the early autumn, under the general editorship of Dr. T. N. Kelynack. The journal will be suited to the requirements of all engaged in child study or working for the betterment of child life. The publishers will be Messrs. John Bale, Sons and Danielsson, Ltd., 83–91 Great Titchfield Street, Oxford Street, London, W.

THE governing body of the Battersea Polytechnic is arranging considerable developments for next session in the work of the Domestic Economy Department of the Battersea Polytechnic. An entirely new third-year course will be introduced. This course will carry forward greatly the application of science to housecraft. It will consist, in the main, of much more elaborate work both on the theoretical and practical sides in the subjects of physiology, hygiene, chemistry, physics, and biology. It is intended that special attention shall be given to the carrying forward on the scientific side of the processes which underlie the arts of cookery, laundrywork, and housewifery. It is intended, too, that students shall spend some of their time in practical research work upon the various biological and chemical processes in which so much of their work will be done.

THE report of the Hebdomadal Council of Oxford University, entitled "Principles and Methods of University Reform," has been published by the Clarendon Press. Lord Curzon of Kedleston, Chancellor of the University, contributes an introduction on behalf of the council. We hope later to deal with the important proposals contained in the report, but attention may here be directed to the question of compulsory Greek and the suggested entrance examination. The council proposes that Greek shall be no longer a compulsory subject, but that every candidate must, in order to pass Responsions, satisfy the masters of the schools in Latin and in elementary mathematics, and also either in (*a*) Greek or in (*b*) two other subjects, one, and only one, of which must be a modern language. The optional subjects include, besides modern languages, English history, elementary politics, elementary trigonometry, statics and dynamics, elementary physics and chemistry, and the general principles of geography and the geography of the British Isles and Empire. The proposal to make Greek an optional subject is, says Lord Curzon in his introduction, based "mainly on the fact that the non-Greek curriculum is now firmly established, not only in the secondary schools receiving grants from Government, but also, as an alternative course taken by many boys, in the older public schools, which supply a large proportion of the students of the University." The question of compulsory Greek has been purposely separated from that of an entrance examination. The scheme for an entrance examination framed by the council is as follows:—There will be, in substitution for Responsions, an entrance examination, conducted on behalf of the University by the Delegates for the Inspection and Examination of Schools. This examination will include three necessary subjects and optional subjects. In order to pass, a candidate must qualify in the three necessary subjects at one and the same time, and must also pass in two of the optional subjects, either when he passes in the necessary subjects or at some other time. The necessary subjects will be English, to be tested by an essay or a composition on materials supplied, *e.g.* précis or reproduction of a passage read aloud; Latin or Greek; elementary mathematics; two papers, (*a*) arithmetic and algebra, (*b*) geometry. The optional subjects will be practically the same as those suggested for Responsions. Referring to the entrance examination, Lord Curzon points out that, in adopting the view that school studies should be excluded from the curriculum of the University, and that all matriculated students should be required to have received a minimum standard of general education, the council believes the University will be acting in its best interests by helping to maintain a proper standard in the schools which prepare for it.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 22.—M. Emile Picard in the chair.—The president announced the death of M. Eugène Rouché.—Paul **Sabatier** and A. **Mailhe**: The catalytic preparation of the phenolic oxides and the diphenylenic oxides. The authors have applied the catalytic properties of thoria to the preparation of phenyl ether and its homologues. The thoria is maintained at a temperature of between 390° C. and 450° C., and the vapour of the phenol passed over it. The yield is good; but if the temperature is raised another reaction, characterised by the elimination of hydrogen, takes place, the oxide of diphenylene being formed. The reaction applies to the cresols and xylenols.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the second quarter of 1910. Observations were possible on fifty-four days, and the results are recorded in tables showing the number of spots, the distribution of the spots in latitude, and the distribution of the faculæ in latitude.—M. **Schaumasse**: Observations of the Metcalf comet made at the Observatory of Nice with the bent equatorial of 40-cm. aperture. The comet appears as a nebulosity of the tenth magnitude, with a well-marked condensation.—Michel **Fekete**: A theorem of M. Landau.—C. **Maltézos**: The real image of Purkinje.—L. **Fondard** and F. **Gauthié**: The composition of carnations with flexible stems and rigid stems. Three American varieties of carnation with rigid stems, and one French variety with flexible stems, have been analysed, and the differences in the stiffness of the stems found to be accompanied with distinct differences in composition.—Ed. **Hesse**: *Trypanoplasma vaginalis*, a new species found as a parasite in the vagina of the leech.—E. **Roubaud**: A Bombex preying on the Glossina of Dahomey. This wasp is one of the very small number of species known to capture the mosquito.

CALCUTTA.

Asiatic Society of Bengal, August 3.—Manindra Nath **Banerjee**: A system of Indian scientific vocabulary. This paper attempts to give Sanskrit equivalents for a number of European scientific terms, mostly on the basis of phonetic resemblance. With the help of dictionaries and grammars, the Sanskrit words are made to yield the meanings warranted by their European originals.—Panchanan **Neogi** and Birendra Bhusan **Adhikary**: The preparation of phenyl-nitro-methane by the interaction of mercurous nitrite and benzyl chloride. The present work is in continuation of Rây and Neogi's work on the preparation of aliphatic nitro-compounds by the interaction of mercurous nitrite and alkyliodides. The authors have prepared phenyl nitrite and alkyliodides.—D. **Hooper**: Materia Medica Animalium Indica. A classified list of substances of the animal kingdom used in Indian medicine, with notes on their origin, history, uses, and chemical composition. The list is compiled from several works on Indian materia medica, with original observations of the author.

THURSDAY, SEPTEMBER 8, 1910.

ORE DEPOSITS.

(1) *The Ore Deposits of South Africa.* By J. P. Johnson. Part ii., The Witwatersrand and Pilgrims' Rest Goldfields and Similar Occurrences. Pp. vi + 51. (London: Crosby Lockwood and Son, 1909.) Price 5*s.* net.

(2) *The Geology of Ore Deposits.* By H. H. Thomas and D. A. MacAlister. Pp. xi + 416. (London: E. Arnold, 1909.) Price 7*s.* 6*d.* net.

(1) THE second part of Mr. Johnson's "Ore Deposits of South Africa," of which the first part was reviewed in NATURE, June 3, 1909, vol. lxxx., p. 395, deals with the goldfields of the Transvaal. The book is intended for the use of prospectors and students, and consists of brief descriptions of each mining field and of short discussions of the genesis of the ores. It is illustrated with sections of the mines, and outline maps of which the shading is not always clearly explained. The author gives an excellent summary of the arguments for the placer and impregnation theories of the origin of the Rand ores, and says that "judging them on their own evidence the writer would unhesitatingly class them as detrital ore deposits" (p. 17). He suspends judgment, however, from the consideration that the gold at Pilgrims' Rest is due to impregnation. The ores at Pilgrims' Rest are quartz stringers in dolomite and altered dolomite; and they are doubtless of the same origin as those in the dolomites of South Dakota, which are strikingly different in all essential characters from the banket of the Rand. Mr. Johnson's remark that the analogy between the ores of Pilgrims' Rest and of the Rand is the strongest argument in favour of the impregnation theory for the banket is not complimentary to the other arguments. The most useful parts of the book are the chapters on the less-known secondary goldfields of the Transvaal.

(2) Messrs. Thomas and MacAlister's "Geology of Ore Deposits" agrees with Mr. Johnson's book in the conciseness with which it summarises the structures of various mining fields. It is, however, world-wide in its range. It should prove of great service as a text-book to students of economic geology who desire a clear statement of current theories. As the authors, in 416 small pages, state the principles of ore formation and explain them by reference to occurrences in nearly every mining country, the work necessarily suffers by extreme compression. There are no references to authorities, and, owing to their absence, the reader is sometimes left in doubt whether evidence opposed to the authors' conclusions has been weighed and rejected or has escaped their diligent search. An omission that might have been avoided is an index of localities. The same mining field may be referred to in different chapters, and so many mining localities are mentioned that a geographical index would have added greatly to the usefulness of the book as a work of preliminary reference. Some statistics of ore yields would also have been an advantage as showing the relative importance of the different processes of mineral deposition; the authors mention some insignificant ore occurrences which are of no economic importance, and some of which have not been worked, and inferences drawn from them as to the origin of the larger ore masses may be invalid. Owing to the wide range of the book it is not surprising that it contains small mistakes, both geological and geographical, in reference to foreign mining fields.

The classification of ores adopted by the authorities is based solely on genetic grounds. They describe first the ores due to the segregation of metals in igneous rocks, a process to which the authors perhaps attach undue importance, judged by the economic value of the ores thus produced. In succeeding chapters they describe ores due to pneumatolysis, to the action of heated solutions resulting from igneous intrusions, to metasomatic replacement, to metamorphism, to precipitation, and to the deposition of detritus. A special chapter describes the changes in ore deposits apart from those included under metamorphism. The authors show remarkably wide acquaintance with the literature of ore deposits and a sound and cautious judgment. They accept the detrital origin of the gold in the Rand Banket, and reject the view that nuggets are formed by deposition from solution in the drifts wherein they are found. The accounts of the British and especially of the Cornish ores are the best in the book, many of the references to the foreign fields being too brief to do more than show the place assigned to the ores in the authors' classification.

One significant and interesting feature in this book is the complete abandonment in a British text-book of that morphological classification of ores which was for so long dominant in this country that it has been described as "*the* British classification."

J. W. G.

OBSERVATIONAL METEOROLOGY.

Meteorology, Practical and Applied. By Sir John Moore. Second revised and enlarged edition. Pp. xxvii + 492. (London: Rebman, Ltd., 1910.) Price 10*s.* 6*d.* net.

DURING the last fifteen years much progress has been made in the study of meteorology, as a comparison between the first and second editions of Sir John Moore's treatise amply demonstrates. Expansion in some directions necessitating curtailment in others has changed and improved the work. As an example of addition we may instance the account of the investigation of the upper atmosphere with the information acquired of the isothermal layer and the behaviour of air currents. This inquiry, practically limited to the interval between the appearance of the two editions, has reacted, in various ways, traces of which will be found in the book. It has given a strong impulse to the work of designing accurate self-recording instruments, necessitating a considerable increase in the chapters devoted to the methods of measurement and registration of climatic factors. Through the increased attention attracted to meteorology and the firmer scientific foundation thus acquired, there has arisen the necessity for a broader, more general view of the factors of operation, in which world-wide areas and cosmical influences are substituted for limited districts and local circumstances. This more philosophic view the author has not discussed with the fulness its importance deserves. Perhaps, it hardly comes within the scheme, but the omission indicates the position the book occupies among treatises on meteorology. It deals with the mechanical processes employed in observation and the discussion of the results obtained, rather than with the problems of general circulation affecting the atmosphere as a whole. It is an admirable treatise on the methods of observation, it demonstrates very satisfactorily what can be accomplished by instrumental means, and what are the objects and advantages to be gained by the systematic collection of details. The principles underlying this aspect of practical meteorology are well illustrated by the description of the official weather service at home, in the United States, and in Canada. This information is thoroughly modern, trustworthy, and interesting. One section is devoted to the consideration of climate as deduced from the records supplied by instrumental means and one to the influence of season and of weather on disease. Perhaps the last is a larger subject than can be discussed adequately in the space allotted to it, but it is a subject on which the writer is an authority, and constitutes an important branch of meteorological science.

ABSTRACT AND OTHER PHILOSOPHY.

(1) *Gustav Freytags Kultur- und Geschichtspsychologie: Ein Beitrag zur Geschichte der Geschichtsphilosophie.* By Dr. Georg Schridde. Pp. ix+95. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1910.) Price 3 marks.

(2) *Lessings Briefwechsel mit Mendelssohn und Nicolai über das Trauerspiel.* By Prof. Dr. Robert Petsch. Pp. lv+144. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1910.) Price 3 marks.

(3) *Hegels Ästhetik im Verhältnis zu Schiller.* By A. Lewkowitz. Pp. 76. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1910.) Price 1.80 marks.

(4) *Über Christian Wolff's Ontologie.* By Hans Pichler. Pp. 91. (Leipzig: Verlag der Dürr'schen Buchhandlung, 1910.) Price 2 marks.

(5) *Zwei Vorträge zur Naturphilosophie.* By Hans Driesch. Pp. iv+38. (Leipzig: Wilhelm Engelmann.) Price 80 pfennigs.

(1) GUSTAV FREYTAG is best known in England as a novelist, and chiefly as the writer of that charming story of German commercial life, "Soll und Haben," which has been translated and published in English as "Debit and Credit." But Freytag was more than novelist. He was also poet, dramatist, and thinker. Born in 1816, and living until 1895, his life—as Dr. Schridde remarks—shows us the very heart-beat of the century, a century of tremendous importance in the history of his country. Politically he was strongly for Bismarckian unification, with Prussian supremacy; philosophically he may roughly be classed as Hegelian, though less abstract, and thus he is also religious, for his "metaphysic transfigures the desiderated calmness, the white light of Reason, into religious faith." Dr. Schridde gives a good account of the influence upon Freytag of Kant, Fichte, Humboldt, Schelling, and Hegel, and is thoroughly in sympathy with his subject, though not refraining from criticism of weak places.

(2) This is a collection of letters exchanged by Lessing, Moses Mendelssohn, and Nicolai, on the subject of the correct principles of tragedy. The proper mixture of sympathy and fear—the two chief emotions to be aroused—is discussed, and the distribution of sorrows among the characters. The hero must be the most severely handled by Fate; as to whether the end shall see virtue rewarded or not, this may be left to the dramatist's discretion. There is much discussion of Corneille, Cibber, and the Greek playwrights, but very little mention of Shakespeare, who was discovered for Germany by Schlegel and Goethe.

(3) This is supposed to be a comparison of the æsthetic of Hegel and Schiller, but as a matter of fact it is mainly concerned with the former. The scheme of the booklet may be guessed by the section titles:—"Idea of the Absolute Spirit," "Idea of the Beautiful," "the Beautiful and the Development of the World Spirit," "Art and Metaphysic," &c. Hegel is good for the metaphysically inclined reader who wants "something craggy to break his mind upon," but to many readers the time spent in wrestling with him seems wasted.

(4) Another typically German pamphlet. Our Teutonic cousins still retain their interest in abstract thought and—in spite of Kant—in the "ontological proof" which, since Comte and Spencer, has become almost extinct in France and England. Herr Pichler gives an amusing parody of the ontological axiom (that as every something must be grounded in either something or nothing, and as nothing can come out of nothing, every something must be grounded in something real) by suggesting that every man has stolen either something or nothing. To take away from nothing is no theft, therefore every man has stolen something. The reader may be left to worry out the fallacy for himself, with a hint to remember "ambiguous middle term."

(5) These two lectures, as we are informed in the foreword, are connected by the chronology of their delivery rather than by their contents. But Dr. Driesch—who, by the way, was Gifford lecturer at Aberdeen two years ago—always has something to say, and no reader will complain of discontinuity in this pamphlet, even if it exists.

Dr. Driesch is a biologist; and, in opposition to the school which has for some time been dominant, he is a vitalist. He holds that life has its own laws; that biology is not merely applied chemistry-physics, but is a thing for itself; that the materialistic or mechanical view of living substance is false. His philosophic position approximates to that of Sir Oliver Lodge in England, and his arguments in support of his opinions are most weighty and—the present reviewer ventures to say—convincing.

COLOUR CHEMISTRY.

A Manual of Dyeing: for the Use of Practical Dyers, Manufacturers, Students, and all Interested in the Art of Dyeing. By Prof. E. Knecht, C. Rawson, and Dr. R. Loewenthal. Second edition. Vol. i., pp. xii+371. Vol. ii., pp. 372–902. (London: C. Griffin and Co., Ltd., 1910.) Price 45s., two vols.

THE first edition of this work was reviewed in NATURE on June 22, 1893, and in the seventeen years which have elapsed since its publication, such rapid developments have taken place in colour chemistry that certain sections of the book have for some time been out of date, and the whole work has for several years been out of print. The issue of the present edition has, therefore, involved a very complete and laborious revision, and this no doubt accounts for the somewhat protracted delay in its issue.

This raises the question whether, for the sake both of authors and purchasers, some scheme could not be devised for arranging and binding a book of this type in such a manner that sections could be re-written and issued separately.

The general scheme of the book has not been materially altered, but vol. iii. of the first edition, which consisted of illustrative dyed patterns, has not been reproduced, and in this the authors have been well advised.

The section dealing with the theory of dyeing processes has been extended to three times its original length, but any general agreement with regard to the theory of dyeing does not at present appear possible, nor have theoretical considerations in the past been of much service in connection with the practical application of colouring matters. It is to be hoped that further investigation will lead to such a unification of ideas that theory may fulfil its proper function of a sign-post for those seeking new fields of practical application.

In the section dealing with textile fibres, five excellent plates replace the older diagrammatic illustrations. While the ordinary fibres are adequately described, the treatment of artificial silk seems hardly to have received that attention to which its present great commercial importance entitles it. There is, for instance, no reference to Thiele silk, one of the chief products now used.

Part vi. comprises a description of the natural colouring matters, and in this section it has been found possible to condense the matter originally published, this being in agreement with the diminished importance of these dye-stuffs from the practical point of view. The recent work of A. G. Perkin, v. Kostanecki, Schmidt, and others, on the constitution of the colouring matters of the natural dye-stuffs, is duly referred to.

The most extensive section of the book is, of course, that dealing with the artificial dye-stuffs, and this has required the greatest amount of revision. Certain entirely new groups of dyes, such as the artificial vat colours, have been introduced since the publication of the first edition, and other groups, such as the sulphide dyes, have been greatly enlarged. Some mention of Tyrian purple might well have been included in view of P. Friedlaender's discovery that it is a dibromindigotin.

A section of the work to which great importance has always been attached is that dealing with the analysis and valuation of materials used in dyeing, and this has received a very thorough revision.

The book in its new edition will again take its place as one of the most important works published on colouring matters and their application.

OUR BOOK SHELF.

La Métallographie Microscopique. By Louis Révillon. Pp. 176. (Paris: Gauthier-Villars, n.d.) Price 3 francs.

THIS is another volume of the small Aide-Mémoire series by the author of the work on "Special Steels," which was reviewed some time ago. Considering the size and price of the book, a good account of the subject is given, though, in common with many other enthusiasts, the author is inclined to claim too much for his subject, p. 7, "et de résoudre tous les problèmes . . .," and in describing the preparation of the polished face of the section for examination, is too severe in his conditions, namely, "perfectly polished so that there remains no scratch visible at the highest power of the microscope." Much time has been wasted in the past in striving after this ideal. It is not necessary, unless when looking for the finest cracks, and, combined with a somewhat elaborate series of precautions, is apt to discourage the reader from beginning practical work. Advice such as that given on pp. 69 and 70 has always been impressed on beginners by the writer, namely, that the section is prepared for observation and study, not merely for photographing, and that the polished section should always be examined carefully before etching in any way, as then small holes, oxides, scoriæ, and sulphides are generally much more easily seen against the polished metallic surface than after etching.

With many of the opinions expressed one cannot agree. The Martensitic interlacing needles do not represent the structure of properly hardened carbon steels, and many practical points might also be controverted, but the work as a whole gives a very fair introduction to a study of the subject from the point of view of a portion of the French school. Osmondite is given, although M. Osmond has specifically repudiated it in *Revue de Métallurgie*. Separate chapters are devoted to special steels, the alloys of copper, other industrial alloys, and the final chapter to the interesting "Macrographie." A. McWILLIAM.

Die Kraftmaschinen. By C. Schütze. Pp. vi+235. (Leipzig: Quelle and Meyer, 1909.) Price 1.80 marks.

THIS little volume is devoted to a non-mathematical description of the various types of motors now employed for power purposes, and of the more important details of each class; windmills, waterwheels, and turbines, steam, gas, and petrol engines, and dynamos and electric motors are all in turn discussed and described. The text is illustrated by a large number of figures, mostly line illustrations, and, as all minute details are omitted, these illustrations will be easily understood and followed by the non-technical reader. The whole volume is, in fact, intended for those who are not experts in this branch of engineering. It will appeal, however, to many who use motors for business or pleasure, and desire to have some knowledge of the principles underlying the design and working of the particular machines they employ. The steam turbine has been rather inadequately treated in comparison with the reciprocating steam engine, but perhaps this was inevitable in a book of this nature, as the latter is still practically unchallenged by its younger rival in many branches of work in which motive power is required.

This is a book which will probably stimulate many of its readers to widen their knowledge of the problems concerned with the generation of energy, and to devote themselves to a systematic study of the subject, and, if it fulfils this, it will have done useful work. T. H. B.

Photomicrographs of Botanical Studies. Pp. 62. (Manchester: Flatters, Milborne and McKechnie, Ltd., n.d.) Price 2s. net.

This booklet contains about a hundred plates, which are photographic reproductions from the microscopical slides offered by the firm above-mentioned for the use of botanical students. The chief impression conveyed by the figures is the limitation imposed upon good microscopical preparations when referred to one focal plane as necessitated by photography. While the value of good slides for demonstration and examination by students is appreciable, one cannot attach much importance to figures which are primarily indices and convey in many cases only a portion of the information that can be derived from the preparations.

Illustrated Guide to the Museum of the Royal College of Surgeons, England. Pp. vi+132. By Prof. Arthur Keith. (London: Issued by order of the Council of the College, and sold by Taylor and Francis, 1910.) Price 6*d*.

Few even of those who constantly make use of the College of Surgeons' Museum can be aware of the vast wealth of material stored there. For it contains not only the greatest anatomical collection in existence, representative of everything included under the term "anatomy" in its widest sense; but it also includes a unique pathological museum, and collections illustrating anthropology, teratology, odontology, and the anatomy of animals and plants, each of which, if standing alone, would make a famous museum. Nor does this exhaust its claims on our interest, for in it is housed the famous collection made by John Hunter, innumerable anatomical and pathological preparations that have served as material for the master-builders of the sciences of anatomy and pathology, and specimens illustrating the history of all that relates to the preservation of dead bodies (starting from the earliest known mummy), the evolution of surgical and dental instruments, and the manifold curiosities of medical science which at various times engaged the attention of the ever-inquisitive Hunter.

The council of the college has earned the gratitude of a very wide circle of students in issuing this "guide," which admirably serves its purpose of indicating what the museum contains and where the various specimens are to be found, and Prof. Keith deserves our heartiest congratulations on the manner in which he has accomplished his task. For he has done something more than merely direct the reader in his wanderings through the vast storehouse of treasures in his charge; out of the abundance of his knowledge and erudition he has crammed a vast amount of interesting and suggestive information into this small volume.

This is only one, and by no means the least, of the many great services which have already marked Dr. Keith's conservatorship of the college museum.

The Photographic Annual, 1910–11, Incorporating the Figures, Facts, and Formulae of Photography. A Guide to their Practical Use. Edited by E. J. Wall. Sixth edition; extended, largely re-written, and revised. Pp. viii+287. (London: G. Routledge and Sons, Ltd.; Dawbarn and Ward, Ltd.; New York: Tennant and Ward; Melbourne: Baker and Rouse Proprietary, Ltd., 1910.) Price 1*s*. net.

Every photographer knows the value and utility of this annual issue, and that this is the sixth issue is sufficient testimony to its merits. There is no doubt that, in preparing such a work as this, and to keep the volume within a reasonable size, great difficulty must be experienced in determining what information to include or omit. The editor has used his discretion wisely, with the result that the present issue should meet with general approval among photographers.

The importance and recent advances made in screen-plate colour-photography is sufficient reason for the first forty pages being devoted to this subject, and here the reader will find a capital *résumé* of the state of affairs up to the present time. Stereoscopic work is next dealt with, and in the twenty-seven pages in which this subject is treated many useful hints will be found. Nearly the same amount of space is confined to some useful notes on development, including time, tank, and thermo methods. Practically the remainder of the book is taken up by the figures, facts, and formulæ, which always form the chief feature of this book.

Being well up-to-date and in a handy form the book should continue its useful career.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Ratio between Uranium and Radium in Minerals.

In his interesting letter (Nature, August 25) Mr. A. S. Russell describes the result of a determination of the amount of radium in a specimen of autunite from Autun, France, made by him in Prof. Marckwald's laboratory, which he found to be only 27 per cent. of the equilibrium amount. The ratio found by Mlle. Gleditsch in Mme. Curie's laboratory for the same mineral was 80 per cent., while Miss Pirret and I recently, for an autunite from Guarda, Portugal, found 44 per cent. Some results I have obtained since the paper with Miss Pirret was published appear to put a new complexion on the matter. Dual measurements of the radium ratio and of the helium content of several specimens of Portuguese autunite have shown that both vary considerably for different specimens of the same mineral. Prof. Piutti ("Helium in Recent Minerals," *Le Radium*, 1910, vii., 178) found that autunite was the only radio-active mineral in which helium could not be detected.

With a very delicate method, similar to that described for the detection of the helium produced from uranium and thorium (*Phil. Mag.*, August, 1908), I have only failed to find helium in one specimen of autunite, while in another the amount was such that Prof. Piutti would have detected it easily. The latter case refers to the specimen for which Miss Pirret and I found 44 per cent. for the radium ratio. The amount of helium was 3·3 cu. mm. per gram of uranium. On the assumptions, which certainly are not true but may not lead to an entirely false result, that the uranium was initially free from all products, and these have been all retained by the mineral, the age of the mineral would be 77,000 years and the period of average life of the parent of radium 132,000 years. The material was, however, not a single piece, a batch of specimens containing 40 per cent. of autunite, obtained direct from the mining syndicate, having been ground up together. From a fresh batch, obtained through a dealer, two single pieces were picked out, the first being an almost pure crystal weighing 2·3 grams, and of so fresh and new appearance that it looked as if it had been withdrawn from its mother-liquor but yesterday, and the second an obviously older looking, greener, and much larger mass containing 46 per cent. of matrix. The first gave a radium ratio of 70 per cent., and in it helium could not be detected. The quantity was not greater than 0·002 cu. mm. per gram U. This quantity would form in about thirty years! For the second, the radium ratio was 44 per cent. and the helium 0·035 cu. mm. per gram U, which would be produced in about 600 years. Lastly, Mr. Russell very kindly gave me the remains of the specimen for which he found 27 per cent. for the radium ratio. It weighed less than 0·5 gram, but the helium was easily detectable. It amounted to more than 0·15 cu. mm. per gram U, some being lost.

If these results are representative, the radium ratio decreases to a minimum and then rises more slowly as the helium content increases. If the latter is taken as a measure of the age of the mineral, the minimum appears to be reached after a few thousand years. This, of course, is exactly what would occur if, when the autunite was formed, the radium (but not its parent) associated with the uranium in its former condition separated with the latter. This in itself is not only possible, but probable, owing to the isomorphism of radium and calcium. But it is a somewhat startling result if initial radium can have any influence on the amount present in a mineral to-day, for this necessitates that the ages indicated by the helium content are not altogether below the truth, and that these beautiful crystals are actually even now in full process of formation.

Frederick Soddy.

Physical Chemistry Laboratory, University of Glasgow.

Stagnant Glaciers

In the notice of the Professional Papers of the U.S. Geological Survey on the "Glaciers, Goldfields, and Landslides of North America," published in Nature of July 21, attention is directed to the peculiar stagnant condition of some glaciers, and to the fact that certain glaciers, after being stagnant for long intervals, suddenly commence to move.

Although the movement of glaciers is such as would take place if they were viscous bodies, there is reason to believe that they have not all the same viscosity. I pointed out in a paper communicated to the Royal Society (Proc. Roy. Soc., 1908, p. 250) that the calculated viscosities of several Swiss glaciers varied from $292{\cdot}2 \times 10^{12}$ to $3{\cdot}17 \times 10^{12}$ C.G.S. units. Although some of the data upon which these figures were based were only estimated ones, I do not think that the different viscosities found are due wholly to errors in the data. In other words, that the viscosity of glacier ice is not a constant, as in the case of water, &c., but varies with variations in the granular structure of the ice, or that there is a limiting stress below which distortion does not take place as with plastic bodies.

So far as I am aware, no glaciers have been proved actually to be stagnant by careful measurement. Generally speaking, the conclusion that a glacier is dead is formed owing to the absence of certain features which are generally associated with glacier movement.

It is very desirable that such statements should be based upon actual measurements only, and also that the actual granular structure of the ice should be given, for there is every reason to believe that the viscosity of glacier ice varies with the size of the glacier grains. Were it not for the fact that the glacier grains are actually broken up by shear planes in the ice, they would gradually become larger and larger until they became so large, and the viscosity became so great, that the ice would scarcely move at all on small slopes. In such a case an earthquake might give rise to fractures in the ice, and by temporarily decreasing the viscosity increase the rate of flow.

R. M. Deeley.

Melbourne House, Osmaston Road, Derby, July 23.

It chanced, strangely enough, that Mr. Deeley's interesting letter reached me at a Norwegian port during the return journey of the Geological Congress party from Spitsbergen, on which Prof. R. S. Tarr, whose work has given rise to the letter, is a fellow-traveller with me. I have therefore taken advantage of the opportunity to discuss the subject with Prof. Tarr and other glacialists of our party.

Mr. Deeley is right in his supposition that the stagnant condition of the "dead ice" in Alaska has been inferred from surface indications, and has not yet been tested by actual measurement. It is, indeed, not likely that the ice of the areas described as "stagnant" is absolutely motionless, nor do I think that this has been implied in the descriptions. Such motion as it may have must however be very small, since it seems that the trees covering parts of the surface-moraines in the "dead" areas show no sign of disturbance.

As hinted in my review, it is evident that rapid advances of glaciers, comparable to those observed in Alaska, have taken place in regions where some other cause than an earthquake must be sought. During our recent journey in Spitsbergen, of which I hope shortly to give some account in these pages, we have been shown by our leader, Prof. G. de Geer, several cases of this kind which he has studied. It may be that Mr. Deeley's explanation of ice-structure will explain these rapid spasmodic movements, but I shall not venture upon a discussion of this difficult physical question. Mr. Deeley has at any rate suggested a line of research which ought to be followed up and experimentally tested in the field.

Stockholm, August 19. G. W. Lamplugh.

The Leaning Tower of Pisa.

The photograph of the "Leaning" Tower of Pisa in Nature of August 4 shows clearly that the top tier is not square with the rest. From a rough alignment with the edge of a postcard, the photograph appears as if the tower was of the order of 25 mm./metre out of plumb when the top tier was put on presumably plumb.

Exact measures of this and of other parts of the tower might afford interesting data as to the epochs of the construction of the tower and of the progress of its "leaning."

Edward G. Brown.

This famous tower will doubtless always be a question, like the man in the iron mask and other historical mysteries. Most architects, however, will be very slow to believe that it would have been built intentionally leaning on the general grounds that, however adventurous the architect, the clients would not have stood it. The analogy of the leaning towers of Bologna is hardly a sound one, as these plain shafts of brickwork, much like tall chimneys, can hardly be other than cases of settlement due to indifferent foundations. It should be remembered that construction was not a strong point with the Italians in the Middle and Renaissance Ages. In the case of the Tower of Pisa, Taylor particularly remarks on the wedge-shaped courses, which show an attempt to straighten the shaft. The best explanation appears to be that the tower was commenced, settled on its marshy bed, and that when the building was continued after a long interval it was considered safe to continue the work up to the limit of stability which could be calculated by the mathematicians of the epoch. The overhang is given by Taylor as 13 feet.

It is rather a pity that so much attention is concentrated by visitors on the tower, whereas the cathedral, Campo Santo, and particularly the Baptistery, are monuments of greater architectural importance. The design of the Baptistery is extremely interesting, and is perhaps the nearest expression of a Gothic dome.

The construction in this case is highly interesting, because the outer dome is supported by a cone, as at St. Paul's, London, but without an inner dome. As, however, the cone is not illuminated from the inside, it has a domical effect. The top of the cone shows externally, to the detriment of the general outline, not being cut off to carry a lantern as at St. Paul's.

Sir Christopher Wren may have known from travellers or by converse with foreign men of science of this example, but it is not necessary to jump to that conclusion, as an ordinary brick kiln or oast house would give the idea, aided by Wren's mathematical analysis of cones as units of high carrying power.

Taylor and Cresy's drawings of the Pisan monuments have every appearance of being most trustworthy, and should be consulted by your correspondent. I had the plates with me when visiting Pisa in 1890, and I had the opportunity to go up the tower and round its galleries. Ruskin has a passage on the setting out of the lower part of the western façade of the cathedral, but I remember the impression produced by my examination was not favourable to his argument.

ARTHUR T. BOLTON.

Victoria Mansions, 28 Victoria Street, Westminster, S.W.

The Origin of the Domestic "Blotched" Tabby Cat.

THE question of the origin of the two types of our domestic cats has been the subject of much controversy, and it is therefore with diffidence that the views here expressed are now put forward. It is, of course, well known that any domestic "tabby" can, at a glance, be assigned to one of the two colour patterns, "striped" or "blotched."

In a recent paper (Proc. Zool. Soc., 1907, pp. 143–66) Mr. R. I. Pocock comes to the conclusion that the origin of *F. catus* (blotched tabby) is "at present quite unknown," and suggests that it is "the survivor of some extinct, probably Pleistocene, cat of Western Europe" (*ibid.*, p. 160); in effect, he regards *catus* as a good species. It seems to have been pretty clearly shown by the same writer that the *torquata* breed (striped tabby) is either the direct descendant of *F. sylvestris* or is the result of a cross between that species and *F. ocreata* (Proc. Zool. Soc., 1907, p. 947, and NATURE, vol. lxxvii., p. 414), which latter is, no doubt, merely a geographical race of *sylvestris*.

In his previous paper (Proc. Zool. Soc., 1907, p. 160) Mr. Pocock remarks that "when two distinct species cross the hybrid sometimes reverts in some respects to the characters of a [supposed] common ancestor of both"; this cannot be denied, but such a cross more commonly results in a form intermediate between the two parents, usually designated as a mongrel. After much diligent search, I have been unable to find a single instance in which complete segregation has taken place in respect of all specific characters *when two well-defined species are crossed*.

The two "types" of tabby, when crossed, always produce individuals which are at once referable to one or the other variety; in short, we get complete (Mendelian) segregation in respect of this character.

It therefore seems to me to be incompatible with the above observed facts, that *F. catus* is the survivor of some extinct cat of Western Europe, for if *catus* were a good species, when crossed with *torquata* we would most certainly have some form of intermediate produced. This, as we know from everyday experience, is contrary to the expressed results of such a cross. From these facts it is suggested as a possible explanation that *F. catus* arose *per saltum* from *F. sylvestris*. In short, I believe that *F. catus* has arisen from *F. sylvestris* as a "sport," and when crossed with its parent species or *inter se* follows the Mendelian law of segregation, as many such discontinuous variations have now been proved to do. At the same time (from evidence which cannot be here brought forward), it would appear that only in extremely rare cases, if at all, can Mendelian action be accountable for the evolution of a species *in nature*.

In opposition to such an origin, Mr. Pocock urges (Proc. Zool. Soc., 1907, p. 160) "the complete absence of evidence that species of Felis are ever dimorphic in pattern, and the ascertained fact that they breed true to their specific and sub-specific type." The objection, of course, is a purely negative one, and there is some evidence to show that animals under domestication are more subject to pronounced variation than in a state of nature.

In the leopard (*F. pardus*) we have a species of *felis* which can most certainly be regarded as dimorphic, in that it produces a black form, and (so far as the somewhat meagre information on the subject goes) in its gametic behaviour is exactly comparable to the case of the "blotched" and "striped" tabby. There are, so far as I know, no data in the case to show which is the "dominant" form, but, from analogy, it is almost certain the black would be dominant over the spotted. It is the hope of obtaining such information in the case of our common cats which has induced me to approach the subject. Finally, it may be said that, although no *direct* proof can be brought forward in support of such a suggestion, I am convinced that a properly conducted series of experiments with the two types would bring to light much evidence in favour of such a view.

Unfortunately, the writer is at present unable to carry out such a series of experiments, and it is hoped that others may hereby be induced to do so.

H. M. VICKERS.

81A Princes Street, Edinburgh, August 20.

I AM glad Mr. Vickers has directed the attention of Mendelians to the question of our two types of "tabby" cat. With the same purpose in view, and in the hope of inducing someone with time and facilities at his disposal to carry out breeding experiments with these animals, I recently communicated to the Mendel Society a paper on this subject, which will appear in the forthcoming issue of the journal. The results of such experiments are sure to be interesting, but whether or not they will settle the origin of the "blotched" tabby is another matter. They may turn the balance of the evidence in favour of this or that theory, but it is doubtful if they will result in more than a hypothetical conclusion. For myself I have quite an open mind on the point. As stated in my original paper on English cats, the "blotched" tabby may be regarded provisionally either as a survivor of some extinct cat that formerly inhabited Europe or as a "mutation" of the "striped" tabby. I reserved the names "*catus*" and "*torquata*" for these two types as a convenient means of designating them, following Linnæus's method, which is still in vogue, of assigning a specific epithet to our domesticated animals, like *Ovis aries*, *Canis familiaris*, and others, when their origin is uncertain or unknown.

I think Mr. Vickers a little overstates the case when he says there has been much controversy on the subject of the origin of these cats, and speaks of their existence as well known. It was the fact that the remarkable differences between them had been practically ignored or unappreciated by zoologists that induced me to discuss the question at some length three years ago. Nor do I think Mr. Vickers himself quite appreciates the distinction I emphasised between dimorphism in pattern and dimorphism in colour. Experience with wild animals shows that pattern is far more stable than colour. Pattern is wonderfully persistent; colour is not. No one would be greatly surprised at finding a black or white example in a litter of spotted hyænas, but it would be admittedly an extremely remarkable thing if a specimen resembling a striped hyæna in pattern occurred amongst them. Such a "mutation" would be comparable to the "mutation," if mutation it be, of the "blotched" from the "striped" tabby cat. Such a mutation in pattern as that supposed in the case of the hyæna may, of course, be produced to-morrow; but, so far as I am aware, no such variation has as yet been recorded, and I write this with full recollection of the curious variations in pattern that have been recorded of the common leopard.

Finally, may I demur to one more statement made by Mr. Vickers, namely, that animals under domestication are more subject to pronounced variation than those in a state of nature? I do not dispute this common assumption, but I am not satisfied that the evidence in its favour amounts to very much.

The questions raised by Mr. Vickers are, however, full of interest; and all that I have said is in justification of the agnostic attitude that I think should be, for the present, preserved towards the origin of the "blotched" tabby cat.

R. I. POCOCK.

Zoological Gardens, August 24.

LAKE BALATON.[1]

LAKE BALATON, or Platten See, is the largest lake in Austro-Hungary, and, in fact, in south-eastern Europe. It is fifty miles long, and is shallow in proportion to its size. It lies in a depression on the Hungarian plain at the foot of the hills of the Bakony Wald. The Hungarian Geographical Society organised a commission, under the presidency of Prof. Ludwig von Loczy, to subject this lake to a thorough investigation. The results are being published in three volumes, of which the first is devoted to geography, geology, palæontology, hydrography, physics, and chemistry; the second to biology; the third to the social and ethnographical geography, including accounts of the watering-places and hot springs, and a bibliography. Four further sections of this work have now been received, and one of them completes the second volume. As the parts are issued in the order of their completion, it is not easy to form from these disconnected fragments a clear impression of the work as a whole. Thus the only contribution yet issued to the introduction, which is to be a geographical memoir on the lake and its district, is a geo-physical appendix, dealing with the determination of gravity by R. von Sterneck, with the influence of variations in gravity on the level of the lake surface by Baron Lorand Eötvös, and a report on the magnetic observations by Dr. L. Steiner. Dr. von Sterneck's results show that gravity is normal over part of the middle of the lake, while it is above normal along a belt of the hills to the north, and it is below normal in a band still further to the north.

Baron Eötvös has determined the relations of the variations in gravity to the level of the lake surface by measurements made on the ice during the winter. His observations were interrupted by the mild winter of 1902, when the lake was inadequately frozen. His results show that Lake Balaton occurs along a tectonic line, and he recognises variations in level due to gravity, similar to those in India, but on a smaller scale. Dr. Steiner has determined the various magnetic elements for the area of the lake, and has investigated the magnetic properties of the rocks.

No other locality in Europe is so convenient for the study of the formation of wide ice-sheets on an inland sea as Lake Balaton, for, in spite of the comparative saltness of the water, its surface is more completely frozen than the Swiss lakes, which being much deeper, therefore cool more slowly. In ordinary winters the whole of Lake Balaton is covered over with a firm ice-sheet. Dr. von Cholnoky has made a detailed study of the ice in all stages of its formation and decay, illustrated by numerous excellent photographs. The ice-sheet is broken into separate floes separated by narrow leads, which are locally known as rianas, and the wind, driving the ice-fields together or against the shore, piles it into ice-hummocks, which on Lake Balaton are known as turolas. Many of the features of the Arctic ice-sheets are found repeated in southern Europe. Dr. Cholnoky, following Buckley and van Hise, draws an interesting comparison between the movements of the ice-sheet and the earth's crust. Blocks of the ice founder, forming areas of subsidence, and long strips sink between parallel faults forming rift valleys separated by horsts, while various overthrust faults are found in the pressure ridges.

Fig. 1.—Hummock formed from fresh ice on Lake Balaton, January 23, 1903.

The volume on the biology of Lake Balaton is now completed by a memoir on the attempts to acclimatise various tropical water-lilies in the Hévizsee, a well-known bathing resort near Keszthely, to the north of the western end of Lake Balaton. This lake is about three hundred yards across, and is fed by hot

Békefi, Kirchen und Burgen in der Umgebung des Balaton im Mittelalter, pp. 363, 1 map, 142 illustrations. Price 20 kroner.) Vienna: Ed. Hölzel, 1907-9.)

springs, so that the temperature of the water is from 32° to 38° C. in summer, and from 26° to 30° C. in winter. A chapter on the composition of the lake water, by G. v. Weszelszky, shows that it contains 0·531 part per thousand of salts, of which the chief are magnesium chloride, bicarbonate of lime, and sodium sulphate. The shape of the lake basin has been carefully determined by Dr. Jordan.

Dr. Lovassy has attempted to acclimatise tropical water-lilies in this pond. He points out the interesting fact that the Nile lotus (*Nymphaea lotus*) is still living in the warm waters of Nagyvared, and a flower stem referred to this plant was discovered in Upper Pliocene calcareous tufa at Ganocz, in Szepes, by Prof. Pax, of Breslau, in 1904. Dr. Lovassy, therefore, holds that the Nile lotus still lives in Hungary as a relic from its former wide extension over southern Europe. He insists that the plant was neither introduced by man nor birds, and that Nagyvared is a natural subtropical oasis. Earlier attempts to plant tropical water-lilies in the Hévizsee were made between 1826 and 1842. Dr. Lovassy's experiments lasted from 1898 to 1906, and were tried on many distinct species; and in connection with the work he has compiled a synopsis of the Nymphaceæ; some species failed altogether, others lived, but would not produce seeds, and only a variety of the Indian *Nymphaea rubra*, for which he founds a new subspecies, *longiflora*, has been successfully acclimatised.

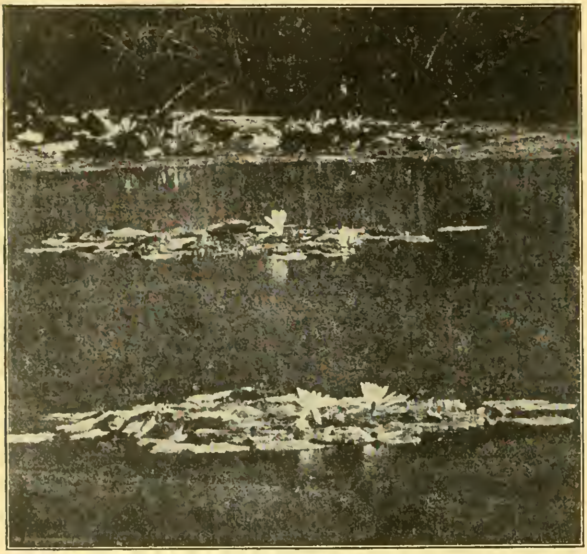

FIG 2.—Water-lilies in the Hévizsee. In foreground some specimens of *Nymphaea lotus*, L., and in background *Nymphaea rubra longiflora*, nov. subsp.

The longest of the four contributions recently received is a memoir by Dr. Békefi on the mediæval churches and castles in the neighbourhood of Lake Balaton. It consists of a detailed account illustrated by plans and photographs, both of the buildings still occupied and those represented by numerous picturesque ruins.

J. W. G.

THE BRITISH ASSOCIATION AT SHEFFIELD.

FROM the point of view of numbers, this year's meeting of the British Association, with a total membership of about 1400, does not take a very high place among the great meetings of recent years; nevertheless, there is only one opinion as to its success. The arrangements have been admirably made, and everyone agrees that no more perfect and convenient place for the reception-room and accessory writing and other rooms could have been provided than has been furnished at the Cutlers' Hall. The local committee, under the chairmanship of Prof. W. M. Hicks, is to be congratulated upon the businesslike way in which it has organised the many and various general affairs of the meeting. The scientific proceedings of the sections have been full of interest, but here no further reference need be made to them, as accounts of the work of the sections will appear in later issues.

The annual report of the council of the association was presented at the meeting of the general committee on August 31. The council presented an address to the King upon his accession to the throne, and in a further letter expressed the hope that he would follow his august father in the patronage of the association. This the King has consented to do.

At the Winnipeg meeting last year a resolution was formulated by the Anthropological Section, relating to inquiries into Canadian ethnology, was supported by the general committee, and referred to the council. This resolution, which was forwarded to the Dominion Government by the council was as follows :—

I. (1) "That it is essential to scientific knowledge of the early history of Canada that full and accurate records should be obtained of the physical character, geographical distribution and migrations, languages, social and political institutions, native arts, industries, and economic systems of the aboriginal peoples of the country.

(2) "That scientific knowledge of the principles of native design and handicraft is an essential preliminary to any development of native industries such as has already been found practicable, especially in the United States, in Mexico, and in India, and that such knowledge has also proved to be of material assistance in the creation of national schools of design among the white population.

(3) "That, in the rapid development of the country, the native population is inevitably losing its separate existence and characteristics.

(4) "That it is therefore of urgent importance to initiate, without delay, systematic observations and records of native physical types, languages, beliefs, and customs; and to provide for the preservation of a complete collection of examples of native arts and industries in some central institution, and for public guardianship of prehistoric monuments such as village sites, burial grounds, mounds, and rock carvings.

(5) "That the organisation necessary to secure these objects, and to render the results of these inquiries accessible to students and to the public, is such as might easily be provided in connection with the National Museum at Ottawa, which already includes many fine examples of aboriginal arts and manufactures, and might be made a

centre for the scientific study of the physical types, languages, beliefs, and customs of the aboriginal peoples."

II. To recommend the council to urge the Dominion Government to include in the schedules of the next Canadian census full inquiries as to precise place of origin, native language, previous status and occupation, year of immigration, and such other information as may be deemed of scientific value for the study of the effects of the Canadian environment upon immigrants of European origin.

The resolution was referred to the Canadian Geological Survey by the Privy Council, and in the course of a reply the director of the survey, Mr. R. W. Brock, stated that the Government had shown appreciation of the value of the work by enabling the survey three years ago to make a beginning in the direction indicated. An ethnologist is at present living with the Eskimo in the Arctic, and a preliminary report on his observations appeared in the Geological Survey summary report for 1908. With the assistance of the Canadian archæological societies and the support which the British Association gave in its resolution, the director expressed strong hopes that something worth while may be accomplished along these lines.

It was subsequently reported to the council by the general officers that information had reached them that the Dominion Government of Canada had authorised the payment of the salary of an ethnologist for the Dominion, and also a grant for the collection of ethnological material. This may be regarded as a direct outcome of the representations made by the British Association.

The important question of the relationship of the sections generally, and the possible desirability of a new subdivision and the incorporation of new subjects was referred to the council by the general committee at Winnipeg. A committee was appointed by the council to consider the matter, and among its recommendations were (1) that the title of Section A be changed to "Mathematics, Physics, and Astronomy (including Cosmical Physics)"; (2) that the question of the combination of geology and geography into one section of two departments should receive further consideration; (3) that there should be a permanent subsection of agriculture, attached to a particular section annually, such as chemistry, economic science, and botany. The proposed changes did not, however, meet with the approval of the general committee. It was resolved at the meeting of this committee on September 2 that the present title of Section A should remain unaltered, that Sections C and E should not be combined, and that the question of the sub-section of agriculture should be referred back to the council.

Sir William Ramsay was nominated by the council to fill the office of president of the association for next year's meeting at Portsmouth, and his nomination was confirmed by the general committee. At the meeting of this committee on September 2 an invitation from Dundee to visit that city in 1912 was unaimously accepted. An invitation to meet in the capital cities of Australia was conveyed by Sir George Reid, High Commissioner of the Commonwealth, and Prof. Orme Masson. The proposal was that the association should spend a few days each in Adelaide, Melbourne, Sydney, and Brisbane. The general committee was informed that the Commonwealth Government has voted 10,000*l*., which is earmarked for oversea expenses, and that the contributions of the several States will include free railway travelling. The minimum time needed for the visit, including the journey out and home, will be about three months. After discussion, it was proposed by Sir William Ramsay that the invitation should be accepted for 1914. The resolution was seconded by Prof. H. B. Dixon and carried by the general committee.

On Tuesday afternoon a special degree congregation was held at the University, when the Duke of Norfolk, as Chancellor of the University, conferred honorary degrees upon the following distinguished visitors and two leading Sheffield men—the Lord Mayor (Earl Fitzwilliam) and Sir Joseph Jonas:—LL.D.: The Right Hon. the Lord Mayor of Sheffield (Earl Fitzwilliam). D.Sc.: Mr. W. Bateson, F.R.S., Prof. T. G. Bonney, F.R.S., Sir William Crookes, F.R.S., Mr. Francis Darwin, F.R.S., Prof. T. W. Rhys Davids, Sir Archibald Geikie, K.C.B., F.R.S., Prof. E. W. Hobson, F.R.S., Sir Oliver Lodge, F.R.S., Sir Norman Lockyer, K.C.B., F.R.S., Dr. H. A. Miers, F.R.S., Sir William Ramsay, K.C.B., F.R.S., Prof. C. S. Sherrington, F.R.S., Sir J. J. Thomson, F.R.S. D.Eng.: Sir Joseph Jonas, J.P., Sir W. H. White, K.C.B., F.R.S. D.Met.: Mr. J. E. Stead, F.R.S.

SECTION B.

CHEMISTRY.

Opening Address by J. E. Stead, F.R.S., F.I.C., F.C.S., President of the Section.

It was with considerable diffidence that I accepted the position of President of this section. The long list of illustrious and eminent chemists who have occupied the chair in the past, men of science of the highest attainments, and usually professors of our educational institutions, is indicative of the very high standard to be followed. As, however, it was urged that a President with experience in the metallurgy of iron and steel was desired, I bowed to the decision of the Council, concluding that even as a mere layman I might, in this address, discuss one or more subjects to which prominent metallurgists have for the past thirty years directed their earnest attention, both in Europe and America. I refer to some of the underlying phenomena connected with the effect of sulphur and silicon on the carbon condition of commercial cast iron.

The effect of sulphur and silicon on cast iron has received the attention of Karsten, Percy, Weston, Howe, Keep, West, Dillner, Bachman, Summershach, Wüst, Johnson, Stoughton, Hailstone, Longmuir, Adamson, Turner and Schuler, Levy, and many others. They all agree in concluding that sulphur tends to make iron white by retaining the carbon in the combined state, and that silicon tends in the opposite direction. Prof. Howe and Dr. Wüst have endeavoured to arrive at the exact quantitative effect of sulphur and silicon in preventing or facilitating the decomposition of the carbides.

Howe recognised that the data available are insufficient on which to make any final conclusion.

Wüst found, by a series of trials, that in pigs containing 3·15 per cent. carbon and about 1 per cent. silicon, on an average 0·01 per cent. sulphur prevented the separation of 0·02 per cent. graphite, but that with 2 per cent. silicon its effect was much less.

It is the general experience, that the effect of sulphur depends on the proportion, not only of silicon, but of the total carbon and manganese, and of the temperature at which the iron is cast, and the size and temperature of the mould into which the metal is run. Under some critical conditions 0·1 per cent. sulphur may prevent the separation of 3 per cent. graphite.

Howe's discovery—that the tendency of silicon, in increasing the decomposition of the carbides, is rapid at first, especially as the silicon rises from zero to 0·75 per cent., and then slower and slower with each further increase—is very important; so also is the generalisation of Messrs. Charpy and Grenet—that the separation of graphite on annealing iron which is initially white, containing the whole of the carbon in the combined condition, begins at a temperature which is the lower the greater the percentage of the associated silicon, and that the separation of graphite, once begun, continues at even lower temperatures than that at which it started.

The evidence advanced by Phillips, Prost, Campredon, Schulte, and others—that, on dissolving sulphurous irons in hydrochloric acid, all the sulphur is not given off as H_2S, and that a part either passes off as $S(CH_3)_2$ or remains behind with the solution as some organic product—was tentatively believed as indicative that the sulphur is chemically associated with the carbon and the iron.

Levy,[1] who has done much good work in the endeavour to determine the relations which exist between iron, carbon, and sulphur, in the alloys of these elements, states, as the result of his research, that there is no conclusive evidence of any chemical union.

In his tabulated results showing the amount of sulphur evolved presumably as $S(CH_3)_2$ on dissolving iron, carbon and sulphur alloys, the maximum is 0·06 per cent., but the average is very much less.

Schulte, on the other hand, had found that from 1 per cent. to 12 per cent. of the total sulphur is evolved as an organic sulphur compound; and Bischoff found an even greater quantity.

The results are apparently conflicting, and it is evidently obvious that more research is required in this direction.

It has been shown by Arnold and McWilliam, and confirmed by others, that carbide of iron does not decompose into graphite and iron during the annealing of steel until it segregates into relatively large masses. Taking this as a basis, Mr. Levy has advanced an explanatory hypothesis as to how it is that sulphide of iron prevents the decomposition of carbides in white irons. He had found that during the solidification of irons free from silicon and manganese, but rich in sulphur, "the sulphide separates at a temperature in the neighbourhood of 1130° C., together with, and as a component of, the austenite-cementite eutectic, forming a triple austenite-cementite-sulphide eutectic, the cementite component of which is interstratified with a jointed pearlite (by decomposition of austenite) sulphide one." He stated that "The presence of iron sulphide in the eutectic introduces intervening layers, which may partly ball up on annealing, but even then leave sulphide films between the cementite crystals; these act almost as emulsifiers, preventing the coalescence of the cementite portion, which is apparently a necessary preliminary to its decomposition into free carbon and iron. These layers and films are so persistent, even on slow cooling, as to retain their position between the cementite crystals, until the metal has cooled well below the temperature of decomposition, so that an iron which might otherwise become grey is retained, even on very protracted cooling, in the white form, by sulphur as sulphide; 0·25 per cent. sulphur being sufficient for this purpose under the moderately protracted cooling conditions of the research. It is not improbable that the mechanical force exerted by sulphide, on separation and cooling, may also prevent the physical conditions necessary for carbide decomposition, which, as is well known, is accompanied by considerable expansion."

It is to be noted that Mr. Levy's argument is based on the effect of the sulphide films in the eutectic, preventing the segregation of the cementite into relatively large masses, which, as he expresses it, "is apparently a necessary preliminary to its decomposition."

His conclusions were based on the examination of hypo-eutectic alloys containing not more than 2·75 per cent. carbon and free from massive plates of cementite.

Whilst admitting that his conclusions may be correct, as applied to the eutectic, some other explanation would be necessary if decomposition did not occur when a considerable quantity of massive cementite initially were to form in the alloy.

That stable massive cementite can be so obtained in iron sulphide alloys I shall presently show.

If it could be shown that sulphur in some form of combination with the iron and carbon does crystallise with the carbides, and that such mixture or solid solution is stable and not readily decomposed, it would be reasonable to conclude that the sulphur is responsible for the stability.

It has been suggested that silicon in iron decomposes the carbides according to the following chemical reaction: $3Si - {}^2Fe_3C = {}^3Fe_2Si - 2C$. The only objection to this explanation is that the silicon is not free in cast iron, as was

[1] "Journal of the Iron and Steel Institute." No. 2, 1908.

proved by Turner, and, moreover, as will be shown presently, it is combined with iron in solid solution before the carbide is decomposed.

Gontermann[1] found that on adding pure silicon to molten iron, the iron and silicon combined with considerable rise in temperature, and I have noticed the same thing even when adding it to carburised iron.

The same authority, who has made a most careful study of the ternary alloys of the iron-carbon-silicon series, has shown that the eutectic freezing-point rises with the silicon from 1130° when silicon is absent, to about 1150° when it reaches 10 per cent., and to 1175° when it is about 17 per cent., and that the carbon in the eutectic of the alloys containing between 0 per cent. and 10 per cent. silicon, falls as the silicon rises by about 0·3 per cent. for each unit of silicon.

The same author proved that the pearlite reversion point in these alloys rises with the silicon on an average of about 30° C. for each unit of silicon in the alloys containing between 0° and 6 per cent. silicon. He concluded, but did not actually prove, that in the region of the curve of unvarying equilibrium two cementites crystallise; one a solid solution of the carbide and silicide of iron; and a second, a mixture of this with another ternary iron-silicon-carbon solid solution.

If the composition of the alloy lies between the curve of saturated silico-austenite and the curve of non-varying equilibrium, saturated silico-austenite primarily forms; and following this a secondary crystallisation of a binary eutectic consisting of this saturated austenite and silico-cementite.

In the year 1901 I described certain unique idiomorphic crystals which had been found in the hearth of a disused blast furnace at Blaina. The crystals were more or less oxidised on their exterior surfaces.

The analysis was as follows :—

	After deducting the Oxygen, &c. Per cent.
Manganese	54·56
Iron	37·71
Carbon	3·91
Silicon	3·82
	100·00

A micro-examination proved the crystals to be quite homogeneous mixtures, or solid solutions. It was difficult to assign to them any definite chemical constitution. They may be considered as silico-carbides of manganese and iron, and, as will be shown presently, bear a close relation to similar crystals which primarily form during the freezing of iron-carbon-silicon alloys.

Having briefly referred to the work of a number of authorities, I now propose to describe my attempts to supplement our knowledge in this direction by a purely micro-chemical research.

In order to understand the remarks which follow, it is necessary briefly to describe the changes which occur when pure iron-iron carbide alloys pass from the liquid to the solid state as are indicated by the researcehs of Osmond, Roberts-Austen, Stansfield, and of Carpenter and Keeling.

In the iron alloys containing less than the eutectic proportion of 4·3 per cent. carbon, described as hypo-eutectic alloys, austenite octohedral crystallites of the fir-tree type first fall out of solution, and these continue to grow until the liquid is so impoverished of iron and enriched in carbon that when the eutectic proportion of 4·3 per cent. carbon is reached, the liquid solidifies and breaks up into carbide of iron and austenite.

The hypereutectic alloys, containing more than the eutectic proportion of carbon, on cooling, first yield carbide of iron crystals, and these continue to grow until, by removal of the excess carbon, the eutectic proportions of iron and carbon are reached. The eutectic in its turn then freezes.

For the purpose of my research it was necessary to select pig metals, grey and high in silicon and white with high sulphur. These were kindly supplied by Messrs. Wilson, Pease and Co. and Messrs. Cochrane and Co., Middlesbrough. They were made from Cleveland ironstone and contained :—

	White	Grey Glazed Iron No. 1	Grey Glazed Iron No. 2
	Per cent.	Per cent.	Per cent.
Combined carbon ...	2·98	nil	trace
Graphite	traces	2·65	3·300
Manganese	0·29	0·72	0·676
Silicon	1·89	5·21	4·321
Sulphur	0·27	0·03	0·025
Phosphorus	1·62	1·56	1·660

It may be accepted that the sulphur in the white iron undoubtedly is the cause of the whiteness of the iron, whilst the excessively high silicon and low sulphur are equally responsible for the graphitic condition of the carbon in the grey irons.

The micro-structure of the high silicon metal was characteristic of all phosphoretic, high-silicon, carbon alloys. Curved plates of graphite cut the mass in many directions, whilst the binary eutectic of phosphorus and iron remained in irregular patches, generally midway between the graphite plates. The ground mass occupying the space between the eutectic and graphite plates consisted of silico-ferrite.

The interesting feature about the structure of the white iron is that there was no iron-iron-carbide eutectic. This had been replaced by the ternary eutectic of iron-phosphorus and carbon, which, according to Dr. Wüst, contains about :—

	Per cent.
Iron	91
Phosphorus	7
Carbon	2
	100

There was evidence that the primary crystals of austenite of the octohedral skeleton type had been the first to fall out of solution, that the second crystal to form consisted of short plates of carbide of iron (cementite); whilst the ternary eutectic of phosphorus, carbon, and iron was the last to freeze and occupied spaces between the cementite plates and the primary crystals.

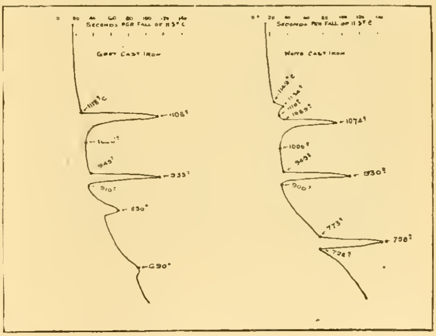

Diagram showing arrest in cooling; grey iron No. 2 on left, white iron on right.

Dr. Carpenter and his assistant, Mr. Edwards, of Victoria University, Manchester, kindly obtained, for the purpose of this address, the cooling curves of these two typical metals. These were as follows :—

Grey Iron.

The long arrest at 1118° indicates a change of state, but is also coincident with important chemical changes. The second long arrest at 945° is due to freezing of the iron phosphorus carbon eutectic. The arrest at 850° indicates the formation of pearlite, and corresponds closely with the arrest in a similar alloy examined by Gontermann. The arrest at 690° is probably due to the formation of pearlite in the eutectic of iron and phosphorus, and is of great interest, for it points to the conclusion that silicon is not a constituent of the austenite of the ternary eutectic.

[1] "Anorganische Chemie, Bd. 59, 1908.

White Iron.

The micro-structure and analysis help more fully to explain the arrests on cooling this alloy.

The first arrest, at 1149° C., is where the primary austenite crystallises with the silicon, as will be shown presently.

The second arrest is where the primary cementite plates freeze.

The third arrest, at 945°, is the freezing point of the ternary eutectic, and is identical with that of the corresponding long arrest of the grey iron.

The fourth arrest, at 77°, is coincident with the formation of pearlite.

Bearing in mind that the manganese in the white iron was insufficient to combine with the whole of the sulphur present to form manganese sulphide, it is obvious that some other compound or compounds of sulphur existed. The microscope clearly revealed the presence of manganese sulphide and traces of free iron sulphide.

The carbide plates were quite free from striations of sulphide, such as had been noticed by Mr. Levy in the eutectic of high sulphur irons.

But for the sulphur present, the silicon would have been sufficient to effect a decomposition of the carbides, and the metal in absence of the sulphur would have given a grey instead of a white fracture. In view of this conclusion, it appeared to be probable that if manganese were to be melted with the metal, it would combine with the sulphur associated with iron, &c., and crystallise as MnS, previous to the solidification of the carbide, or independently, and that the metal would then become grey on cooling.

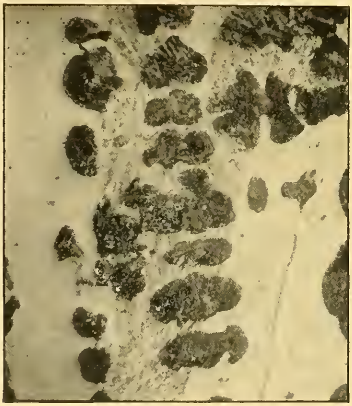

FIG. 1.—Cleveland White Iron.
White = massive plates of Fe_3C.
Dark = pearlite, the decomposed austenite.
White and half-tone = ternary Fe—C—P eutectic.

In order to test this, a portion of the metal was melted in a clay pot with a little pure manganese, free from carbon—sufficient to give 1 per cent. of manganese, which was more than sufficient to combine with the whole of the sulphur. As soon as the mass was melted it was at once poured into a sand mould and allowed to set. When cold, it broke with a grey fracture corresponding to what is known as hard forge, and the combined carbon, instead of being about 3 per cent., was reduced to 0·6 per cent., a result proving the correctness of the hypothesis.

It is well known that when manganese or chromium and some other metals are present in large quantities in pig irons, these metals, as carbides, crystallise with the carbide of iron, forming double carbides, and these are much more stable than the massive pure iron carbide. It appeared reasonable to believe that if sulphide of iron, or some iron-sulpho-carbon compound, were to crystallise with the carbides it would have a similar effect.

Remembering that the conclusions on this question, as to whether sulphur does or does not crystallise with the carbides, are conflicting, it is evident that the only possible way to find out whether sulphur does so crystallise is to separate the carbide from the iron and test it for sulphur. With this object, a considerable quantity of the original Cleveland white metal was crushed to the very finest powder. It was then treated with a 10 per cent. solution of hydrochloric acid in water in large excess, and the action of the acid was allowed to continue until evolution of gas ceased. The insoluble matters, consisting mainly of carbides and phosphides, were filtered off, washed and dried, and were ground down in an agate mortar to a still finer powder, so as to liberate any mechanically entangled sulphides. The powder so dealt with was again treated with acid as before, after which the residue was filtered off, thoroughly washed with water, was transferred to a separate vessel, and was boiled with strong caustic-potash to dissolve any decomposition products.

The residue was again filtered off, was washed and dried, and submitted to analysis. The residue when dried weighed about 45 per cent. of the original metal, and contained as follows:—

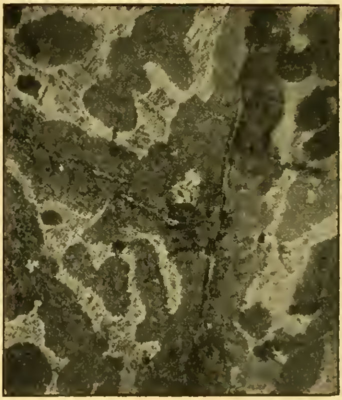

FIG. 2.—Cleveland Glazed Iron.
Ground mass = silico-ferrite.
White complex = iron—iron phosphide eutectic.
Straight dark lines = graphite.

	Per cent.
Iron	92·43
Carbon	6·06
Silicon	0·12
Sulphur	0·12
Phosphorus	0·97 (6·2 per cent. phosphide of iron)
Water, &c.	0·30
	100·00

A second trial was made with the same metal; but, in this case, repounding and acid treatment were repeated three times, so as to eliminate the possibility of mechanical inclusion of sulphide or iron. The sulphur found in the remaining carbides was 0·1 per cent.

As the manganese in this metal was not sufficient to form manganese sulphide with the sulphur, it seemed desirable to determine whether or not, when the manganese is in sufficient quantity, sulphur would crystallise with the carbide. For this purpose the white chilled part of a crushing roll was experimented upon. The centre part was open grey iron, and contained 3·1 per cent. of the carbon as graphite.

The white chilled portion contained:—

	Per cent.
Combined carbon	3·75
Graphitic carbon...	Trace
Manganese	0·65
Silicon	0·70
Sulphur	0·10
Phosphorus	0·23

It was crushed to powder and treated exactly in the same way as previously described for the separation of carbide. The residue contained by analysis:—

	Per cent.
Silicon	0·028
Sulphur	0·016

a result showing that only a minute quantity of sulphur was crystallised with the carbide. Whether a different result would follow if both sulphur and manganese were greatly increased has yet to be determined.

Having proved that sulphur in some undetermined state of chemical combination does crystallise with carbide of iron, an attempt was made to determine the maximum amount of that element the carbide will retain under the most favourable conditions. With this object in view, a considerable quantity of very pure white iron, containing only traces of silicon, sulphur, and phosphorus, and 3·5 per cent. of carbon, was melted in a plumbago crucible, and when in a molten condition sticks of roll sulphur were forced under the surface of the metal, and afterwards the mixture was briskly shaken up with the sulphur which had liquefied on the surface.

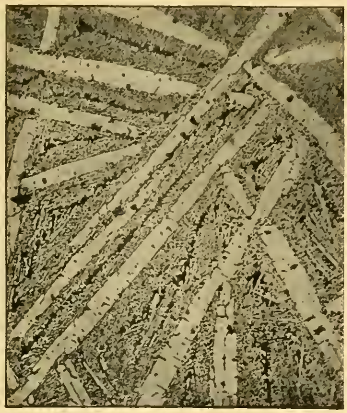

Fig. 3.—Iron-Carbon-Sulphur Alloy (4·37 per cent. Carbon).
White thick bands = massive carbide of iron.
Complex structure = iron—iron-carbide-sulphide-pearlite eutectic.

Precisely the same result was obtained as described by Karsten, who had made a similar experiment. A metal was produced having a white fracture and large cleavage faces. The micro-structure was similar to that of hyper-eutectic iron carbon alloys. Large plates of carbide cut the metal in many directions, whilst between the carbide plates was located the triple carbide-sulphide-pearlite eutectic, so accurately described by Mr. Donald Levy.

The carbide plates themselves were peculiar in having circular prismatic inclusions of sulphide of iron symmetrically arranged at right angles to the sides of the plates. In horizontal sections of these plates they appeared as circular dots, sometimes arranged in continuous lines, suggesting that the sulphide had been actually in solution with the carbide when the metal was liquid, that they fell out of solution together, the sulphide separating and segregating along the cleavages of the carbide.

A portion of this sulphurous material was remelted and treated with a second quantity of sulphur. This time, in addition to sulphide of iron, a considerable quantity of the soot-like substance described by Karsten floated to the surface, and free graphite separated and stuck to the sides of the crucible.

The analyses of these metals are as follows:—

	After the first addition of Sulphur Per cent.	After the second treatment with Sulphur Per cent.
Carbon	4·37	4·39
Sulphur ...	about 1·00	1·00
Silicon	0·03	0·05

From which we may conclude that the maximum degree to which the carbon can be concentrated by this method is about 4·4 per cent. In these trials the carbide certainly had sufficient opportunity to become saturated with sulphur in each case. Both of the metals were crushed to exceedingly fine powder, and were treated with acid to decompose the free sulphides. The residues were repounded and treated with acid a second time, and afterwards with strong potash solution. After this treatment, analyses of the insoluble residues indicated in one case 0·09 per cent. sulphur, and in the other 0·08 per cent. *From this it would appear that carbides will not carry in solid solution more than about 0·1 per cent. of sulphur.*

Fig. 4.—Same as Fig. 2, heat-tinted and more highly magnified.
Broad bands = massive carbide of iron with inclusion of sulphide of iron.
Complex structure = jointed eutectic of Fe—Fe_3C—FeS.
The white specks are all FeS.

The metal containing 4·37 per cent. carbon and 1 per cent. sulphur, even on prolonged annealing, did not become graphite, a proof that the massive carbides present were quite stable.

The microscope reveals the fact that in almost all commercial white irons containing much sulphur the greater part of the sulphur is combined with either manganese or iron, and that the sulphides mainly exist as independent inclusions. It appears reasonable to assume that the manganese sulphide is without influence on the carbon condition, and that, although iron sulphide may have some influence, in the way suggested by Mr. Levy, on the eutectic, *it is the sulphur that crystallises with the carbide which is mainly responsible in preventing the separation of graphite by making the carbide more stable.*

If it is assumed that the stability of the carbide depends on the quantity of sulphur which crystallises with it, and not on the total amount present in the metal carrying the carbides, it is clear that a great field of research is now open, the borders of which I have barely touched to corelate their stability and sulphur contents.

The microscope does not show in what constituent the silicon crystallises. It is known that in grey irons it is associated with the ferrite and pearlite; but grey iron is the final result of the decomposition of carbide of iron and possibly silico-carbides, which primarily form during solidification, and although the silicon in the decomposed product may be entirely associated with the iron, it is no proof that initially some of it may not have crystallised with the carbides.

In the white Cleveland iron, previously referred to, it is probable that the several constituents are present in the following proportions:—

	Per cent.
Silico-pearlite, the residue of the original austenite octahedral crystallites	42·50
Iron carbide in plates	33·66
Iron, phospho-carbide eutectic	23·10
Manganese sulphide	0·38
Iron sulphide	0·36
	100·00

When fractionally dissolving the powdered metal in acid, it was the iron and associated silicon of the pearlite which passed into solution, and the carbide and phosphide which remained insoluble, and as these contained only 0·12 per cent. silicon, or about 0·06 per cent. on 100 parts

FIG. 5.—Same as Fig. 4. Section cut parallel to the surface of a massive carbide plate.
The ground mass is carbide of iron.
The white dots are sulphide of iron.

of the original metal, it is evident that the pearlite must have contained $1·89 - 0·06 = 1·83$ per cent. of the silicon, or on 100 parts of it $\frac{100 \times 1·83}{42·5} = 4·3$ per cent., and that about 97 per cent. of the total silicon had crystallised with the austenite.

A little reflection will lead to the conclusion that if the carbon in the Cleveland white iron were to be gradually increased, the proportion of primary austenite crystallites would decrease; there would be less and less of them to carry the silicon, and this element would be concentrated in the diminishing solid austenite. It also follows that if the carbon were to be so increased that no primary austenite would form, the silicon would have to crystallise in some other constituent.

In the example, referred to above, of the chilled casting, the carbides contained only 0·028 per cent. silicon, or 0·016 per cent. on the original metal. In this case, therefore, about 98 per cent. had crystallised with the primary austenite.

The question as to what amount of silicon will crystallise with the austenite so as to saturate it is probably variable with other variables. To determine this by chemical analysis would involve an exceedingly tedious research.

It is probable that as it increases, and as the austenite approaches more and more nearly to the saturation point, a gradually increasing proportion of the silicon will crystallise with the carbides.

It is well known that molten low silicon grey irons, in the absence of any appreciable quantity of sulphur, gives a white fracture when slightly chilled. Irons with above 5 per cent. silicon, when similarly treated, are supposed not to behave in the same manner, and this is quite true when any ordinary method of chilling is adopted. For instance, when the liquid silicious glazed metal No. 1 was run into water, the chilled iron contained graphite; but when a large drop was suddenly pressed into a sheet as thin as paper between cold plates of iron, the chilled metal was quite white, and no graphite could be detected on dissolving it in nitric acid. The metal so chilled was difficult to dissolve in acid, and the silica produced, instead of forming a gelatinous bulky residue, remained in a close, dense condition—indeed, the thin chilled sheet, after all soluble matter had been removed, remained a rigid sheet of dense coherent silica, whereas the same metal allowed to cool slowly from the liquid state in a sand mould yielded to acid gelatinous silica.

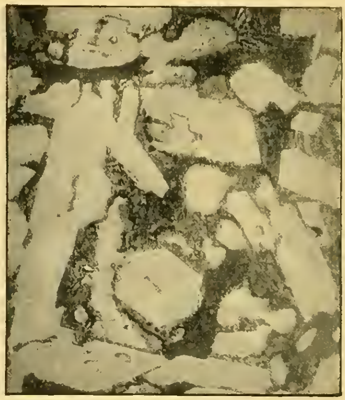

FIG. 6.—Glazed Cleveland Iron after melting with a little Sulphide of Iron.
White crystals = primary carbo-silicide of iron.
Dark = the second cementite.
Complex structure = iron-carbon-phosphorus eutectic.

The different behaviour to acid treatment of the chilled as contrasted with that of the slowly cooled metal indicates that the condition of the silicon in rapidly chilled metal is different from its condition in the same metal slowly cooled.

In 1895 Mr. T. W. Hogg, of Newburn Steel Works, published an account of a very interesting observation, in which he showed the difference in the silicon solubility in different parts of the same pig iron, a portion of which was white and a portion grey. The iron referred to contained:—

	White part Per cent.		Grey part Per cent.	
Combined carbon	3·88	4·33	0·98	4·66
Graphitic carbon	0·45		3·68	
Silicon	0·65		0·85	
Manganese	1·63		1·60	

He determined the solubility in dilute acid of the silicon in each portion, and found that the silicon soluble in hydrochloric acid was, in the grey part = about 81 per cent. and in the white part = about 48 per cent.

He found also that the silica left on treating the two varieties of metal in acid differed in character—that from the white portion was dense, whilst that from the grey metal was much more voluminous. The white metal contained the eutectic proportion of carbon, and therefore it could not contain any austenite crystallites; indeed, with the silicon 0·60 per cent. also present, it must be regarded as a hypereutectic alloy, and on that account we are forced to conclude that the silicon must have crystallised with the carbide.

It has long been known that on dissolving grey ferrosilicon containing even 6 per cent. silicon the silica gelatinises, whereas when the silicon approaches 10 per cent. much of the silica remains in a dense form. It is almost certain that during the solidification of the grey part of Mr. Hogg's pig iron a rich silicon cementite must have primarily formed, for the high carbon would not allow the formation of any primary silico-austenite; when this cementite decomposed the silicide part of it would become diluted with the iron of the decomposed carbide. It was, no doubt, this diluted solid solution in the cold grey metal which yielded the gelatinous silica.

That silicon does diffuse into iron, even at relatively low temperature, was proved by Lebeau. He found that free silicon and iron, when heated together *in vacuo* at 960° C., chemically combine, a fact I have fully confirmed, although it is impossible to get silicon to combine with iron on heating them together in a cementation furnace where oxidising gases have access to the silicon.

FIG. 7.—An Iron-Carbon-Silicon Alloy, free from Phosphorus, made more stable by Sulphur.
Broken-up structure in the centre=the eutectic of two cementites, silico-carbide and carbide.
Half-tone=the carbide cementite.
Dark area=decomposed eutectic.
Light portion at right lower corner=crystallite of silico-pearlite.

To determine whether silicide of iron would diffuse into and precipitate the graphite in white iron, a sample of crushed white iron free from impurities, containing 3·5 per cent. of carbon, was mixed with 10 per cent. by weight of a silicon alloy containing 20 per cent. of silicon ($=Fe_2Si$), also in powder. The mixture, after compression in a short piece of iron tube, was heated for two hours at 1000° C. in an atmosphere of hydrogen gas, and was then removed and cooled in air.

For comparison, a portion of the crushed white iron was treated in the same way.

The combined carbon in the metals before and after heating were as follows:—

	Before Per cent.	After Per cent.
In while metal alone	3·5	3·44
,, ,, and silicide	3·20	0·60

Not only does this trial prove that silicide does diffuse into carbide of iron and precipitate graphite, it has also an important bearing on the question as to why silicon in pig iron, even in small quantities, causes the carbide to be decomposed. In the experiments with the chilled part of a casting containing only 0·7 per cent. silicon and 3·75 per cent. carbon, it was shown that the carbide contained only 0·028 per cent. silicon, and that 98 per cent. of the total silicon was concentrated in the pearlite; yet this white iron, on heating to 1000° C., became quite grey. *Are we not justified in concluding that it was the diffusion of silicide of iron from the silico-austenite into the carbides which caused the separation of graphite?*

As I had proved, first that sulphur crystallises with and makes the carbide of iron more stable, and second that in the presence of a fusible mother liquor rich in phosphorus, after the austenite crystallisation is complete, the carbide crystallises out in plates and not as iron carbide eutectic, it appeared probable that if, as Gontermann premised, two kinds of cementite actually form during the solidification of iron-carbide-silicon alloys, it might be possible to obtain them in a separate state by melting the rich silicon alloys with a little sulphur.

In order to test this, a portion of the No. 1 grey glazed metal was melted, and when fluid a little sulphide of iron was mixed with it. The mixture was then cast in sand.

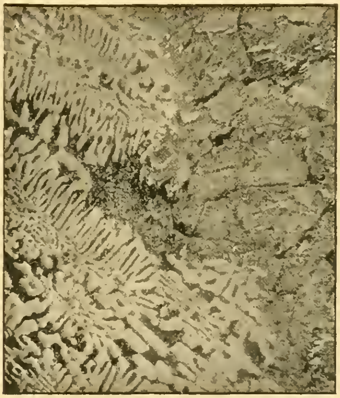

FIG. 8.—Pure Iron-Iron Carbide Eutectic, the cooling of which was arrested before the complete decomposition of the Carbides into Austenite and Graphite.
White=carbide of iron. Black lines=graphite.
Half-tone=pearlite.

Owing to the rapidity of the melting, some of the graphite escaped and floated on the surface of the metal.

When cold it was found that the lower part of the small casting gave a white fractured surface, whilst the upper part was close grey.

The analyses were as follows:—

	White part Per cent.	Grey part Per cent.
Combined carbon	2·06	0·60
Graphite	trace	1·46
Manganese	0·03	0·03
Silicon	5·41	5·40
Sulphur	0·88	0·91
Phosphorus	1·50	1·50

The grey part, although slowly attacked by cold acid, did dissolve, yielding much voluminous silica. The white part was almost inert, and only dissolved in strong hydrochloric acid with difficulty, and when the iron was dissolved out the remaining silica was of the dense variety, from which it would appear that the effect of the sulphide is akin to that of sudden quenching.

It was the micro-structure of the white portion, however, which was of unique interest. On "heat-tinting" two kinds of hard crystals appeared, one more readily coloured by heating than the other. The more resistant crystals were idiomorphic, and were furnished with their terminal angles, but as they were embedded in the surrounding metal it was impossible to form any exact idea of the crystalline system to which they belonged.

The second order of crystals had evidently solidified at a later period, as their forms were interfered with by those of the idiomorphic type; they were much like ordinary plates of carbide of iron. The ground mass contained indications of octahedral on fir-tree crystallites and a well-developed phosphorus iron eutectic of the honeycomb type. This eutectic was the last to freeze, as it filled the spaces between the plates of the hard crystals. There was no pearlite excepting in the eutectic of phosphorus and iron. We can only tentatively conclude that, of the two cementites, the idiomorphic crystals contained the greater part of the silicon, because of their greater resistance to oxidation, and probably consisted of carbo-silicide of iron, with sufficient sulphur in them to make them stable; also that the second crystals were carbide of iron, possibly containing a lesser quantity or no silicide in solid solution.

A further series of experiments was made on a portion of the same metal. In this case the molten iron was mixed and agitated with free sulphur instead of sulphide of iron, and the metal was at once poured into a sand mould in a thin layer. When cold it was quite white in fracture, and had large, brilliant cleavage faces.

It had the following composition:—

	Per cent.
Combined carbon	2·60
Manganese	Trace
Silicon	6·65
Sulphur	0·93
Phosphorus	2·08

The sulphur had evidently effected concentration of the silicon, phosphorus, and carbon by removing some of the iron, as sulphide of iron was actually formed and floated on the surface of the iron. It was fractionally dissolved as described in previous cases, and the residue (72 per cent. of the weight of the original metal) was tested and found to contain:—

	Per cent.
Carbon	2·92
Manganese...	Trace
Silicon	6·70
Sulphur	0·062
Phosphorus	1·410

This insoluble fraction evidently consisted of both classes of crystals, together with some phosphide of iron. Efforts were made to separate the crystals by chemical means, but without success.

On the long and continued action of strong hydrochloric acid a residue was obtained containing a little less carbon and more silicon than were present in the mixture, an indication that the less soluble portion is different from that more soluble.

The micro-structure was similar to that of the metals of the previous trial, but as the carbon and silicon were higher the carbo-silicide was in greater quantity. It crystallised in long flat plates, and not in relatively short idiomorphic crystals.

It is probable exception may be taken, with some justification, that the sulphur does not simply arrest the decomposition of the cementites, which I have premised primarily form, but may act in some other unknown way. An attempt was therefore made to find out whether they could be obtained by some other method without the aid of sulphur. As it is known that the ternary eutectic of iron, phosphorus, and carbon melts at about 945° C., it appeared probable that if silicon in small quantity were to be melted with an iron-carbon-phosphorus alloy very rich in phosphorus, the two kinds of cementites would fall out of solution at a lower temperature, and would probably not decompose into graphite and silico-austenite in cooling down after their formation. To ascertain whether or not this would be the case, a fusible iron-phosphorus-carbon alloy containing more than the eutectic proportion of carbon was made. It had the following composition:—

	Per cent.
Iron	91·89
Phosphorus...	5·37
Carbon	2·62
Silicon, &c.	0·10
Sulphur	0·02
	100·00

Four hundred grams were melted with sufficient silicon alloy to yield in the mixture:—

	Per cent.
Carbon	2·4
Phosphorus	5·0
Silicon	2·90
Sulphur	0·02

When melted, a portion of it was cast in a sand mould; the remainder was allowed to cool in the crucible.

When cold, that cooled in the crucible was quite grey, whilst the portion cooled in sand was white at the lower part and grey on the top part of the casting, results which proved that the alloy was very unstable, and that decomposition of the lower part of the casting was arrested by the slight chilling effect of the cold sand.

On microscopic examination of the white portion, the ground mass was found to consist of the binary phosphorus iron eutectic, whilst two different cementites were embedded in it; one much more rapidly coloured on "heat-tinting" than the other. The colours of the constituents of the properly heated and polished metal were as follows:—

Cementite (*a*)	White
,, (*b*)	Red
Phosphide of iron	Purple
Iron pearlite crystallites	Grey

The part which broke with a grey fracture consisted of octahedral crystallites of silico-pearlite, the binary phosphorus iron eutectic, and undecomposed (red) cementite crystals, but there was a complete absence of the (white) cementite crystals. Graphite was also present in exceedingly fine plates, resembling what is known as temper graphite.

The evidence here is conclusive that even in the absence of sulphur:—

1st. Two cementites had formed.

2nd. That one cementite is much more unstable than the other variety, and decomposes in advance into silico-austenite and graphite.

Having proved that two different kinds of cementite do actually form and crystallise in the phosphorus eutectic, it remained to ascertain in what way these crystallise in the absence of the phosphorus eutectic.

For this purpose two hypo-eutectic alloys were prepared without any phosphorus, but with sufficient sulphide of iron to check the decomposition of the carbides.

They contained:—

	1 Per cent.	2 Per cent.
Carbon	2·40	2·10
Silicon...	3·17	7·10
Sulphur	1·21	0·82
Phosphorus	0·02	0·02

These when cold, after casting in sand, broke with white fractures.

The carbides separated in the manner previously described contained:—

	1 Per cent.	2 Per cent.
Carbon	6·16	3·00
Sulphur	0·09	0·08
Silicon	0·97	7·93
Percentage of carbides insoluble in acid	27·5	50·00

The repeated acid treatment in this, as in all previous cases, no doubt dissolved a portion of the carbides, and what was actually weighed represented only a part of those actually present in the alloys.

In No. 2 alloy, after polishing and "heat-tinting," the microscope proved the presence of a few fir-tree crystallites embedded in a ground mass of cementite and a eutectic containing the two kinds of cementite, the No. 1 specimen containing a much smaller proportion of the cementite rich in silicon than No. 2.

As the metals had been somewhat rapidly cooled, the alloy No. 2 was remelted, and was then allowed to cool in the crucible, so as to obtain a more coarsely crystallised eutectic. When cold, on polishing and "heat-tinting," the eutectic was clearly seen. There were the remains of large primary silico-austenite crystallites, plates of the red-coloured cementite, and a well-developed eutectic consisting of the (red) coloured and (white) cementites.

The cooling having been slow, this compound constituent had suffered partial decomposition in isolated patches into graphite and silico-ferrite, whilst the cementite coloured red remained intact.

There can be little doubt that the residue left insoluble in acid consisted of the two cementites, but in what proportion it is impossible to tell, as a method for isolating them has yet to be found.

Had the alloy contained a greater proportion of carbon, the amount of cementite rich in silicon would have been in much greater proportion.

The trials, incomplete and necessarily imperfect as they are, go far to prove, just as Gontermann premised, that during the solidification of high silicon pig irons two cementites fall out of solution together as a eutectic mixture.

They also have proved that the carbo-silicides are exceedingly unstable, breaking up into silico-austenite almost as soon as formed. *It is the instability of these silico-carbides which is mainly responsible for the graphitic character of grey irons rich in silicon and low in sulphur.*

Summary and Conclusions.

(1) The experimental results advanced show proof that carbide of iron in presence of iron sulphide crystallises with a minute quantity of sulphur not exceeding about one-thousandth part of the weight of the carbide, but the nature of the iron-carbon-sulphur compound has not yet been determined.

(2) It seems almost, if not absolutely, certain that it is the sulphur crystallised with the carbide which makes the latter stable.

(3) The evidence appears to support the view, long held by some, and more recently accepted by others, that during the freezing of iron-carbon-hypo-eutectic alloys after the crystallisation of the primary austenite, and in the eutectic and hypereutectic alloys, it is the carbide, and not graphite, which primarily forms, and that the carbide afterwards decomposes into graphite and austenite.

(4) It has been proved by chemical methods that when the hypo-eutectic alloys, low in silicon, freeze, nearly all the silicon crystallises out with the primary austenite; and it follows that on gradually increasing the carbon so as to reduce the quantity of primary austenite, the silicon remaining constant, the austenite which does form must be as gradually enriched in silicon up to saturation point, and, when that point is reached, the excess silicon crystallises out with a portion of the carbide of iron to form carbo-silicide of iron. Other elements remaining constant, the same result must follow on gradually increasing the silicon.

(5) In the alloys of eutectic proportion and in the hyper-eutectic alloys, as no primary austenite can form, the silicon crystallises primarily with the carbide.

(6) In Cleveland pig iron containing about 1·5 per cent. phosphorus, a ternary eutectic of iron-carbon-phosphorus takes the place of the iron-iron-carbide eutectic. In white irons containing 3 per cent. carbon and under 2 per cent. silicon, after the primary austenite has fallen out of solution, carrying practically all the silicon, it is not iron-iron-carbide which forms, but independent plates of cementite, or carbide of iron, and after these have crystallised and the residual mother liquor has arrived at the composition of the ternary iron-carbon-phosphorus eutectic, the latter solidifies at 945° C.

(7) In Cleveland irons which become grey on cooling, and in which there is no primary austenite, the same iron-carbon-phosphorus eutectic is the only eutectic to form during cooling, and, instead of a ternary iron-carbon-silicon eutectic, two independent cementites crystallise—one a silico-carbide and the other carbide of iron, possibly containing a little silicide in solid solution. The micro-examination of the cold alloys, to which a little sulphur had previously been added when the metals were melted, led to the conclusion that it is the carbo-silico-cementite which primarily crystallises.

(8) There is evidence that the primary carbo-silicides are exceedingly unstable, and are the first to decompose into graphite and silico-austenite.

(9) In the absence of any sensible quantity of phosphorus, two cementites form—one the silico-carbide cementite, the other the carbide cementite—and these crystallise together as a eutectic mixture.

(10) The exact composition of the two cementites has not yet been determined, as no chemical method has been found for their isolation.

(11) It is evident that it is the exceedingly unstable character of the silico-carbides which is responsible for the greyness of commercial metals rich in silicon and low in sulphur.

(12) Silicide of iron when heated at 1000° C. with pure white iron free from silicon effects the decomposition of the carbide of the white iron. Based on this observation, the hypothesis seems justifiable, in cases where all the silicon present in hypo-eutectic alloys crystallises out with the primary austenite, that after the carbide has solidified diffusion of the silicide follows, and this leads to the decomposition of the carbide of iron into graphite of iron.

(13) Many of the results arrived at by chemical analysis support the hypothetical conclusions of Gontermann, who depended mainly on data obtained by thermal methods of treatment.

In conclusion, it will be clear from what I have stated that there are many gaps yet to be filled. I hope that the knowledge of this fact will lead others to follow up the research, which, in its present stage, is far from complete.

SUB-SECTION OF B.

AGRICULTURAL SUB-SECTION.

Opening Address by A. D. Hall, M.A., F.R.S., Chairman of the Sub-section.

I believe it is customary for anyone who has the honour of presiding over a section of the British Association to provide in his presidential address either a review of the current progress of his subject or an account of some large piece of investigation by which he himself has illuminated it. I wish I had anything of the latter kind which I could consider worthy to occupy your attention for the time at my disposal; and as to a review of the subject, I am not without hopes that the sectional meetings themselves will provide all that is necessary in the way of a general review of what is going forward in our department of science. I have, therefore, chosen instead to deal from an historic point of view with the opinions which have prevailed about one central fact, and I propose to set before you this morning an account of the ebb and flow of ideas as to the causes of the fertility of the soil, a question which has naturally occupied the attention of everyone who has exercised his reason upon matters connected with agriculture. The fertility of the soil is perhaps a vague title, but by it I intend to signify the greater or less power which a piece of land possesses of producing crops under cultivation, or, again, the causes which make one piece of land yield large crops when another piece alongside only yields small ones, differences which are so real that a farmer will pay three or even four pounds an acre rent for some land, whereas he will regard other as dear at ten shillings an acre.

If we go back to the seventeenth century, which we may take as the beginning of organised science, we shall find that men were concerned with two aspects of the question—how the plant itself gains its increase in size, and, secondly, what the soil does towards supplying the material constituting the plant. The first experiment we have recorded is that of Van Helmont, who placed 200 lb. of dried earth in a tub, and planted therein a willow tree weighing 5 lb. After five years the willow tree weighed

169 lb. 3 oz., whereas the soil, when redried, had lost but 2 oz., though the surface had been carefully protected meantime with a cover of tin. Van Helmont concluded that he had demonstrated a transformation of water into the material of the tree. Boyle repeated these experiments, growing pumpkins and cucumbers in weighed earth, and obtaining similar results, except when his gardener lost the figures, an experience that has been repeated. Boyle also distilled his pumpkins, &c., and obtained therefrom various tars and oils, charcoal and ash, from which he concluded that a real transmutation had been effected, "that salt, spirit, earth, and even oil (though that be thought of all bodies the most opposite to water) may be produced out of water."

There were not, however, wanting among Boyle's contemporaries men who pointed out that spring water used for the growing plants in these experiments contained abundance of dissolved material, but in the then state of chemistry the discussion as to the origin of the carbonaceous material in the plant could only be verbal. Boyle himself does not appear to have given any consideration to the part played by the soil in the nutrition of plants, but among his contemporaries experiment was not lacking. Some instinct seems to have led them to regard nitre as one of the sources of fertility, and we find that Sir Kenelm Digby, at Gresham College in 1660, at a meeting of the Society for Promoting Philosophical Knowledge by Experiment, in a lecture on the vegetation of plants, describes an experiment in which he watered young barley plants with a weak solution of nitre, and found how their growth was promoted thereby; and John Mayow, that brilliant Oxford man whose early death cost so much to the young science of chemistry, went even further, for, after discussing the growth of nitre in soils, he pointed out that it must be this salt which feeds the plant, because none is to be extracted from soils in which plants are growing. So general has this association of nitre with the fertility of soils become, that in 1675 John Evelyn writes: "I firmly believe that where saltpetre can be obtained in plenty we should not need to find other composts to ameliorate our ground"; and Henshaw, of University College, one of the first members of the Royal Society, also writes about saltpetre: "I am convinced, indeed, that the salt which is found in vegetables and animals is but the nitre which is so universally diffused through all the elements (and must therefore make the chief ingredient in their nutriment, and by consequence all their generation), a little altered from its first complexion."

But these promising beginnings of the theory of plant nutrition came to no fruition; the Oxford movement in the seventeenth century was but the false dawn of science. At its close the human mind, which had looked out of doors for some relief from the fierce religious controversy with which it had been so long engrossed, turned indoors again and went to sleep for another century. Mayow's work was forgotten, and it was not until Priestly and Lavoisier, De Saussure, and others, about the beginning of the nineteenth century, arrived at a sound idea of what the air is and does that it became possible to build afresh a sound theory of the nutrition of the plant. At this time the attention of those who thought about the soil was chiefly fixed upon the humus. It was obvious that any rich soils, such as old gardens and the valuable alluvial lands, contained large quantities of organic matter, and it became somewhat natural to associate the excellence of these fat, unctuous soils with the organic matter they contained. It was recognised that the main part of a plant consisted of carbon, so that the deduction seemed obvious that the soils rich in carbon yielded those fatty, oily substances which we now call humus to the plant, and that their richness depended upon how much of such material they had at their disposal. But by about 1840 it had been definitely settled what the plant is composed of and whence it derives its nutriment—the carbon compounds which constitute nine-tenths of the dry weight from the air, the nitrogen, and the ash from the soil. Little as he had contributed to the discovery, Liebig's brilliant expositions and the weight of his authority had driven this broad theory of plant nutrition home to men's minds; a science of agricultural chemistry had been founded, and such questions as the function of the soil with regard to the plant could be studied with some prospect of success. By this time, also, methods of analysis had been so far improved that some quantitative idea could be obtained as to what is present in soil and plant, and, naturally enough, the first theory to be framed was that the soil's fertility was determined by its content of those materials which are taken from it by the crop. As the supply of air from which the plant derives its carbonaceous substance is unlimited, the extent of growth would seem to depend upon the supply available of the other constituents which have to be provided by the soil. It was Daubeny, Professor of Botany and Rural Economy at Oxford, and the real founder of a science of agriculture in this country, who first pointed out the enormous difference between the amount of plant food in the soil and that taken out by the crop. In a paper published in the Philosophical Transactions in 1845, being the Bakerian Lecture for that year, Daubeny described a long series of experiments that he had carried out in the Botanic Garden, wherein he cultivated various plants, some grown continuously on the same plot and others in a rotation. Afterwards he compared the amount of plant food removed by the crops with that remaining in the soil. Daubeny obtained the results with which we are now familiar, that any normal soil contains the material for from fifty to a hundred field crops. If, then, the growth of the plant depends upon the amount of this material it can get from the soil, why is that growth so limited, and why should it be increased by the supply of manure, which only adds a trifle to the vast stores of plant food already in the soil? For example, a turnip crop will only take away about 30 lb. per acre of phosphoric acid from a soil which may contain about 3000 lb. an acre; yet, unless to the soil about 50 lb. of phosphoric acid in the shape of manure is added, hardly any turnips at all will be grown. Daubeny then arrived at the idea of a distinction between the active and dormant plant food in the soil. The chief stock of these materials, he concluded, was combined in the soil in some form that kept it from the plant, and only a small proportion from time to time became soluble and available for food. He took a further step, and attempted to determine the proportion of the plant food which can be regarded as active. He argued that since plants only take in materials in a dissolved form, and as the great natural solvent is water percolating through the soil more or less charged with carbon dioxide, therefore in water charged with carbon dioxide he would find a solvent which would extract out of a soil just that material which can be regarded as active and available for the plant. In this way he attacked his Botanic Garden soils, and compared the materials so dissolved with the amount taken away by his crops. The results, however, were inconclusive, and did not hold out much hope that the fertility of the soil can be measured by the amount of available plant food so determined. Daubeny's paper was forgotten; but exactly the same line of argument was revived again about twenty years ago, and all over the world investigators began to try to measure the fertility of the soil by determining as "available" plant food the phosphoric acid and potash that could be extracted by some weak acid. A large number of different acids were tried, and although a dilute solution of citric acid is at present the most generally accepted solvent, I am still of opinion that we shall come back to the water charged with carbon dioxide as the only solvent of its kind for which any justification can be found. Whatever solvent, however, is employed to extract from the soil its available plant food, the results fail to determine the fertility of the soil, because we are measuring but one of the factors in plant production, and that often a comparatively minor one. In fact, some investigators—Whitney and his colleagues in the American Department of Agriculture—have gone so far as to suppose that the actual amount of plant food in the soil is a matter of indifference. They argue that as a plant feeds upon the soil water, and as that soil water must be equally saturated with, say, phosphoric acid, whether the soil contains 1000 or 3000 lb. per acre of the comparatively insoluble calcium and iron salts of phosphoric acid which occur in the soil, the plant must be under equal conditions as regards phosphoric acid, whatever the soil in which it may be grown. This argument is, however, a little more suited to controversy than to real life; it is too fiercely logical for the things themselves, and depends upon various assumptions holding rigorously, whereas we have more reason to believe that they are only imperfect approximations to the truth. Still, this view does merit our careful attention, because it insists that the chief factor in plant production must be the supply of water to the plant, and that soils differ from one another far more in their ability to maintain a good supply of water than in the amount of plant food they contain. Even in a climate like our own, which the text-books describe as "humid" and we are apt to call "wet," the magnitude of our crops is more often limited by want of water than by any other single factor. The same American investigators have more recently engrafted on to their theory another supposition, that the fertility of soil is often determined by excretions from the plants themselves, which thereby poison the land for a renewed growth of the same crop, though the toxin may be harmless to a different plant which follows it in the rotation. This theory had also been examined by Daubeny, and the arguments he advanced against it in 1845 are valid to this day. Schreiner has, indeed, isolated a number of organic substances from soils—di-hydroxystearic acid and picoline-carboxylic acid were the first examples—which he claims to be the products of plant growth and toxic to the further growth of the same plants. The evidence of toxicity as determined by water-cultures requires, however, the greatest care in interpretation, and it is very doubtful how far it can be applied to soils with their great power of precipitating or otherwise putting out of action soluble substances with which they may be supplied. Moreover, there are as yet no data to show whether these so-called toxic substances are not normal products of bacterial action upon organic residues in the soil, and as such just as abundant in fertile soils rich in organic matter as in the supposed sterile soils from which they were extracted.

As, then, we have failed to base a theory of fertility on the plant food that we can trace in the soil by analysis, let us come back to Mayow and Digby, and consider again the nitre in the soil—how it is formed and how renewed. Their views of the value of nitrates to the plant were justified when the systematic study of plant-nutrition began, and demonstrated that plants can only obtain their supply of the indispensable element nitrogen when it is presented in the form of a nitrate; but it was not until within the last thirty years that we obained an idea as to how the nitre came to be found. The oxidation of ammonia and other organic compounds of nitrogen to the state of nitrate was one of the first actions in the soil which was proved to be brought about by bacteria, and by the work of Schloesing and Müntz, Warington and Winogradsky, we learnt that in all cultivated soils two groups of bacteria exist which successively oxidise ammonia to nitrites and nitrates, in which latter state the nitrogen is available for the plant. These same investigators showed that the rate at which nitrification takes place is largely dependent upon operations under the control of the farmer; the more thorough the cultivation, the better the drainage and aëration, and the higher the temperature of the soil, the more rapidly will the nitrates be produced. As it was then considered that the plant could only assimilate nitrogen in the form of nitrates, and as nitrogen is the prime element necessary to nutrition, it was then an easy step to regard the fertility of the soil as determined by the rate at which it would give rise to nitrates. Thus the bacteria of nitrification became regarded as a factor, and a very large factor, in fertility. This new view of the importance of the living organisms contained in the soil further explained the value of the surface soil, and demolished the fallacy which leads people instinctively to regard the good soil as lying deep and requiring to be brought to the surface by the labour of the cultivator. This confusion between mining and agriculture probably originated in the quasi-moral idea that the more work you do the better the result will be; but its application to practice with the aid of a steam plough in the days before bacteria were thought of ruined many of the clay soils of the Midlands for the next half-century. Not only is the subsoil deficient in humus, which is the accumulated débris of previous applications of manure and vegetation, but the humus is the home of the bacteria which have so much to do with fertility.

The discovery of nitrification was only the first step in the elucidation of many actions in the soil depending upon bacteria—for example, the fixation of nitrogen itself. A supply of combined nitrogen in some form or other is absolutely indispensable to plants and, in their turn, to animals; yet, though we live in contact with a vast reservoir of free nitrogen gas in the shape of the atmosphere, until comparatively recently we knew of no natural process except the lightning flash which would bring such nitrogen into combination. Plants take combined nitrogen from the soil, and either give it back again or pass it on to animals. The process, however, is only a cyclic one, and neither plants nor animals are able to bring in fresh material into the account. As the world must have started with all its nitrogen in the form of gas, it was difficult to see how the initial stock of combined nitrogen could have arisen; for that reason many of the earlier investigators laboured to demonstrate that plants themselves were capable of fixing and bringing into combination the free gas in the atmosphere. In this demonstration they failed, though they brought to light a number of facts which were impossible to explain, and only became cleared up when, in 1886, Hellreigel and Wilfarth showed that certain bacteria, which exist upon the roots of leguminous plants, like clover and beans, are capable of drawing nitrogen from the atmosphere. Thus they not only feed the plant on which they live, but they actually enrich the soil for future crops by the nitrogen they leave behind in the roots and stubble of the leguminous crop. Long before this discovery experience had taught farmers the very special value of these leguminous crops; the Roman farmer was well aware of their enriching action, which is enshrined in the well-known words in the Georgics beginning, "Aut ibi flava seres," where Virgil says that the wheat grows best where before the bean, the slender vetch, or the bitter lupin had been most luxuriant. Since the discovery of the nitrogen-fixing organisms associated with leguminous plants, other species have been found resident in the soil which are capable of gathering combined nitrogen without the assistance of any host plant, provided only they are supplied with carbonaceous material as a source of energy whereby to effect the combination of the nitrogen. To one of these organisms we may with some confidence attribute the accumulation of the vast stores of combined nitrogen contained in the black virgin soils of places like Manitoba and the Russian steppes. At Rothamsted we have found that the plot on the permanent wheat field which never receives any manure has been losing nitrogen at a rate which almost exactly represents the differences between the annual removal of the crop and the receipts of combined nitrogen in the rain. We can further postulate only a very small fixation of nitrogen to balance the other comparatively small losses in the drainage water or in the weeds that are removed; but on a neighbouring plot, which has been left waste for the last quarter of a century, so that the annual vegetation of grass and other herbage falls back to the soil, there has been an accumulation of nitrogen representing the annual fixation of nearly a hundred pounds per acre. The fixation has been possible by the *azotobacter* on this plot, because there alone does the soil receive a supply of carbohydrate, by the combustion in which the *azotobacter* obtained the energy necessary to bring the nitrogen into combination. On the unmanured plot the crop is so largely removed that the little root and stubble remaining does not provide material for much fixation.

Though numerous attempts have been made to correlate the fertility of the soil with the numbers of this or that bacterium existing therein, no general success has been attained, because probably we measure a factor which is only on occasion the determining factor in the production of the crop. Meantime, our sense of the complexity of the actions going on in the soil has been sharpened by the discovery of another factor, affecting in the first place the bacterial flora in the soil, and, as a consequence, its fertility. Ever since the existence of bacteria has been recognised, attempts have been made to obtain soils in a sterile condition, and observations have been from time to time recorded to the effect that soil which has been heated to the temperature of boiling water, in order to destroy any bacteria it may contain, had thereby gained greatly in fertility, as though some large addition of fertiliser had been made to it. Though these observations have been repeated in various times and places, they were generally ignored, because of the difficulty of forming any explanation: a fact is not a fact until it fits into a theory. Not only is sterilisation by heating thus effective, but other antiseptics, like chloroform and carbon bisulphide vapour, give rise to a similar result. For example, you will remember how the vineyards of Europe were devastated some thirty years ago by the attacks of phylloxera, and though in a general way the disease has been conquered by the introduction of a hardy American vine stock which resists the attack of the insect, in many of the finest vineyards the owners have feared to risk any possible change in the quality of the grape through the introduction of the new stock, and have resorted instead to a system of killing the parasite by injecting carbon bisulphide into the soil. An Alsatian vine-grower who had treated his vineyards by this method observed that an increase of crop followed the treatment even in cases where no attack of phylloxera was in question. Other observations of a similar character were also reported, and within the last five years the subject has received some considerable attention, until the facts became established beyond question. Approximately the crop becomes doubled if the soil has first been heated to a temperature of 70° to 100° for two hours, while treatment for forty-eight hours with the vapour of toluene, chloroform, &c., followed by a complete volatilisation of the antiseptic, brings about an increase of 30 per cent. or so. Moreover, when the material so grown is analysed, the plants are found to have taken very much larger quantities of nitrogen and other plant foods from the treated soil; hence the increase of growth must be due to larger nutriment and not to mere stimulus. The explanation, however, remained in doubt until it has been recently cleared up by Drs. Russell and Hutchinson, working in the Rothamsted laboratory. In the first place, they found that the soil which had been put through the treatment was chemically characterised by an exceptional accumulation of ammonia, to an extent that would account for the increased fertility. At the same time, it was found that the treatment did not effect complete sterilisation of the soil, though it caused at the outset a great reduction in the numbers of bacteria present. This reduction was only temporary, for as soon as the soil was watered and left to itself the bacteria increased to a degree that is never attained under normal conditions. For example, one of the Rothamsted soils employed contains normally about seven million bacteria per gram—a number which remains comparatively constant under ordinary conditions. Heating reduced the numbers to 400 per gram, but four days later they had risen to six million, after which they increased to more than forty million per gram. When the soil was treated with toluene a similar variation in the number of bacteria was observed. The accumulation of ammonia in the treated soils was accounted for by this increase in the number of bacteria, because the two processes went on at about the same rate. Some rearrangements were effected also in the nature of the bacterial flora; for example, the group causing nitrification was eliminated, though no substantial change was effected in the distribution of the other types. The bacteria which remained were chiefly of the class which split up organic nitrogen compounds into ammonia, and as the nitrate-making organisms which normally transform ammonia in the soil as fast as it is produced had been killed off by the treatment, it was possible for the ammonia to accumulate. The question now remaining was, What had given this tremendous stimulus to the multiplication of the ammonia-making bacteria? and by various steps, which need not here be enumerated, the two investigators reached the conclusion that the cause was not to be sought in any stimulus supplied by the heating process, but that the normal soil contained some negative factor which limited the multiplication of the bacteria therein. Examination along these lines then showed that all soils contain unsuspected groups of large organisms of the protozoa class, which feed upon living bacteria. These are killed off by heating or treatment by antiseptics, and on their removal the bacteria, which partially escape the treatment, and are now relieved from attack, increase to the enormous degree that we have specified. According to this theory, the fertility of a soil containing a given store of nitrogen compounds is limited by the rate at which these nitrogen compounds can be converted into ammonia, which, in its turn, depends upon the number of bacteria present effecting the change, and these numbers are kept down by the larger organisms preying upon the bacteria. The larger organisms can be removed by suitable treatment, whereupon a new level of ammonia production, and therefore of fertility, is rapidly attained. Curiously enough, one of the most striking of the larger organisms is an amœba akin to the white corpuscles of the blood—the phagocytes, which, according to Metchnikoff's theory, preserve us from fever and inflammation by devouring such intrusive bacteria as find entrance in the blood. The two cases are, however, reversed: in the blood the bacteria are deadly, and the amœba therefore beneficial, whereas in the soil the bacteria are indispensable, and the amœba become noxious beasts of prey.

Since the publication of these views of the functions of protozoa in the soil, confirmatory evidence has been derived from various sources. For example, men who grow cucumbers, tomatoes, and other plants under glass are accustomed to make up extremely rich soils for the intensive culture they practise, but, despite the enormous amount of manure they employ, they find it impossible to use the same soil for more than two years. Then they are compelled to introduce soil newly taken from a field and enriched with fresh manure. Several of these growers here have observed that a good baking of this used soil restores its value again; in fact, it becomes too rich, and begins to supply the plant with an excessive amount of nitrogen. It has also been pointed out that it was the custom of certain of the Bombay tribes to burn vegetable rubbish mixed, as far as possible, with the surface soil before sowing their crop, and the value of this practice in European agriculture, though forgotten, is still on record in the books on Roman agriculture. We can go back to the Georgics again, and there find an account of a method of heating the soil before sowing, which has only received its explanation within the last year, but which in some form or other has got to find its way back again into the routine of agriculture. Indeed, I am informed that one of the early mysteries, many of which we know to be bound up with the practices of agriculture, culminated in a process of firing the soil preparatory to sowing the crop.

My time has run out, and I fear that the longer I go on the less you will feel that I am presenting you with any solution of the problem with which we set out—"What is the cause of the fertility of the soil?" Evidently there is no simple solution; there is no single factor to which we can point as *the* cause; instead, we have indicated a number of factors any one of which may at a given time become a limiting factor and determine the growth of the plant. All that science can do as yet is to ascertain the existence of these factors one by one and bring them successively under control; but, though we have been able to increase production in various directions, we are still far from being able to disentangle all the interacting forces the resultant of which is represented by the crop.

One other point, I trust, my sketch may have suggested to you: when science, a child of barely a century's growth, comes to deal with a fundamental art like agriculture, which goes back to the dawn of the race, it should begin humbly by accepting and trying to interpret the long chain of tradition. It is unsafe for science to be dogmatic; the principles upon which it relies for its conclusions are often no more than first approximations to the truth, and the want of parallelism, which can be neglected in the laboratory, gives rise to wide divergencies when produced into the regions of practice. The method of science is, after all, only an extension of experience. What I have endeavoured to show in my discourse is the continuous thread which links the traditional practices of agriculture with the most modern developments of science.

NOTES.

MADAME CURIE and M. Debierne have presented a joint memoir to the Paris Academy of Sciences announcing that they have succeeded in isolating pure radium. The metallic radium obtained is reported to be of a brilliant white colour, which blackens when exposed to the air. It burns paper, rapidly decomposes water, and adheres to iron.

THE chief chemist of the Barrow works of Messrs. Vickers, Sons and Maxim announces the discovery of an alloy which is believed to be superior to anything of its kind hitherto manufactured, and is to be known as duralumin. While being slightly heavier than pure aluminium, it is reported to be as strong as steel, and it can be rolled, drawn, stamped, extended, or forged at suitable temperatures. It is less corrodable than other high aluminium alloys under all the usual corrosive tests, and possesses many valuable properties. It is only one-third the weight of brass.

ACCORDING to *Science*, Dr. Charles Fahlberg, who was associated with Prof. Ira Remsen in the discovery of saccharine, died at Bad Nassau on August 15.

THE *Times* announces the death, at Cintra, of Prof. Pedroso, president of the Geographical Society of Lisbon.

THE centenary of the death of the famous Italian naturalist Filippo Cavolini will be commemorated by a series of meetings to be held in Naples on September 12–14. The arrangements are in the hands of a committee, the presidents of which are Profs. Monticelli and Cavara, professors of zoology and botany in the Royal University of Naples, and the inaugural meeting will be held in the Great Hall of that University on September 12 at 10 a.m.

THE following are the arrangements for the opening of the winter session of the London medical schools:—St. George's Hospital, King's College Hospital, and London Hospital will open on October 1. At the first-named Dr. S. Squire Sprigge will deliver an oration "On Prizes." St. Bartholomew's Hospital, Charing Cross Hospital (at which Dr. F. W. Mott, F.R.S., will deliver the eighth Huxley lecture, on "The Hereditary Aspect of Nervous and Mental Diseases"), Guy's Hospital, London (Royal Free Hospital) School of Medicine for Women (at which an address on "Women's Sphere in Medicine" will be given by Dr. E. W. Roughton), Middlesex Hospital, St. Mary's Hospital, University College Hospital, and Westminster Hospital will reopen on October 3. The opening day for St. Thomas's Hospital is October 4, and that of the London School of Tropical Medicine is October 14, when Dr. H. A. Miers, F.R.S., will give an address. At the opening of the medical school of the Victoria University of Manchester, on October 3, Prof. W. Thorburn will speak on "The Evolution of Surgery."

THE second International Congress for the Preservation of Game was opened at Vienna on Monday last. At one of the sections a message from King George to Mr. F. C. Selous, urging the desirability of making international provision for the preservation of migratory game birds, especially woodcock and quail, was read. A resolution in the sense of the King's message was adopted by the section. The next congress, which will meet in three years' time, is to be devoted chiefly to the preservation of game outside Europe.

SPEAKING as president of the twenty-fifth Congress of the Royal Sanitary Institute (now in session at Brighton), Sir John Cockburn said the history of the growth of sanitary science is epitomised in that of the Royal Sanitary Institute, which during the last quarter of a century has exercised a continually increasing influence for good on the health of the nation. Cleanliness, fresh air, pure food, and prevention of infection are the key-notes of modern medicine. In every city ample provision for baths should be made available for the masses. But cleanliness should not be confined to external appearance. Clean air is required. It is true that recent years have witnessed some improvements in this respect. The ventilation of our theatres also is not so bad as it was. It is perhaps in railway travelling that those who love to keep their bodies pure suffer most. There are smoking carriages for those who affect the weed; why not fresh-air carriages also, in which any occupant could demand that one at least of the windows shall be kept open? The objectors generally express the fear of catching cold. It is high time that this fallacy were exploded. What is called a cold in the head is an infectious disease, and is caught nowhere so readily as in close compartments. Fresh air, far from being the cause, is the best preventive.

THE treaty by which the Sovereign rights of the Korean Emperor are transferred to the Emperor of Japan came into effect on Monday, August 29, when it was promulgated in Seoul and Tokyo. The Korean peninsula, about equal in size to Great Britain, has thus become an integral part of Japanese territory. The Japanese Embassy has issued the following announcement, received from the Foreign Office at Tokyo, referring to the annexation:—(1) Korea shall hereafter be named "Chosen"; (2) the Government-General shall be established in Chosen; (3) the Residency-General and its accessory offices will be in existence for the present, and the Resident-General will exercise the functions of the Governor-General; (4) the issue of special passports for the people of Chosen is abolished, and hereafter the Chosens will be treated on an equal footing as the Japanese in the matter.

IT being possible to allot space in the Chemical Court of the reconstituted British Section of the Brussels Exhibition only to little more than half of the original exhibitors, a letter has been addressed by Sir Boverton Redwood, chairman of the Chemical Industries Committee, to the remaining firms asking them to funish a descriptive account of their exhibits, with photographs if possible, for display on a wall space which has been appropriated for the purpose. It is suggested that a convenient size for the framed account would be 4 feet by 3 feet, but in exceptional circumstances it is hoped that room may be found for a larger frame. Frames will be supplied free of cost by the Exhibition Branch of the Board of Trade, to whom photographs should be sent at the earliest possible date, as the new British Section of the exhibition is to be formally opened on September 15.

THE twenty-first annual general meeting of the Institution of Mining Engineers is to be held at Nottingham on Wednesday, September 14, when the following papers will be presented:—The mining school at Bochum, Prof. H. Louis; progress in the use of exhaust-steam power, Mr. J. Burns; the Elliott-Jones vertical coke-oven, Mr. T. C. Futers. In addition, the undermentioned communications, which have already appeared in the Transactions of the institution, will be open for discussion:—A storage-battery extension to a three-phase colliery power-plant, Mr. W. Maurice; measurements of the increase of temperature in bore-holes, with the depth, the technics, and practical importance of the same for geological prognosis, with reference to new measurements in Mexico, Borneo, and in Central Europe, Drs. J. Kœnigsberger and M. Mühlberg; experiments illustrative of the inflammability of mixtures of coal-dust and air, Prof. P. Phillips Bedson; some memoranda concerning coal-dust and the essential principles of the coal-dust theory, Mr. H. W. G. Halbaum; the use of concrete for mine support, Prof. W. R. Crane; fire-damp caps and the detection of fire-damp in mines by means of safety-lamps, Messrs. E. B. Whalley and W. M. Tweedie; equipment for the study of flame-caps and for miscellaneous experiments on safety-lamps, Prof. G. R. Thompson.

The second International Conference for the Study of Cancer is to be held in Paris on October 1–5 under the presidency of Prof. Czerny. French, English, and German are to be the official languages of the conference. Intending members should give notice to the treasurer, Dr. A. de Rothschild, 6 rue Saint-Philippe de Roule, Paris VIIIe.

The ninth International Conference on Tuberculosis will take place at Brussels on October 5–8. Among the subjects likely to be brought under consideration are:—Hereditary tuberculosis contagion; the pre-disposition to the disease; the protection of children against tuberculosis; tuberculosis and the school; the part of women in the campaign against tuberculosis. Reports on the progress of the war against tuberculosis in different countries, milk supply, solar radiation, international statistics, and international marks indicating the condition of the lungs will be presented, and a paper will be read by Dr. Nathan Raw on the general measures recommended by the International Conference to the public authorities for the prevention of the spread of tuberculosis in different countries. The address of the Secretariat of the conference is Avenue Van Volxem, 253, Forest-Brussels.

In connection with the Turin International Exhibition to be held in 1911, there is to be a competition in the transmission and reception of messages with Morse, Hughes, and Baudot apparatus. According to the *Electrician*, the tests will begin on August 22, and will be open to members of either sex of the staffs of telegraph administrations and army or navy telegraphists. The tests will include twenty minutes' transmission and thirty minutes' reception of messages by the Morse apparatus, the receiving being done with either the sounder or the writing instrument; and one hour of transmission by Hughes apparatus, mechanical or electrical, and with either E or W key; and one hour of transmission by Baudot quadruple apparatus. The text will be in languages suitable to the operators, will be printed on sheets containing fifty words each, and will consist of words, groups of letters, and figures. The text will be different for each system, but the same for competitors in the same system. A special test for reception by sounder and the writing of the text by a writing machine (the writing machine being provided by the competitor) will also be held, if not less than ten competitors belonging to three different administrations apply by June 15, 1911. The transmission will be effected in accordance with the International Telegraph Regulations. There will be a championship cup, which will remain the property of the successful competitor, and be competed for by competitors who gain a prize in each of the three systems (Morse, Hughes, and Baudot). There will also be an international representation prize cup to be competed for by groups of three competitors who all represent one State, and have between them won prizes in all the three sections. There will also be individual prizes—ten for the Morse, eight for the Hughes, and eight for the Baudot tests. Applications must be sent by June 15 next to the Secretariat General, Bureau du Concours International de Telegraphie, Rome.

In *Man* for August Mr. C. M. Woodford describes a remarkable stone-headed axe from Rennell Island which he has been fortunate enough to acquire. He shows that this weapon is in type quite different from the examples with which it has been compared found in Malaita, in which a nodule of iron pyrites is attached to a handle ornamented with nautilus or pearl shell. In the Rennell Island example, the head, formed apparently of a basaltic stone, is star-shaped with eight projections, and is attached to a plain handle made of a hard, dark wood, probably *Afzelia bijuga*. The union is effected by an ingenious system of rattan lashings, which pass through holes in the handle.

Mr. T. Sheppard, the energetic curator of the Hull Museum, in his annual report for 1909 records important accessions to the valuable collections in his charge. On the antiquarian side, the most important addition is the famous Brigg boat, constructed from a single trunk of oak, 50 feet long and 6 feet broad. From the caulking Mr. Slater has been able to identify a good list of mosses and hepatics, these being the earliest records of the kind for the county. This boat has formed the subject of no fewer than forty monographs prepared by members of various learned societies, and Mr. Sheppard has in hand a descriptive handbook of this important object. A grey ware jar from North Lincolnshire has also been received, containing coins of the Emperors Valens, Julian II., Gratianus, Valentinianus, and Constantinus II., all of the fourth century A.D., with a curious ring bearing an image of the dove and olive branch, probably of Christian origin, and dating from the fifth century. The museum has also been fortunate in acquiring two important collections of birds, one that of Mr. Fertune, of Yorkshire birds, occupying forty cases; the second that of Sir H. Boynton, from Burton Agnes Hall, in 200 large cases. Both these important collections are now being catalogued and arranged for exhibition.

Mr. W. C. Farabee reprints from the Proceedings of the American Antiquarian Society for October, 1909, an account of the strange race known as the Machyengas, who inhabit the region lying between the base of the Cordillera and the Upper Ucayaali and Urubamba rivers in eastern Peru. The most remarkable fact about them is that they have no fear of the dead, and do not hesitate to touch the corpse and dispose of it without any ceremony, simply flinging it into the river to be eaten by fish. This results from the absence of any belief in the return of the soul, which after death enters the red deer. This animal, though not regarded as sacred, is not used for food. When asked what becomes of the spirit, they reply, "Nothing; that is the end of it when it enters the deer." Their deity Idioci, "the big man of the sky," is otiose, and has little concern with the world except that he thunders and sends rain. He is treated with indifference, receiving no prayers, offerings, or dances; they have no charms or fetishes, and are controlled by no power or influence outside themselves. This is a remarkable picture of a tribe bound by no conventions or restraints of religion or custom.

The Bulletin of the Sleeping Sickness Bureau (No. 19, July 26) contains a progress report on the Uganda sleeping-sickness camps from December, 1906, to November, 1909, by Dr. A. P. Hodges, principal medical officer. It deals particularly with the treatment of the disease. The conclusions are that the prospect of curing sleeping sickness by medicinal treatment has not materially increased, that the percentage of apparent cures is practically negligible from the point of view of stamping out the disease, that the percentage of apparent cures continues to diminish with lapse of time after treatment, while the death-rate continues to increase, and that there is no decided superiority of one mode of treatment over another of those known to be of benefit.

The July number of the monthly *Folia Neuro-biologica* thoroughly maintains the reputation of that magazine for usefulness as a bibliographical review of neurology. Of the three original articles contained in this number, perhaps the most interesting is a paper by Dr. Ferruccio Rossi on the cutaneous innervation of the lumbo-sacral region in the dog. The author concludes (1) that spinal transection at various levels in this region reveals very precise limits between cutaneous sensibility and insensibility; (2) that these limits are constant and characteristic for each segmental level; (3) that transection between the 13th dorsal and 1st lumbar, between the 1st and 2nd, 2nd and 3rd, or 3rd and 4th lumbar segments involves only a single *dermatom*, while yet more distal transections involve more than a single *dermatom*; (4) that the results obtained are of value for the study of the dorsal and ventral axile lines of the extremities, and for the topical diagnosis of spinal lesions.

To the Bulletin of the Royal Academy of Belgium, Classe des Sciences, 1910, No. 5, Mr. A. Rutot contributes an article on the existence in Belgian caverns of layers containing remains of Arctic rodents. Such layers have been already identified in Swiss and German caves in association with those containing the so-called mammoth-fauna, which indicates a moderately cold climate, and includes the Aurignacien and Solutreën stages. One of these rodent zones—the Middle Magdalenien—contains a fauna comparable to that of the European and Asiatic steppes, while a second includes one of the type of the Siberian tundra. Both these layers belong to the reindeer epoch; but the tundra-like fauna alone indicates absolutely Arctic conditions, *Myodes torquatus*, *Arvicola gregalis*, and *Lagomys pusillus* representing the Arctic type of rodents. The researches of the author reveal the interesting fact that almost precisely identical faunistic, and therefore climatic, conditions obtain in the caverns of the Meuse valley and other districts in Belgium, where, however, the Solutreën stage is practically unrepresented.

According to the *Field* of August 3, no fewer than nine "schools" of caa'ing whales, *Globicephalus melas*, were observed out at sea by some men occupied in capturing sea-fowl on the bird-rocks at Vagö, in the Færöes. Of these, 250 were surrounded by the boats and driven into Midvag, and killed the same evening. The next morning, when the take was being distributed, news came that another very large school had made its appearance at Sand, some twelve miles distant, but that no attempt at driving them towards the land had been made, the number of boats present being inadequate for the purpose. Many of the Midvag people at once started for the spot, and as a result of the combined attack which ensued 400 more whales were secured. The value of the products of a whale of this species is about 3*l.* 7*s.* 6*d.*

The *Emu* for July contains an excellent coloured plate of the white-fronted fantail (*Rhipidura phasiana*), a species first described by Mr. de Vis in 1884, on the evidence of a specimen collected near the mouth of the Norman River. In addition to a portrait of the late Dr. Sharpe, this issue also includes various papers on Australian bird-life, chiefly of local interest.

In part i. of vol. xl. of the Memoirs of the Museum of Comparative Zoology at Harvard College, Mr. Glover M. Allen gives coloured figures of living specimens of that rare insectivorous mammal *Solenodon paradoxus* of San Domingo, based on living specimens recently received by that institution. These show that the general colour is some shade of tawny or rufous, with a variable amount of black on the back and throat, and a pale nuchal spot. They further indicate that the well-known figure of the other species of the genus, *S. cubanus*, given by Peters is incorrect in showing the tail bent laterally, this appendage being incapable of such lateral movement except near the tip. The two species were formerly believed to be distinguished merely by colour, but it is now ascertained that there is a difference in the number of the vertebræ. Much information with regard to the skeleton, muscles, and viscera is given in Mr. Allen's memoir.

A study of the distribution of the Mollusca in connection with an ecological survey of a marsh area on the Chicago River is discussed by Mr. F. C. Baker in a Bulletin (vol. viii., art. 4) of the Illinois State Laboratory of Natural History. The author is especially concerned with showing how ecological observations may throw light on the taxonomic relation of species.

Mr. S. T. Dunn places on record in the *Kew Bulletin* (No. 6) a historical account of the Hong Kong herbarium, in which he duly acknowledges the valuable services of Mr. C. Ford, who was for thirty years curator, and of Sir Joseph Hooker, whose latest assistance has been rendered in the form of a personal revision of the balsams. The miscellaneous notes in the same number of the journal contain several interesting items, including a letter from Mr. H. N. Ridley describing the botanical features observed on a journey to the north-west of the Malayan peninsula, where he traced the change from a Malayan to a Siamese flora about Gunong Terai; a collation of data concerning the germination of the rubber-yielding species *Manihot dichotoma*, *M. piauhyensis*, and *Funtumia elastica*; also a communication regarding the Guayule industry in Mexico.

An article on the genus Citrus, contributed by Mr. A. W. Lushington to the *Indian Forester* (June), claims attention both as a systematic revision of a difficult genus of cultivated plants, and because the author attempts to identify the plants yielding the numerous Indian varieties of citrus fruit. Four classes or subgenera are defined. Firstly, there is *Citrus trifoliata*, regarded as the most primitive. Then there are the species bearing four-petalled flowers, and presenting other typical characters, represented by the caffre, sour and sweet limes. A third class is characterised by five-petalled flowers, usually white, and a fruit with a loose skin, of which the mandarin is an example; while the fourth class includes the pomelo, lemons, Seville orange, and citron, which agree in the production of a fruit with a firmly adherent skin and flowers normally five-petalled.

A correspondent informs us that he recently found growing on the cliffs near Osmington, Weymouth, among a large quantity of ordinary blue chicory, several plants which bore white flowers corresponding in every respect with the ordinary chicury except in colour. Though this is an uncommon occurrence, the white variety of the common chicory has been recorded before. Syme in "English Botany" (v., p. 123) gives the colour as "pale bright-blue varying to white," and Hooker, "Students' Flora" (p. 210), says flowers "bright blue, rarely white."

THE summary of the weather issued by the Meteorological Office for the summer season comprised by the thirteen weeks from June 25 to September 3 shows that the mean temperature was rather below the average except in the north and west of Scotland, but the difference from the normal was nowhere large. The absolute maximum temperatures ranged from 80° to 83° in all the districts of the United Kingdom with the exception of the north and south of Ireland and the Channel Islands, where the highest temperature was in each case 79°. The lowest shade temperatures ranged from 30° in the east of Scotland and 34° in the north of Scotland and the south-west of England to 40° in the Midland counties, 41° in the south of Ireland, and 47° in the Channel Islands. The largest aggregate rainfall was 13·71 inches, in the west of Scotland, and the lowest 6·81 inches, in the east of England. There was an excess of rain over the entire kingdom except in the north of Scotland, the greatest excess being 2·77 inches, in the south-west of England. The number of rainy days ranged from eleven more than the average in the south of Ireland to five less than the average in the north of Scotland. The largest number of rainy days in any district was sixty, in the south of Ireland, and the least forty-four, in the south-east of England. There was a deficiency of bright sunshine for the thirteen weeks in all districts except in the north of Scotland and the north of Ireland. The greatest deficiency was 135 hours in the Channel Islands, 126 hours in the south-east of England, and 113 hours in the north-east of England. At Greenwich the mean temperature for the three summer months this year was 1° below the average, the mean being 61°. The absolute maximum temperature was 82·3°, which is decidedly low in comparison with former summers, and there were forty-three days with a temperature of 70° or above, which is a rather larger number of warm days than some recent summers. The aggregate rainfall was 8·10 inches, which is 1·32 inches more than the average, but is less than in the summer of either 1908 or 1909. The deficiency of bright sunshine at Greenwich for the three months was 170 hours.

THE meteorological chart of the North Atlantic and Mediterranean for September (first weekly issue, August 18), published by the Meteorological Committee, gives an interesting account, with daily synoptic charts, of the weather over the Atlantic for a week ending August 17, and throws considerable light on the cause of the changeable weather over the British Islands during that period. Between August 11 and 14 a barometric depression passed slowly from about 55° N., 30° W., to the neighbourhood of our western coasts, causing showery weather generally over western Europe, and thunderstorms in many parts of the United Kingdom on the night of August 14. During the latter half of the period another depression developed over eastern Canada, and furnished a good example of such disturbances crossing the whole of the North Atlantic. It arrived off the west of Scotland by the morning of August 17; changeable weather therefore again set in, and south and south-west winds became strong on parts of our western and southern coasts.

THE director-general of Indian observatories has issued a memorandum, dated August 6, on the monsoon conditions prevailing during June and July, with anticipations for August and September. The combined distribution of rainfall in June and July was rather irregular, being considerably in excess in some provinces and in defect in others. In July the monsoon conditions were weak over a large area, and an almost complete break in the rains occurred in the second and third weeks. From information obtained as to the conditions over a large part of the earth's surface since the date of the memorandum of June 9 (see NATURE, July 28), the director-general concludes, *inter alia*, that the general outlook appears more uncertain than usual, but there is no reason for expecting a large defect in the total amount of rainfall during August and September.

THE *Annuario* of the Rio de Janeiro Observatory, 1909–10, contains, in addition to ephemerides and astronomical data for the two years stated, a large number of tables relating to the physics of the globe. The tables usually employed in the reduction of astronomical and meteorological observations, and the values of the various units are very complete and handy for reference. The compilation extends to 405 octavo pages, but contains no original scientific discussions.

Le Radium for July devotes seven pages to tables of constants of ionisation and of radio-activity compiled by Prof. T. H. Laby. The following constants are tabulated:—Rates of re-combination of ions, their mobilities, the electric charges they carry, the quotients of the charges by the masses, path and velocity of α rays, number of α particles emitted by radium, heat developed by radio-active substances, and a number of other radio-active and atomic constants which may be calculated from these. In the same number M. W. Duane, of Madame Curie's laboratory, gives a description of an arrangement for registering photographically the number of α particles emitted by a radio-active substance, founded, like the counting method of Prof. Rutherford and Dr. Geiger, on the augmentation of the ionisation of a rarefied gas within a closed vessel by the collision of the α particles with the molecules. The vessel, of small capacity, is of ebonite, closed below by a brass plate having a small window in it covered with a thin sheet of mica. The radio-active substance is placed below the window, and the brass plate is raised to an electrical potential nearly sufficient to cause a discharge to take place between it and a wire electrode at the top of the vessel, which is connected to a gold-leaf electroscope. An image of the gold leaf is formed on a photographic film moving behind a slit. The gold leaf is brought back to the normal position after each displacement by means of a leak produced by polonium outside the electroscope. Several reproductions of photographs obtained are given, which show the displacements produced by the α particles, but the author gives a further photograph showing displacements obtained without α particles, the explanation of which he is not yet in a position to give.

THE current number of the *Zeitschrift fur physikalische Chemie* contains another contribution from the van 't Hoff Laboratory at Utrecht on the allotropy of the elements, the alleged allotropy of lead having been examined by E. Cohen and K. Inouye. During the electrolysis of solutions of lead salts, it was shown by O. Lehmann that two kinds of crystals can be formed according to the conditions, one crystallising in the regular and the other in the monosymmetric system. It has now been found that cells set up with these different crystals show no difference of electromotive force, from which it is concluded that these two crystalline forms are not really allotropic modifications.

THE July issue of the Journal of the Association of Teachers in Technical Institutions has reached us. Its leading contents include the address of the president of the association, Mr. J. Wilson, in Birmingham last June, and an address delivered by Dr. Robert Pohl to the west Yorkshire branch of the association last April. Both these discourses have already been dealt with in these columns.

THE Cambridge University Press gives notice that it has taken over the copyright and control of the "Encyclopædia Britannica," and that it will publish the new and complete edition (the eleventh) about the end of the present year. The work entirely supersedes all previous editions, and brings its survey down to the summer of 1910. The whole of the twenty-eight volumes will be issued at one time, in two forms, an ordinary paper impression and one on India paper. To many readers the thin paper edition will come as a great boon.

THE Geologists' Association announces that its jubilee volume, "Geology in the Field," is now completed, and that an index to it is in preparation, and will be issued shortly.

OUR ASTRONOMICAL COLUMN.

REDISCOVERY OF D'ARREST'S COMET (1910c).—A telegram from the Kiel Centralstelle announces the rediscovery of D'Arrest's comet, by M. Gonnessiat, on August 26. The comet is of the fourteenth magnitude, and its position at 9h. 32·6m. (Algiers M.T.) on the day of discovery was R.A. = 16h. 48m. 25·3s., dec. = 9° 42′ 50″ south; this position lies in Ophiuchus about 5° E. of ζ Ophiuchi.

This comet was discovered by D'Arrest in 1851, and has a period of about 6·5 years. In 1903 it escaped observation, but was observed, after passing perihelion on May 21, in the summer of 1897.

An ephemeris for the comet is published in No. 4437 of the *Astronomische Nachrichten* (p. 344). The observations indicate that corrections of −1m. 17s., +5·1′, should be applied to M. Leveau's ephemeris (*Bulletin astronomique*, vol. xxvii., p. 81), and the following places result:—

Ephemeris 0h. M.T. Paris.

1910			α (h. m.)		δ (° ′)
September	9	...	17 28·8	...	−16 53·4
,,	11	...	17 35·4	...	−17 53·3
,,	13	...	17 42·3	...	−18 52·0
,,	15	...	17 49·4	...	−19 49·2

Owing to the low declination and the fact that the magnitude is only 14, observations in these latitudes are not very promising.

THE RECENT OCCULTATION OF η GEMINORUM BY VENUS.—Observations of the occultation of η Geminorum by Venus on July 26, made at several observatories, are reported in No. 4435 of the *Astronomische Nachrichten*. MM. Baldet, Quénisset, and Antoniadi found, at Juvisy, that the times of immersion and emersion were 15h. 2m. 9s. ± 2s. and 15h. 5m. 39s. ± 0·5s. (M.T. Paris) respectively, the duration of the occultation being 3m. 30s. ± 2·5s. A notable feature of the emersion under good conditions was the suddenness with which it took place; within 1½ or 2 seconds from the first suggestion of reappearance, the star regained its normal brightness. Apparently the rays were not deviated more than 0·3″, and there was no change in the colour of the star. From the fact that the augmentation of the star's light extended over 1½ or 2 seconds, the observers deduce that the height of the planet's atmosphere, producing the absorption, is about 80 to 110 km.

SEARCH-EPHEMERIDES FOR COMETS 1889 V. (BROOKS) AND 1890 VII. (SPITALER).—A set of elements and a search-ephemeris for Brooks's comet, 1889 V., are published in No. 4437 of the *Astronomische Nachrichten* by Dr. Bauschinger. The probable time of perihelion passage is 1911 January 8, and the ephemeris covers the period August 4, 1910, to February 20, 1911. This comet is of special interest owing to its having thrown off four fragments, one of which became brighter than the parent body, in 1889. Seen in 1903, it was single and of the fourteenth magnitude, so that its detection at the coming approach is doubtful. According to the ephemeris, the comet was at its nearest to the earth at the beginning of August, and its present position (September 9) is in Sagittarius at α = 19h. 37·4m., δ = −29° 55·2′ south.

The rediscovery of Spitaler's comet is still more doubtful. Discovered in 1890, its period was found to be about 6½ years, but it was not seen in 1897 or 1903. However, Herr F. Hopfner has calculated elements for the present approach, and publishes them, with nine four-day search ephemerides, in No. 4437 of the *Astronomische Nachrichten*. The different ephemerides are calculated for different dates of perihelion passage covering the period September 12 to November 15 in eight-day intervals.

THE SUN-SPOTS OF 1909.—A statistical summary of sun-spots, as observed at the Royal Observatory of Capodimonte during 1909, is published by Dr. E. Guerrieri in No. 6, vol. iv., of the *Rivista di Astronomia* (Turin). In it are given numerous tables showing analyses, in different forms, of the frequencies, areas and numbers of spots, faculæ, &c., which should prove useful to anyone discussing solar phenomena. The mean diurnal frequency of spot groups for the year was 3·6, 1·7 less than that for 1908; the mean diurnal number of spots was the same, 30·5 in each year.

WATER VAPOUR ON MARS.—The conditions obtaining on Mount Whitney during the Lick Observatory expedition researches in September, 1909, are discussed by Prof. Campbell in No. 3, vol. iv., of the Journal of the Royal Astronomical Society of Canada (p. 212). Prof. Campbell combats the idea that they were unfavourable, and says that on September 1 and 2, when the photographs were taken, the nights were as perfect for the purpose as could be wished. He also points out that with a nearly evanescent *a* band, the more water vapour one attributes to the terrestrial atmosphere, the less remains attributable to that of Mars.

MEASURES OF DOUBLE STARS.—Dr. Lau's tenth list of double-star measures appears in No. 4436 of the *Astronomische Nachrichten*. It contains the places, recent measures, and the colours of 122 Σ and 6 OΣ stars, and in some cases the formula giving the nature of the variation in distance and position-angle. It is not without significance, perhaps, in the discussion of the colours of double stars, that, in the majority of cases, where both stars have the same colour the colour is given as "white"; where they differ, the colours are most often complementary.

THE PERMANENT INTERNATIONAL COMMITTEE FOR THE "CARTE DU CIEL."—We have now received the volume giving an account of the meeting of the permanent committee for the execution of the *Carte photographique du Ciel*, which took place in Paris in April, 1909. The volume gives a list of those who attended, and a detailed account of the discussions and resolutions; but as the meeting was reported at length in our issue of June 10, 1909, there is no need to refer further to its proceedings.

METEORS AND BOLIDES.—No. 1, vol. iv., of *Palaestra*, a monthly journal issued at Asti, Italy, contains an interesting paper by Prof. Guido Cora on meteors and bolides. The paper was suggested by the appearance of a remarkably fine bolide at Casalbordino (Abruzzi) on December 3, 1909, and contains a discussion of the appearance, the frequency, and the general phenomena attending the appearance of meteors.

HISTORY OF NAVIGATION.—An interesting article on the determination of position at sea, written by Prof. Marguet, appears in No. 13 of the *Revue générale des Sciences*. The author discusses the histories of the compass, the log, and astronomical determination, paying particular attention to such matters as the difference between the magnetic and true north, and illustrating his descriptions with cuts of instruments such as the astrolabe and arbalestrille.

Meteoric Fireballs.—The Rev. W. F. A. Ellison, of Fethard Rectory, Waterford, reports that on August 28, at 11h. 29m. G.M.T., he was surprised by a very brilliant flash, which on first thought he supposed to be vivid lightning. Instantly looking upwards, however, he saw a bright meteor-streak extending from $330°+35°$ to $125°+75°$. It was fully half a degree wide, and part of it remained in sight three or four minutes, and drifted several degrees to the west.

Mr. Ellison has been very successful in recent years as an observer of fireballs, and describes this one as an exceptionally grand example. Unfortunately, he did not see the direction of its flight, but the radiant must have been either in Sagittarius or the head of Ursa Major.

The Rev. J. C. W. Herschel, at Wellington College Station, Berks, saw a splendid Perseid on September 2 at 9h. 5m. p.m. It passed from near the Polar Star to θ Draconis, crossing β Herculis, and vanishing in the region of Ophiuchus. The duration was about three seconds, and the meteor projected a streak along the greater part of its course. The probable radiant was near ϵ Persei, and the height of the object from about 72 to 44 miles over Wellingboro' to Yeovil. Its visible trajectory covered 125 miles at a velocity of about 41 miles per second.

Further observations are, however, required of these fine meteors before trustworthy heights and velocities can be computed.

RECENT HITTITE DISCOVERY.

THE object of the lecture is to show in outline how the memory of the Hittites as an imperial people has been recovered and what their place in world-history was. This recovery dates from the finding in 1834–45 of two prehistoric cities at Boghaz Keui and Uyuk in north-western Cappadocia. Their sculptures and inscriptions were ultimately recognised by Sayce as belonging to the same family as certain inscriptions and sculptures which had been found at Hamath and elsewhere in Syria after 1870, and also some other monuments observed in Asia Minor at Ibriz and near Smyrna. These Syrian monuments had been already ascribed to a people which, under the name of *Kheta* or *Khatti*, played a large part in the Syrian relations of Pharaohs of the XVIIIth to the XXth Dynasties, and in those of the Assyrian kings; and this people, it was generally agreed, was identical with the "children of Heth" or Hittites of the Old Testament. If the latter were responsible for the monuments in question in Syria, then, too, in some sense, they were responsible for the monuments in Asia Minor; and, in any case, it was clear that a very peculiar and important civilisation, covering a large area of the Nearer East in the Second Millennium B.C. and the early part of the first, had been forgotten by history.

Scholars and explorers made continual efforts during the next quarter of a century to elucidate this civilisation, and succeeded so far as to place its origin in Asia Minor, and to fill up, more or less, by the discovery of many new monuments, the geographical gaps dividing those first observed. They found that these lay, roughly, along lines of communication leading from north-western Cappadocia to the south and west, and they established in fact that not only northern Syria but west central Asia Minor showed such monuments in almost every part. But fundamental questions—who were the authors of this civilisation? where precisely was its chief focus? and who shared its development?—had still to be left open; and it was not until Boghaz Keui came to be excavated by Winckler and his companions in 1906–7 that they could be answered.

At the last-named site, known for some years to produce cuneiform tablets partly in Babylonian, partly in an unknown tongue, the excavators explored a large megalithic group of ruins in the lower city and fortifications and certain other structures in the upper, besides clearing and re-examining the long-known religious rock-reliefs of Iasily Kaya. Besides several mural sculptures, of which the most interesting shows an armed Amazon, the explorers came on a number of cuneiform tablets, chiefly in the ruins of the earlier portions of the lower megalithic building, which was evidently a palace. These tablets proved to be in the main Foreign Office archives of six generations of kings, who ruled over the Hatti of Boghaz Keui in the fourteenth and thirteenth centuries B.C. They conclusively prove that the Hatti of Cappadocia were the *Kheta* who fought with Egypt at Kadesh, and made the famous treaty with Rameses the Great. The first important reign was that of Subbiluliuma, contemporary of Amenhotep IV.; the last was that of Hattusil II., the "Khetasar" who made the treaty with Rameses. But we know from Babylonian, Assyrian, and Egyptian records that, both before and after these kings, the Hatti were a power in western Asia, and we have to credit them with a history of at least a thousand years. The tablets show that Subbiluliuma extended Cappadocian power over north Syria and even over great part of Mesopotamia, where the Mitanni had formerly been dominant; and that this wide dominion, extending even to the Babylonian frontier, was preserved by his chief successors, Mursil and Mutalla, and not lost until after the reign of Hattusil II., who treated with both Egypt and Babylon as an equal. Startling as this revelation is, we now see that without the existence of such a Hittite power the wide distribution of the Hittite monuments, civilisation, and physical type would have remained inexplicable; and we recognise in Boghaz Keui the natural focus from which these radiated over Asia Minor and Syria. But we recognise also that many of these monuments and much of the Hittite civilisation were work of other peoples than the Cappadocian Hatti—peoples who had learned of the latter and in many cases outlasted them. Other phenomena, too, are explained by the revelations at Boghaz Keui, notably the failure of the Ægean power of Crete to effect a lodgment in Asia Minor, and the long continuance of the Hittite name and fame in Syria. Moreover, they account, as nothing else can, for the Oriental influence which acted on the earliest Hellenic civilisation, especially in Ionian art and religion. For not even the early contact between the Muski-Phrygians and Assyria appears to have resulted in sufficient orientalisation in Phrygia and Lydia to explain the Greek phenomena. The real distributing agency of Orientalism was in Cappadocia, the art and religion of which were of the required type.

It is evident, then, that a great, if forgotten, part has been played in the relations between East and West by the civilisation which occupied so long the whole land bridge between Asia and Europe. The long survival and great extension of Hittite influence in Syria has been illustrated by the excavations at Sinjerli and Sakje Geuzi, and by recent discoveries in the basin of the middle Euphrates on both sides of the river. But an immense field remains to be explored, and other important sites must be thoroughly examined, notably Carchemish, Marash, and Malatia. When even one of these is dug according to the best modern methods a flood of light will be thrown on Hittite archæology; and with the help which the decipherment of the Boghaz Keui tablets not in Babylonian will afford to the decipherment of the Hittite inscriptions, already phonetically interpreted in no small measure by Sayce, the study of the Hittite civilisation will take its place in the field of scientific history.

[1] Discourse delivered at the Sheffield Meeting of the British Association by D. G. Hogarth.

THE INTERNATIONAL ZOOLOGICAL CONGRESS AT GRAZ (AUGUST 15–20, 1910).

THE eighth international congress of zoologists has been a most enjoyable one, even though it has not been marked by any striking pronouncement. No president could have carried out the arduous duties of his office more successfully than Prof. von Graff. To him in a large measure was due the representative character of the meeting. The committee under his presidency worked hard to ensure the comfort of the visitors and the smooth conduct of the meetings. That this was no small task may be judged from the fact that some five hundred members and participants came to Graz on August 14 and 15, and that in the five days of the congress more than 100 papers had to be read. One disadvantage of this abundance of communications was the limitation of discussion, which might have been surmounted had the members exercised the art of compression. As it was, papers were frequently read *in extenso*, and valuable time was thus lost. Some confusion was caused by the carrying over of papers from one day to the next, but the committee must be congratulated on the manner in which they organised the proceedings and surmounted difficulties, which in most cases were caused by the very success of the congress.

For such an international gathering Graz was a fortunately chosen meeting place. This "pearl of Styria" lies in beautiful scenery, and wears a peaceful and picturesque air. The Stadt-Park and the Schloss-berg form convenient shady spots in which the leisurely life of the town can be studied, whilst in the "Hilmteich" woods, the methods for bird-protection are seen in the most modern form. Gatherings at these and other points were arranged during the intervals of congress-business, and were greatly enjoyed, for, with the exception of two evenings, the weather remained fine.

The meetings themselves took place in the large "Stephanien-Saal" in the mornings, and in the university buildings in the afternoons. On the first day (August 15) the congress inspected the university, and more especially the zoological institute, where President von Graff guided the members over the charming building over which he rules. Then followed the official reception and opening of the congress. The only papers read that day were a long discussion by Prof. Delage on the methods and results of experimental parthenogenesis; a kinematographic representation of sea-urchin development (by M. F. Vlés and Mdlle. Chevroton); and a description of the biology of the lower Danube by Dr. Antipa. A pleasant evening was spent at the Hilmteich, where one realised the truly international character of this gathering.

The most important paper given during the second day of the congress was one by Prof. Gaupp, of Freiburg, on the affinities of the mammalia as deduced by the study of the skull. Dr. Gaupp is, of course, a well-known authority on this subject, and he treated it from a broad comparative standpoint. Stress was laid on the primordial or cartilaginous cranium, and the descriptive part of the paper was illustrated by a series of exquisite models made by Ziegler under the supervision of Gaupp and others. Amongst many detailed points of interest was the fact that the gristly skull of the young rabbit presented a closer agreement with that of the lizard than did the skull of Echidna. The relationships of the Mammalia, so far as the primitive skull was concerned, pointed rather to reptilian than to amphibian ancestry. Dr. Gaupp subsequently gave a series of demonstrations of the models used in his lecture.

Another paper of importance was that by the veteran zoologist, Geheimrath F. E. Schultze, on the air-sacs of birds, illustrated by a series of casts of the lungs and air-sacs taken from a number of representative and familiar birds. These models were exhibited during the course of the congress, and formed a triumph of technique. They consisted of metallic castings, and exhibited the relationships of the different sacs by a carefully chosen system of colours. No such clear demonstration of the anatomy of this difficult subject has ever before been carried out.

During the afternoon of each day the congress divided into eleven sections, thus showing the extent to which specialisation has proceeded in zoology. The cytologists and protozoologists constituted the first of these, and the chief subjects of interest in this section were the nature of the cell-elements, particularly the meaning of the chromosomes and their relation to sex. These papers, however, were of a highly technical character, and are difficult to summarise until the printed report appears. Very few papers on Protozoa were communicated, the most interesting being one by Dr. Enriques on the experimental determination of conjugation among Infusoria, and a long discussion by Dr. Hartmann on the nature of the nucleus in Protozoa and the bearing of this subject on general cytology.

In the second section papers were given on the anatomy and physiology of Invertebrata. Prof. Pelseneer led off with an interesting account of the occurrence of hermaphroditism in Lamellibranchs, and traced a relation between this condition and certain bionomical factors. It appears that hermaphrodite forms are much commoner than is generally supposed, especially among bivalves that are either commensal in habit, or that lead a deep-sea life. Another paper of interest was that by Mr. E. Ray Gregory on the water vascular system of one of the cake urchins (Echinarachinus). M. Rousselet exhibited specimens of Trochosphæra, and there were several papers dealing with purely histological topics. In the section devoted to Vertebrate problems, there were several contributions to the anatomy and development of the lymphatic system, including some beautiful demonstrations of the lymphatics in tadpoles by Dr. Hoger, in the cat by Drs. Huntington and McClure. Prof. Lee, of Minneapolis, exhibited a most valuable series of early stages in the development of Rodents peculiar to North America. Prof. Hubrecht described the placenta and early development of that strange Malayan mammal, Galeopithecus. Dr. Franz gave an account of the relation between motor activity and the development of the thalamencephalon in the development of fish; and Principal Jordan a most attractive description of the Bering Sea fur seal.

The most popular sections, however, were those that dealt with experimental and bionomical problems, and the list of papers read before them is so large that only a mere and arbitrary selection can be made. Of these, the paper on colour-physiology by Dr. Paul Kammerer, of Vienna, was the most interesting. For some time past Dr. Kammerer has subjected specimens of various Amphibia (*Salamandra maculosa, S. atra,* Molge, spp., *Rana esculenta, arvalis,* &c.), Reptilia, and Mollusca to the influence of various coloured surroundings, and has also reared the offspring of these animals under certain conditions of light and background. By the aid of coloured lantern slides, the author showed how the colouration both of the under and of the upper surface responded to this treatment, how the question of sex complicated the result, and how the offspring appeared to inherit a tendency to develop colouring similar to that induced in their parents without the influence of similar surroundings. The backgrounds employed were chiefly yellow earth and black earth, and the results were only broadly stated (the paper suffering, as did so many others, from congestion of business). Dr. Gadow, of Cambridge, made an interesting speech on the nature of Amphibian colouring, but further discussion was prohibited by the lateness of the hour. Subsequently Dr. Kammerer showed spirit-specimens of his experimental animals. A somewhat disappointing paper on a closely allied subject—the formation of pigment in birds—was contributed by Dr. Riddle, of Chicago. In this Dr. Riddle stated that "both the kind and quantity of melanic pigment produced by a bird . . . are dependent on nutritive and other local and temporary conditions." The disappointment lay in the fact that no explanation of what these conditions were, was given. The paper was mainly an attack upon the results obtained by Miss Durham on the pigments of guinea-pigs.

Prof. Woltereck contributed a further instalment of his work on Daphnids, and showed how variations in the body were correlated with sexual changes. On this subject Dr. Langhans, of Prague, also spoke, urging the evidence he had obtained as to the inheritance of acquired characters in this group. One of the longest experimental papers was that by Prof. Conklin on the power of regulation in Echinoderm eggs. After centrifuging such eggs for a short time, the cytoplasm of the eggs is drawn away from its initial position, but when the eggs are removed from the centrifuge the regulative power shows itself by causing a symmetrical arrangement of the cells. The diverse behaviour of the two polar cells was very clearly shown, and the influence of the length of time of centrifuging was also explained by a series of lantern slides taken from some two thousand preparations.

In another section, Prof. Crampton gave a well-illustrated account of the distribution of species of Partula, based upon his explorations in south-eastern Polynesia. He pointed out the extremely definitely localised character of the species and the evidence for mutation. In the same section, Prof. Carpenter, of Dublin, described an interesting fossil Isopod from the Irish Devonian. Several other palæontological papers dealt with the problem of extinction, and with certain Annelids, Reptiles, and Insects.

Regarding the congress as a whole, one is struck by its increasing scope. It is attended not only by professional and amateur zoologists, but by anatomists, physiologists, and geologists. The problems it discusses touch upon questions of the greatest interest to pathologists and to sociologists. The experimental treatment of zoology is being increasingly adopted, whilst the older systematic problems are being studied afresh. The present is a time of data-collecting on an enormous scale, but no fresh principles are as yet forthcoming, and there is a marked tendency to confine the treatment of the subject to non-controversial matters. One comes away from Graz impressed by the huge amount of zoological work now being done, by the community of spirit that animates its devotees in all countries, and by the value to the cause of peace which such gatherings represent. These sentiments were emphasised in the speeches at the banquet which closed the congress.

THE THIRD INTERNATIONAL CONGRESS OF SCHOOL HYGIENE AT PARIS, AUGUST 2–7, 1910.

THE comparative abstention of German school-hygienists from the third congress was a regrettable feature, and considerably diminished its value from a scientific point of view. The preponderance of Latin influence led to much rhetoric in the sections, and the records of the congress are those of trends of opinion rather than of work accomplished.

The subjects set down for general discussion on the three working days of the congress were, in order:—(1) Uniformity of method in medical inspection; (2) instruction in sexual hygiene; and (3) the training and appointment of the school doctor. The first of these alone presented any general scientific interest. A problem awaiting solution is how to frame the records of inspection so that trustworthy statistics can be obtained by which the influence of varying environments can be compared and alterations from decade to decade satisfactorily established. The discussion was opened by Dr. James Kerr in a paper the value of which could not be over-estimated. He postulated that the two aims of medical inspection (the remedial and the statistical) must be separately considered, for no medical inspection carried out on *all* children is ever likely to be done at public cost to such an extent that it can be of any great value for scientific purposes; when quantitative estimates or comparisons are made, even between schools in the same town or classes in the same school, the results are often not really worth the paper they are written upon. As the result of long experience, he stated that ultimately one is content with only spending as much time as is absolutely necessary on detailed examination, valuable for scientific purposes, and in only examining in such detail sufficient numbers of children to reduce any errors of experiment within such limits that the results will afford a trustworthy standard; the examination of all children in that way is quite unnecessary. For scientific work, he claimed it is best that each topic be examined as a separate problem on data carefully selected and carefully defined by each investigator, and that general inspection should be carried on merely with a definite practical aim of relief to children who present obvious or gross defects. Without this there is great danger of scientific progress being arrested, and the whole movement becoming a lifeless routine of collecting inaccurate and valueless records. It is to be hoped that Dr. Kerr's opinions as here expressed will receive due attention from the authorities in Whitehall, for it is indubitable that much of the work being done in the country at present is utterly unscientific, and has already become the lifeless routine that Dr. Kerr is desirous of guarding against.

The rest of the work of the congress was split up into thirteen sections and sub-sections. Comparing the discussions with those of the second International Congress of 1907 in London, two branches of general school hygiene stand out in which most activity has taken place during the intervening three years. These are physical education and open-air schools. In Section vi., which dealt chiefly with the latter, carefully collated facts were forthcoming which proved alike the wide extension of the movement and the uniform good results obtained without distinction of climate or race. It was Dr. Neufert, of Charlottenburg, who shadowed forth the future developments arising out of the experience gained in the open-air schools. Why should the advantages of the open-air school be limited to the debilitated and unhealthy? If good for them, it must be good also for the normal. All our schools must in future approximate to the open-air ideal, and more activity must take the place of the sedentariness which is now the rule. In connection with the question of activity, it is interesting to note also how the attention paid to manual training has grown during the past three years. Scarcely mentioned in 1907, its advantages are in 1910 independently pressed in many sections and from many points of view by various workers.

Dr. Mumford, of Manchester, dwelt upon its importance in developing the association centres in the brain, where the various sense organs are organised in relation to the combination and arrangement of the muscles. Herr Schrag, of Berne, pointed out the importance of manual training as a link between the various subjects in the curriculum. Prof. Blazek, of Austrian Poland, brought forward the results of ergographical investigations, demonstrating the effects of manual training in developing certain mental qualities of readiness and concentration, and Dr. Schuyten, of Antwerp, supported this with facts proving the effects in diminishing inattention of satisfying the motor needs of the organism.

In Section iv., on physical training, many communications of importance were read. Dr. Digby Bell, of the British Naval School of Physical Exercises, insisted upon the necessity of rescuing the subject from the taint of quackery which still hangs around it. M. Demeny, of Paris, introduced his new system of physical education founded upon continuous movement in opposition to the alternations of fixed contraction and relaxation of muscles upon which older methods are based; his paper was rendered more valuable by a demonstration upon a pupil, which certainly upon æsthetic, and in the writer's opinion upon physiological grounds, showed his method to be superior even to the Swedish movements, which at present hold pride of place in our systems.

A question of great importance to medical inspectors is the discovery of a trustworthy mathematical formula which shall determine the state of nutrition of a child in relation to physical measurements. Prof. Guttmann, of Vienna, examined various formulæ, and came to the conclusion that the best is that of Bornhardt, viz. $G = BL/240$, where G = body weight, B = chest circumference, L = height, and 240 is a constant representing the mean of a very large number of measurements.

Amongst some valuable papers in Section ix. (teaching methods and syllabuses) was one by Dr. Janale, of Prague, giving the results of extensive investigations on fatigue in the school children of that city by Ebbinghaus's combination method, from which he concluded that a single long morning session *per diem* is superior to two shorter sessions occupying both morning and afternoon. Another was by Prof. Schuyten on "inattention" as measured in school over yearly periods by dynamometrical experiments accompanied by memory tests. In the first place, inattention is a natural and inevitable result of physiological activity. It is increased by defective conditions of sanitation and diminished by wise distribution of subjects in the time-table. The best results appear to be obtained by not mixing up together daily the various subjects in the curriculum, but by grouping together homologous subjects on each particular day. This is in direct opposition, of course, to the usual arrangement in school time-tables at present.

The congress, it will be seen, presented many features of great general interest, and its practical results will undoubtedly be considerable. It was satisfactory to hear from the lips of one of the Secretaries of State of France, at the concluding meeting, a pledge that the Government would carry into effective operation the proposals upon school hygiene already before the Chamber.

VETERINARY RESEARCH IN THE TRANSVAAL.

THE present veterinary bacteriological laboratories of the Transvaal Department of Agriculture are situated eight miles to the north of Pretoria, on a farm comprising altogether some 2000 acres of land. They were ready for occupation on October 1, 1908, but, before this time, research in South Africa had to be conducted under less favourable conditions. In 1898, a three-room building of wood and iron lined with brick formed the laboratory, and the equipment of this was "sadly deficient." Calf vaccine lymph was made here, but the preparation was suspended when the late war broke out in the latter part of 1899. In 1901, the laboratory, after having been used during the war as a stable, had now added to it a rinderpest station for the manufacture of serum, and by 1905 it had grown into a heterogeneous collection of buildings, mostly constructed from old wood and iron, from buildings destroyed during the war. Not only were the buildings unsuitable, but they were also unhealthy, enteric fever constantly occurring among the staff, so that in 1906 it was decided to establish the present laboratories.

It may be of interest to consider the work done in these earlier years.

In 1896, rinderpest devastated S. Africa, thousands of cattle dying, and preventive inoculation was introduced. In 1898, at the old laboratory at Daspoort, calf vaccine lymph was made to vaccinate the Kaffirs when a serious outbreak of small-pox took place among them. In 1901–3, rinderpest serum was made in the Daspoort laboratory. In 1905, experiments were made which eventually resulted in the discovery of a serum for inoculating mules against horse-sickness. In 1902, at the close of the war, the introduction of East Coast fever, a new and devastating disease, took place; the disease was, however, at once studied, and means devised for preventing its spread.

A consideration of this work, then, shows what a practical character there had always been in the research work in the old laboratory, and we shall see that this is equally true of the new ones.

The present building comprises some three dozen different rooms, suitably fitted, each for its own particular object.

In the pathological laboratory, 1362 specimens were reported on in one year, and here is studied the histological pathology of various diseases, especially horse-sickness, East Coast fever, and other piroplasmoses.

In the zoological laboratory, the study of the entozoa of the sheep is a matter of great practical importance to the sheep-farmer. In another room, mallein, tuberculin, quarter-evil vaccine, and pleuro-pneumonia cultures are prepared. Three rooms are reserved exclusively for the preparation of rabies vaccine. In yet another room, the vaccine for blue-tongue and a horse-sickness serum are prepared. Of the former, 200,000 doses, and of the latter 1000 tubes, are sent out annually.

An entirely separate building is used for the preparation of calf lymph; three-quarters of a million tubes have been sent out into all parts of S. Africa during the last two years. The laboratory is evidently splendidly equipped with its centrifugal room, still room, serum store, animal room, operating theatre, post-mortem hall, museums, lecture rooms, &c., but we note one important omission, viz., a library, of which there is no account.

Front View of the Veterinary Bacteriological Laboratories at Onderstepoort, Pretoria.

This, the commemoration publication, besides the historical account of the laboratory which we have abstracted, contains five papers. The first is by Dr. Arnold Theiler, the Government veterinary bacteriologist, and is on the very interesting and important subject of "Immunity in Tropical and Sub-tropical Diseases."

He gives an excellent and concise statement of the whole question. This article is worthy of a place in a commemoration number, but as regards the other papers, while in themselves good pieces of research work, there is no special reason for their appearance here. We miss any general account of the animal diseases of S. Africa, rinderpest, horse-sickness, heart-water, and so on; and we should have welcomed a general account and summary of the piroplasmoses and the mortality due to them. Nor do we find any general account of ticks, and the methods taken to combat them. We should have welcomed also a summary of the state of our knowledge on animal entozoa and their economic importance.

The volume presents evident signs of haste in issue from the press. Some of the papers teem with misprints, some are characterised by an almost complete absence of punctuation, while again, in many instances, the language used and the construction of the sentences are so slip-shod as to render them almost meaningless. The volume has a number of excellent illustrations of the staff of the various departments, but the glazed paper on which the book is printed is very trying to the eyes. We may note, too, that on the title-page and cover the laboratories are called "the Veterinary Bacteriological Laboratories," though in the introductory chapter they are termed the "Veterinary Research Laboratories," a better term, we think, for, as we have seen, the work is by no means confined to bacteriology. The laboratory has, we feel sure, under its distinguished head a great future before it, and we venture to offer our heartiest congratulations on its new career.

HALLEY'S COMET

A LARGE number of publications dealing with observations of Halley's comet have appeared during the last week or two, and from them we extract a few of the more important results.

Prof. Barnard, in No. 4431 of the *Astronomische Nachrichten*, deals with the observations he made during the time when the comet was at its least distance from the earth. The observations in the early morning were greatly interfered with by clouds and smoky skies, but the conditions were better after May 17. Prof. Barnard pays particular attention to the observations made during the early mornings of May 18 and 19, and directs attention to a bright pillar of a luminous character seen near the south-eastern horizon. The main feature was the rather broad beam of light, resembling the beam of a searchlight, which stretched obliquely from the eastern horizon to the Milky Way in Aquila, a length of 107°. Between 2h. and 3h. a.m. this was very conspicuous, and Prof. Barnard describes its dimensions and position with respect to neighbouring stars, showing that it was considerably inclined to the ecliptic. This is evidently the phenomenon referred to generally as the tail, but to the observers at Yerkes there appeared the other mass of luminosity, apparently quite separate from the beam, that extended to the south-eastern horizon. Not having been able to observe the comet regularly prior to August 18, Prof. Barnard hesitates to make a definite proposition, but he suggests that this phenomenon was the main tail, whilst the bright beam was only a separate streamer. It involved the ecliptic, and observations on August 19 showed it to be a real phenomenon connected with the comet; at 2h. 20m. a.m. it showed a more definite upper edge, bounded, roughly, by the stars β and γ Piscium and η and ζ Aquarii, and it joined the brighter beam near γ Pegasi. Observations made earlier in May showed several streamers, of which the long bright beam seen on May 18 may have been one, and they also indicated that on May 18 the breadth of the main tail should have been much greater than the beam actually was. Should Prof. Barnard's surmise prove correct, the evidence for the earth's passage through the tail about May 19 would be greatly strengthened.

Curious sky effects during May 19 were also recorded, and were unusual enough to suggest a connection with the comet. At noon, and for several hours afterwards, a horizontal bar of brilliant prismatic colours, with the red uppermost, was seen in the south at an altitude of about 20°, and around the sun was a prismatic halo of 22° diameter.

After its passage, the comet was a brilliant object at Williams Bay, and to Prof. Barnard "it far exceeded all expectations as a spectacular display." On May 26 the tail could be traced to a distance of 63°, and for 25° of its length was very conspicuous. On May 20 the head was about ½° in diameter, and appeared like a nebulous star with a yellowish colour, but on May 24 it was recorded as bluish-white. On this date, however, there was apparently a double nucleus. To the naked eye and with opera-glasses there appeared a nucleus of sensible diameter and of a beautiful bluish-white colour, whilst in the 5-inch finder this was seen to be but an intense nebulosity surrounding a smaller, well-defined nucleus of eighth or ninth magnitude, and of a decidedly yellow colour. Thus naked-eye and telescopic observations on that date would refer to two different nuclei of opposite colours. For several nights about May 27 the tail appeared to diffuse northwards as high as Jupiter, and on a photograph taken on June 6 it is seen that the comet had discarded its tail, which was drifting away from it, and had formed a new one at a slightly different position-angle.

In the same journal Herr Sykora records an observation of the comet on the solar disc at 20·95h. (M.T. Tashkent) on May 19. A 13-cm. image of the sun was projected, and the comet was seen, like a finger-mark on paper, with a diameter of 1 cm.; during the three minutes that observations were not prevented by clouds, the relative motion of the supposed cometary image was about 0·5 cm.

Dr. Hartmann also contributes a note on the measures of the surface brightness of the comet made at Sonnwendstein. First he suggests that, instead of such indefinite terms as "bright," "faint," &c., a definite scale of standardised surface-brightnesses should be employed, the standard unit being referred to a definite illumination produced by a standard lamp under defined conditions. This unit is called a *phos* (*ph.*), a thousandth part of it a *milliphos* (*mph.*), a millionth part a *microphos* (*mkph.*); for the multiples the prefixes *kilo-* and *mega-* are suggested. Then he describes a method of using the photometer where the image of the object is seen through a hole pierced in a mirror fixed in the focal plane of the objective. By measured variations of the source of illumination, the surface of the mirror is brought to the same brightness as the focal image of the object. Again, by using suitable screens, the different radiations from any object may be directly compared, and for Jupiter Dr. Hartmann finds a range from red to green of 27 to 68 mph. (milliphos).

The results obtained by this method, comparing various parts of the comet on different dates, are very interesting. They are too numerous to give fully here, but one or two examples will serve to illustrate them. May 23, 9h. 2m. (M.E.T.), mean brightness of nucleus and the surrounding area of 22″ diameter: white, 220 mkph., yellow, 180 mkph., green, 410 mkph.; 9h. 27m., nucleus alone: white, 620 mkph., red, 360 mkph., orange, 630 mkph., yellow, 730 mkph., green, 1350 mkph. On May 26 a number of observations, including the nucleus, the area surrounding it, and the tail, were made, and for the tail, at 3m. 42s. in R.A. behind the head, a value of 0·22 mkph. was found. For comparison, Dr. Hartmann found on May 31 that the surface brightness of the Ring Nebula was 1·2 mkph., and for the inner space 0·6 mkph.; a bright area of the Milky Way, in Cygnus, gave a value of 0·05 mkph.

M. Antoniadi suggests that the tail, seen by Prof. Eginitis, turned towards the sun on May 20, was only a minor sheath; his observations, and those of Dr. Hartmann and others, show the tail as a sickle-shaped object with its *convex* side turned sunwards.

That the comet was a fine spectacle at Tokio is shown by a table giving the magnitude, length of tail, &c., as seen by Mr. K. Saotome, of the Tokio Observatory, reproduced in the *Astronomische Nachrichten*.

In No. 4433 of the same journal Drs. Cowell and Crommelin discuss the different elements published by various calculators for the 1910 osculation. These agree fairly well except in the value given for the mean motion (μ), in which there are grave differences. M. Iwanow adopted Pontecoulant's value for 1835, which the Greenwich observers have shown to be 0·05″ in error, and should therefore have arrived at a perihelion date differing from theirs by about one month. That this is not so indicates that some serious error crept into his calculations, and it is suggested that, as the difference is so important from a gravitational point of view, the discordance should not be allowed to remain unproved. Mr. Merfield and Messrs. Crawford and Meyer appear to have deduced their value of μ from the recent observations alone, a procedure which Drs. Cowell and Crommelin deprecate as untrustworthy; and the value obtained by the Berkeley computers is enormously in error. According to the Greenwich calculators, the value for 1910 is $\mu = 46{\cdot}6747''$, but this cannot yet be accepted as definitive.

A number of observations of the comet's brightness, made by Prof. Wendell, Mr. Leon Campbell, and Dr. Holetschek, are also published in the *Astronomische Nachrichten*, and the Harvard observations are plotted with the theoretical curve derived from the formula $1/r^2\Delta^2$; this shows very plainly the physical action produced by the solar rays as the comet got nearer the sun, the magnitudes increasing during this period beyond the rate demanded by the formula.

In No. 1, vol. xxxii., of the *Astrophysical Journal* Mr. Slocum describes the observations of the sun made at the Yerkes Observatory on May 18 and 19. Direct photographs and spectroheliograms are reproduced, and will serve as comparisons for any phenomena that may be attributed to cometary influence; nothing abnormal was noted.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Dr. H. Wren, of Birkbeck College, has been appointed professor of pure and applied chemistry at the Municipal Technical Institute, Belfast.

Mr. J. M. Caie, organiser in Inverness and Ross for the North of Scotland College of Agriculture, has been temporarily appointed lecturer in agricultural education in the college in the place of Mr. R. B. Greig, who has gone to Australia as a member of the Agricultural Commission.

Next session will be the hundred and fifteenth of the Glasgow and West of Scotland Technical College. In 1886 the present college was formed by the amalgamation of several institutions, including Anderson's College, which dated from 1796. The new calendar provides abundant evidence of the flourishing condition of the various departments included in the college. The first section of the new buildings, consisting of five large wings, we notice, was opened in 1905. The second section was opened in 1908, and comprises the main entrance hall, additions to the library and mechanics' laboratories, class-rooms for the decorative trades, and laboratories for dyeing, bleaching, &c. The third section was opened in the following year, and contains additional accommodation for civil engineering, engineering drawing, and other subjects. The fourth section will, it is expected, be ready for the coming session, and within it provision will be made for the department of textile manufacture. The plan of confining each department to one floor has been followed in nearly every case, with the result that the internal arrangements are well adapted to promote efficiency in working. The whole building comprises over seven acres of floor space, and forms one of the largest structures in Great Britain devoted to education.

The sixth annual report of the Education Committee of the County Council of the West Riding of Yorkshire deals, among other matters, with the part the committee has taken in providing university and technical education in the area for which it is responsible. The grants of 4500*l.* to the University of Leeds and 1500*l.* to the University of Sheffield have been continued. In addition to these sums, the University of Leeds has received 775*l.* to provide extension science lectures, instruction in coal mining, and free studentships for disposal by the County Council; and the University of Sheffield 500*l.* for Saturday mining courses and other purposes. So far as technical education is concerned, the greatest difficulties continue to be encountered in the rural portions of the Riding, where the meagreness of population and the prevailing conditions of life and work are less favourable to the successful maintenance of evening schools than in the more populous areas. In the mining districts the difficulty, which has always been a serious one, of maintaining regular attendance, has been accentuated during the session owing to the operation of the Eight Hours' Act rendering it almost impossible for students to change their shifts. The committee has the matter under consideration, and hopes to find a solution of the problem before the opening of the coming session. A satisfactory increase in the proportion of students attending for group courses of instruction is again reported. Practically all the West Riding schools are now organised on this basis, with the result that the educational equipment of the students is much more effective than when attendance for isolated subjects was the general rule.

The issue of *Science* for August 19 last contains an article providing tables giving data in regard to the degrees of doctor of philosophy conferred by the universities of the United States. There were conferred this year 353 degrees, not quite so many as in the three preceding years, when the numbers were 366, 378, and 387. Almost exactly half the degrees conferred last year were in science. The universities, however, differ considerably in the relative importance of their work in science. Chicago appears to be the best balanced; it has conferred just half its degrees in the sciences and half in other subjects. At the Johns Hopkins and Cornell about 60 per cent. of the degrees are in the sciences, whereas the percentage is about 40 at Harvard, Yale, Columbia, and Pennsylvania. There is not a preponderance of the sciences in the State universities, the percentage of degrees at Wisconsin being only 37 and at Michigan 38. Boston University appears to have conferred only three scientific degrees out of seventy-four. There was this year a large fall in the number of degrees in science conferred by Columbia, eleven, as compared with twenty-one and twenty-three in the two preceding years. Cornell, on the other hand, conferred this year twenty-seven degrees in science, surpassing all the other universities. Interesting particulars as to the varying popularity of different subjects of science are given. Chemistry, with forty-eight degrees, leads, having about double the numbers in physics, zoology, psychology, and mathematics. Botany comes next, and there is then a considerable drop to geology, followed by physiology and astronomy. In the case of the subjects not ranked under the natural and exact sciences, most degrees have been given in English history, economics, and philosophy.

On September 6 the *Times* published its first Educational Supplement, and if subsequent issues reach the same high standard of interest and usefulness, these supplements should do a great deal to educate the general public in educational matters and to develop an intelligent appreciation of the importance of securing for this country as efficient a system of national education as can be found anywhere. The articles, which are numerous, deal with many aspects of a complex problem; they are all, moreover, inspired by a broad outlook and a desire to assist the attainment of efficiency. Great prominence is given to the work of secondary schools and universities, and the importance of securing the right relationship between these grades of education is emphasised. One article, entitled "New Universities and New Schools," comes appropriately after the address of the principal of the University of London to the British Association last week. It deals with the difficult question of where the work of the secondary school should end and where that of the university should begin, and endeavours to make clear what precisely may be expected of a student desiring to matriculate. The writer properly maintains that it ought not to be impracticable to devise a leaving certificate in which both the views of schoolmasters and the university authorities are represented. The passport of entry to the university must certify both that the student is fit to leave school and that he has this or that range of abilities and equipment to enable him to undertake the work expected of him. The new venture deserves to succeed, and we commend this first issue to the attention of all who are interested in educational matters.

The forthcoming opening of the winter session of work at the technical colleges throughout the country is, as usual, preceded by the publication of a large number of new calendars and prospectuses. Among these, that of the Municipal School of Technology, Manchester, takes a prominent place by reason of the completeness of its provision of instruction in every phase of technical education which is likely to appeal to students in south Lancashire. This calendar, which runs to some 520 pages, shows that the school is fulfilling thoroughly its object of providing instruction in training in the principles of science in their application to the industrial arts. We are glad to notice that the authorities here insist that it is impossible for a student to obtain full benefit from the courses of instruction unless there has been adequate previous preparation, and that students are required to pass an entrance examination in subjects of general knowledge or to produce evidence satisfactory to the principal of their attainments. Special attention may be directed to the fact that the courses in the respective departments prepare for the degree of Bachelor or Master of Technical Science of the Victoria University of Manchester in the case of students who have matriculated, and that special courses of fourth-year post-graduate study and research are offered. The University of Liverpool publishes separately the particulars in connection with the faculty of engineering, of which Prof. J. A. F. Aspinall is chairman. The courses of study in the faculty afford a general scientific training for those who intend to become engineers, naval architects, architects and surveyors. The training is to be regarded as either preliminary to, or supplementary of, a pupilage under some engineer or course of apprenticeship with some engineering firm. Arrangements are made for students to spend the summer vacation in works, or to take a voyage as junior engineers in steamships. The prospectus of the evening classes and of the secondary school in connection with the East Ham Technical College points out that the numbers of students seeking admission have been so great that it has been found necessary to increase the accommodation by converting some of the workshops into class-rooms, and building a separate block of workshops and gymnasium at a cost of 3000*l*.

THE Aërial League of the British Empire proposes to found a practical school of aviation as a memorial to the late Hon. C. S. Rolls. In a circular letter recently received from the secretary of the league it is pointed out that such schools only exist abroad, and that few opportunities exist in England where students may attend laboratory classes; also that there are absolutely no facilities (except for very rich men) for practical tuition in the construction and handling of flying machines or for experimental testing of the selected designs of deserving inventors. A subcommittee of the league has been at work for some time past upon the project, and their proposals (which have been approved by the executive committee) are as follow:—(1) The primary aim of the school is to provide training in aëroplane manufacture and flight and to obtain a class of men grounded in the whole subject from beginning to end, the instruction to include such laboratory and theoretical work as funds and the gifts of apparatus may permit. The proposed laboratory to be situated centrally in London, to be open for the use of students from various technical institutions already providing elementary classes in the theory of flight, and also for public demonstrations in order to spread interest. (2) The school of aviation to be situated as near London as possible, and to be open to men who have undergone courses of training in great engineering schools, competent engineers, and mechanics. (3) The attention and the practical work of students to be chiefy directed to securing machines offering greater trustworthiness and stability, lower power and fuel consumption, diminished capital cost and expense of maintenance, and a higher factor of safety than the apparatus now used mostly in sporting contests. (4) In order that an early start may be made, two machines should be bought at once. Students themselves to build all further machines, and also those of selected inventors whose ideas are judged to be worthy of construction and practical trial. The result of this will be that novel machines can be built and tested at very low cost, and students, inventors, and instructors will alike benefit by the experience and analysis of results obtained. (5) Funds to be administered by an independent committee of management, including practical men of science and education experts. The estimated cost of the school is 1300*l*., and that of its running for the first year 1200*l*., *i.e.* 2500*l*. for the year, and the league solicits the generous and prompt support of all sympathisers.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 29.—M. Armand Gautier in the chair.—Joannes **Chatin**: The posterior sclerotic ring in birds.—M. **Gonnessiat**: Observation of the D'Arrest comet at the Observatory of Algiers. This comet was detected at Algiers on August 26, appearing as a feeble nebulosity with a slight central condensation of the fourteenth magnitude.—M. **Baillaud**: Remarks on the above. This comet has a period of six years eight months, and was not seen in 1904. Its position coincided with the calculations of M. Leveau, the difference between the calculated and observed positions being less than the ordinary field of a telescope.—Kotaro **Honda**: The law of variation of the coefficient of specific magnetisation of the elements by heating. Instead of the two laws of Curie, the author proposes the following: the effect of a rise of temperature on the magnetisation coefficient of an element is similar to that of a small increase of the atomic weight of the element. The experimental data in support of this are given.—G. D. **Hinrichs**: The atomic weights of precision of oxygen and silver.—M. **Busignies**: Some ethylenic cyclic derivatives (ether oxides) and their bromine derivatives. The alkyloxybenzophenones are treated with magnesium alkyl iodides, and give alkyloxydiphenylethylene and its homologues. The bromine addition compounds of these have also been prepared.—E. **Voisenet**: New researches on bitter wines and the acrylic fermentation of glycerol. Determinations of the amounts of acrolein in various wines showed that the bitterness increased with the amount of acrolein present.—Z. **Skrzynski**: Contribution to the study of mycosic sero-diagnosis.

THURSDAY, SEPTEMBER 15, 1910.

BIBLIOGRAPHY OF ATLASES.

Library of Congress. A list of Geographical Atlases in the Library of Congress, with Bibliographical Notes. Compiled under the direction of Philip Lee Phillips. Vol. i., Atlases. Pp. xiii+1208. Vol ii., Author List; Index. Pp. 1209–1659. (Washington: Government Printing Office, 1909.) Price 2.35 dollars the two vols.

THOUGH making no claim to be a complete list of atlases, this work marks a very important step towards a much-needed annotated bibliography of such publications, nothing on a similar scale having ever been attempted before. The collection dealt with is important enough to represent a large proportion of the whole material in existence, and the information supplied, both in the form of general notes and of complete lists of the maps contained in the more important atlas, will be of great value to students. These lists are of particular service in the case of early works, often found incomplete or broken up into their constituent items, but of great interest from the point of view of the history of geography.

In such early works the present collection is comparatively rich. The set of editions of Ptolemy's "Geography," so valuable as presenting a view of the progress of knowledge, on the academic side at least, during the century and more following the discovery of America, makes a near approach to completeness. Ortelius is well represented, and in a somewhat less degree, Mercator, though there is no copy of the great Italian atlas of Lafreri, somewhat earlier in date. Nor do we find the *Speculum nauticum* of Waghenaer, the earliest example of a purely hydrographical atlas, though we meet with Dudley's "Arcano del Mare," and many later works of a similar kind. Most of the best modern atlases are, of course, included. As might be expected, works American, either in origin or subject-matter, decidedly predominate, the items under "United States" numbering about two-fifths of the whole.

Valuable as the catalogue certainly is, and great as has evidently been the labour expended upon it, it could hardly be that imperfections should not be noticeable in matters of detail. The entire absence of headlines giving an indication of the broad subdivisions of the subject is a drawback, as is also the reference in the index, not to the pages of the work, but to the *numbers* of the main entries, placed as these are in no very conspicuous position, and never repeated when an entry covers several pages. The general arrangement is somewhat illogical, *special* subject headings always preceding *general* ones, though special topographical headings again follow the latter. In the notes the vague references to authorities are irritating (*e.g.* "cf. Nordenskiöld," after a quotation from that author). There seems no very consistent plan as regards the choice of atlases for analysis; thus there is no full list of the maps in Nordenskiöld's "Facsimile Atlas," though, curiously enough, some of the maps find a place in the index, when borrowed by other authors. It is certainly useful to find all the publishers of atlases grouped under "Publishers" in the index, but this hardly justifies the omission of the individual names from their proper places.

Universal knowledge cannot, of course, be expected from the best of editors, but further expert assistance might have saved some errors, these being sometimes due to the unquestioning acceptance of statements by earlier writers. Thus the fifteenth-century editor of Ptolemy, Dom Nicolaus Germanus, still appears as "Donis." The statement that the 1598 Italian version of Ptolemy was due to Cernoti is correct only in regard to the new matter added by Magini. The famous fifteenth-century map of Nicolas de Cusa is ascribed to Nicolas "Cusana," and, stranger still, the sixteenth-century humanist, Loriti, or "Glareanus" (so named from Glarus, in Switzerland), appears as "H. Loritz de Gloria."

But these are, after all, small matters to be set against the undoubted value of the catalogue, both for purposes of reference and as a step towards a still more complete list of atlases which we may hope to see published some day.

LEAD AND ZINC PIGMENTS.

Lead and Zinc Pigments. By Dr. C. D. Holley. Pp. xix+340. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1909.) Price 12*s*. 6*d*. net.

OWING to various causes, the development of the paint industry in the United States has been of a very special and interesting character. On the one hand there has been a large demand for ready-mixed paints for the protection of the wooden buildings which are still so common in that country, and on the other the existence of large deposits of zinc lead ores has led to the preparation of sublimed whites, which are largely used in the making-up of ready-mixed paints. In addition, there is the tendency, which we find in all industries in America, to replace hand by machine methods, and thus develop new and modified processes. A book, therefore, on the manufacture of lead and zinc pigments, written by one so thoroughly familiar with all the processes as Dr. Holley, is of great interest to English readers.

In the first place, a detailed description will be found of the mechanical processes of white-lead manufacture which have been so successful in the United States, although they never seem to have succeeded in replacing the ordinary Dutch process in this country. Detailed descriptions of the Carter process, the Matheson process, and others will be found, evidently written by one who is thoroughly familiar with them, while the photographs of actual plant are of great interest. In addition, the preparation of sublimed lead pigments, which has become of such great importance in the United States, although used to a comparatively small extent in this country, including sublimed white and sublimed blue lead, the preparation of zinc oxide, and the preparation of the mixed lead and zinc paints which are a big feature of the American paint industry, and are obtained by subliming mixed lead and zinc ores, and which contain various proportions of zinc oxide and lead sulphate, are fully described. The preparation also of the oxides of lead and lead chromes is dealt with, and the preparation and properties of zinc sulphide paints.

A very complete account is also given of the elaborate practical tests of various paints which are being made on special experimental stations in the United States at present, with the view of deciding which paints are most durable for outside use. These experiments are giving some very valuable results. For instance, the usual assumption in this country that white lead is the best pigment for protection of outside surfaces has apparently been quite disproved by these results. Zinc white, or mixtures of zinc white with white lead, prove to be more durable. These experiments are still being continued and the results published from time to time, and should be carefully watched by architects and engineers in this country, where similar experiments might well be carried out. The physical and chemical properties of these various whites and their analyses are also thoroughly dealt with; in fact, the whole book contains a great deal of very valuable information written from the American point of view, and should therefore be of special interest to all those connected with the paint industry in this country.

A. P. LAURIE.

METEOROLOGICAL TABLES.

Tables for the Reduction of Meteorological Observations. Prepared by Dr. G. C. Simpson, under the direction of Dr. Gilbert T. Walker, F.R.S. Pp. ix+95. (Calcutta: Government Printing Office, 1910.)

THE present revised edition of Blanford's meteorological tables, prepared for the routine work of the Indian meteorological service, contains in all sixteen tables, of which the first and last pairs are for the interconversion of barometric heights and of temperatures in the English and metric systems. The remaining tables are in English units. The relationship 1 metre = 39·37079 inches, adopted from the international tables, is an example of fictitious accuracy which might be discarded in view of the values found by Rogers (1893), 39·370155, and Benoit (1902), 39·370113. The same criticism applies to the expressions for the corrections to the barometric height H, for the variation of gravity with latitude (λ), and altitude (h), viz. $0{\cdot}00259 \cos 2\lambda\, H$ and $5{\cdot}97 \times 10^{-8} h\, H$. The arrangement in table vii., for reducing the barometer to sea-level, or for finding differences of height, is excellent. The *logarithms* are tabulated, and the temperature and humidity terms have been combined by assuming a constant value for the mean air-pressure occurring in the latter; the result is that the complicated process involved in applying the Smithsonian or international tables has vanished, and the desired value may be obtained by a simple calculation as accurately as the observations ordinarily allow. It is, however, *not* necessary to apply the latitude correction to the barometer readings in finding differences of height.

The major part of the volume is devoted to humidity tables for reducing psychrometric observations for temperatures between −20° and 130° F., and for pressures 29·7, 27·7, 25·8, 23·4, 19·7 inches. Presumably 25·8, 23·4 were retained because they are approximately the mean pressures at altitudes of 4000 and 7000 feet respectively, but it seems inappropriate to determine the increments of the argument, *pressure*, by unequal increments of *altitude*. The tables are strictly applicable to observations taken in light winds only.

A useful little table gives the mean daily range of pressure determined from ten tropical stations.

The tables are well and carefully printed on good paper, but the volume might with advantage be made of a more convenient size. The adoption of the principle, common in logarithmic tables, of neither printing nor allowing space for unnecessary figures, would permit this without sacrificing clearness.

E. GOLD.

PLANTS AND GARDENS.

Sweet Peas. By H. J. Wright. Pp. xi+116. Price 1s. 6d.

Pansies, Violas, and Violets. By Wm. Cuthbertson, J.P., and R. Hooper Pearson. Pp. xi+116. *Present-Day Gardening*, edited by R. Hooper Pearson. (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 1s. 6d.

Die Hiede. By W. Wagner. Pp. 200. (Leipzig: Quelle and Meyer, n.d.) Price 1.80 marks.

Niedere Pflanzen. By Dr. R. Timm. Pp. 194. (Naturwissenschaftliche Bibliothek für Jugend und Volk.) (Leipzig: Quelle and Meyer, n.d.) Price 1.80 marks.

Das Holz. By H. Kottmeier and F. Uhlmann. Pp. iv+143. (Leipzig: Quelle and Meyer, 1910.) Price 1.25 marks.

Der Pflanzengarten, seine Anlage und seine Verwerkung. By Prof. F. Pfuhl. Pp. 152. (Leipzig: Quelle and Meyer, 1910.) Price 2.50 marks.

THE dictum as to the endless making of books may be applied with particular force to works relating to gardening and nature study at the present day. To such an extent has the gardening fashion seized the country that every class of plants must now have its own special treatise. The two books first on the list are the opening volumes of a series entitled "Present-day Gardening," produced under the editorship of the editor of the *Gardener's Chronicle*, and they appear to be excellent alike in their coloured illustrations and in the letterpress. The illustrations are remarkably good examples of colour printing, and it is only in the case of some of the lilac shades that some criticism might be made. The text is both interesting and practically useful, and the plan followed is similar in both volumes, opening with some historical notes, general culture, the value of the plants for decoration, an account of standard varieties, &c. If forthcoming volumes maintain the level of those before us, the series should find high favour with the gardening public.

In "Niedere Pflanzen" and "Die Heide" we have two small German natural history books; the former deals with ferns, mosses, fungi, and algæ, and is a wonderfully compact and comprehensive little book, copiously illustrated with a frontispiece of Equisetum in colour. "Die Hiede" opens with an inferior coloured plate of Culluna, with attendant insects, but the letterpress demands full praise and the illustrations throughout the text are well executed. The history of the heath lands, the component plants, &c., are described in detail, and the biology of the flowers is also fully dealt with; a chapter is devoted to the trees of the heath land. The latter portion of the book gives an account of the animal life of the moor, and numerous figures are given of the various insects associated with this formation. Both volumes are practical and useful works, and the latter especially affords a model which might well be copied in England.

"Das Holz" is a short practical forestry manual, which, in small compass, gives a mass of useful information as to forestry matters in general, such as wood structure, measurement of timber, felling, haulage, &c., and of the industries connected with timber. A book on these lines would probably find a ready sale in England, and be of considerable value.

"Der Pflanzengarten" is concerned with the design and usefulness of a garden as a place for study, and is principally occupied in giving a description of the garden at the Kgl. Mariengymnasium, Posen, and with an account of the plants found therein.

OUR BOOK SHELF.

The Black Bear. By William H. Wright. Pp. vi + 127. (London: T. Werner Laurie, n.d.) Price 6s. net.

IN this well-illustrated volume the author has done for *Ursus americanus* that which he accomplished so successfully for *U. horribilis* in its fellow (see NATURE, vol. 82, pp. 423–4, 1910). The first fifty pages are devoted to a young black bear reared and tamed by Mr. Wright, while in the remainder the distribution and habits of the species are discussed in a manner indicative of intimate knowledge. Indeed, the author's acquaintance with the black bear appears to be as close as with its larger grey cousin. "Cinnamon" bears, it is shown, may be either of the black or the grey species, and the author is disposed to regard the glacier-bear (*U. emmonsi*) and the white bear of Gribble Island (*U. kermodei*) as specifically inseparable from the former. From among a number of interesting notes, attention may be specially directed to the author's observations with regard to the extremely small size and imperfect development of new-born bears, especially those of the present species. The cubs of the black bear are at first "absurdly small and pitifully helpless, weighing only from 8 to 18 ounces each, according to the number in the litter, and are born about two months before the dam emerges from her winter quarters." An old bear will weigh about 400 lb.; and the pups of a 40 lb. dog will be as large as the cubs of a bear of this weight. To explain this, the author suggests that a hibernating bear, which, of course, takes no food, could not nurse cubs proportionately so large as those of the dog; and, whether or no this be the right explanation, there can be little doubt that there is some connection between the hibernating habit and the diminutive size of the cubs.

The book is pleasant reading, and full of hunting and forest lore.

R. L.

Chemistry for Photographers. By Chas. F. Townsend. Fifth edition, revised. Pp. 129. (London: George Routledge and Sons, Ltd.; Dawbarn and Ward, Ltd., n.d.). Price 1s. net.

THE more of chemistry and physics the photographer knows the better is he able to understand his work, to overcome difficulties, and to meet new contingencies. It is impossible to set forth the main facts of chemistry in so small a volume as this, even if the matter is restricted to those subjects that have an immediate bearing on photography; but it is possible to do something useful in this direction even within so few pages. The author commences with burettes and pipettes, and goes on, rather unnecessarily, to gallipots and jampots. We do not think that such expressions as "The iron, as it were, says to the silver, 'You've got my NO_3; drop it!' And the silver has to drop it," assist in representing the subject clearly, and in this case the description would appear to give an incorrect impression. From about the middle of the book the chemistry almost disappears in favour of practical and empirical formulæ, with short instructions for various photographic operations. Some of the author's statements are open to criticism. We read, on p. 62, that "all chemical reactions are reversible." That as, when a photographie plate is exposed to light "there is no outlet for the products of decomposition—the excess of bromide or other halogen set free on reduction in this case—a state of equilibrium is reached at a certain point. If decomposition is carried beyond this point, reversal sets in, which may go the whole way until the original compounds are re-formed." At p. 86 we read that carbon tissue is thin, and at p. 94, in the five and a half lines devoted to Dr. Smith's "Uto" paper, that "it is rendered colour sensitive by means of anethol." Other misleading or unpractical statements might be quoted. A photographer who wishes to know something about combining proportions, the general properties of acids and alkalies, and a few other elementary chemical matters, will probably find what he wants here, with a good many items of miscellaneous information added.

Die Aufzucht und Kultur der Parasitischen Samenpflanzen. By Prof. E. Heinricher. Pp. v + 53. (Jena: Gustav Fischer, 1910.) Price 2 marks.

FOLLOWING upon his original investigations on Lathræa and other parasitic genera of the Scrophulariaceæ, Prof. E. Heinricher has prepared this small volume dealing with the propagation and cultivation of parasitic seed-plants that will appeal especially to gardeners charged with the supply of material for botanical laboratories. The notes refer to well-known European parasites and hemiparasites, and some less common genera, such as Tozzia, Osyris, and Phelipæa. One of the most interesting is *Osyris alba*, which flourishes and produces fine suckers on willows. *Phelipaea biebersteinii*, one of the Orobanchaceæ indigenous to the Crimea and the Caucasus, is worth growing for its flower; its natural host is *Centaurea dealbata*. Another novelty recommended by the author is a pot of *Melampyrum arvense*, which feeds on the roots of several shrubs and small trees.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Lord Morton's Quagga Hybrid and Origin of Dun Horses.

WILL you allow me to suggest that some of the data which speculators upon the antecedents and the history of the horse have made much use of are not too trustworthy?

First, I would suggest that there is doubt whether Lord Morton's famous quagga hybrid is a hybrid at all. Agassé's portrait of it and of its sire and dam are to be seen in the museum of the Royal College of Surgeons in London. According to the portrait, the hybrid was a bay with black "points," the blackness mounting just to the pastern joint, as it does in many bays.

Chestnut has been shown to be recessive to all other colours; and a chestnut never has black "points." Prof. Cossar Ewart tells us that "in their body colour none" of his hybrids took after their sire, the Burchell zebra, a close relation to the quagga. Now, in Lord Morton's case, we have a chestnut mare producing a bay, a colour she certainly does not contain. Is that possible?

Again, we have a chestnut and a quagga, whose legs were white, or, at any rate, a dirty white, producing a foal with black "points." Is that also possible? Unfortunately, there is one disturbing element in what has just been put forward; but it is not serious. I understand that Agassé may have painted the "hybrid" from a drawing, not from the life. But in a case so critical, and with Lord Morton at least to keep him right, it is scarcely possible he could have given the "hybrid" a colour and "points" it did not possess.

Next, I would suggest that the dun colour in horses is not a reversion. In view of the fact that one of our greatest men believed in the dun reversion, and also that it led him and others to argue the primitive horse to be dun and striped, my suggestion may be held to be very presumptive. All the same, it must be made.

In April last, the Royal Dublin Society published a paper for me on "The Inheritance of Coat Colour in Horses," in which it was pointed out somewhat tentatively, because the evidence then at command was small, that dun is dominant to chestnut, black, bay, and brown, and recessive to grey; while its relation to roan was not clear. Since that time a considerable body of further evidence has been got, and it all confirms the original conclusion. Accordingly, a dun foal cannot be got unless one of its parents is either a dun or a grey or a dun roan. Greys are, therefore, the only colour that could throw dun "reversions."

My chief purpose in asking you to publish this letter is to beg for evidence on the points at issue from anyone who would be good enough to send it. What is wanted is evidence—

(1) As to the body colours and leg markings of hybrids between zebras (especially Burchell zebras) and chestnut horses, and

(2) As to the parentage of dun horses.

Perhaps it may be well to say that, if there is difficulty in distinguishing bays, duns, and chestnuts, the following can usually be relied upon:—Unless white "stockings" intervene, bays and duns have always black "points." In bays the colour of the nostril patch is nearly always lighter than that of the face, but in duns there is no distinct break between the colours of the nostril patch and the face. Chestnuts have not black "points"; their legs are coloured like their bodies.

JAMES WILSON.

Royal College of Science, Dublin.

PROF. WILSON thinks the "bay" filly which Lord Morton says he obtained by crossing a chestnut mare with a quagga was not a hybrid, because he assumes that a chestnut does not contain a bay colour, and that the offspring of a white-legged quagga and a chestnut mare would not be likely to have black "points." Prof. Wilson also thinks "that the dun colour in horses is not a reversion," and that the primitive horse was not, as Darwin and others believed, "dun and striped."

The prevailing colour of all the wild Equidæ now living in Asia is dun, and the wild horse (*Equus przewalskii*) has dark points and usually a light muzzle. As crosses between varieties of Burchell zebras with white "points," and crosses between zebras and ponies have, usually, dark patches at the fetlocks, and as the body colour of zebra-horse hybrids is usually yellow, rufous, or leather-dun, it may be assumed that the remote ancestors of the modern zebras only differed in their coat colour from Prejvalsky's horse in being more richly striped.

The drawing of Lord Morton's filly by Agassé might be said to represent a bay or a bay-dun—that the filly was a bay-dun rather than a bay may be inferred from Lord Morton saying that in her colour, as well as in her form, the hybrid filly afforded "very decided evidence of her mixed origin." A light chestnut Iceland pony mare in my stud produced a bay-dun with dark "points" to a yellow-dun Prejvalsky stallion, and a richly striped yellow-dun Highland mare produced first a dark bay with dark "points" and then a light bay (also with dark "points") to a chestnut thoroughbred (Diplomat). I am hence not surprised that Lord Morton's chestnut Arab produced a filly of a bay or bay-dun colour to a quagga.

It has hitherto, so far as I know, not been pointed out that there are two kinds of duns, viz.:—(1) duns without either a dorsal band, shoulder or leg stripes, and (2) duns *with a dorsal band* and, as a rule, more or less distinct bars on the legs—sometimes also with zebra-like markings on the face, neck, shoulders, and trunk, and spots on the hind quarters. Duns *without stripes* of any kind are now and again obtained when a grey is bred with a black or with a bay. The dun colour in these unstriped horses is apparently not a reversion. Moreover, the offspring of two unstriped yellow-duns may be bay or brown.

Yellow-duns with a dorsal band and at least vestiges of leg bars are, in all probability, either the descendants of a long line of dun ancestors or are reversions. Owing to the elimination of duns by breeders—the Arabs thought duns only fit for Jews to ride—there probably does not exist to-day a yellow-dun thoroughbred, but now and again one sees a well-bred yellow-dun hunter with distinct leg bars—a descendant, perhaps, of the dun mare or the dun Arab which figure amongst the ancestors of Touchstone.

That dun is latent in some bays and blacks was proved recently by a black Shetland mare from Unst producing to a bay Arab (Insaf), with a dorsal band and leg bars a richly striped yellow-dun. There are striped white, yellow, leather, and mouse duns. I have obtained a striped white dun from a red-roan Arab mare and a yellow-dun Norse stallion; a striped yellow-dun from a bay Sumatra stallion and a mouse-dun Shetland-Welsh mare; a striped leather-dun from a yellow-dun Highland stallion and a chestnut Shetland-Arab mare; and a mouse-dun from a yellow-dun Highland stallion and a black Highland mare.

My crossing experiments do not support the view that chestnut never contains bay or that yellow-dun is always dominant with chestnut, bay, brown, and black—they on the whole support the view that characters are "patent" or "latent" rather than, as Mendelians say, "present" or "absent."

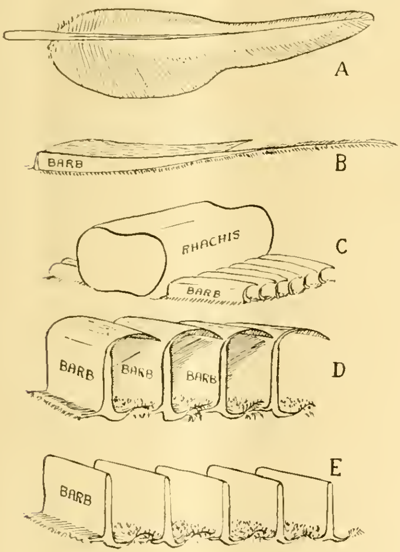
As to the colour of hybrids between a Burchell zebra and chestnut mares, I have little to say. A chestnut polo-pony mare produced three hybrids. In the first two (twins) the body colour at birth was of a rufous tint, and the stripes of a faint reddish-brown colour. When full grown, the body colour was of a leather-dun hue, the stripes being a slightly darker shade of the same colour. In the third hybrid the body colour, golden-dun at birth, was eventually a dark yellow-dun. The stripes in this third hybrid are of a brown colour, and extremely well marked on the neck and limbs. Dark-brown patches at the fetlocks represent black "points."

J. C. EWART.

An Undescribed Feather Element.

In all the European ducks, geese, and swans, and in certain game birds, there is a remarkable feature about the structure of the primary feathers that seems to be hitherto undescribed. The under surface of a feather from such a bird bears a distinct glistening "mirror" occupying that portion of the web adjoining the rhachis. It is quite visible to the unaided eye in any position of light, and may be readily detected by the finger-tip. A closer examination shows this area to consist of a series of narrow silvery (sometimes golden or brassy) membranes each closely overlapping the next distal barb. For illustration I have chosen the fourth primary of an adult Bewick's swan. In Fig. A the glistening area is left unshaded; in Fig. B a single barb is figured, with its membrane; Fig. C shows a portion of the rhachis with the web cut across to show the barbs with their membranes in section; Fig. D gives in transverse section four barbs with the curved membranes. This will be rendered clearer by a reference to the fifth diagram, which figures the barbs on a normal feather taken from a cormorant. In this bird the membranes are wanting.

So far as British birds are concerned, this feather



element is present only in the ducks and their allies, where it is always conspicuous; in the four British grouse, where it is again striking; and in the partridge and the pheasant. In certain exotic game birds (Lophortyx, Tragopan, Gallus, Catreus, &c.) it is quite absent, and this makes its uniform constancy in the Anatidæ all the more noteworthy. The total absence of the structure in the feathers of Steganopodes, Alcæ, Pygopodes, Gaviæ, and Tubinares suggests that it is not essential to the feathers of water birds; and it is, moreover, as conspicuous on the feathers of the Anatidæ with terrestrial habits as it is on those of the truly aquatic ducks. This leads one to look upon it as vestigial of some earlier structure, and as such it might be used for taxonomic purposes.

The diagram of the primary shows the emarginations or notches of the web that have been, and still are, used in the classification of birds—Circus, for example. The use or meaning of these notches has not been explained, so I may be allowed to point out that the shapes of the outer primaries are governed by the law of Avanzini. Prof. Roy, in Newton's "Dictionary of Birds," has shown how this law affects the general shapes of the wing feathers, but does not notice the notches. When the wing is fully extended, with the primaries spread out like the fingers of a hand, each feather must necessarily function as a separate wing or sail. As the position of the rhachis cannot be altered, the web is trimmed away to the necessary degree. The new feathers appear fully formed, but, in many cases, I have reason to suspect that the notching is increased by the subsequent wear of the adjacent feathers.

Stepney Borough Museum, E.

An Interesting Donkey Hybrid.

In his letter on the "Origin of the Domestic 'Blotched' Tabby Cat" (NATURE, September 8, p. 298), Mr. Vickers says, "after much diligent search I have been unable to find a single instance in which complete segregation has taken place in respect of all specific characters *when two well-defined species are crossed.*" Our knowledge of specific characters is too limited to make such a claim provable if put forward; but I have recently seen a hybrid between two very distinct species which, at all events, approaches that standard. This is a donkey belonging to Sir Claud Alexander, Bart., which he tells me was bred by Hagenbeck between a male dziggetai, or Mongolian donkey (*Equus hemionus*), and a female Nubian donkey (*Equus asinus*). Both these gentlemen are well acquainted with the species in question, which, as every zoologist knows, are very distinct forms. Yet, unless I had been told that the animal was a hybrid, I should unhesitatingly have identified her as a pure-bred African donkey. Her colour is grey, her legs are strongly barred with black, and she has a sharply defined black shoulder-stripe and black mottling at the base of the long ears. All these characters belong essentially to the African, as opposed to the Asiatic, species.

In one point an approximation to the Asiatic type is shown. This is a widening of the spinal stripe towards the croup, a feature which is certainly more marked than in any African donkey I have seen. Still, the stripe is not nearly so wide as in the dziggetai; and, seeing how variable is the width of this stripe in quaggas belonging to the same local race, I do not feel sure that its width in the donkey in question is not an individual peculiarity independent of inheritance.

It is quite true, as Mr. Vickers says, although he expresses the fact somewhat differently, that the progeny of two distinct species usually combines the characters of the parents in such a way as to be describable as intermediate between them. The notorious case of Ward's zebra may be quoted as an instance in point. Until its history was known and its true nature ascertained, this animal was regarded as a distinct species intermediate between Chapman's quagga and the mountain zebra. It is, in reality, as I have elsewhere shown, a hybrid between the two; and I cite the case here for comparison with that of the donkeys. Whereas the two striped species of Equus produced an "intermediate" when crossed, the two nearly self-coloured species gave a very different result, thus proving the impossibility of foretelling what the progeny will be like when two well-defined species interbreed. It may be claimed, moreover, I think, that this remarkable hybrid donkey weakens the force of Mr. Vickers's contention that the "blotched" and "striped" tabby cats can hardly be representatives of distinct species because their kittens are not intermediate between the two types when crossed.

R. I. POCOCK.

Zoological Gardens, September 1.

British Marine Zoology.

It is possible to have a considerable amount of sympathy with Mr. S. Pace and also with his critic, Prof. MacBride, and at the same time to differ from both on some points. Mr. Pace aims high in both :—(1) his "bibliography of all works dealing with the biology of the European seas," and (2) his "exhaustive faunistic survey of the marine life at one or more points on our coasts," and marine biologists must wish him all possible success in his venture; but the doubt remains whether he has not undertaken more than he can carry out, and whether it would not require the libraries and the staff and all the other resources of one or more scientific societies to produce the first, and the united work of the marine laboratories and other investigating organisations round the coast to deal adequately with the second object.

But even if Mr. Pace falls short of his ideal, he may still produce much—both bibliographical and faunistic—that will be of use in marine biology. This is a case where the success will depend entirely upon the proved utility. If Mr. Pace's bibliographical "Contributions," as they are called, give us something substantial that the other "Records" do not, we shall all use them and be thankful, and that is probably all Mr. Pace desires.

In regard to the "exhaustive and continuous systematic biological survey," one cannot but doubt whether Mr. Pace quite realises the magnitude of what he has set before him. I have been attempting for some years—with considerable support from others—to make a systematic survey (I do not think I ever imagined it would be exhaustive) of one small part of the coast in one little section only of marine zoology—viz. plankton—and I have found that the resources of a university laboratory and a fairly well-equipped biological station, a special steamer with expensive apparatus and a good many assistants, are all required to provide, and to deal with, sufficient data; and I believe that others, both in this country and elsewhere, have had much the same experience.

But still Mr. Pace, with a movable biological station of "relatively simple and inexpensive equipment," may do good faunistic work on parts of the coast not at present covered by the existing marine laboratories; and I must dissent from Prof. MacBride's attempt (NATURE, p. 253) to discourage such work. Every new biological station becomes a centre of useful work, brings in its contributions to knowledge, interests its local public, obtains support for scientific work, and rears up young naturalists, both professional and amateur. Prof. MacBride rightly alludes to the foundations laid by "the splendid amateurs of the last generation." I agree with him that "a great service to science would be accomplished if we could resuscitate this race"; and I believe that local biological stations are the most hopeful influences working in that direction.

Nor can one agree with Prof. MacBride in his evident desire to see one marine station at Plymouth monopolising the marine biological investigations of the whole country. Even if such a state of affairs were possible, the single station could not overtake all the functions of the half-dozen—such as Cullercoats, St. Andrews, Millport, Port Erin, &c. For example, take the needs of local universities. How could Plymouth be to St. Andrews what the Gatty marine laboratory is, or serve Newcastle as the Cullercoats laboratory does? In Liverpool, again (to take the case I know best), the zoology school has had about twenty senior students each year lately who have required a vacation course of marine biology, and have obtained it at very little expense at Port Erin. These students could not have gone to Plymouth: the distance and the expense are prohibitive. Or take the needs of local sea-fisheries authorities. Could a single marine station anywhere on the south coast serve adequately the Northumberland or the Lancashire districts?

Prof. MacBride says, "we should therefore regret very much to see another 'station' started." It reminds one of the opinions expressed some years ago that the number of universities in England should not be increased. Fortunately, such views did not prevail, and the provincial universities of England are justifying their existence. It will be the same with those centres of marine investigation which we call "stations." Each new one properly established in a suitable locality, and wisely directed, will have its own functions to perform, and will attract students and supporters—and each, I believe, will receive the support it deserves. I have long thought there ought to be a fine biological station in the Firth of Forth in connection with the great University of Edinburgh; surely there ought to be one on the south-east coast within easy reach of London, and possibly South Wales or the Bristol Channel might have another. That would not be too many for England. There are more than that number in America, although Prof. MacBride writes as if Wood's Hole alone served the zoological schools of that country as he suggests Plymouth should do here.

I cannot understand Mr. Pace's contention that the intrusion of the economic motive "must arrest, if it does not entirely hinder, scientific research"—and Prof. MacBride seems to approve the view. Has it done so in the case of the Kiel "Kommission," or of the International Organisation for the Exploration of the North Sea in the interests of fisheries exploitation? The reviews in NATURE from time to time of the scientific publications of the Scottish Fishery Board and the Irish and other scientific fisheries departments sufficiently show that scientific research is greatly promoted by these bodies with "economic motives."

Prof. MacBride does not, of course, intend to mislead us in any way, but the incompleteness of his statement in regard to Wood's Hole may give the erroneous impression, to those who do not know the facts, that there is no economic work carried on at that celebrated centre of fisheries investigation and cod and lobster hatching! The fact is that there are two well-equipped laboratories working side by side at Wood's Hole—the one for teaching and research, under the direction of Prof. Frank R. Lillie, and the other (and older one) for research and economic work, belonging to the Government Fisheries Bureau, formerly the U.S. Fish Commission. The latter, although dominated by the economic motive, has produced much good scientific work; and Dr. F. B. Sumner's recent faunistic survey of Vineyard Sound and neighbouring waters, issued from that "fisheries" laboratory, is probably very much on the lines of the work advocated by Mr. Pace, which he and (?) Prof. MacBride seem to think would be arrested or hindered by such an environment. For my part, I believe the economic environment to be most stimulating to scientific research in marine biology, so long as there is perfect freedom to carry on such research.

I think Prof. MacBride's final sentence would lead the reader to suppose that there was now only one biological station in Canada. When I left Quebec last October there were three! It is a rapidly advancing country: there may be more now. W. A. HERDMAN.

Port Erin Biological Station, August 28.

I THINK that Prof. Herdman in his letter in which he criticises a recent article of mine in this journal has misunderstood my meaning in one or two points. Nothing could be further from my wishes than to see one station monopolising all the biological work of the country. I quite agree with him that biological science would be better served by a multiplicity of stations, *provided that these were adequately equipped with funds and with workers*. All I contended was that in the present state of affairs in Great Britain it would be better to concentrate scientific support on one station which, so far as buildings and appliances are concerned, is adequately equipped, than to have it spread over a number of stations poorly provided with funds and with staff, and, *ipso facto*, incapable of affording opportunities of really first-class work. Prof. Herdman thinks that each new station will attract local support and enlarge the number of the devotees of marine zoology. I sincerely trust that he is right; but my experience has been that a poorly equipped station comes to be regarded by the local friends of education as an expensive toy, which they soon tire of supporting. Mr. Pace's appeal was primarily to the professional zoologists, and as the support of these is at present not sufficient to keep one station in proper financial health, I did not see how they could be expected to support two.

Prof. Herdman is mistaken in supposing that I agree with Mr. Pace that economic work necessarily "arrests, if it does not hinder, scientific research"; but I am sure he will agree that a station the sole aim of which was scientific would be the ideal one, and I must point out that his accusation of "incompleteness" in my statement that Wood's Hole was such a station is entirely unjustified. It is true, as Prof. Herdman says, that there are *two* stations in Wood's Hole, one supported by the Federal Government and devoted entirely to economic work, and the other supported entirely by zoologists; but the station which has attained world-wide fame, owing to the quantity and quality of the research which has issued from it, is the second and purely scientific one. I never maintained that Wood's Hole was the sole station in the States, but the number of stations there is far less in proportion to the number of universities than it is in this country. Prof. Loeb and the senior Chicago students for years spent every summer in Wood's Hole, although Chicago and Wood's Hole are 1000 miles distant, a striking commentary on Prof. Herdman's complaint of the distance of Plymouth as a bar to its usefulness to Liverpool students.

One word, finally, as to the Canadian stations. Prof. Herdman states that when he left Quebec last October there were three stations, not one as I had led readers of NATURE to suppose. As for ten years I was a member of the board under whose charge these three stations were placed, I can claim to know something about them, and I reiterate my statement that there is only one properly equipped station in Canada, which is situated in St. Andrew's, New Brunswick, and which was constructed in 1907 as the successor to a movable station which for seven years had been moved from place to place in eastern Canadian waters. Of the other two stations, one is situated on Lake Huron, and is very insufficiently equipped, and no work of any consequence has as yet been done there. The third is on Vancouver Island, and when last I heard of it (in the spring of 1909) it consisted of a wooden shanty, a boat, and one local naturalist, but all three stations were supervised by one board, an ideal far, as yet, from attainment in Great Britain.

E. W. MACBRIDE.

The Origin of the Domestic "Blotched" Tabby Cat.

SINCE writing my previous letter I have had an opportunity of seeing Mr. Pocock, and was glad to hear that he himself had brought the question of the origin of our domestic cats before the Mendelians.

Mr. Pocock has also brought to my notice an instance in which complete segregation has taken place in the first generation in the case of a cross between the Nubian donkey (*Equus asinus*) and the dziggetai (*E. hemionus*), in which the offspring was *practically* indistinguishable from the African species, with this exception, that the dorsal stripe was rather broader. There seems to be a general tendency for ass hybrids to resemble one parent more closely than the other. Curiously enough, I have myself since come across another such instance in the Chrysomelid genus Leptinotarsa.

Mr. W. L. Tower (Biol. Bull., Wood's Hole, xviii., 1910, p. 296, Pl. iv.), in experimenting with *L. undecemlineata* × *L. signaticollis*, discovered that under certain conditions of temperature the individuals produced in the first generation were indistinguishable from the female parent, and, what is stranger still, when interbred continued to produce this type for six generations! Different conditions of temperature gave different results; for instance, one experiment involving the same parentage gave "a single class of adults intermediate between the two parents, a mid-type." No consistency of gametic behaviour is here observable as is the case with our domestic cats, except in so far that certain conditions of temperature are always associated with one particular result.

Previous discussion on the origin of our domestic cats has certainly been concerned more with the *sylvestris* type, and the present interest in the *catus* type is entirely the result of Mr. Pocock's work in this direction; at the same time, the same writer says (Proc. Zool. Soc., 1907, p. 146), "of 'tabby' cats, as fanciers well know, there are two kinds." From the first I have appreciated the difference between dimorphism of colour and pattern, and the case of the leopard was brought forward as comparable "in its gametic behaviour" to the case of the "blotched" and "striped" tabby, though I freely admit this may not have been very clearly expressed in my letter.

The question of greater variation under domestication than in a state of nature rests more on botanical than on zoological evidence; I do not, however, push the inference further than being of some conditional value. Conservation of type is, however, an important factor in nature. We must, I think, for the present concur with Mr. Pocock in having an open mind and preserving an agnostic attitude on this subject.

H. M. VICKERS.

81A Princes Street, Edinburgh, September 10.

THE REFORM OF OXFORD UNIVERSITY.

IN the course of last year, Lord Curzon, as Chancellor of the University of Oxford, published a weighty memorandum on the "Principles and Methods of University Reform." The various proposals therein contained have formed the subject of exhaustive deliberations by the Hebdomadal Council, some of the results of which have been from time to time made public in the *Oxford University Gazette*. The committees entrusted by Council with the task of considering in detail the measures of constitutional and administrative reform suggested by the Chancellor's memorandum have in nearly every instance presented their report; and these reports, having been fully discussed, and accepted, with modifications, by Council, are now published in a volume which has lately been distributed to all members of the Congregation of the University.[1]

The conclusions arrived at by Council, which now await the verdict of the larger legislative bodies, Congregation and Convocation, are summarised by the Chancellor in an ably written introduction, couched in moderate and statesmanlike language. The changes advocated, though not revolutionary, are far-reaching in character, and bear evidence of very careful consideration of all the various interests and conditions involved. The first matter dealt with is the constitution of the University. On this head it is proposed to abolish the arrangement by which Council, the body which has the sole power of initiating legislation, is composed, as to its elected members, of heads, professors, and members of Convocation in equal proportions. The election is in future to be thrown open without distinction of "orders." Congregation is to be made more completely representative of the teaching and administrative elements in the University and colleges by the doing away with the qualification of mere residence. Convocation, the ultimate legislative authority, is to remain, as at present, the general assembly of all members of the University who have taken the M.A. degree and retained their names upon the books. The powers of Convocation are to be in some respects restricted, but it is provided that fuller opportunities of exercising the franchise shall be accorded than at present exist.

An important series of proposals, which have been embodied in a draft statute, relates to the reconstitution of the existing faculties and the creation of a general board of faculties which shall relieve Council of much of its present business with regard to examinations, and shall control the administration of the Common University Fund at present managed by a special delegacy. The changes suggested under this head, if carried out, will have the effect of limiting to some extent the independent action of the colleges, and of putting greater power, under the general supervision of the University itself, into the hands of the whole body of teachers in a given subject. It is a serious attempt towards improved co-ordination.

A measure which is likely to be discussed with much keenness, and to meet in some particulars with vigorous opposition, is the suggested establishment of an entrance examination to be passed before coming into residence; with which provision there is linked an assertion of the principle that Greek should no longer be required as a necessary subject for a degree in arts. It is perhaps not generally realised that although each college exacts its own requirements, differing in different cases, there exists at present

[1] Principles and Methods of University Reform. Report of the Hebdomadal Council, with an introduction submitted on behalf of the Council by Lord Curzon of Kedleston, Chancellor of the University. Pp. xli+98. (Oxford: Clarendon Press, 1910.)

no examination qualifying for entrance to the University. "Responsions," with its several alternatives, has gradually assumed the virtual position of such an examination; but there is still, so far as the University is concerned, no obligation to pass any one of these examinations before matriculating. The scheme outlined by Council provides for making either Latin or Greek optional, and allowing as substitutes certain modern languages, together with other subjects, such as elementary history, politics, chemistry, and physics. This provision is to apply to the existing Responsions, pending the establishment of a regular entrance examination.

A subject which has engaged the attention of Council at considerable length is that of the admission of a poorer class of students. The report is unfavourable to the project of a distinctively working-man's college within the University, but apparently not to the foundation of halls and hostels for students of narrow means, should endowments be forthcoming for such a purpose.

On the general question of finance, the report advocates the constitution of a new finance board, chosen partly from Council and partly from members of Convocation, both resident and non-resident, charged with the duty of advising the University as to its financial policy, and of reviewing the published accounts of University and colleges. The Chest Office would remain as an account office, an estates committee and office of works for the University; but the delegacy of the Common University Fund would cease to exist, its functions being transferred to the proposed general board of the faculties.

In dealing with the subject of fellowships, scholarships, and exhibitions, Council has been to a great extent limited by the fact that these matters are, under existing conditions, largely the private concern of the various colleges. Many recommendations have, however, been made, several of which there is reason to think are not unacceptable to the majority of the bodies concerned. It is proposed that scholars should have the option of resigning some or all of their emoluments, while keeping the name and status of scholar, the money thus saved going to the exhibition fund of the college, or being directly applied for the benefit of necessitous students. Exhibitions, it is thought, should be chiefly or entirely eleemosynary, and freedom should be allowed, under reasonable conditions, for scholars to pursue some other subject than that for which they were elected. The system of prize fellowship receives a modified degree of approval, and the bestowal of fellowships on a large scale expressly for research is discouraged. On the whole, the system of these pecuniary aids to learning would remain, even if all the suggestions of Council were adopted, very much as it is under present conditions. Many will think that the interests of learning and research, as distinct from routine teaching, have here received insufficient recognition.

Other matters which have come under consideration are the establishment of a diploma to suit the special requirements of a business career, the length of the academical year, the reform of the electoral boards for certain professorships, and the admission of women to degrees. Further steps are promised in all these directions.

In the foregoing remarks the aim has been to give a general idea of the proposals which have commended themselves to the Hebdomadal Council, under the presidency of the energetic Chancellor of the University. Criticism has for this purpose been avoided, but it is certain that opinions will greatly differ as to the merits of many of the measures advocated in the Chancellor's introduction and Council's report. All, however, we venture to think, will sympathise with Lord Curzon in bespeaking the serious consideration of Congregation and Convocation for the result of so much thought and labour. The spirit in which the work of reform has been taken in hand could not be better expressed than in the concluding words of the Chancellor's introduction, words which we here take the liberty of quoting:—"We have made no attempt to build a new Oxford on the ruins of an old. We have too profound a conviction of the part that is still capable of being played by the older universities, and, as we think, by our own in particular, in the life of the nation, to wish in any degree to impair either its essential character or its inspiring influence. We want Oxford to remain what it is, but to become, if it may be, better; still to keep alive the transmitted flame, but to see that it illumines every corner of the temple of knowledge and is accessible to all sections of the community; above all, since our University is an imperial training ground for character and intellect, to arrange that the scheme of life which produces the former is worthy and sound, and that the scheme of instruction which develops the latter is comprehensive and efficient."

F. A. D.

MEDICAL EDUCATION IN THE UNITED STATES AND CANADA.[1]

THE Carnegie Foundation has a dual function, to provide pensions for the profession in the United States and Canada, and "to encourage, uphold, and dignify the cause of higher education." It is in connection with the latter that the trustees have undertaken a study of medical education in these countries. The report, prepared by Mr. Abraham Flexner, a trained chemist, is in many respects a remarkable document, the publication of which, we are not surprised to hear, has caused a great sensation. There is no country in the world with medical schools at once so good and so bad as the United States. It would be hard to parallel in Europe conditions so favourable to the study of medicine at Harvard or the Johns Hopkins. On the other hand, a very large number of the medical schools are on a purely commercial basis, and offer an entirely inadequate education.

The report is divided into two parts. The history of medical education in the United States and its present status are set forth; the story is then told of the gradual development of the commercial medical school (a distinctly American product), of the modern movement for the transfer of medical education to the universities, and of the efforts to improve the standard of preliminary education. The present condition of medical studies is then fully discussed, and a forecast of the possible future is attempted.

The second part of the report gives in detail a description of the medical schools in each State, and in each province of Canada. Attention may be directed to chapters ii. and iii. of the report, dealing with the proper basis of medical education, and the actual basis, as containing much that is of interest to us in this country. The sections, too, on the laboratory branches and on the hospital and the medical school are very instructive; the first section is, in fact, an exceedingly able presentation of the whole subject of medical education. It is urged that the 155 medical schools at present existing should be reduced to thirty-one by abolition and consolidation.

The second part of the report is a critical analysis

1 "Medical Education in the United States and Canada." A Report to the Carnegie Foundation for the Advancement of Teaching. By Abraham Flexner, with an Introduction by Henry S. Pritchett. (Bulletin Number Four.) Pp. xviii+346. (New York, 1910.)

of every medical school in the United States and Canada under the heads of "Entrance Requirements," "Attendance," "Teaching Staff," "Resources Available," "Laboratory Facilities," "Clinical Facilities." The condition of some of the commercial schools is scarcely conceivable, and Chicago is well called, in respect to medical education, the plague-spot of the United States. Englishmen will read with interest the report on the condition of medical education in Canada, and it is nice to hear that in point of construction and equipment the Toronto and Montreal laboratories are among the best on the continent. Praise is meted out to the medical school in the comparatively new city of Winnipeg.

It is the purpose of the Foundation to proceed at once with a similar study of medical education in Germany, France, and Great Britain, "in order that those charged with the reconstruction of medical education in America may profit by the improvements in other countries." We understand that Mr. Flexner will be in this country early in October to pursue his work. The report cannot but be most helpful. It is thoroughly well done; perhaps the only legitimate criticism is an insufficient appreciation by its author of the extraordinary progress which higher medical education has made in the United States in the past twenty-five years.

THE SHEFFIELD MEETING OF THE BRITISH ASSOCIATION.

THE meeting of the British Association at Sheffield concluded with the usual votes of thanks on Wednesday of last week. The attendance of members from outside was quite up to the average, but the influx of new local members was small, with the result that the year was a lean one for grants for research, and it was found necessary to draw on the balances from former years. Notwithstanding, however, the small local support of the association itself, the reception accorded was a very warm and hearty one, and the arrangements left little to be desired. A special feature of the meeting was the visits to the large works, the magnitude of the operations carried out, and the combination of science with practical organisation making a great impression on the association as a whole. Indeed, the hearty cooperation of city and University, and the way in which science is applied in all the large industries, has been a matter of constant reference amongst members, whilst the natural beauties of the surrounding district have come as a surprise to all. With the possible exception of one or two sections, the scientific level of the papers read was high, and although no startling new discoveries were announced, there were many papers showing very real progress on old lines. Possibly the meeting may be remembered as that at which the achievement of at last isolating the positive electron was announced by Sir J. J. Thomson.

The constitutional question of the relation between the sections and their constitution has been very fully discussed, but with no final result. The matter is a difficult one. The multiplication of sections tends to overweight the association, as well as to increase the difficulties of the locality to provide the accommodation required for additional section and committee rooms with their assortment of lanternists and attendants. It is becoming increasingly difficult for a large town of the second rank adequately to house the association. It was admirably provided for in Sheffield—a city of close on 500,000 inhabitants—but the number of towns comparable with it can be counted on the fingers of the two hands. On the other hand, it is difficult to see to what already existing action a new subject, such, for example, as agriculture, could be attached as a sub-section. Some think no new branches should be admitted; others suggest that the papers on such a branch should be distributed amongst existing sections according to their affinity; whilst yet another suggestion has been made that the papers should be read at a joint meeting of several sections interested, *e.g.* agricultural papers at a joint meeting of sections B, K, and F. At the recent meeting, however, the subsection of agriculture has been a very successful and live one, managed in all respects as a separate section, and with a full complement of good papers.

At this year's meeting the attempt to bring together men of science of different categories working in allied subjects has been tried to a larger extent than in former years. There have been quite a large number of joint meetings of sections for the discussion of definite questions. It cannot be said that the result has been so generally successful as could be desired. Everybody acknowledges theoretically the value of such meetings, and most of those who have attended them their practical failure—at least, with certain brilliant exceptions, which merely show what they might be. The truth is that the conditions of success for such meetings have not been grasped by the organisers or the openers. It would be good policy on the part of the council to call a meeting of past recorders and sectional presidents to discuss this particular question. The complaint is very general that insufficient time is allowed, and no doubt there is some basis for this, but such discussions are apt to die out earlier than arranged, with consequent waste of time unless the whole discussions with set speakers is prearranged. Many of the most interesting discussions have been those arising spontaneously on some single paper. Not being reported, a speaker feels able to throw out half-considered suggestions or impressions of the moment, which strike fire and kindle the imagination of others, while all would hesitate to publish them in set form. Such discussions are really useful to the experts, and always interesting to the general audience. The failure of set discussions is as often as not due to the speaker who introduces the subject. Not a few feel called on to read a long paper of an hour's duration, taking the edge off the attention of their hearers and distracting them with a mass of details, instead of succinctly laying before them the definite points which require discussion. These remarks have been illustrated by special cases at the recent meeting. The joint discussions might be made so valuable that it is to be hoped the Council will take some steps to ensure that they are.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY PROF. A. P. COLEMAN, M.A., PH.D., F.R.S., PRESIDENT OF THE SECTION.

The History of the "Canadian Shield."

CAN there be any greater contrast than Pleistocene Boulder Clay resting on Archæan gneiss, the latest of rocks covering the earliest, with almost the whole known history of the world in the interval between? It is a fascinating occupation for a geological dreamer to sit on some hillside in Scotland or Finland or Northern Canada, where the schists and gneisses rise in rounded ridges or bosses through Boulder Clay, and ponder on all the strange happenings that separate the clay from the rock beneath.

The clay, melting from its enclosed boulders under the frosts and rain, seems the very emblem of the fleeting things of yesterday; while the Archæan gneiss and greenstones are the type of the solid, imperishable framework of the earth, on which all the later rocks rest.

The Boulder Clay recalls the white surface of a

Continental ice-sheet with summer blizzards sweeping across it like those of the Antarctic tableland, while the gneiss beneath tells of a molten magma cooling during millions of years beneath miles of overlying rock.

It is the meeting-place of the geological extremes, and their contact marks the greatest of all discordances.

One thing the clay and the gneiss have in common—both were long neglected by geology; the Pleistocene beds because they were not rocks, but only "drifts," confused and troublesome things, hiding the real rocks, the orderly stratified formations; the "basal complex" because its schists and gneisses were fossil-less, complex, and mysterious products of the dim beginnings of a world still "without form and void." The molten sphere, with its slowly consolidating crust, belonged rather to the astronomer than the geologist.

Geology has, of course, long lost that attitude, and now finds some of its most seductive problems in these once neglected extremes of the earth's history. Those who distrust the "glacial nightmare" are now very few in number; but there are still revered veterans, like Prof. Rosenbusch, who speak of the Archæan gneisses as parts of the earth's *Erstarrungskruste*, and who frame theories of the earth's cooling and wrinkling in its hot and furious youth.

Over more than half of Canada the field geologist is forced to occupy himself with both the Pleistocene and the Archæan, since the two are almost everywhere together, while the fossil-bearing beds of the vast intervening time are absent. The seemingly unnatural conjunction is not entirely without advantages, for the Pleistocene has furnished the clue to certain very puzzling problems of the Archæan, as will be shown later.

The geologists of the world have long known the broad outlines of the Canadian Archæan or pre-Cambrian area through Suess's masterly portrayal of the "Canadian Shield," and through Dana's account of the "V Formation," about which the North American Continent was built up.

It must be remembered, however, that, though most of the territory has been roughly traversed by Bell, Tyrrell, Low, and other explorers, only a few districts in the south have had their geology worked out in detail, because of their valuable deposits of silver, nickel, and iron ores. It is only in these districts, and comparatively recently, that the succession of pre-Cambrian formations has been determined with certainty. In the wide spaces of the north only the most general relationships are known.

It is intended to bring together here our knowledge of the most ancient chapters in the history of North America as disclosed by recent field work.

Physiographic Features.

In its physiography, the Canadian Shield shows the features that might be expected from one of the oldest and most stable land areas of the world. It was reduced in very early times to a peneplain, but later was elevated, permitting the rivers to begin a process of dissection. This process had a recent interruption by the Pleistocene Ice Age, which blocked many of the valleys with moraines and gave rise to the most extensive tangle of lakes in the world. Physiographically, as well as geologically, the region shows a dramatic mingling of extreme youth with extreme old age.

The best account of this rejuvenated peneplain has been given by Dr. A. W. G. Wilson,[1] who shows that the gradients are very gentle, and suggests that two or more facets can be distinguished as having slightly different inclinations and as having been carved at different times. Here it will be unnecessary to take the matter up except in a general way.

The peneplain has been unequally elevated, parts standing 3000 or 4000 feet above the sea, and other parts sinking beneath its surface. Only at two marginal points can the Archæan surface be said to rise as mountains—in the Adirondacks, projecting south-east into the State of New York, and in the Nachvak peninsula, just east of Ungava Bay.

To the south-west and south the shield sinks, almost imperceptibly in many places, beneath the older Palæozoic rocks, and the same is true around the central depression of Hudson Bay. Toward the south-east the shield breaks off suddenly along the great fault of the Lower St. Lawrence, and apparently the precipitous north-east shore of Labrador indicates faulting on even a larger scale. It has been suggested that Greenland, the Highlands of Scotland, Scandinavia, and Finland may have been parts of a single great shield, now separated through the settling down of the sea-bottoms.

In detail, the region is full of variety of hill and valley, waterfall, river, and lake; but, on the whole, it is monotonous to the ordinary traveller from the constant repetition of similar forms, since there are no real mountain ranges and few outstanding "monadnock" hills to break the sky-line. The sweep of horizon from every hilltop seems horizontal, the summits around seldom rising more than 200 or 300 feet above the valleys, and all reaching nearly the same elevation.

The geologist finds, however, that this impression of general flatness is deceptive. In reality, the rock structures are usually more nearly vertical than horizontal, as in most Archæan regions. The schistose rocks, which form so much of the surface, commonly show dips of more than 60°, so that it is clearly a mountain region planed down to its foundations. The arrangement of valleys, ridges, and hills generally follows more or less closely these ancient rock forms.

Geological Structure.

Until recently, most of the geological work done in this northern territory has been track surveys following Indian canoe routes. Here and there moraines or old lake deposits hide the rocks for a space, but usually the geology is admirably displayed as one's canoe threads the intricate waterways of sprawling lakes spilling over from one irregular basin into another. On entering a new district there seems a hopeless confusion of pinkish gneiss and grey-green schist, but presently orderly forms take shape upon the map as the numberless bays and islands are explored, and the ground plan of vanished mountain ranges begins to show itself. Dr. Andrew C. Lawson, in his brilliant study of the Lake-of-the-Woods and Rainy Lake regions in 1884 to 1888, first brought out distinctly the relationships, and later work has added greatly to our knowledge of these ancient structures.

The typical arrangement is that of rounded or oval batholiths of gneiss, or of granite merging at the edges into gneiss, with schists dipping steeply away from them on all sides. Where the batholiths approach one another the green schists occupy narrow troughs between. As shown by Lawson, they are evidently the bottoms of synclines nipped in by the rising areas of granite and gneiss. Round these eruptive masses the schists have a strike parallel to the edge of the gneiss, so that they do not form ordinary synclines, but widen and narrow and swing in curves to adjust themselves to the varying relations of the batholiths. The meshes of green schist are often not complete, the curving ends feathering out to a point. In such places erosion has eaten the surface down below the bottom of the syncline.

The batholiths in Western Ontario are of all sizes, from a mile to sixty miles or more in diameter, and they are commonly somewhat elongated from west to east or from south-west to north-east. They do not always follow one another in orderly succession, but may lie scattered irregularly, almost like bubbles on foamy water. Yet on the large scale one can recognise a general trend in the direction of the longest axes of the batholiths, and the average strike of the schist in the various regions lies between 50° and 80° east of north, conforming to the same direction. This general east-north-east trend of the basement structures doubtless reveals the axial relations of the Archæan mountain ranges.

It is sometimes stated that the so-called V formation of North America was made up of two ranges converging toward the south, the easterly arm of the V parallel to the Appalachian mountains and the westerly one to the Rocky Mountains. The structural arrangement just outlined does not confirm this view, but suggests irregularly parallel chains, cutting the direction of the Rockies about

[1] "The Laurentian Peneplain," *Jour. Geol.*, vol. xi. No. 7, pp. 615–659.

at right angles and that of the Appalachians at an acute angle.

Of what kind were the mountains erected on these bubble-like foundations of gneiss, set in meshes of schist? In many places they do not seem to have formed continuous ranges such as those of the Rockies, but rather groups of domes of various sizes. Some of them were comparatively low; others seem to have been lofty, though broad. Of the low ones, the best known is that of the Grande Presqu' Isle in the Lake-of-the-Woods, an oval of gneiss eighteen by thirty-two miles in dimensions. Here the up-swelling could not have been great, since the schists dip away from the gneiss at low angles all round, and patches of green schist, remnants of the roof, or perhaps of unusually large blocks stoped from above, are found here and there in the interior.

On the other hand, the Rainy Lake batholith, thirty by fifty miles in dimensions, must have risen as a lofty dome, since the surrounding schists dip away at high angles (60° to 90°). The arch of which they were the bases must have swung thousands of feet above the present surface of the batholith. Passing inwards from the Keewatin, one finds at first immense slabs of the schist shifted a little and enclosed in gneiss, then bands of green material with softened edges, and finally darker cloudy streaks in the gneiss, representing more perfectly digested bands. As Lawson has shown, the outer edge of the batholith is of greyish hornblende syenite gneiss or hornblende granite gneiss, while the interior is of ordinary mica granite gneiss. The outer part has absorbed a certain amount of basic Keewatin material.

One cannot doubt that this zone of green schist fragments, followed by greyish hornblende rock, originally extended over the dome as well as round its edges. In the middle there is now a width of ten or twelve miles of the ordinary Laurentian gneiss. This implies, of course, that the upper part of the dome, afterwards removed, was several miles in thickness, and that the mountain mass rose correspondingly above the synclinal valleys. It must not be assumed that the dome had a regular surface, nor that it was unbroken. Such a batholith as that of Rainy Lake was not made by a single sudden up-welling of granite, but by a long succession of slow inflows from various quarters. Meantime, the rocks above must have been stretched and fractured during the long ages of elevation, and must have been exposed to the usual destructive forces, which may even have kept pace with the elevation during its late stages when differences of level became pronounced.

The coarse-textured granitoid gneiss making up the batholith must have cooled at great depths and exceedingly slowly.

The Raising of the Domes.

Some curious dynamical problems are involved in the raising of the domed mountains. It is conceivable that fluid lava could be forced by the unequal pressure of shifting mountain blocks through a suitable system of pipes into cisterns, so as to form laccolithic domes, but no such mechanism seems possible with batholiths. The granite of the batholiths was plastic rather than fluid, as shown by its having been dragged into the gneissoid structure. The areas affected covered sometimes 1000 square miles. We know of no system of dykes to serve as pipes or passages, of no solid floor beneath, of no faulted blocks to provide the pressure. It is generally assumed that the protaxial granites and gneisses in great mountain ranges have risen because of the relief from pressure beneath anticlines due to lateral thrust. It is doubtful if these irregularly scattered ovals, sometimes thirty miles across, can be adjusted to any system of anticlines.

Some years ago I ventured another explanation. Granite is specifically lighter than most of the greenstones and schists of the Keewatin, and molten granite, even if not at a very high temperature, is lighter than the relatively cold rocks above it. If the rocks above were unequally thick, so that some areas were less burdened than others, it is conceivable that these differences in gravity might cause the granite to creep slowly up beneath the parts with the lightest loads, while the overlying rocks sagged into synclines in the heavily loaded parts.[1]

Whatever their cause, these oval batholiths enclosed by meshes of schist are the most constant feature of the Canadian Archæan, though in many places erosion has cut so deeply that the meshes have all but disappeared, leaving only straight or curving bands of hornblende schist enclosed in the Laurentian gneiss. Very similar batholithic relations of the Laurentian with the Grenville series of Eastern Ontario are described by Drs. Adams and Barlow, though the batholiths are generally much smaller. Batholithic mountains were typical of the Archæan in North America, and, at least in some cases, also of Archæan regions in other parts of the world.

Subdivisions of the Canadian Pre-Cambrian.

Until recently the rocks of the Canadian Shield were usually divided into three parts—the Laurentian, the Huronian, and the Animikie and Keweenawan, the last two being only doubtfully included in the pre-Cambrian. These three divisions are still the only ones shown on the latest general map prepared by the Geological Survey. Lawson's separation of the Keewatin as a lower group than the Huronian was generally recognised as valid, but in practice the subdivision of the two in mapping was difficult, and was only carried out in detailed surveys. His proof that the Laurentian was eruptive and later than the Keewatin was accepted.

As the classification adopted by the American geologists in the Lake Superior region differed from that used in Canada, a Correlation Committee was appointed five or six years ago to draft a compromise, which runs as follows:—

Keweenawan
  Unconformity
Huronian { Upper (Animikie)
    Unconformity
  Middle
    Unconformity
  Lower }
  Unconformity
Keewatin
  Eruptive Contact
Laurentian

This compromise system is now generally in use in Canada, though if Canadian relationships alone were considered the Animikie would be separated from the Huronian and placed closer to the Keweenawan, and the Laurentian would be treated as consisting of eruptive rocks frequently later in age than the Lower Huronian.

The most natural classification for Canada would be as follows:—

Keweenawan
  Unconformity
Animikie
  Great Unconformity
Huronian { Upper
  Lower }
  Great Unconformity
Keewatin
Laurentian = post-Keewatin or post-Huronian granite and gneiss.

The laccolithic domes described on previous pages were formed partly in the interval between the Keewatin and the Lower Huronian, but mostly later than the Lower Huronian. Over much of the shield, however, our knowledge of the relations is not sufficient to separate the mountain structures of the two ages.

Let us now consider the history of the region during the successive periods suggested above.

Conditions during the Keewatin.

One naturally asks what the conditions were in Keewatin times before the earliest known laccolithic mountains were raised. The granitic texture of the eruptives implies very slow cooling under great pressure. The old interpretation of these rocks, following the usual conception of the nebular hypothesis, made them parts of the

[1] Bull, *Geol. Soc. Am.*, vol. ix. pp. 223-238.

earth's original crust, which cooled under the tremendous weight of an atmosphere including everything volatile at red heat, an atmosphere 200 or more times heavier than at present. We know, however, that this cannot apply to the Laurentian gneisses of Canada, since they push up eruptively through great thicknesses of older rocks—the Keewatin in the north and west, and the Grenville series in the east, including large amounts of water-formed deposits. Though these older rocks are now found only on edge in synclines protected on each side by domes of gneiss, there can be no doubt that they once spread out wide and flat on the surface of the earth.

The eruptives of the Keewatin have received most attention, but sedimentary rocks occur in it at all levels and with thicknesses of hundreds or thousands of feet. They include Lawson's Couchiching, with its great areas of mica schist and gneiss formed from what were originally muddy and sandy sediments. In other places quartzites and arkoses, slates and phyllites, represent less metamorphosed clastic materials. The slate is often black with carbon. In the north-west there is little limestone or dolomite, but the Grenville and Hastings series of the east, which are probably in part of Keewatin age, contain thousands of feet of limestone. All the ordinary types of sedimentary rocks were being deposited on the Keewatin sea-bottoms, and one type unlike modern sediments—the banded silica and magnetite or hematite of the "iron formation." The rock last mentioned belongs to the top of the Keewatin, and is very widespread. Its crumpled jaspers have attracted much attention because of their association with iron ore, but in reality the other varieties of sedimentary rocks are present in far greater amount both as to thickness and extent.

In almost every part of the western region there are associated with the sediments great sheets of basic lavas, agglomerates, and ash rocks, as well as smaller amounts of quartz porphyry, &c., showing that the Keewatin was one of the periods of great volcanic activity in the world's history. It is somewhat puzzling to find these predominantly basic volcanics in the Keewatin, while all the underlying eruptives of the Laurentian are decidedly acid, chiefly granite or syenite in composition.

The extensive sedimentary and eruptive rocks of this earliest formation imply that the ordinary geological processes were at work at the very beginning of known geological time, before the Archæan mountains came into existence. There must have been broad land areas where rocks like granite or gneiss weathered to mud and sand, probably under a cool climate, for the greenish arkoses and slates charged with carbon suggest cold rather than heat.

In the north-west volcanoes were active, but the east was comparatively free from eruptions. Both volcanic ash and ordinary clay and sand seem to have been spread out on the sea bottom in the Lake Superior region, and probably seaweeds throve in the mud. In the Grenville region the waters seem to have been clearer, and limestones were deposited on a very large scale, sometimes pure, but often muddy and mixed with a good deal of carbon, so that fucoids probably flourished here also.

If we reconstruct the conditions of the Keewatin, we must then assume continents which have entirely vanished, on which weather, rain, and rivers worked, sweeping sediments down to the shallow or deeper seas to be spread out on a bottom which has also disappeared. The sediments and lavas and tuffs may be said to rest on nothing, for the once fluid or plastic Laurentian gneiss, cradling their synclines and pushing up from beneath them, could not have been the foundation on which they were laid down. Though the floor on which they once rested has nowhere been found, one may be certain that its materials included silica, alumina, and alkalies in the right proportions to fuse into a granitic magma, and this is practically all that is known of the pre-Keewatin world in Canada.

Rise and Fall of the Early Laurentian Mountains.

After the work of the volcanoes, of rain and frost and rivers, of winds and tides and currents, had piled up miles of rock in Keewatin times, there came a great upheaval of mountains over thousands of square miles of the early Archæan surface. Possibly the earth was already shrinking through loss of volcanic material and of the steam and gases that exhale in eruptions. The Atlantic floor may have been settling down, thrusting inwards from the south-east, pushing up the weakened earth's crust beneath the shield into mountain rows; or it may be that some other cause must be sought for the somewhat haphazard domes which arose over such wide areas.

It may be suggested that the many thousands of feet of lava and stratified materials had so blanketed the lower-lying rocks that the heat from beneath crept up into them, softening and semi-fusing them, until in the slow lapse of time they began to flow sluggishly, ascending to form the wide-based domes of the Laurentian mountains. The source of the internal heat need not be discussed here. Uranium, with its various progeny, may have been as active then as now, or a more rapid axial rotation may have kneaded the discrete particles of a mass of planetesimals, and so warmed them up to the heat of fusion.

Then followed the deliberate and almost complete destruction of the great mountain system during a long period of time, which has left no known Canadian record. The sediments derived from this destruction may have been piled on the bed of the Atlantic as it sank. It is possible that Sederholm's Bottnian in Finland may partially fill the gap.

Whatever disposal was made of the débris, several thousands of feet must have been carved from the mountains and swept out of view during the immense interval which separates the Keewatin and early Laurentian from the Lower Hurnnian, for the next series of rocks rests with a great discordance on the upturned edges of the synclinally disposed Keewatin schists and the truncated domes of Laurentian gneiss.

The Huronian.

The Lower Huronian has very different relationships from the Keewatin. Where least disturbed, as north of Lake Huron and in the Cobalt region, the floor beneath it is often well preserved. Dr. Miller has shown that at Cobalt the surface of Keewatin and Laurentian was hilly or hummocky before the basal conglomerate of the Lower Huronian was deposited; and Prof. Brock, in describing the Larder Lake district to the north, refers to "the clean-swept and often rounded surface of the older rocks on which it is frequently laid down."[1]

The basal conglomerate of the Lower Huronian contains pebbles and boulders of all the Keewatin and Laurentian rocks that went before, and among them are found beautifully striated stones. It is the oldest known Boulder Clay or tillite. The vast period of subaërial destruction that carved away the early Laurentian mountains ended in a glacial period, the ice-sheets of which covered many thousands of square miles of North America, just as the last great period of peneplanation ended with the Pleistocene ice-sheets.

It is not a little impressive to see modern till resting on the Huronian tillite, and including fragments of it as boulders. It is possible to break out from the modern glaciated surface stones the underside of which received their polish and striæ in the Lower Huronian, while their upper surface has been smoothed and scratched by Pleistocene ice movements.

At Cobalt the tillite is accompanied by slate, which may be compared in all essential characters except hardness with the stratified clay of adjoining lake deposits of Pleistocene Age. The most recent and unconsolidated beds make clear the origin of some of the most ancient and, in appearance, most different rocks in the world.

In the Lake Huron region the action of ice was probably followed by an invasion of the sea, for the tillite is succeeded by thousands of feet of quartzite, arkose, and conglomerate, and by a few hundred feet of limestone. Possibly much or all of the limestones of the Grenville and Hastings series, which Dr. Adams reckons among the great limestone formations of the world, were formed at about the same time.

The Middle Huronian (Logan's Upper Huronian) is separated by a basal conglomerate, possibly glacial, from

[1] "Bur. Mines, Ont.", 1905, p. 31.

the Lower Huronian; but the break does not seem very profound, and the rocks do not differ much from those just described.

The least changed parts of the Huronian extend as a wide band for 200 or 300 miles north-east of Lake Huron, and in this area the uneven surface of Laurentian and Keewatin beneath the Lower Huronian Boulder Clay preserves for us a portion of the earliest dry land, the earliest peneplain known in America, and possibly in the world. This band has remained comparatively stable, while, so far as our information goes, all other parts of the Canadian Shield have undergone violent changes.

Rise of the Late Laurentian Mountains.

The Lower Huronian tillite has been found in many places throughout the Archæan region, over a stretch of 1000 miles from east to west, and 700 miles from north to south, so that in all probability deposits like the Pleistocene till covered most of the surface.

Everywhere, however, except in the band extending north-east from Lake Huron, it seems to have been involved in later mountain building, and has been so sharply folded in with the Keewatin as to destroy the appearance of unconformity. It is instructive to note that so long and momentous an interval was entirely overlooked by geologists or treated as of small importance until a few years ago. There is usually no angular discordance to be observed, and the secondary schistose structures of Keewatin and Huronian are similar and parallel. The Huronian boulder conglomerate has often been rolled out to a schist in which only the harder boulders can be recognised as lenses; and sometimes even they are lost entirely, so that no evidence of discordance remains.

It is evident that the invasion of the later Laurentian granites and gneisses was accompanied by very important dynamic and metamorphic effects. Most of the batholithic domes of North-western Ontario are post-Lower Huronian, and date perhaps from the Middle Huronian or the interval between it and the Upper Huronian (Animikie).

The granites and gneisses of this second time of mountain building have not been distinguished in mapping from those of the first in most places, and as they are both of precisely the same habit, it will probably never be possible to separate them completely. Thus far both have been included under the name Laurentian, which must be considered as representing a lithological facies rather than a geological period. It may be, however, that the formation of batholithic mountains never really ceased from the end of the Keewatin to the end of the Lower Huronian. As the rocks called Laurentian are entirely eruptive, they should not be limited to a definite time, but only to a definite set of conditions as to composition, rate of cooling, and amount of pressure.

As in the earlier cycle, the period of mountain-building was followed by a period of destruction, ending in a peneplain of very wide extent.

The Animikie or Upper Huronian.

The interval between the lower formations and the Animikie is of great magnitude, perhaps even greater than that between the Keewatin and the Lower Huronian, and Lawson has suggested for it the name of the Eparchæan Interval. The Animikie has not been found resting on the Middle Huronian in Canada, so that this formation may partly bridge the chasm. Unless the Middle Huronian quartzites include part of the products of erosion, we have no evidence as to the disposal of the many thousands of cubic miles of materials removed from the later Laurentian mountains.

The Animikie begins in most places with a thin basal conglomerate lying almost horizontally on the upturned edges of the previous schists and gneisses. Above this come chert, black slate, and other sediments, sometimes to the extent of 8000 or 10,000 feet. The slate often contains carbon enough to make an important coal region if collected in definite beds.

The whole no doubt implies a transgressing sea, which ultimately must have covered a very large part of the Canadian Shield, since rocks of this age are found over wide surfaces north-west of Lake Superior, near Lake Mistassinni, in the heart of Labrador, on the east side of Hudson Bay, and near Great Bear and Dubaunt lakes. These rocks are found in Labrador up to 1575 feet above the sea. This level, if extended in all directions, would submerge three-fourths of the Archæan peneplain.

At present these areas, though large, are widely separated; and it may be rash to assume that even soft, easily weathered rocks, like the Animikie slate, could have been completely removed from the intervening spaces. It is probable, however, that less than half of the Archæan then remained as dry land.

The Keweenawan.

There is an interval marked by a small discordance and a basal conglomerate between the Animikie and the Keweenawan, but the break in time was apparently not great. The two groups of rocks often occur together, though in many places the Keweenawan sediments overlap on to the Archæan, as in the neighbourhood of Lake Nipigon. Most of the Keweenawan sedimentary rocks are of shallow-water varieties, such as sandstone and conglomerate. At various places on the north-east shore of Lake Superior a coarse basal conglomerate is found as remnants preserved in small valleys or ravines in the granite. The ancient surface is now in process of resurrection by erosion, and the boulders once rolled on a Keweenawan shore are being freed from their matrix and once more set in motion by the waves of Lake Superior.

The Keweenawan, like the Keewatin, was a time of vigorous volcanic activity, and in post places the lava-sheets and laccolithic sills of diabase connected with their eruption far surpass the sediments in amount. The volcanic rocks are generally basic in character, and probably most of the diabase dykes widely found in almost all parts of the Canadian Archæan are of this age. The important deposits of copper, nickel, and silver in Northern Canada are closely bound up with the Keweenawan basic volcanic rocks or with deeper-seated diabases, probably of the same origin.

Here, as in the Keewatin, we are confronted with floods of basic lava coming up from unknown sources through the acid Laurentian gneiss. Do these basic lavas represent heavier segregations settling to the bottom during the slow movements of the granitic magma as it climbed into the Archæan batholiths? One might imagine these heavier and more liquid parts sinking beneath the lighter, more viscid, magmas of the domes, and remaining fluid until the mountain masses above had become completely solid. The supposed thrust from the Atlantic basin to the south-east might then bring strains to bear on the solid crust, more or less shattering and shifting its masses, squeezing up the still molten diabase through all the fractures and pores.

Several remarkable basins were formed in the Archæan peneplain by the ascent of these lavas, permitting the massive roof which formerly covered them to collapse by block faulting or by the formation of an irregular syncline. The basin of Superior seems to be of this nature. It is still rimmed by the Keweenawan lavas, sometimes accumulated to the thickness of 50,000 feet. Just to the north is the smaller basin of Lake Nipigon, with its edges and islands of biabase sheets, and to the east, near Sudbury, is the extraordinary synclinal basin, with which the great nickel mines are connected. These basins seem to have resulted from the collapse of the solid crust because of the removal of support when basic eruptives ascended from beneath.

Palaeozoic History.

The exact relation of the Keweenawan to the Cambrian is somewhat in doubt, though most geologists make it pre-Cambrian. The St. Mary's, or Lake Superior, sandstone, which rests upon the Keweenawan with a slight discordance and overlaps upon the Archæan, is generally called Cambrian; it contains no fossils, and occurs only along the shores of Lake Superior and St. Mary's River, so that its position in time is uncertain.

Potsdam sandstone, either Upper Cambrian or Lower Ordovician, rests upon the planed-down Archæan surface at the Thousand Islands and other points in Eastern Canada, often with a conglomerate at its base; and undoubted Ordovician limestones feather out upon the

Laurentian all the way from Saskatchewan and Manitoba on the north-west through Ontario to the city of Quebec on the east. These limestones represent an important transgression of the sea upon the Canadian Shield. Apparently the old hummocky surface was often pretty cleanly swept, so that limestone with very little fragmental material rests immediately upon the gneiss, but in other cases there is arkose or a basal conglomerate of Laurentian materials.

Occasionally Archæan hills rise island-like through the shaly limestone, which tilts away quaquaversally, as if the hill had protruded through the sediments. This appearance is probably due to the settling and shrinking of the mud in its consolidation to rock. Drill-holes east of Lake Ontario show that there were valleys hundreds of feet deep between these Archæan hills, so that in this region the peneplain was far from complete. These inequalities may be considered foot-hills of the Adirondack mountains farther east.

There is reason to believe that before the close of the Ordovician the sea crossed from the region of Lake Winnipeg to Hudson Bay, flooding all the lower parts of the shield; but probably most of Labrador and part of Franklin, north-west of Hudson Bay, remained as dry land.

The Silurian follows on the Ordovician without a discordance, and at this time the sea probably submerged an even larger part of the shield, since the Silurian limestone of James's Bay is only 250 miles from that south of the Great Lakes, and there are two outliers between—on Lakes Nipissing and Temiscaming. It may be added that the highland of Silurian limestone crossing Southern Ontario, with a bold escarpment facing north-east, rises hundreds of feet higher than the watershed towards Hudson Bay. The escarpment facing the Archæan "old land" corresponds to the Scandinavian "glint," and has a similar relation to the lakes of the Archæan border.

The Devonian Sea also encroached south of James Bay and along the south-west side of the shield from Clear Lake, in Saskatchewan, to Great Bear Lake.

What took place on the Archæan continent while the coal forests flourished on the lowlands to the south and to the far north is unknown, since no Carboniferous rock has been found on its surface.

Mesozoic and Cenozoic History.

Early Mesozoic times are a blank, but a few small outcrops of Cretaceous rocks resting on the Archæan toward the south-west show that portions of its rim were once more under water. Dr. Wilson believes that an important facet of the peneplain should be dated from the Cretaceous, since planation was going on in parts of the United States at this time; but no positive evidence of this is at hand.

Nor is there any evidence as to its history in the Tertiary before the oncoming of the Ice Age of the Pleistocene, when its whole surface was scoured more than once by great glacial sheets. The mantle of decayed rock which must have accumulated during the long dry land stage was almost completely swept away, leaving the rounded surfaces of ancient rock fresh and clean beneath the Boulder Clay.

In an important inter-Glacial interval and in post-Glacial times much of the morainic material was assorted in great lakes the shore and deep-water deposits of which cover large parts of the surface. With the departure of the ice, the sea once more transgressed upon the lower parts of the shield, but the land has been rising since, leaving a belt of marine deposits up to about 500 feet around the shores of Hudson Bay, the St. Lawrence, and the Atlantic.

How much of the Shield has been Covered?

It is generally stated that the Canadian Shield has been dry land since the Archæan, and hence that erosion has been taking place ever since that time. This is probably true for part of the north-eastern portion of the shield, and perhaps also the north-western, but much of the area, especially toward the south, was buried in early days under Palæozoic sedimentary rocks, and so protected from further destruction. These sediments are still being slowly stripped from the Archæan in many places.

This may account for the greater proportion of Huronian and Keewatin rocks in the south as compared with the north. It is probable that in the unprotected northern parts weathering agencies have eaten the higher Archæan rocks completely away from the Laurentian gneiss beneath. Before asserting this positively, however, it may be well to await more thorough exploration of the little known north.

It is possible, but not very probable, that the whole area was at one time covered with Ordovician or Silurian shale and limestone. If so, all traces of this capping have been removed from hundreds of thousands of square miles of its surface.

There is one very impressive feature of the Archæan as found beneath the later rocks. The peneplain, with its rounded, hummocky surface, seems exactly the same when one strips from it recent Boulder Clay, early Palæozoic shale or sandstone or limestone, Keweenawan eruptives, or even Lower Huronian tillite, where this has remained undisturbed. It is as though all the millions of years of destruction since the Middle Palæozoic had made only unimportant changes in the pre-Cambrian peneplain. When it is recalled that peneplanation took place twice in the pre-Cambrian, before the Lower Huronian and before the Animikie, one is almost driven to think that pre-Cambrian time is far longer than post-Cambrian.

Relation of the Shield to the Palaeozoic.

Except toward the east, the Canadian Shield sinks gently beneath Palæozoic beds, in most cases retaining its character as a peneplain. How far does it continue to the south and west beneath the sedimentary rocks, and to what depth does it extend?

The results of drilling at Toronto, eighty miles south of the contact, show gneiss and crystalline limestone at a depth of 1200 feet below the surface, or 940 feet below sea-level. Near Lake Erie, 130 miles to the south of the contact, the Archæan is reached at a depth of 3300 feet—2700 feet below sea-level. Its slope to Toronto is at the rate of 20 feet per mile, and from Toronto to Lake Erie at the rate of 35 feet per mile. This corresponds fairly well with the dip of the overlying Palæozoic rocks.

As the peneplain rises more than 1300 feet above sea-level at the watershed 300 miles north of Lake Erie, there is a difference of 4000 feet in a north and south direction, and if comparison is made with the Adirondack mountains 250 miles to the east, the difference even amounts to 6600 feet. It is probable, however, that the Adirondacks were a residual group of mountains never reduced to the general peneplain level. It is clear that the pre-Palæozoic peneplain has been greatly warped in later ages, perhaps as a result of the increasing load of sediments piled on its southern edge.

One is apt to think of these ancient crystalline rocks as an exceedingly solid and resistant block of the earth's crust, likely to undergo little deformation, so that this evidence of warping or doming of the surface comes as a surprise. In reality, shiftings of level under changes of load are normal in every region, and have been going on along the southern border of the Canadian Shield all through Pleistocene times, and perhaps continue now.

The proof of this is to be found in the differential elevation of the shore-lines of the great post-Glacial lakes, which ascend with an increasing grade toward the north (N. 20° E.). In the case of Lake Iroquois, the difference in level between the two ends of the earliest shore is more than 500 feet, and the grade toward the north even rises to 6 or 7 feet per mile. If we add 230 feet of deformation of the marine beaches, which followed Lake Iroquois toward the north-east after the final melting of the ice, there is a known change of level amounting to 730 feet within late Pleistocene times. There is reason to believe that similar changes of level took place during the inter-Glacial period recorded at Toronto and to the north.

The Pleistocene sinkings and risings are naturally accounted for by the piling up and removal of the thousands of feet of ice in the Glacial periods, though probably isostatic equilibrium was not reached in these movements.

We know that the ice was more than 4000 feet thick, since it passed over the tops of the Adirondack mountains.

This thickness of ice is equal in weight to about 1600 feet of rock, while the greatest known elevation since the removal of the load is not much more than 700 feet, implying that a weight of 900 feet of rock can be supported by the shield. It may be, however, that in the interior of Labrador, where no beach-lines give evidence as to changes of level, the doming is much greater than the amount suggested.

It is of interest to note that these adjustments to change of load take thousands of years to accomplish. The rise due to the melting of the Labrador ice-sheet may be going on slowly now, 30,000 or 40,000 years after the load was lifted.

These sinkings and risings must be accomplished by plastic flow outwards from beneath the loaded area or inward toward the area relieved of its load.

Instead of a rigid, unyielding shield, we must conceive a stiffly flexible covering over a plastic substratum, where during thousands of years adjustments of level, amounting to hundreds of feet, may take place; and during millions of years of removal of load by erosion, or of piling on of load through sedimentation, changes of level of thousands of feet can be accomplished. Such changes have taken place on the southern and western sides of the shield without any known rupture, while on the east the adjustment has been accomplished in part by great faults.

Has the Archæan, which is supposed to underlie the stratified rocks in all parts of the world, undergone the same vicissitudes?

Summary.

The history of the Canadian Shield begins in pre-Keewatin times, with land surfaces on which weathering took place, and seas in which mud and sand were deposited. If the earth were ever molten, that stage had long been passed before the Keewatin sediments were laid down, for they include carbon, probably derived from fucoids, which could not have lived in a hot sea.

The pre-Keewatin land surfaces and sea bottoms have totally disappeared, so far as known to Canadian geology. Apparently they have been fused and transformed into the gneisses of the Laurentian.

The Keewatin was a time of great volcanic activity, lava streams and ash rocks surpassing in amount the thick sheets of sediments. At the end of the Keewatin the thousands of feet of volcanic and clastic rocks were lifted as domes by the up-welling of batholiths of early Laurentian gneiss.

Then followed a profound gap in the record, during which the mountains were levelled to a hummocky peneplain. This gap represents a very long period of weathering and destruction on a land surface, ending in glacial action on a large scale.

The Lower Huronian begins with the deposit of a thick and widespread Boulder Clay, followed up by a transgression of the sea in which mud and sand, and also limestone and chert, were deposited.

After a short break similar processes went on in the Middle Huronian. During the Middle Huronian, or in the interval between it and the Upper Huronian (Animikie), mountain-building was renewed on a grand scale, many synclines of Keewatin and Lower Huronian rocks being caught between the rising batholiths of late Laurentian gneiss. A broad central band of the Lower Huronian escaped this process, however, and has preserved its original attitude on a floor of Keewatin and Laurentian.

The Animikie or Upper Huronian sediments which rest on the planed-down floor of upturned Lower Huronian, Laurentian, and Keewatin rocks, consist largely of chert and carbonaceous slate or shale, which lie nearly horizontal and have undergone very little change.

The Keweenawan follows the Animikie with only a small break, and includes shallow water-beds of sandstone and conglomerate, accompanied by immense outflows of lava. As a result of the outpouring of lava, great basins, like that of Superior, resulted. It is probable that during the Animikie and Keweenawan most or all of the Canadian Shield was covered by the sea.

The Keweenawan is generally held to mark the close of the Archæan (or Algonkian or Proterozoic). Low reports portions of these formations as having been caught in mountain-building of the Laurentian type in Labrador, but commonly they have not been disturbed.

During early Palæozoic times the Canadian Shield was more than once encroached upon by the sea, though probably much of the peninsula of Labrador, and perhaps a region north-west of Hudson Bay, escaped.

From the Devonian to the Pleistocene the shield seems to have remained dry land, and part of the Ordovician and Silurian capping of sediments was removed during this long period.

The succession of Pleistocene ice-sheets completed the work of denudation, and at the end of the Ice Age many thousands of square miles of the lower portions were once more beneath the sea.

Last of all, the region has been rising at unequal rates in different parts, as shown by the warping of marine and fresh-water beaches.

The surface of low hills and rounded knolls of gneiss and schists beneath the Pleistocene Boulder Clay resembles in every way that beneath the flat shales and limestones of the early Palæozoic, or the nearly horizontal sediments of the Animikie, or even the undisturbed parts of the Lower Huronian Boulder Clay. It may be that much of the surface has been covered with sediments and restored to daylight by subaërial erosion several times in succession. The greater part of the carving-down seems to have been done before the Animikie—*i.e.* within pre-Cambrian times—and the pre-Huronian surface seems as mature as any of the later ones. The bearing of this on the length of early geological time is evident. Pre-Huronian time includes the laying down of thousands of feet of Keewatin sediments, the elevation of early Laurentian mountains, and the levelling of these mountains to a peneplain. It may be as long as post-Huronian time.

NOTES.

PROF. F. W. DYSON, F.R.S., Astronomer Royal for Scotland, has been appointed Astronomer Royal in succession to Sir William Christie, K.C.B., F.R.S., who is to retire on October 1.

AT the age of seventy-eight years, and in his native place, Lunel, Eugène Rouché, the well-known mathematician, recently passed away. He entered the École Polytechnique in 1852, and on completing his course there devoted himself to teaching, in which he was very successful, and the composition of text-books, which quickly obtained a high and deserved reputation. The treatise on geometry which he wrote in partnership with Charles de Comberousse may be fairly called a classic, and is an excellent example of what such a work ought to be; many teachers in this country must have found it a most useful source to draw upon, both for theorems and for examples. Engrossed as he was by these occupations, Rouché found time to write a number of original notes and papers, and his talents received fitting recognition in 1896, when he was elected a free member of the French Academy of Sciences in succession to Baron Larrey. Friends who knew him intimately bear witness to his personal charm and vivacity, and the academy, on August 22, passed a vote of sympathy with his widow and family, after hearing a brief account of his career from the president, M. Emile Picard.

IN the death, in his seventy-seventh year, of Prof. Friedrich von Recklinghausen, of Strassburg, pathology loses one of its most distinguished investigators. Working along the lines marked out by Rokitansky and Virchow, v. Recklinghausen played a conspicuous part in building up our knowledge of pathological anatomy during the second half of the nineteenth century. His researches threw a great deal of light upon many aspects of disease of the circulatory system, especially the phenomena of thrombosis and embolism, well described in his great "Handbuch der allgemeinen Pathologie des Kreislaufs und der Ernährung," published in 1883. He devoted great attention to the study of "fibroid" tumours of the uterus and other pathological conditions of the female genital system, which formed the subject of another of his treatises. He also added greatly to our knowledge of general bone-diseases, such as rickets, osteomalacia, and acromegaly, and especially of the pathological changes in the form of the skull caused by rickets. His observations on the nature of a curious frog-like swelling under the tongue called "ranula," on hæmatogenous pigmentation of the skin, and on the heart condition he called "segmentatis myocardii," are well known; but perhaps his discovery of the association of multiple fibrous tumours of the skin with the distribution of cutaneous nerves is that most usually associated with his name as "Recklinghausen's disease."

MR. C. A. BRERETON, whose death, at the age of fifty-nine years, occurred on Monday last, was for many years associated with Sir John Wolfe Barry, K.C.B., F.R.S., in important engineering enterprises, such as the construction of the Barry Docks and railways, the Middlesbrough Docks, Surrey Commercial Docks, and the new bridge across the Thames at Kew. He also did a good deal of engineering work for the Caledonian, North-Eastern, Metropolitan, Metropolitan District, Whitechapel and Bow Railways, parts of the Great Northern and Piccadilly Tube, and for the Government of Natal. In recent years he was in business on his own account.

THE death is announced, in his fifty-ninth year, of Mr. William Earl Dodge Scott, curator of the department of ornithology at Princeton University. He was the author of "Bird Studies," "Story of a Bird Lover," "Birds of Patagonia," and many technical papers in scientific journals. Mr. Scott had done field work for the British Museum, the American Museum of Natural History, and other institutions.

DR. ROBERT AMORY, a well-known American writer on physiology and therapeutics, has died at his summer home at Nahant, Mass. He was born in 1842, graduated in medicine at Harvard in 1866, and was appointed in 1869 lecturer at Harvard on the physiological action of drugs. He was afterwards professor of physiology at the medical school of Bowdoin College.

THE death is announced, at the age of seventy years, of Mr. John Langton, consulting surgeon to St. Bartholomew's Hospital, and a former Hunterian professor of pathology and surgery at the Royal College of Surgeons. In 1900 he was Bradshaw lecturer.

IN connection with the fourteenth Flemish Congress of Natural and Medical Science, an International Scientific Exhibition will be held in Antwerp on September 17–25 next. The exhibits are to be classified as under:—Section i., physico-chemical sciences: including new apparatus and inventions, laboratory installations, lanterns, microscopes, and the scientific applications of photography; collections of chemical productions, geological specimens, and crystals. Section ii., biological science: apparatus for experimental research and demonstration, zoological and botanical collections, fossils, microscopical preparations, and photomicrographs. Section iii., medical science: experimental apparatus, pathological specimens, radiograms, surgical instruments and appliances; operation-room, sanatorium, and hospital furniture; electro-medical and X-ray apparatus. Section iv., scientific books and reviews.

THE twenty-seventh convention of the Association of Official Agricultural Chemists is to be held at Washington on November 10–12, when communications on the following subjects are to be given:—Phosphoric acid; nitrogen; potash; soils; inorganic plant constituents; insecticides; water; food adulteration; dairy products; foods and feeding stuffs; sugar (chemical methods and molasses methods); tannin; drugs and medicinal plants.

AN International Congress of Tuberculosis is to take place in Rome on September 24–30 of next year. Prof. Guido Baccelli is to be the president, and Prof. v. Ascoli, of Rome, the general secretary.

THE statue (by Mr. Bruce-Joy) of Lord Kelvin which is to be erected in Belfast is, according to the *Westminster Gazette*, in an advanced stage of completion. Lord Kelvin is represented as holding in his right hand the design of a gyroscope, and by the side of the effigy is a model of the Kelvin compass. The statue is to be cast in bronze, and will stand on a pedestal 12 or 13 feet high.

A GRANITE obelisk erected in the parish churchyard of Forfar to the memory of George Don, the Scottish botanist, was unveiled last week by Mr. G. Claridge Druce, who gave an address on Don's achievements as a botanist.

ACCORDING to the *Lancet*, the remainder of her estate (in addition to a million francs already bequeathed) has been left to the Pasteur Institute in Paris by the widow of the Marquis de Beauregard de Maubreuil d'Orvault.

THE New York correspondent of the *Times*, writing on September 12, states that Prof. Macmillan, who accompanied Commander Peary on his last voyage, reports from Labrador that he has made a successful exploration of the region westward from Davis Inlet to George River and the home of the Nasquapee Indians. Three lakes, the largest of which, called Misternipi, was twenty-five miles wide, were discovered.

THE American Philosophical Society gives notice that in December next it will award its Magellanic gold medal "to the author of the best discovery, or most useful invention, relating to navigation, astronomy, or natural philosophy (mere natural history only excepted)." Candidates for the award, who may be of any nationality, must send their claims (in English, French, German, or Latin) to reach the society in Philadelphia by November 1, but the award will not be made for any communication already published or for which a prize has been given elsewhere. Each MS. must bear a motto, device, or other signature, the author sending the society a sealed letter giving his real name and address in addition to the motto, &c., upon his essay.

A REUTER message from Paris states that a private conference of the official delegates of the various Governments at the Pure Food Congress has arranged to make certain methods of analysis international, with the consequence that when any food is in future submitted to an analytical test it will have to conform to that international standard.

IN the June issue of the *Philippine Journal of Science* Messrs. R. B. Bean and F. S. Planta publish the third of their studies of Filipino racial types at Taytay, this portion of the memoir being devoted to women. In measurements of the body, the greatest differences appear between the Primitive and the Iberian types, the women approximating to the former and the men to the latter. Between these comes the Australoid type, which in the crural index resembles the Negrito. In head measurements, the women have relatively broader heads, faces, and noses than the men; in other words, they are more Primitive than the local men or the women of Siberia, with whom a useful comparison is made. We now possess some materials for disentangling the complex racial elements in the population of the archipelago. As is usual with the work of this school of anthropology, the memoir is provided with elaborate statistical summaries and excellent photographic illustrations.

In our article on "Malaria Prophylaxis in India" (August 25), we remarked upon the somewhat discouraging fact that no instance of a drainage scheme with successful result was put before the recent Malaria Conference at Simla. Since then, however, we have received the report of an interesting lecture on the prevention of malaria by Dr. Malcolm Watson, of the Federated Malay States (Selangor). As is well known, Dr. Watson has long been conducting, with the assistance of the Government and Dr. Travers, the senior medical officer, an extensive campaign against malaria, principally by the method of drainage, and his lecture gives a brief but very interesting account of the work done. In two large stations, Klang and Port Swettenham, the disease has been almost entirely banished by drainage alone, with a saving of more than 400 lives per annum. As the case mortality of malaria is only about 1 per cent., this saving of mortality means an enormous saving in morbidity, which doubtless the inhabitants are able to appreciate. A similar improvement has been made in all the flat rural areas in the State, especially in many of the rubber plantations. Here the disease is carried by *Myzorhynchus umbrosus*, which does not breed easily in any running water; so that mere open surface drains suffice to banish the insect, especially when accompanied by removal of jungle. In the hilly land, however, *Nyssorhynchus willmori* appears to be the carrier—an insect which breeds readily in rapidly running streams—with the result that the ordinary drainage methods will probably be useless, closed pipe drains and other methods being required. Dr. Watson's energetic and long-continued campaign demonstrates not only the utility of drainage, which he maintains is the fundamental method against malaria, but also the fact that it must be intelligently carried out. It is probably neglect of this latter principle which has caused most of the reputed failures. Many other points are referred to in the lecture. For example, rice fields are found to be almost free from malaria, owing to the fact that, for some unexplained reason, the malaria-bearing species of Anopheline cannot thrive in their waters. Dr. Watson strongly emphasises the necessity for research on this point, and urges that a time may come when we may be able to deal with malaria at much less expense than by any method known at present—"we will be able to play with species of Anophelines, say to some 'go' and to others 'come,' and abolish malaria with great ease, perhaps hardly at any expense." We understand that a book by Dr. Malcolm Watson on "The Prevention of Malaria in the Federated Malay States" will shortly be published by Major Ross, with the aid of subscriptions from a number of rubber plantations collected for the purpose by Sir Frank Swettenham, the distinguished founder of the Federated Malay States. It seems a pity that Dr. Malcolm Watson was not invited to attend the malaria conference at Simla.

The Proceedings of the Royal Physical Society of Edinburgh (vol. xviii., No. 2, July) contain an interesting note by Prof. Graham Kerr on the presence of a posterior vena cava in Polypterus. The author points out that this vein, which forms so characteristic a feature of the higher vertebrates, is made up of two elements, being formed anteriorly by the primitive hepatic vein and posteriorly by the hinder portion of the posterior cardinal (inter-renal). The manner in which this has come about is indicated by the condition of the lung-fishes, Lepidosiren and Protopterus, in which the posterior extremity of the liver has become fused with the anterior extremity of the right kidney, and a venous anastomis has been established between these two organs, the large hepatic vein forming a direct channel for the passage of blood from the right kidney to the heart. It is interesting to find in the ganoid Polypterus that, while the primitive hepatic vein is developed into a large posterior vena cava which joins the fused posterior cardinals posteriorly, the anterior ends of the posterior cardinals still persist in a well-developed condition, though much larger on the right side than on the left. Polypterus in this respect combines the condition met with in higher vertebrates with that which is characteristic of fishes generally.

According to the report for 1909 and the first half of the current year, further particulars with regard to the movements of turbot and plaice have resulted from the investigations undertaken by the officials of the Northumberland Sea Fisheries Committee. A turbot, for instance, liberated at Skate Roads in August, 1907, was retaken nearly two years later about fifty miles from Aberdeen, while a plaice returned to the sea at the former locality in July, 1907, was recaptured in the following December near the Bell Rock. Experiments in artificially breeding lobsters have proved unsuccessful.

No. 2 of the tenth volume of the *Museums Journal* is chiefly devoted to a report of the conference held at York in July last, when the president, Dr. T. Anderson, devoted his address to volcanoes and their treatment in museums. Photographs are regarded as the best means of illustrating volcanic phenomena in public exhibition, as models and sketches alike nearly always show an exaggeration of the vertical scale, while the first-named of these are costly.

In the May issue of the Proceedings of the Philadelphia Academy Mr. T. Barbour relates the history of the discovery of the Chinese alligator, and the gradual acquisition of fuller knowledge of the species. It is stated that only a dozen specimens are known in collections, only one of which, and that recently acquired, is in America. The species appear to have a very limited distribution in the Yang-tse valley, most of the twelve specimens having been obtained near Wuhu and Chinkiang, although records exist to Poyang Lake and Nankin.

Zebras and zebra-hybrids form the subject of an illustrated article by Dr. E. Trouessart in *La Nature* for August 27, in which reference is made to the proposal to regard the members of the *Equus burchelli* group as specifically inseparable from the quagga.

As an appendix to the description of a new species of Platysaurus, Mr. J. Hewitt furnishes, in the Annals of the Transvaal Museum for November, a useful key to the genera of South African lizards.

It will be within the recollection of most botanists that Messrs. James Backhouse, of York, promoted a scheme in 1899 for the supply of botanical material to colleges and schools for demonstration and research, although recognising that for some time, at any rate, the venture would not be self-supporting. Subsequently the interests were transferred to the British Botanical Association, of which Dr. A. H. Burtt became the director. After ten years, notwithstanding the expansion of the original scheme and the increased demands due to the extension of nature-study, it has become apparent that the institution cannot exist as a private venture, and therefore it is proposed to enlist the help of individuals interested in the aims of the association and convert the undertaking into a public association of subscribers. This decision was formulated at a meeting of botanists and others, and an executive committee was elected to proceed with the enrolment of members and associates. As the institution exists purely for the preferment of botanical study and research, it is to be hoped that sufficient subscribers will be forthcoming to ensure its permanence.

THE seventh part of the *Prodromus Florae Britannicae*, an elaborate and critical revision of the British flora that is being prepared by Mr. F. N. Williams, has now been published by C. Stutter, 110 High Street, Brentford, and the author announces that the next part will conclude the Sympetalæ and the first volume. The present part enumerates thirty-five genera, beginning with Plantago and ending with Vaccinium, but the sequence of families is unusual. Two species new for Britain are recorded under Plantago, while five species only are admitted under Mentha, as the author follows the views elaborated by Malinvard, that several species generally accepted are merely hybrids. Among the numerous interesting notes attention is directed to the remarks on the oxlip, the occurrence of two blue pimpernels, and the use of the word "anthemia" for the whole mass of flower clusters of *Stachys arvensis*.

A NOTE on the protection of timber against white ants appears in the Transactions of the Royal Scottish Arboricultural Society (vol. xxiii., part ii.). Three processes are described, of which one is a contrivance for destroying white ants by pumping a poisonous smoke through their galleries, while the others are timber-treatment measures. Details of the Powell process are not disclosed, but "blue oil" is the specific which apparently has received recognition at the War Office.

DR. SVEN HEDIN contributes a short paper to the July number of *Petermann's Mitteilungen* in which he summarises the scientific results of his journey in Tibet during the years 1906–8. Preliminary notes on the meteorological observations and the geological collections are added by Dr. Nils Ekholm and Dr. Anders Hennig. The Swedish Government has voted a sum of 75,000 kroner, to be paid in equal instalments in 1911, 1912, and 1913, towards the cost of publication of the detailed reports, which are to consist of three volumes of memoirs and an atlas in two volumes. The text, which will extend to about 1500 pages, will consist of reports on geographical discoveries and observations, memoirs on the physical geography of Tibet, and special papers by Dr. Ekholm on meteorology and hypsometry, Dr. Olsson on astronomical observations, Dr. Hennig on geology, and Prof. Lagerheim, Dr. Ostenfeld, and others on botany. A map of Tibet on a scale of 1 : 1,000,000 will appear in 1912.

THE last number of the *Sitzungsberichte* of the Bavarian Academy of Sciences contains a communication from Prof. A. Rothpletz on the cause of the Californian earthquake of 1906, in which he points out that the triangulation of the central area of the region affected by the earthquake shows that it has undergone an extension amounting to about 1 in 30,000. This expansion may be explained by one of three hypotheses:—(1) as the result of the relief of tangential pressure in the earth's crust; (2) by a transference of heat and change in position of the isogeotherms; or (3) by magmatic intrusion; the first two being excluded as not fully accounting for the observed displacements, the third is accepted. The earthquake is, therefore, regarded as belonging to the class called cryptovolcanic by Prof. Hörnes, which Prof. Rothpletz prefers to call "injection" earthquakes; and as the San Francisco earthquake is considered to be due to movement along the San Andreas fault, indirectly caused by deep-seated intrusions, it becomes an injection-fissure earthquake.

THE eleventh "Review of Mining Operation in the State of South Australia," for the half-year ending December, 1909 (Adelaide, 1910, 26 pages, 3 plates), reports that the mining industry was hampered by the strikes at Broken Hill and of the New South Wales colliers, and by the low price of copper, the most important mineral in South Australia. Further progress is reported in boring for coal in the Permo-Carboniferous rocks of the Northern Territory, but only three inch seams of inferior coal were found during the six months reported. The most novel mine in South Australia is that being opened in the Carnotite lode, near Olary, and the report includes a short account of the mining operations in progress, and an analysis of the ore made under the direction of Prof. Dunstan. The ore is to be worked for radium. An attempt is being made to supply the tube mills at Broken Hill with flints from the local beaches. The flints now used are sent from Europe, and are said to come from Iceland, but as they are shipped to Australia as ballast, they have hitherto held the market against the local supply.

IN vol. vii., No. 1, of the fifteenth series of the Palæontologia Indica (Mem. Geol. Surv. India), Mr. F. R. C. Reed describes and illustrates a series of Cambrian fossils obtained by an officer of the Indian Survey from the Bhabeh rocks of Spiti, which, from the evidence of very scant remains, were provisionally assigned by the late Dr. Stoliczka to the Lower Silurian. A large proportion of the fossils consists of trilobites, none of which, so far as the condition of the specimens admits of forming an opinion, can be identified with European or American types; consequently, a number of new names appear in the memoir.

THE Rev. Dr. A. Irving writes to say that the letters of Messrs. Deeley and Lamplugh on "Stagnant Glaciers" in NATURE of September 8 (p. 297) "seem to overlook the important causal factor of solar radiation in connection with the question," and directs attention to an article of his, entitled "Solar Radiation and Glacier Motion," in NATURE, vol. xxvii., April 12, 1883, in which a series of laboratory experiments on the subject, with deductions, is given. The article in question was supplementary to a paper by the author on the mechanics of glaciers, which appeared in the Quarterly Journal of the Geological Society for February, 1883.

WE have received the report of the Hydrographer on Admiralty Surveys for the year 1909. The report shows that during the year extensive revisions of the charts of home waters were made by four vessels, the largest areas sounded being off the west coast of Scotland. Very important additions to our knowledge of British Columbian waters were made by H.M.S. *Egeria*, the increase in size and number of ships using the Edye, Beaver, and Schooner passages making the surveys of these channels specially valuable. H.M.S. *Mutine* carried out a number of important lines of soundings off the west coast of Africa, and in Australian waters H.M.S. *Fantôme* laid a line between Thursday Island and Cartier Island, the latter being formally annexed by Captain Pasco on March 17.

The connection between non-periodical variations of rainfall and famines in German East Africa is discussed by Dr. E. Kremer in No. 1, year 1910, of *Aus dem Archiv der Deutschen Seewarte*. Normal annual rainfall values can only be safely calculated from thirty to forty years' observations, and monthly values require a much longer period. These are not available for the district in question; the author directs attention to the fact, but he makes the best possible use of the short series at his disposal and of the information obtainable from travels and expeditions. The German colony extends from latitude 1°–12° S., and longitude 29°–40½° E., and the rainfall may be divided generally into one rainy period in the south and two rainy periods in the north. The greater part of the country has less than 40 inches of rain per annum; only the central and northern coastal districts and the mountainous parts receive more, while the whole of the interior tableland, to about longitude 33°, receives less than 30 inches. The author discusses the possibility of predicting famines or scarcity on the lines successfully followed in India, and shows, *e.g.*, that scanty rainfall, or its unfavourable distribution, in Zanzibar is followed by famine over a large part of the East African coast, and further that the distribution of atmospheric pressure in the months preceding the rainy periods is intimately connected with the amount of subsequent rainfall.

The Royal Meteorological Institute of the Netherlands has issued a paper, by Dr. P. H. Gallé, in which a large number of wind and current observations, chiefly from the Indian Ocean, are examined with the special purpose of testing the theories of Nansen and Ekman with regard to the effect of the deflecting force of the earth's rotation in changing the direction of drift currents and to the speed of current set up by wind action. Dr. Gallé finds that when the drift influence is alone at work in producing surface current, the angle between the wind and the resulting current is between 40° and 50°, substantially in agreement with the theoretical values. A wind velocity of 1 metre per second produces an average speed of current of between 4 and 5 centimetres per second.

Mr. H. T. Ferrar contributes an interesting paper on "The Creation of an Artificial Water-table in Egypt" to the July number of the Cairo *Scientific Journal*. The author is of opinion that the modern irrigation constructions in themselves have had little direct effect in raising the level of the subsoil water in the Nile delta, but he deals specially with the changes induced in the irrigation system of Lower Egypt by the works of Mohammed Ali Pasha, who in 1820 excavated a number of deep perennial canals capable of discharging the low-level summer supply of the Nile. Observations made at more than one hundred and fifty experimental tube wells support the view that there are two water tables in Lower Egypt: (1) a natural water-table, which is independent of the works of man except locally where extra permeability allows a constant supply of irrigation water to be added; and (2) an artificial water-table which was created by the act of the introduction of perennial irrigation by Mohammed Ali Pasha. It is thought that the artificial water-table (2) has gradually become higher, owing mainly to excessive watering of crops, until at the present day it has a deleterious effect upon the fertility of the soil. Mr. A. Lucas offers some criticism of Mr. Ferrar's conclusions in the August number of the same journal.

The *Journal de Physique* for September contains the full text of a communication made to the French Physical Society in March last by M. C. Féry, describing a spectrograph with a prism having spherical faces so designed that the image of the slit is in focus on the photographic plate. Both faces of the prism are concave to the incident light, and the back surface is silvered so as to reflect the light. The slit, the centres of curvature of the two faces, and the spectrum produced are on a circle which has the radius of the first surface of the prism for diameter. With a prism of quartz a metre from the slit and screen, the spectrum photograph obtained is 22 centimetres long, and the definition is very good throughout. Like the Rowland concave grating, the apparatus is astigmatic.

A new form of colorimeter has been sent for our inspection by Messrs. E. B. Atkinson and Co., Hull. The liquid to be tested is placed in a rectangular glass cell of a few cubic centimetres capacity, by the side of which works a vertical hollow glass wedge filled with a standard coloured solution. By means of a screw the wedge is raised or lowered, thus bringing various thicknesses of the standard colour into the same field of view as the cell. Both liquids are viewed horizontally through a slit against a white background, and the position of the wedge is adjusted until a depth of tint is found equal to that of the liquid under examination. A graduated scale shows how much the wedge has been raised, and by reference to a chart the corresponding proportion of colouring ingredient in the liquid is obtained. Wedges calibrated for certain purposes—*e.g.*, the colorimetric determination of iron, copper, ammonia, hæmoglobin, iodine—are supplied by the makers; but the user can himself readily calibrate the instrument for his own particular purposes. For example, a medical man could with little trouble construct a standard hæmoglobin chart for his own district. Other advantages claimed for this "universal" colorimeter are (1) saving of time, a reading requiring only about a minute; (2) exactness, since the two colour surfaces compared are contiguous; and (3) economy of cost. The apparatus appears to be especially suitable for operations involving a number of colorimetric estimations of the same type.

The fifteenth number (No. 3 of 1910) of the Italian review *Scientia*, now in its fourth year, is largely occupied with philosophy. The ideas of Poincaré, Bergson, Einstein, and the Pragmatists naturally form the text of discussions, such as that by F. Severi on "Hypothesis and Reality in Geometrical Science," or Chwolson's "Can we apply Physical Laws to the whole Universe?" or F. Enriques's criticism of Pragmatism. The theory of two star-streams interpenetrating one another is described by Mr. A. S. Eddington, of the Royal Observatory, Greenwich. M. Guignebert sketches the rise of Christianity in accordance with the sifted conclusions of recent research. Mr. Abegg's article on "Chemical Affinity" has a pathetic interest, from the fact that while it was in the press the author met his death in an aëronautic accident. The useful *rassegne* of various sciences are continued; Mr. E. S. Russell reviews the claims of epigenesis *versus* evolution. The advantages of a "mnemonic" theory of heredity, in accordance with the suggestions of Semon, Rignano, and Francis Darwin, involving an "interiorisation of external stimuli," is well put. M. Landry supplies his annual review of economic research. M. le Comte de Baillehache defends his system of electric units—a dimensional system—put forward last year in his "Unités électriques." Reviews of scientific periodicals, notes of scientific meetings, and critical notices of books, make up an issue that is very level in quality. The books reviewed are worth noting, viz. E. Borel, "Elements de la Théorie des probabilités"; Marcel Landrieu, "Lamarck, le fondateur du transformisme"; Georges Bohn, "La naissance de l'intelligence"; Georges Dwelshauvers, "La synthèse mentale"; W. Lexis, "Theorie der Bevölkerungs und Moralstatistik"; A. Solmi, "Storia del diritto italiano"; H. Bouasse, "Bachot et bachotage."

We welcome the first annual number of the Journal of the Bedales School Scientific Society. This society has been in existence for some years, holding meetings of the kind familiar in schools; and its members have also been engaged on pieces of experimental work, some touching the edge of new inquiry. This year the society prints accounts of certain members' work, as well as reports of the meetings, and the Journal shows that at Bedales science is at once a favoured pursuit in free time, and a well-treated part of the curriculum. The subject-matter is limited to physics and chemistry; next year, perhaps, biological notes might be included—Hampshire is an interesting county—and short articles as well as longer papers may suitably find a place in such a periodical. Of the papers, that by D. Jarintzoff on the rare earths is worthy of mention, as a painstaking attempt to grapple with the separation of metals of the cerium group, and shows careful reading as well as experimenting. A paper on coherer-action shows resource and ingenuity; the writer is rash, perhaps, in criticising a paper by Robinson, whose work was watched by Drude himself. A word of praise is due to the society's committee for the careful preparation of the Journal.

The Thermal Syndicate, Ltd., of Wallsend-on-Tyne, has sent us a reproduction of a photograph of the remains of their exhibit of "Vitreosil" laboratory apparatus at the Brussels Exhibition, from which it is evident that the fused silica ware successfully resisted the great heat to which the pieces had been subjected; some of the larger pieces had, however, been broken by the falling of heavy girders.

The ninth volume of the *Journal of Experimental Zoology* is, according to *Science*, to be a memorial to Prof. W. N. Brooks, prepared by his former students at Johns Hopkins University, and will be issued in four parts towards the end of the present year. It will contain a biographical sketch by Prof. H. V. Wilson, accompanied by three portraits in heliotype.

A useful list of binoculars and telescopes has reached us from Messrs. F. Darton and Co., 142 St. John Street, E.C., copies of which may be obtained from the address given.

OUR ASTRONOMICAL COLUMN.

Metcalf's Comet, 1910*b*.—No. 4440 of the *Astronomische Nachrichten* contains new elements and a daily ephemeris for Metcalf's comet. The elements were calculated by Dr. Kobold from places observed on August 11, 17, and 25, and give the time of perihelion as August 26·04673 (M.T. Berlin). The following is an extract from the ephemeris:—

Ephemeris for 12h. (M.T. Berlin).

1910	α (1910·0) h. m.	δ (1910·0) ° ′	log *r*	log Δ	Mag.
Sept. 14	15 30·4	+17 13·9	0·2862	0·3442	11·4
,, 18	15 29·2	+17 22·8	0·2877	0·3578	11·5
,, 22	15 28·4	+17 31·8	0·2895	0·3701	11·5
,, 26	15 27·9	+17 41·4	0·2916	0·3815	11·6
,, 30	15 27·8	+17 51·7	0·2939	0·3919	11·7

From this we see that the comet is now apparently nearly stationary about half-way between τ' and ι Serpentis. A note from Prof. Pickering states that when discovered, visually, by the Rev. J. H. Metcalf on August 8, the comet was of about the eighth magnitude.

A Suspected New Planet.—On examining a plate taken for Halley's comet on June 6, Prof. J. Comas Sola found the trace of an unknown, but undoubtedly real, object, which he suspects to be a tenth-magnitude minor planet. During an exposure of one hour the motion was apparently nearly due N. and S., making an angle of about 50° with the ecliptic; the following approximate position depends upon the position of the nucleus of Halley's comet according to Prof. Seagrave's ephemeris:—1910 June 6, 9h. 20m. (G.M.T.), R.A. = 10h. 13m. 22s., N.P.D. = 90° 40·5′; the motion in N.P.D. was of the order of +45′ *per diem* (*Astronomische Nachrichten*, No. 4440).

Definitive Elements for Comet 1852 IV.—A comprehensive discussion of the orbit of the comet discovered by Westphal, at Göttingen, on July 24, 1852, is published by Herr Adolf Hnatek in Nos. 4438–9 of the *Astronomische Nachrichten* (pp. 345–87). The final result confirms the period of sixty-one years, the actual value being 61·5554 years, and this comet should return in 1913.

A Suggested Volcanic Origin of Martian Features.—The theory that the various features and variations on the surface of Mars may be due to volcanic action is advocated by Dr. Wilhelm Krebs in No. 4439 of the *Astronomische Nachrichten*. During the opposition of 1909 various new features were observed, and these are held to indicate volcanic action, while the network of "canals" is compared with the network of seismic and volcanic tectonic lines met with in the earth's crust.

The Passage of the Earth through the Tail of the 1861 Comet.—In the September number of the *Bulletin de la Société astronomique de France*, M. R. Baer, of Rouen, describes the phenomena observed by him at Horbourg (Alsace) at the time of the earth's passage through the tail of comet 1861 II. He points out that the vertical pillar of light then seen by him at the northern horizon was analogous to that described by recent observers as being visible during the predicted passage of the earth through the tail of Halley's comet.

The Spectrum of Cyanogen.—No. 6, vol. xxxix., of the *Memorie di Astrofisica ed Astronomia* contains a note in which Comte de Gramont and M. Drecq discuss some results recently obtained by them during a research on the spectra of various mixtures of salts. They find evidence that the chief "cyanogen" band (3883·6) may be produced under conditions where the presence of the cyanogen compound is unlikely, carbon and nitrogen being present, however. Thus they suggest that the function of cyanogen may be simply to supply carbon and nitrogen, and that the appearance of this band does not necessarily imply the presence of the poisonous compound. Further, they point out that if this result be established, the passage of the earth through the tail of a comet such as Halley's, in the spectrum of which the band at 388 was prominent, becomes still less likely to produce any evil effects.

Researches on the Colours of Stars.—Employing the *réseau* method devised by M. Henry, M. Osten Bergstrand examined the spectra of a number of stars to compare the effective wave-lengths radiated by different spectral types and by different classes of coloured stars. The results are published in vol. ii. (series iv.), No. 4, of the Proceedings of the Royal Society of Sciences of Upsala, and embody several important conclusions. Among other things, M. Bergstrand finds that the stars may be sharply divided into white and yellow, with a marked discontinuity between the colour classes G.W.+ and W.G.−. For the white stars, the effective wave-length is, in the mean, about 420 $\mu\mu$, and for the yellow stars it ranges from about 435 to 450 $\mu\mu$; the corresponding spectral classes are B and A and K and M respectively. The effective radiation of pronounced red stars is about 460 to 470 $\mu\mu$. The intermediate classes, G.W.+ and W.G.− of the Photometric Durchmusterung of MM. Müller and Kempf, and the spectral classes F and G of Prof. Pickering, are relatively rare. It is also pointed out that as the effective wave-lengths vary between 411 and 470 $\mu\mu$, the employment of the same coefficient of refraction for all stars is inadmissible.

"MOCK SUNS."—From Mr. James F. Ronca we have received an account of the appearance of the phenomenon usually known as "mock suns," or "parhelia," which was observed by him at Eastbourne between 12.55 and 1.55 p.m. on September 10.

Mr. Ronca did not see the commencement of the apparition, but states that at 12.55 p.m. there was a slight haze, and some very thin clouds, distributed fairly uniformly over the sky, and, symmetrically described about the zenith, there was a brilliant circle of white light on the circumference of which lay the actual sun; two other points on this circle stood out as exceptionally brilliant spots. Then, with the sun as its centre, there was a much fainter, small circle, tangential to which there appeared a brilliantly coloured band intersecting the large circle at two points equidistant from the sun. This coloured curve could be traced only with difficulty beyond the confines of the large circle, but at the points of intersection with the latter the colours were of extraordinary brilliancy, the red in all cases being nearest the sun.

Mr. Ronca's account shows the phenomenon to have been of an extraordinary brilliancy, which was maintained for twenty minutes after he first saw it, and did not disappear finally until 1.55 p.m.

THE RELATION OF SCIENCE TO INDUSTRY AND COMMERCE.[1]

THE subject of this paper is so comprehensive that there will be no difficulty in understanding that attention has been restricted to one or two aspects of it only, and chiefly (since the paper is written by one engaged in educational administration) to that relation which exists between the scientific and technical education provided at higher institutions in this country, and the after careers of students. Even that relation cannot be treated in anything like an exhaustive manner within the limits assigned to me. My attention was specially directed to this matter some eighteen months ago by an opportunity which presented itself of reading some 150 letters written by past students of universities or of institutions of university rank. The letters were representative of an entire body of students whose education had been assisted. They came from students, men and women, who had taken degrees or diplomas in varying numbers during each of the last fifteen years. Four months ago, when, at the invitation of the committee of this section, I undertook to read this paper, steps were taken to extend the field of information. Some five hundred letters of inquiry were addressed to teachers of repute at home, in France, Germany, and America; to representative firms of employers, mostly at home, some abroad; and to thirty of His Majesty's consuls in Europe, Asia, and the two Americas. There have been before me also the written views of the presidents of vast industrial and commercial concerns in the United States, views collected in 1903 when I visited America as a member of the Mosely Commission. On the whole, my letters of inquiries have been treated with much sympathy, and I have had to examine a very considerable body of evidence of all kinds. I owe a great debt of thanks to the many distinguished men of science, and to many well-known leaders of industry and commerce, who have so generously given attention to my inquiry and have been kind enough to give me their views, some of them at great length.

I have endeavoured in what follows to reflect as faithfully as I can the different sets of views, and to add to them some views and suggestions, the result of my own experience.

Evidence from 150 Graduates.

First, as to the views of the 150 past students. These students all belong to the class for whom the earning of a living is imperative, and in the main they represent Oxford and Cambridge, and the London institutions of university rank.

Among minor points made by them are these:—The engineers emphasise the need of workshop practice under commercial conditions, finding that their future is in danger of being marred by lack of "works" experience, and some of those who have become industrial chemists express the need for five years' training: three for degree and two for research. The view of the engineer students needs no elaboration, for nowadays there is almost universal agreement that some form of the "sandwich" system affords the best possible method of training. The views of the chemists will be referred to later.

The students also complain that posts are obtained not on merit, but through influence. This contention is pointedly illustrated by a university college professor, who states that he knows one man who holds a most important berth, and is undoubtedly a first-class man in every sense of the word. This man took his university training as a mechanical engineer, and graduated with first-class honours, and did this after having had works' training extending over some eight years. On leaving college the man approached every mechanical firm of importance in Scotland in the hopes of getting a start. He found it impossible to do so. Finally, *through influence*, he did manage to obtain a junior berth, and is now the head of an important concern.

The most striking feature of the present occupations of the students is that only 10 per cent. have found their way into industry or commerce; another 10 per cent. have entered the higher ranks of the Civil Service, including technical posts. Some half-dozen are in the Church; another half-dozen are practising medicine; the remainder have taken to teaching, and it is clear in a fair number of instances that selection of a profession was not a matter of choice, but one of necessity. Many a man, towards the end of his university career, discovers for the first time that he has nothing to offer in the industrial or commercial market in return for a salary. If he has no technical knowledge or skill, he is, so far as his education helps him, in the same position as a secondary schoolboy, even if he is not handicapped on account of his greater age. Of those, also, who possess technical knowledge or skill, such as students of engineering or chemistry, a good many find themselves offered terms which pride, or poverty, or both, forbid them to accept. With pride I have no concern and no sympathy. Poverty is a different affair. When a man has spent his last penny in completing his university career, and when there is also pressure from home, there is no real choice between teaching, which is obtainable at 2*l*. or 3*l*. a week, however inadequately equipped the man may be for this purpose, and an office or a workshop at anything from, say, 10*s*. to 30*s*. per week. Sometimes the factory, shop, or business-house offers nothing, and occasionally a premium is required. It will easily be understood that in such circumstances an appeal is made by the students for more help in finding posts for university honours men, who are not eligible for the Civil Service, and who do not care to turn schoolmasters, and it will not be difficult to appreciate that at the critical point in his career—the selection of a means of earning a livelihood—a man is apt to write harshly of some of the slackness of university life, and to complain, as one of the most successful of them has done, that he wanted to be made a chemist, but his university insisted on his wasting his time on Divinity and did not even ask for German!

Evidence from the Staffs of Universities and of Technical Institutions.

A great change in the relations of the university and the market has occurred during the last quarter of a century. The general advance in the standard of education has produced a larger sympathy on the part of the market for educational institutions and their products; and the movement in favour of technical education has widened the range of objects of university education and the social classes from which university students are drawn, and has perhaps compelled the universities to have regard to the diversities in the world's work and to the functions they should discharge in preparing their students to live. During the period referred to a large number of technical institutions have sprung up all over the United Kingdom, and within quite recent years there have been strong influences at work to bring about coordination, if not incorporation of

[1] A paper read before the Educational Science Section of the British Association at the Sheffield meeting, by Mr. R. Blair.

the greatest of the technical institutions with the universities within the area of which they have emerged. The danger in the process of amalgamation is that it may be premature. It may come about before the realisation of what each institution in its own way, and in its own time, has had to contribute to national problems, and before it has been fully recognised that the annexation of a technical school is not merely the end of a rival, but the beginning of a new public responsibility, and that in the result the vitality and, if you like, the harsh industrialism and commercialism of the technical institution may be too much submerged by "academic control."

The evidence placed at my disposal shows, on the whole, a tone of great hopefulness. The hopefulness of tone to which I have referred is common. It is displayed by the newest of the large municipal technical institutions in the heart of a great industrial centre, and by some of our oldest universities. It is becoming evident that the institutions are recognising that, however much the market, in its quest after cheapness, has failed to distinguish the real from the spurious article, the institutions have been without much blame for placing inefficient machines on the market. An eminent professor of chemistry tells me that his whole "professional life is strewn with examples of the unwillingness of industry and commerce, the State, and municipal authorities of this country to take advantage of the services of young men who have received the highest technical training as chemists." But, he adds, "there is a tolerably rapid improvement taking place," and "we who are urging the importance of employing these highly trained young men have to remember that there has been a great lot of poor stuff turned out from the universities and technical colleges, and that the British manufacturer has a good deal to say in his own defence."

Agriculture and Allied Industries.

It is in connection with the agricultural colleges that there appears to be the least difficulty in showing that the students have found posts in agriculture or in allied industries. The case of agriculture may be somewhat exceptional. There has been so much development in this industry in recent years that there was bound to be a considerable demand for trained men. Moreover, many of the young men who have undergone a course of training in agriculture have done so in order to fit themselves for farming, or otherwise dealing with land as land agents or farm managers, on their own account. Further, it has for a fair number of years now been obvious that study in the agricultural colleges had to be combined with practice on the farm. The agricultural colleges also report that there is a considerable demand for their students in various branches of foreign and colonial land development work, such as tea, coffee, cotton, and rubber planting, management and extension of irrigation colonies, forestry, stock farming, and so on. A certain number of students trained at agricultural colleges are in demand for commercial undertakings in businesses associated with agriculture. For example, the German Potash Syndicate has a number of men representing their interests in various parts of the world who were educated at one of our oldest agricultural colleges, and the Permanent Nitrate Committee and the Sulphate of Ammonia Committee have also appointed agents or representatives who have gone through a similar course of training. The principal of the college attributes this preference for men who have received a college education instead of those who have had a business training only to the fact that the work undertaken by these representatives combines a large propagandist element with ordinary business management.

In Ireland the State directly organises the application of scientific education and of scientific knowledge to agriculture and allied industries. The Department of Agriculture and the county committees alone take advantage of young men who have received the highest technical training in agriculture. Since 1903 some sixty or seventy men have passed through the faculty of agriculture in the Royal College of Science, and all have been employed by the department or by the county committees. Farmers in Ireland operate on too small a scale to warrant them in employing experts as is done by large industrial concerns. Those who want expert assistance can get it through the county committees, or, for special work, from the department. In this way the faculty of agriculture is exerting a strong influence on agricultural practice. Leading farmers—those of the best education—make most use of the expert, and the smaller men follow them. In this way the influence of the Royal College of Science is far greater than is usually supposed to be the case. The college course fits men to take up the important positions of itinerant and special instructors, and the whole course has been designed specially for the one purpose. Moreover, the instructor and expert, after leaving college, are kept in touch with the work of the college and with that of instructors in other counties than their own or those adjacent. If the college taught, so to speak, in the air, and was not, as it is, part and parcel of a great organised system, it would do little good. No students of agriculture attend except those selected to become teachers and experts under the department and the local authorities. For such teachers and experts there is always a demand, since some of those who have been trained and who have worked as experts for a time leave—some to business, others go abroad to take up work as teachers or experts in the colonies.

In addition to this main work, the college trains experts in forestry, horticulture, and creamery management, and in these branches of Irish industry the trained men perform the same functions towards these industries as the agricultural expert does to agriculture proper. While no one who intends to become a farmer takes the Royal College of Science course—since this last would be out of all proportion to the capital invested in even the larger farms in Ireland—quite a number now attend shorter and less expensive courses at the Albert Agricultural College and elsewhere. There are thus other channels through which the higher technical training at the Royal College reaches those engaged in the agricultural industry, since these local colleges, stations, and winter schools are staffed by Royal College men who keep in touch with the central institution. The lesson which Ireland has to teach is that the faculty of agriculture in the Royal College of Science is part of a great organisation directly serving the interests of the agricultural industry, and not an independent institution pursuing knowledge for its own sake, or educating students without certainty of their profitable employment.

Engineering.

The evidence from the engineering colleges and institutions is also, on the whole, satisfactory. Here and there may be found somewhat doleful notes to the effect that the large majority of State departments and local authorities do not lay themselves out to take advantage of technically trained men, and in one case a view that has much popular currency has been put to me in fairly strong terms. It is to the effect that employers, especially those who have not very large and important undertakings, but who, nevertheless, would have their businesses improved by securing technically trained men, have an ignorant prejudice against such assistance. It is suggested as the possible explanation of their attitude that the employers fear that if they engaged men of greater attainments than themselves, they would simply be raising up possible opponents in their own line of business. There may be much truth in this view, which does not, of course, apply to first-class firms. But there is, I think, another worth full consideration: that the size of the business concern (the amount of capital sunk in it) has much to do with the employer's attitude. The employer does not possess the faith that will enable him to risk the addition of another salary to his working expenses; and no one, without a fair trial, is able to give him the mathematical demonstration which he seeks that the salary might often be saved merely out of the waste of materials which exists owing to the absence of scientific knowledge on the part of his men of the materials they are handling, and to their having to feel their way by experiments that are more in the nature of guesses. Such firms will be converted only by the example of others.

There is abundant evidence, however, that there is much less prejudice than formerly; that there is a growing tendency on the part of State and municipal authorities to secure for their services engineers who have received the highest training; and that this attitude is especially true of certain industries, the success of which depends absolutely upon highly competent, trained scientific experts, as, for example, the steel industry. I suggest that the growth of this attitude corresponds generally in time with increased recognition on the part of the teaching institutions that engineers cannot be wholly made at college. The colleges have at length realised that the student must from the first learn the limitations of practical engineering, and that this can be done by the introduction of a practical atmosphere, and without sacrificing any of the physical principles of engineering already well taught at the colleges.

One of our ancient universities says, "We have not now much reason to be dissatisfied with the attitude of employers towards our (engineering) students." Several of the largest of the technical institutions say they have no difficulty in placing their best students, and one university college states that there is a standing demand as soon as the college year ends, from several of the heads of engineering establishments within the neighbourhood of the college for the best students. But these heads of firms demand the "best," and are willing to pay a living wage right off to youths who have never before been in works, and have only their college training as qualification. It is added that second- or third-rate men are in very little demand, and there is often a difficulty in not being able to recommend youths of sufficiently high standard to fill vacant posts. This case recalls other colleges where students (the "best," at all events) have no difficulty in securing places owing to the personal connection established between the heads of the neighbouring works and the head of the engineering department.

The return issued by the Appointments Board of the University of Cambridge in February of this year is specially interesting. This return shows that the number of candidates for the mechanical sciences tripos whose names appeared in the honours lists of the years 1894 to 1906 inclusive was 252, that the Board obtained information as to the posts held by 176 of these men; of the 176, only 23 were engaged in teaching, while 122 were engaged as engineers in some manufacturing or commercial concern or in the public service at home or abroad. The return is the more satisfactory in that 133 of the names belong to the years 1902 to 1906, and in that most of the men have to spend at least two years as probationers of some form in works before they can secure a definitive appointment of any kind.

It has been pointed out to me, both by professors and the heads of large engineering firms, that there is still a defect in the college training of young engineers which ought to be immediately remedied. The view is so well presented by one of the colleges that I give it *in extenso*. "There are certain defects in the average college training. I consider that the question of cost in design, and the commercial side generally, receive quite inadequate attention in most colleges. Practically all engineering firms exist for making profit. Modern competition makes economic design, good efficiency, and cheap upkeep absolutely imperative. The employer wants men who can in their designs give the most for the money. It is therefore insufficient to teach design on physical principles alone. Methods of production, ease of repair, depreciation, even conditions of transit in large machines, all these and more must be considered in effective design. Such limitations as these should, I think, be brought before the student in greater measure than they are attempted at present. This will tend to 'practicalise' the student while his mind is still formative."

Chemistry.

The case of chemistry is more difficult. There is, unfortunately, no room for doubt that the British chemical industry has suffered largely by foreign—chiefly German—competition; and possibly no section of British manufacturers has been so severely lectured as those in whose processes applied chemistry was capable of playing a large part. The chemical manufacturers were told to follow their German rivals by enlisting the assistance of the chemist trained in the scientific laboratories at our leading institutions, and that the industrial face of Great Britain would be changed. The manufacturer did not apparently grasp the meaning of the arguments or the appeal: he may possibly have comforted himself with the feeling that as things had been, so would they be; he may even have looked at the works that needed reconstruction, at the state of the Patent Laws, at the character of the supplies of raw material, at labour, at capital, at agents, markets and means of transport, and may have come to the conclusion that the professorial lecturers understood none of these things; he may have chosen a chemist from an analyst's office or from a medical school, and have failed to discover that chemists were of any value. Whatever he did, and for whatever reason he did it, it has been stated in the papers before me that he did not give much heed to the scolding from the professorial chairs: he could not be persuaded that scientific education was essential to his business. And so in time the penalty had to be paid, and that, unfortunately, by many who had no choice in the matter. Perhaps, after all, the chemical manufacturer merited less odium than has been heaped on him. It is a human quality to believe in your fortifications until they are reduced to ruins at your feet. It may be true, also, that the chemical manufacturer was not tactfully wooed; and it certainly is true that under the name of chemist enough rubbish was supplied to him to break down his faith in the panacea. Twenty years ago the research chemist qualified for industrial work could scarcely be obtained from English laboratories. He had to be imported from Germany. The English schools turned out only analytical machines. The influence of a few well-known chemists and of the 1851 research scholarships has changed all this, but the manufacturer has not yet recovered from his early disappointment.

It is gratifying to find evidence of change. The public may not yet believe that "scientific activity is the real and solid basis of national prosperity," and all manufacturers may not yet be fully prepared to endorse the view that "industrial development is ultimately dependent on scientific development," or everywhere to demand chemists trained in *research* writ large, but they are learning or receiving lessons sometimes in ways not altogether creditable to British intelligence. One of our most distinguished chemists, and a man of large experience inside and outside of the college laboratory, says:—"I am very clearly of opinion that, with very few exceptions, the State and municipal authorities do not lay themselves out to take advantage of men from twenty to twenty-two years of age who have received the highest technical training as chemists. Municipal authorities require the services of men who have had a specialised training as chemical experts in connection with the working of the Food and Drugs Acts, and there is a tendency on their part to prefer the services of men who are willing to take underpaid positions. This does not conduce to the efficiency of the working of the Food and Drugs Acts, and the general community suffers in consequence of the lax administration of these Acts. Municipal authorities occasionally require the services of engineers and chemists in connection with municipal undertakings, as in gas and water supplies. As regards the chemists they employ in connection with such undertakings, I think, on the whole, the community is adequately served; the chemists employed, for example, in the manufacture of gas are, as a rule, well trained and competent to discharge their duties. As regards private employers, I am of the opinion that British manufacturers, as a body, are not yet fully sensible of the advantage which they might obtain by the employment of skilled chemists in manufactures in which chemistry plays a prominent part. There are, however, exceptions. Some of the best equipped works of this country—usually wealthy concerns—strive to keep in the forefront of industrial progress. We have in this country an increasing number of men of foreign extraction who are engaging in chemical manufacture, and it is significant to note that such employers are far more prone to enlist the services of expert chemists than are the rank and file of our own manufacturers. I think this is due to the circumstance that the advantages of a university training have come home to these people more directly than to our manufacturers, and they are more quick to perceive the material advantages of the application of the highest training in pure and applied science to their industries. I could give a number of illustrations of this fact by pointing to the existence of foreign firms who have secured for themselves in this country a pre-eminent position."

The statement as to the increasing number of men of foreign extraction engaging in chemical manufacture in England who are far more prone to enlist the services of expert chemists than are the rank and file of our own manufacturers points a lesson which is well illustrated from two other quarters. The secretary of the Cambridge Appointments Board says (*Empire Review*, January, 1905):—"A feature of the lists of matriculations (at Cambridge) for the years 1880–95 is the recurrence of German names, with the note, 'Now assisting his father in business.' From this it would appear that the representatives, naturalised in England, of the nation which has, more than any other, astonished the world by its industrial progress, have deliberately chosen for their sons a University career as a preliminary to business life."

The other illustration comes from British business life. Only one letter from a British manufacturer emphasises the need of research, and that is signed by a chemical manufacturer with a German name. As to evidence of change, one of the largest technical institutions says:—"We are fairly sure of placing at once all the best men who have taken a graduating course in any branch of applied chemistry." Another technical institution—probably the largest—states:—"We have been unable, during the last three or four years, to meet all the demands upon us for trained chemists, and at this moment we are unable to make nomination to two or three most important posts for which trained chemists are required because all our men are satisfactorily placed." From one of our oldest universities comes the statement:—"There is no difficulty in placing chemists of the highest rank in first-rate technical posts. By highest rank I mean people with approximately fellowship standing and great originality." Sir William Ramsay writes:—"Some months ago I had the curiosity to pick out from my class-lists, back to about 1890, one hundred names of men (and women) whose subsequent history I know. The result was, roughly: 60 in industry (analysts, private or in works, managers, proprietors of works, &c.); 25 in teaching posts (assistants in universities or university colleges, schoolmasters and a few professors—about 6); and 15 given up (married women, men who have changed their profession or dead)." The most gratifying fact about this analysis is that it suggests that 60 per cent. of Sir William Ramsay's students are pursuing industrial chemistry for a living.

An examination of the after-careers of the 1851 exhibitioners reveals the following results. It will be remembered that science scholarships are awarded annually by the Commissioners of the 1851 Exhibition. The scholarships are awarded for research in the experimental and observational sciences bearing upon industries. The nomination of scholarship holders is made by the authorities of twenty universities and university colleges within the British Empire, and, with rare exceptions, these nominations are confirmed by the Commissioners. The scholarships are of the annual value of 150*l*. a year, and are ordinarily tenable for two years. Between 1891 and 1906 there were awarded 262 scholarships. Of the holders, 145 are now engaged as professors, assistant professors, lecturers, or assistants in science colleges or other educational institutions; 76 hold positions in manufacturing firms or in public departments, and the remainder may be conveniently classified thus: scholars recently retired, 6; continuing research in private capacity, 12; engaged in professional pursuits, 10; deceased, 6; occupations unknown, 3; no longer engaged in scientific work, 4, of whom 3 are ladies. I find on further analysis that, of 112 scholars whose branch of science was chemistry, 50 are, or have been, engaged in industrial chemistry.

I am not able to provide more statistical details. As a rule, universities, university colleges, and technical institutions have not kept records of the after-careers of their students, and until quite recently most of the universities (and some not yet) have not had any organised means of giving assistance to students who may be seeking posts at the end of their college career.

Looking at the matter quite broadly, I see no reason for believing that the number of highly trained chemists who find their way from colleges into industrial chemistry is anything else than insignificant, compared with similar figures for Germany or the United States of America.

The following facts may aid in understanding the conclusion of "insignificant" which I have reached. In 1904 and 1905 an average of 400 chemists received the doctor's diploma or the technical high school diploma in Germany; with the materials at my disposal I have been unable to convince myself that there were in 1908 300 students of all faculties of applied science taking a fourth-year day course in British universities and technical colleges.

For some of these results our system of degree-giving is denounced in no measured terms. An able university professor says:—"The fact is, the whole thing—university teaching of chemistry—is turned upside down. Much of our university work is simply good secondary work. A pass B.Sc. degree, for example, is about the standard of a school-leaving certificate in a civilised country. Universities lay down syllabuses, time-tables, hours of work, and spend a large proportion of their energies in examination grinding. They teach for examinations instead of teaching for the diffusion and advancement of scientific knowledge. When a man arrives at a university he has a 'curriculum,' in other words, simply a glorified school syllabus, laid out for him, and is promised a degree in three years if he is a good boy. They do not do that in Germany. We are not," he continues, "really quite so bad in this country as regards our so-called 'honours' degrees, but the centre of gravity is wrong for all that. . . . The centre of gravity of the English system is still in the examination hall, even though a good man does stay on for several years of research afterwards." Others, who have clearly devoted themselves to a study of the matter, demand a five years' course for the making of a chemist, three for degree and two for research.

One of the most thoughtful memoranda sent to me by a university professor shows:—"On entering the research laboratory the graduates are rarely independent thinkers, and their knowledge is essentially 'book knowledge.' When freed from the necessity to attend lectures or to work for examinations they seem to pass through a stage when they actually have to struggle to develop their resources, and often the students with the best degrees make the poorest research workers. . . . Again, the business faculties of the students at this stage are poor, and their knowledge of modern languages as applied to scientific or commercial work is quite inadequate. These are deficiencies which I have to make good in the research department. . . . Students at this stage are not qualified to take up positions of responsibility. The graduate of twenty-two has, however, many latent possibilities which may be successfully developed by a course of research work." The time spent by the graduates in research work in the university laboratory is from two to three years, and the average age of the students on leaving is twenty-four to twenty-five. "Taking an average case," the professor continues, "I can say that at the end of the first year the research student has commenced to think for himself, to anticipate difficulties, and to overcome them when encountered. He begins by suggesting new working methods, and finally proposes new topics of research. He has a working knowledge of scientific and technical French and German, knows the original literature of his special topic, and is generally conversant with modern research thought. His business style has also improved greatly. A considerable advance in these respects takes place during the next year, and in most cases a two years' course is sufficient to produce a man who has had a good education and who knows how to use it. It is my experience that when students with this training enter technical work they master the literature of their new subject very quickly and effectively. They seem to be able in a short time to form an estimate of the present position and future possibilities of the new subject and to bring their speculative faculties into play. I therefore regard the time spent at research as a necessary part of scientific training if university graduates are to enter the field of technical work, and men thus equipped make most valuable officials, even taking into account the fact that they have no previous experience in the supervision of workmen, and have generally no knowledge of chemical engineering." But the British parent does not care to afford to keep his sons at the university until they are twenty-four to twenty-five years of age, especially as a period of probation has afterwards to be served in works, unless he sees that his money is going to be a good investment. And so we come back again to the manufacturer.

Other Subjects.

As to many of the other subjects in which the universities and higher technical institutions touch industry and commerce—architecture, biology, economics, and modern languages—there is little to be said on the side of the institutions. Biology is comparatively an unploughed field; the opportunities for economics are not yet fully developed. Railways, banks, insurance companies, and great business houses might, say the colleges, pay more attention to the really able economist. At the School of Economics a course of lectures in administrative subjects was arranged in the autumn of 1906 in order to equip officers for the higher appointments on the administrative staff of the Army and for the change of departmental services. This course is now annually attended by thirty officers selected for the purpose by the War Office. In order to provide the teaching required by candidates for the degree of B.Sc. in the faculty of economics and political science with honours in transport, the department of the school dealing with this subject has been developed. The lectures in this department, besides being open to students in the faculty, are attended by some 300 students engaged in railway administration. These students are drawn mainly from the staffs of the following railway companies:—the Great Western, the Great Eastern, the Great Northern, the London and South-Western, the Great Central, and the Metropolitan, their fees being in many cases paid for them by their companies. The lectures are also attended by members of the staffs of the other London railways, and occasionally by officials of Indian, colonial, and foreign railways, and other persons.

As for modern languages, it is alleged by the teaching institutions that the fundamental business attitude of England is entirely wrong. It will be seen later that this last view is amply confirmed from important and well-informed sources.

One further point of view of the colleges. Personality is by far the greatest factor; no amount of training can produce an exceptional man out of a man whose initial natural qualities are only second class.

VIEWS OF INDUSTRIAL AND COMMERCIAL FIRMS.

Answers to my inquiries have been received from a considerable number of large shipowners, from a few large shipbuilders, from nearly all the great railway companies, from a good many banking and insurance companies, from manufacturers of all kinds, and from employers' federations representing very large interests.

Elementary School Training.

Almost all explain their preference for elementary-school boys in such a way as to pay a well-deserved compliment, directly to the adaptability of the elementary-school boy, and indirectly to the existing system of elementary education. A good many speak in high terms of the value of evening schools, including technical institutes and schools of art. Banks and insurance companies almost invariably (but other firms as well) seek for the secondary-school product. There is some call for the man trained at the highest institutions, but this call is so much confined to firms the works or business of which require technical skill, that it is fully evident that the others do not yet feel the need for such men, nor know how to use them. There appears, also, with some frequency, the traditional fling at the public schools and at the universities.

Catch the boy as he leaves the elementary school, and induce him to attend evening classes; add to that the training of the workshop or the business house, and you have the fairly common plan of training those who will rise above the rank of "hands." From the best of these come the foremen; from those in turn the sub-managers are selected, and so on. It is interesting to see, however, that the possibility of a change is not unforeseen. "It happens," says one of our greatest industrial leaders, "that at the present moment all the men who fill the positions of responsibility in our office come from elementary schools. Naturally, they belong to a period when secondary schools were not so accessible as now, and probably the same remark may not be applicable to their successors."

There is much dissatisfaction with the existing system in those trades or industries in which apprenticeship was once common. "Time off" is occasionally allowed to attend day technical classes. But there is evidence that such a plan of training would not be generally acceptable, and I am told by one representative of a large set of interests that "the whole question of the method of teaching boys their trade in and on the works, seems in need of reform, . . . it is hardly possible for anything to be done in this way except by some compulsory scheme affecting all employers"; and by a representative of another vast set of interests that "As a matter of fact, the whole question of technical education is so unavoidably mixed up with the apprenticeship question in such a form as to make it impossible to deal with one without the other. Furthermore, the apprenticeship question is so clouded by the conflicting interests of the various unions, the unsatisfactory state of the law as regards employers, and other difficulties, that nothing short of a far-reaching Parliamentary scheme is likely, so far as my experience goes, to materially alter the situation."

The markets call emphatically for the "practical" man. A view more sympathetic with higher education, and not altogether uncommon, may be stated thus:—A man with practical training alone can do much; a man with technical training alone can do little; a combination is, therefore, essential. If only one can be had, which would be regrettable, that must be the practical man.

While, as I have already said, employers generally express the highest appreciation of the value of evening schools, technical institutes, and schools of art, as supplementary to the workshop, the factory, and the office, there is a good sprinkling of severe criticism. It is alleged that the schools are not practical, and that teachers of art as well as of science display much ignorance of the manufacturing process and of the limitations imposed by materials, machinery, and generally of the conditions of work and organisation necessarily enforced in a commercial business. This is, of course, no new view. It has been expressed to me all over the three kingdoms, and I fear there is much truth in it. Part of the ignorance is due to the exclusiveness of the manufacturer, who dreads the theft of his secrets. But the impression left on the employers is partly the fault of the schools. It was one of the defects of the technical education movement that it was hasty and tumultuous. Schools were not graded. Teachers and institutes set up claims impossible of fulfilment, and the British public misunderstood. Hence the doing, unfortunately not yet ended, of much mischief, which has had to be repaired.

This is, perhaps, the best place to direct attention to one of the commonest features of the employers' views. They think that evening schools, technical institutes, and schools of art may help the individual pupil; it does not enter their minds that such schools may aid their industries.

I have devoted more attention to the elementary side of technical education than might, at first sight, appear necessary. My object has been to show what the employer thinks of what he comes most in contact with. His views in that respect may serve as a guide to the kind of appreciation he is likely to give to that of which he knows less.

Higher Education.

I am much disappointed to find that a works of a technical character and with a world-wide reputation, says, "The men technically trained up to 20–22 years of age employed by us are comparatively few in number, and are generally such as have had special introduction to us," and I am also much surprised to find a large and well-known firm of engine-makers saying, "We have never had any application from the universities." Another firm, the name of which is a household word, says, "There are no proper ——— schools" (naming an important and common article of commerce which forms the subject of large industrial works), "in this country such as are found on the Continent, so it would be difficult for us to get properly trained men of 20 to 23 years of age straight from the university to fill the highest posts in our business." On the other hand, a professor of chemistry at a university, in which great stress is laid on the value of chemical research, says, "It is, perhaps, an index of the slender relationship between commercial chemistry and scientific work to state that although all the research done in my laboratory is in ——— " (using exactly the same term as the firm), "I have never had a single inquiry for a chemist from a manufacturer producing or using these compounds." I hope to serve as a labour exchange between this laboratory and that factory.

There is, again, a common impression that the training in the universities and higher institutions is not sufficiently practical, and much fear is expressed that the university man would not care for the continuous and laborious routine of commercial life. A gigantic association in the north of England, with extensive business ramifications all over the world, and at the works of which considerable chemical knowledge and a general scientific training is necessary, says: 'For our works, the youths who come to us have had a public school or grammar school education of modern type. They are taken from school and sent to the works for twelve months, after which, if they show ability, it is arranged that they should take a three-years' day course at a technical school and obtain the degree of B.Sc. They then go to our own laboratory, and a training specially suitable to our requirements is given to them." They add, "Provided a youth appears to be energetic and not to have suffered materially from the defects often induced by such a course, we should upon the whole prefer a man who had been to a university. . . . For our best positions in the commercial departments we prefer boys of 18 or 19 from good public schools" (I think it is the Manchester Grammar School type which is in mind), "to those who are younger, and we are equally glad to have university men, provided they are energetic and fond of work. Our opinion of the usual result of a course at the university is that it is not calculated to induce this spirit. The length of the vacations, and the great freedom enjoyed by undergraduates, do not form a good preparation for the absolute tie, the long hours, and the very short holidays of a business life."

This particular view was written in the north of England. Whether true as a criticism of some phases of our university life and work, it represents too common a view to be omitted. It is not true of some of our largest technical institutions, and I cannot think that it is true of the younger universities. But it may serve to show these institutions what spade work they must undertake. Let me return to criticisms. A general manager of one of our great railway companies says, "We have in the past appointed a few university men, but it is not an experiment which we are repeating." On the other hand, the general manager of another large railway company says, "In my opinion, no man is fitted for the higher posts in the engineering world unless he has received a full university education, and it is a great advantage to a man in the industrial and commercial world if he has had, and has made proper use of, a university training." And again by another, "The university or other technical institute curriculum does not enter into our estimate of the fitness of the individual. It is certainly in favour of the lad who has enjoyed it, but it is, after all, only a means to an end, and unless it has been intelligently employed by the favoured student, the less fortunate lad with definite aim is not irremediably out of the running."

The head of a chemical manufacturing company, which employs university trained men, puts his views thus: "We invariably find that men who come to us with the highest technical qualifications, either from a technical institute or from the universities, require a considerable time before they are able to utilise their knowledge practically. An analyst, for example, will take some time before he recognises the fact that analyses must be done quickly and accurately, and that no mistake in analyses is permissible; with regard to experimental work, it is also some time before a university man can be got to distinguish between results which are likely to be of practical value and those of only theoretical interest. Some men acquire their experience very quickly, others very slowly or not at all."

One more quotation under this head. A consulting engineer with a large practice, who employs twelve university or technical college trained men, in addition to a large technical staff of a lower grade, says, "I am a thurough believer in university and scientific training, but there is, no doubt, considerable difficulty in combining the university and practical training."

The general absence of replies of any importance from salesmen and merchants not manufacturers, may be taken as indication that the minds of business men of that type are not interested in the prublems presented to them by my letters of inquiry. The opportunities for the propagandist commercial traveller and for the economist have still to be developed. But when the War Office and great railway companies make use of the School of Economics, other State and municipal departments and great corporations will, sooner or later, follow.

Finally, the industrial and commercial firms point out, as the colleges do, that other qualities than those which generally show in an academic career are necessary in the fields of commerce and industry. Those are the business or economic sense, alertness, capacity for work, loyalty to the firm's interests, push, perseverance, social qualities, including good manners towards clients, tact towards subordinates, and capacity to get the best out of them, and generally the power to control men and things. These qualities do not, as a rule, show early, and consequently firms should in their own interests make the basis of selection large and broad.

In concluding this section, let me say that many British manufacturers, especially those under younger management, are displaying their economic sense in a new and interesting direction. Firms manufacturing common commodities and employing thousands of hands have invited me to visit their works, and have shown me that not only do they employ scientifically trained engineers and chemists, but they employ public-school men as managers, they employ on their permanent staff doctors and dentists for the sake of their hands, they provide much for the social and economic welfare of their workers, and generally they show that they take as much interest in the human as in the other material which comes into their works; and they do this, not as philanthropists, but as business men. They find that in the interests of their business the human material, as much as the coal and the steel and the sugar and the flour, can respond with more efficiency to scientific and generally enlightened management.

WHAT THE CONSULS-GENERAL SAY.

It is impossible to ignore the unanimity of the story told by H.M. Consuls and the experience and earnestness and sense of responsibility of the men who tell it. The main question submitted to them was this:

It has been said from time to time that British firms (merchants, manufacturers, and so on) do not sufficiently apply scientific methods to the canvassing of the various markets of the world, and in particular that, as a rule, their travellers and agents do not know the language of those with whom they are dealing; that advertisements, prospectuses, and so on are published in English, with English weights, measures, and money terms; that British firms do not sufficiently study the needs of the markets; and that in general there is a want of activity and enterprise of the right kind. The answer is, "To a large extent, true." And this answer is so emphatic, so unanimous, and withal so moderately stated and so clearly expressed, that it is not possible to regard it as incredulous. The story is as follows.

Commercial Education.

British merchants and manufacturers (and British shipowners) until about thirty years ago may be said to have had rather more than their share of the world's trade, and, comparatively speaking, made money so easily that they grew over-confident, relaxed their energies, and took little pains to improve their business methods as time went on and to learn from their competitors. It is only from about that time that they have begun gradually and slowly to realise—through the falling off of profits and through losing a share of the markets which they used to monopolise—that the traders and manufacturers of other countries, in particular those of Germany and of the

United States, have made up their minds to have, and have already succeeded in obtaining, a larger proportion of the world's trade than was previously left to them by Great Britain.

Our leading manufacturers are so strong, and their work of such excellence, that they can push themselves in any market; but it is not the same with other firms, and if these were to amalgamate they would acquire great strength. Cooperation is adopted in our shipping business with marked success, and should serve as an example for other industries.

The Britisher believes in competition and the survival of the fittest. The results, it is alleged, are a limited number of robust units and a mass of mediocrity which cannot resist foreign cooperation either in the home or foreign markets.

The great trouble is the lack of enterprise on the part of British firms in sending out travellers. Lamentation on this head is loud and frequent. Figures for two European countries are given to me. The first country is eminently suited for trade with England, more especially just now when the two countries have so much in common, and when "things English" are so much in vogue. The total number of commercial travellers' licences issued at "A" (the capital) during 1909 was 1203. During the same year 357 licences taken out at other towns were presented to the "A" police for visa. The 1203 licences were issued as follows:—to German commercial travellers, 605; to British, 142; to other nationalities, the remainder. Of the 357 the Germans had 146, the British 37; the remainder were distributed among various nationalities. The other country is also one which would also appear to be eminently suited for British trade. In the year 1908 (the figures for 1909 were not available) 7000 commercial travellers visited this country; 4700 were of German nationality, 1500 French, 61 represented Great Britain, the rest various.

In general, there is no complaint against the natural qualities of the British traveller; "a smart British business man accustomed to travel and deal with foreigners has no equal the wide world over, but, alas! there are too few of them." Another says:—"As regards the other qualities—push, activity, enterprise, and so on—they all seem to exist in such satisfying degrees in the British commercial man that if he direct his attention to rectifying the faults arising through this insular attitude, and the lack of commercial education which so narrows his outlook, the future would then look at least as hopeful as it does in any other country." A third maintains:—"There is no inherent quality in the Britisher which prevents his being able to compete successfully, not only in capturing new markets, but also in ousting his rivals who have been there before him. On the contrary, he possesses in as great as, if not in a greater, degree than any other nation just those qualities which eminently fit him for such work—endurance, perseverance, reliability (a very great adjunct), and concentration." And so on.

Until by scientific education the British realise that commerce means an intricate and complex organisation of intimately interconnected parts, they will lose many an opportunity, and their Consulates and Chambers of Commerce will be unable to do for them the work which could easily be done. Engineering, it is pointed out to me, is looked upon as a science, but commerce is not.

Metric Measures.

Failure to adopt the metric system places British manufacturers at a decided disadvantage. A French merchant, accustomed to one system of weights and measures, uniform and exact, resents receiving quotations from England in quantities which are absolutely mysterious to him. Circulars and price-lists, printed only in English with English weights, measures, and prices, are often sent to the Continent of Europe beautifully, even artistically, printed and illustrated; but they are of no practical use, as they are not understood by the persons for whose inspection they are intended. Only in cases where it is known that some member of the foreign firm is well acquainted with English, or has already dealt with English firms, can any practical result be looked for by sending out English catalogues. Further, a good deal of delay and inconvenience is sometimes caused at the Custom House through the use of the English system of weights and measures, owing to the fact that all weights and measures have to be reduced to the metric system before the goods are cleared.

Foreigners will not buy goods simply because they are British. The man who wishes to sell and to increase the number of his clients must seek the goodwill and favour of the buyer, and not look to the buyer so much to accommodate himself to the ideas and business rules of the manufacturer. Enough stress cannot be laid on the vital importance of personal acquaintance with the country, the people, their customs, needs, weaknesses, likings, and prejudices; and also with the local methods of doing business—in short, with everything and anything that can and does affect the market.

In this connection I would like to recall what Lord Cromer said to Lord Reay's Committee on the Organisation of Oriental Studies in London: "It is quite possible for an Englishman to pass half his life in the East and never understand anything about Easterns."

Foreign Languages.

If the requirements, industrial and commercial, of any country are to be understood thoroughly, a knowledge of the language of that country is essential. One Consul says:—"I have seldom met a foreign traveller who does not speak one or two languages besides his own." Another says:—"I have very seldom, I might say almost never, met an English commercial traveller who knew a word of ——" (the language of the European country from which he writes). If I were at liberty to identify the individual, by naming the country, it would be seen that his statement, while appearing incredulous, would really appear to be highly credible. Another Consul says —and others write to the same effect:—"Lastly, but perhaps first in importance, is the fact, which cannot be brought home too strongly to every young commercial man, viz. the absolute necessity of learning foreign languages. English, it is true, is spoken everywhere abroad, and although fresh business may possibly be secured in foreign countries by men who speak nothing but English, the circumstances are exceptional, and point to the fact that the goods are absolutely wanted and none others, and not to any special acumen on the part of the salesman. The majority of travellers, however, have goods to offer which are by no means unique, and in the sale of which they will have to compete very severely with rivals. The case of the man in this country (an extensive country, with large trade possibilities) who speaks nothing but English is too obvious to need any elaboration."

I will add but one further quotation:—"Until it is realised in the English system of education that modern languages are useful as means of communication between persons, and are not merely theoretical subjects in which a knowledge of grammatical rules results in the pupil being awarded a prize, they will probably continue to be handicapped." He adds, "I speak feelingly on this subject, as my own children have been able to converse comfortably in four or five languages, and after two or three years at a first-class school have since entirely forgotten how to use them, although two of the said languages are in their regular school course. I understand, for instance, that although when conversing they use the subjunctive mood naturally and correctly after certain conjunctions, they are unable to write out a list of all the conjunctions which govern the subjunctive, and consequently they are made to spend their time learning this and such-like rules instead of adding to their vocabulary as an infant does by daily practice."

The languages which these officers call upon the British traveller to learn are French, German, and Spanish. A knowledge of French will carry any commercial traveller through France, Belgium, Russia, Italy, and Switzerland, as well as through many parts of Germany. For Germany and Austria, German is necessary. Spanish is wanted for the Peninsula and the South American trade.

Let me repeat that the views set out above are not mine. They are those of His Majesty's Consuls at stations distributed over four continents.

THE PRESENT POSITION AND NEEDS.

I have now come to the last section of this paper. For fear of being misunderstood, let me say at once that I have no lack of respect for our ancient universities, and that any appearance of such in this paper is quite unintentional. It would, indeed, be difficult to exaggerate the share which our oldest universities have had in the formative life of this country, and the work of the past is still necessary. Universities must continue their detached work; they must pursue knowledge for its own sake or for the purely mental training it gives; they must continue to produce statesmen and churchmen and lawyers and doctors and schoolmasters, and they must educate the leisured classes. I would even go so far as to say that it is a national asset to have institutions setting the standard of efficiency and honour in national games. But the modern world needs something more, especially from the departments of applied science. The sympathy and support which these departments have received from the public have, to a large extent, been based on the belief that they would contribute to the success of national industry and commerce. The same holds true of the large technical institutions with day departments for young manhood. There is a public need, and in some cases a public demand. It is our object to increase the demand.

I have no magician's wand to offer as a means of revolutionising public opinion, and I should like to make clear that I have no thought of advocating mere imitation of German methods, which would be extremely foolish, if not disastrous. The industrial and commercial conditions and the character and traditions of the people of Britain and Germany are dissimilar. Again, the German universities endeavour to send out men ready to take their place immediately, not in the ranks, but as officers in the industrial and commercial armies. Further, the British system of education is so different that not to give heed to what exists would certainly court failure. Many useful lessons may, however, be gathered from a study of German methods; but possibly our most useful lessons are to be gathered from America, where the character of the people is more like our own, and where it is clearly realised that whatever training of the highest kind a man may have, he must still begin in the ranks and climb his way to the top. It has been said that British character and methods produce a few brilliant units and a mass of mediocrities. The surest road to success would probably be for the mass of mediocrities to adopt the methods of the brilliant units.

The normal attitude of the employers, if not of the public, may be expressed in three sentences:—(1) Only those value higher education who have felt the need for it. (2) The purely practical man can do much, the purely theoretical man can do little; a combination is therefore necessary. Should one quality only be obtainable, which would be regrettable, that quality should be the purely practical. (3) Teaching institutions may assist individuals to get on; they form no essential part of our industrial or commercial system.

For these three sentiments I suggest that we are all anxious to substitute three others:—(1) Setting aside exceptions, every man who achieves success must give so much time to fit himself for his work, whether the time is given in college under guidance and discipline or is expended in self-education. (2) In the end, and again setting aside exceptions, the man who has received the highest training in college under guidance and discipline will, other things being equal, achieve by far the greatest success. (3) The work of research and training carried on in technical school and university college is an integral part of any nation's successful industrial and commercial organisation.

Organisation and Management.

How is the substitution to be accomplished? The demand of the shareholders of an industrial or commercial concern for dividends forms a great stimulus to intelligence and activity on the part of the staff. Without such stimulus in a technical school or faculty of applied science there is a tendency for things to become comfortable. I suggest the following:—

(1) The management of all technical institutions and departments of applied science should be put on a business footing. The ordinary governing bodies, as a rule, serve for ordinary governing purposes. The chief need is that of consultative committees attached to all specialised faculties or departments, such committees to be advisory and to be composed of industrial or commercial leaders or experts of the highest reputation. This is probably the best and surest means of enlisting the full sympathy of industrial and commercial leaders. The faculty or department, the curriculum and the examinations, would benefit by having its work and methods criticised sympathetically by experts of the first rank. Such a committee would form the surest medium of communication between the college and the workshop; and its formation would certainly be followed by a wide extension of the appreciation of the advantages of technical education, because the captains of industry would learn exactly the character of the work done in college and how in practice to utilise it.

The head of the teaching department and his staff would by this means gain easy access to factory and workshop, and bring back some of their atmosphere to the laboratory. On the examining committee of the engineering department of the Glasgow and West of Scotland Technical college are the engineering director of the Fairfield Shipbuilding and Engineering Co. and the engineering director of John Brown and Co., Clydebank Shipbuilding and Engineering Works. Such men would probably be generally recognised as the leaders in their particular profession on the Clyde. I understand that it is their practice to look in great detail through worked papers and designs, and to give the engineering department of the college the benefit of their criticisms. Employers, parents, and students cannot but have faith in the instruction given in an institution so aided. Let me make it quite clear that I am not advocating a mixed governing body, but an advisory committee of experts attached to each technical department. Governing bodies should consult such advisory committees before appointing the head of a department or even the principal of a college or technical institution. In the qualifications of principals and heads of departments it is customary to give too much consideration to academic status and too little to industrial experience and business capacity. Such a consultative body as I have referred to would act as a corrective in this respect.

(2) A connection should be maintained with old students and a record kept of their after-careers. One of the means of success of the American colleges is the list of after-careers of their students. It is almost incredible how little has been done in Britain in this respect. I hope parents and the public generally will develop a habit of asking for such a list.

(3) At each technical institution and university there should be an organisation to assist students in getting placed. The Blue-book recently issued by the Board of Education shows how much English universities have in the past neglected this aspect of their work, and how much there is still to be done to establish appointments committees or bureaus. I am not overlooking the fact that much excellent work has been done by individual professors and occasionally by the secretary or the principal. But this was unorganised. I am asking for an organisation. The manufacturer and the merchant have been denounced in no measured terms by representatives of learning for their short-sightedness in not applying scientific methods to manufacturing and business processes; could not the manufacturer and the business man retaliate that not only have university and technical college goods been of such various qualities that it was impossible to discriminate, but also that scientific principles—even common business empirical methods—have not been applied to the marketing of school and college products? It is a discredit to the universities and technical colleges that they have so long neglected this obvious means of assisting students, this obvious means of promoting the cause they proclaimed.

(4) A change in curriculum and in degree requirements. Let me read some remarks on American colleges which I wrote in 1904. "Again, there is, in each American institution, a considerable 'mortality' or shedding of students. Some students find their general preparation insufficient; some find the pace too great; others find their funds give out; and some are advised that they have made a bad selection. In such cases the American student accepts advice, and acts promptly. At every step a student's work is known, and the faculty—staff of professors in each department—every four months discuss fully a student's work. The middle of the third year is the critical point in a student's career. At this stage the requirements of the Institute of Technology demand a final decision as to choice of work. Fifteen men in one department were, at this point, recently advised to change their courses or to withdraw from the institute. I was informed that, as a rule, 25 per cent. of the civil engineering students drop off at the same stage. These numbers have to be added to those who have previously 'fallen by the way.' The greatest patience is extended to the students, and the best advice is offered to them; but in the interest of the individual, as of the standing of the institute and of its influence on industrial work, such shedding of students is regarded as inevitable, and is acquiesced in. It does not follow that the men are 'wasted.' As a rule they find employment of a lower character than they were aiming at; they change the directions of their careers, to their own great advantage, or they pursue a course of studies on the same lines at a secondary institution—a two-year course school."

It appears to me that such kind of advice and action is necessary in British teaching institutions, but it is hardly possible under existing conditions.

(5) Another means of bringing the college class-room and laboratory into closer connection with factory, workshop, and office would be more liberal provision of short, specialised courses suitable to the heads of firms or their successors. I am not referring to that provision of evening courses which is made in technical schools and schools of art, but to provision, whether day or evening, of advanced courses for industrial and commercial leaders or their successors in institutions which there could be no presumed loss of self-respect in attending. Such courses are provided at several colleges; they need multiplication. I know that a large number of able men obtain, at much expense, instruction through private agencies, because the best institutions do not appear to cater directly for their needs under suitable conditions.

(6) As to modern languages, three things are necessary for the majority of students:—(i) less the scholar's and more the utilitarian point of view; (ii) more concentration during the later school and college years; and (iii) speaking generally, a better class of teachers.

In conclusion, let me say that this preliminary study of a very large question has disclosed much hopefulness of the future. The obstacles which university and other highly trained men encounter in getting a footing in the industrial world are still formidable, and the breaking down of the barriers between our highest teaching institutions and commercial life forms a specially difficult task. But there is plenty of need for first-class men, and there is not much difficulty in getting the exceptionally good man placed. It is gratifying, too, to find that His Majesty's Consuls speak in the highest terms of the personal qualities of our foreign commercial travellers.

On the side of education, too, there is much hopefulness. A distinguished university writer not long ago stated that the object of university education "was not how to keep our trade, but how to keep our souls alive." Between such a representative of university education and the business man who inquires what is the money value of a degree there is little room for accommodation. But the writer did an injustice to the universities, and the facts as to the objects of university education are against him. It may be true that in the long view the keeping of our souls alive is the object of university education, but even the oldest of our universities are becoming conscious that the immediate condition of saving our souls alive is that of saving our trade.

ROYAL SANITARY INSTITUTE.

THE twenty-fifth annual congress of the Royal Sanitary Institute, held at Brighton from September 5–10, was attended by upwards of 1200 members. To the address of the president, Sir John Cockburn, K.C.M.G., we have already referred (NATURE, September 8). Seeing that no fewer than sixty-three papers were printed *in extenso*, and many of them "taken as read" before discussion, it will be understood that it is impossible, within the limits of our space, to do more than glance at the general aspects of the work of the congress, endeavouring to indicate the drift of opinion on some of the more important questions which were raised. All problems relating to the health and physical well-being of the community are regarded as coming within the province of the Institute. In the Lecture to the Congress Dr. Arthur Newsholme set forth the now well-known statistics of diminishing birth-rate, and considered the arguments in favour of, and against, the present crusade against infant mortality. "Is it worth while to dilute our increase of population by 10 per cent. more of the most inferior kind?" The diminishing fertility-rate is as noticeable in the ranks of skilled artisans as it is in the ranks of the well-to-do. He concluded that it has not been proved that the inferiority of the offspring of the most fertile class, the unskilled, is due to inferiority of stock so much as to the unsatisfactory conditions into which they are born, and he strongly deprecated the attitude of that section of eugenists whose pass-word is "Thou shalt not kill, but need'st not strive Officiously to keep alive." The services of health visitors and the adoption of the Notification of Births Act are, the lecturer considered, the most hopeful agents and means whereby the death-rate of early life may be reduced.

The numerous papers and discussions we can but summarise under separate headings. *The Municipal Control of Tuberculosis.*—Compulsory notification of all cases was strongly advocated, and the removal of cases which cannot be nursed at home, without risk of spreading infection, to the empty wards of fever hospitals and small-pox hospitals; the risk of cross-infection being *nil* if suitable administrative measures be adopted. This system had its initiation in Brighton, so far as the use of hospitals is concerned, and its value has been thoroughly proved. Patients receive the educational treatment which gives them a practical understanding of the lives which, for the sake of other people, as well as for their own, they must henceforth lead. *Preventive Medicine in School Life.*—Much consideration was devoted to the work of the school medical officer, the administration of the Education Act of 1908 being, as everyone acknowledged, in a tentative and, in many respects, a very unsatisfactory phase. More financial support is needed. Inspection without school clinics is in many districts in which there is difficulty in obtaining treatment of very little use. The question of the periodical disinfection of school premises led to warnings regarding the danger of "sprinking a little carbolic acid, and leaving the rest to Providence." There are, indeed, few subjects in which sanitary authorities themselves are more in need of education than in the use of disinfectants. Faulty drains are not reconstructed, nor are their dangers lessened by an antiseptic odour which allays the anxiety of the public. Several papers were read upon school planning, and opinion appeared to be universally in favour of the Derbyshire and Staffordshire type, which provides efficient cross-ventilation of every class-room. Cross-lighting must, however, be avoided as far as possible. Open-air schools on the lines of the Thackley (Bradford) school, in which each class-room has a verandah for fine weather, were commended. Rectangular class-rooms with more direct lighting and warming by the sun's rays are to be preferred to square rooms. Appliances for drying cloaks and shoes should be provided. The treatment of tuberculous children and of the pre-tubercular was brought forward by Dr. Broadbent, who strongly advocated teaching such children in the open air, and a modified curriculum. The X-ray treatment of ring-worm was approved; but the utmost caution is necessary at the present time, lest its unskilful application should throw it into disrepute. *Disease Carriers.*—Probably about 3 per cent. of the cases of typhoid fever which have recovered from the disease continue to breed and distribute the germs (Brückner). To scarlet fever, diphtheria, cerebro-spinal meningitis, and measles some risk of the same kind is attached. The importance of this matter can hardly be exaggerated. Instruction in cleanliness, periodical examination of the excreta of typhoid carriers, disinfection of the alimentary canal by drugs, are obviously necessary; with restriction to such occupations as afford the least opportunity for the dissemination of disease. *Control of Foods.*—There can be no hope of freeing the milk supply from the bacillus of tubercle without more effective control of milk growers and milk sellers. At present the milk supply can be stopped only for one particular district, and the farmer is at liberty to send the condemned milk to any other district without incurring any penalty. *Housing and Town Planning.*—Dr. Fremantle argued that the expense and opposition which an attempt to proceed under the Regulations of 1910 will entail will deter municipalities from taking advantage of the Act. *Sewage Disposal.*—C. Chambers Smith maintained that economy in the disposal of sewage may be carried much further than at present. Sedimentation tanks and percolating filters are less expensive than contact beds. Shenton advocated the sterilisation of sewage effluents by hypochlorite of lime, proving with well-ordered figures the need for this final destruction of bacterial life, and showing the efficiency and inexpensiveness of the agent recommended. An interesting paper on the influence of underground waters on health was read by Baldwin Latham, who associates the epidemic appearance of fever with a fluctuating level of subsoil water, and especially with an unusually low water level.

A conference of women on hygiene was held under the presidency of the Countess of Chichester, at which questions of great practical importance in relation to the artificial feeding of infants and the influence of the employment of married women upon infant mortality were discussed; but the subject which aroused most interest was "Home-making Centres"—centres for the teaching of what in Canada is defined as household science. Whatever other items may be introduced into the curriculum to meet the needs of particular localities, the chief subjects taught at such centres must always be cooking, housewifery, dressmaking, the care of infants and children, personal and domestic hygiene.

In the popular lecture, which brought the proceedings of the congress to a close, Dr. Alex. Hill took the opportunity of directing attention to some of the recent triumphs of sanitary science, quoting especially from the report of Sir Rubert Boyce on the condition of the West Indies:—"Look to your laurels, Brighton! 'The West Indies are rapidly becoming the sanatoria which nature surely intended them to be.'" He next proceeded to expound the principles of Mendelism, answering, incidentally, Dr. Archdall Reid's objection that they have only been shown to hold good for human abnormalities and for the characters of cultivated plants and domestic animals by pointing out that, unless characters are either so unusual as to be "abnormal" or so much exaggerated by breeding as to be outstanding, it is impossible for the biologist to isolate them as allelomorphs. He then submitted a scientific basis for Dr. Newsholme's contention that all infant lives must be cherished by the community by showing photographs of a white albino guinea-pig from which the ovaries were removed soon after birth and replaced by those of a black guinea-pig; one of several litters of young, all black; and their white albino sire. The doctrine of the continuity of germ-plasm, the lecturer said, by throwing the origin of the individual so far back, has profoundly modified our ideas of the heritability of the moral and pathological characteristics of the immediate parents.

The congress was fruitful in discussion, and those who attended it will carry away many new conceptions and discard some misconceptions; but amongst the many congresses which meet at this season that of the Sanitary Institute stands somewhat apart in that it supplies the stimulus for the publication of a large number of papers of permanent value. Medical officers of health and others stationed in distant parts of Britain find in it an opportunity of putting their observations and reflections in print, and submitting them in this form rather than orally, to a considerable body of their fellow-workers. An admirable and extensive Health Exhibition was organised in connection with the congress.

INTERNATIONAL CONGRESS OF PHARMACY.

THE tenth International Congress of Pharmacy was held in Brussels on September 1 to 6, and was attended by over five hundred pharmacists. The Governments which sent official representatives were those of France, Italy, Spain, Russia, the United States, Norway, Denmark, Sweden, Holland, Greece, Hungary, China, Japan, the Ottoman Empire, Venezuela, the Argentine Republic, the Republic of San Salvadore, Guatemala, Haiti, and Chili. The delegates from the Pharmaceutical Society of Great Britain were Mr. Edmund White, a member of the society's council, and Mr. E. S. Peck, one of the permanent hon. secretaries of the British Pharmaceutical Conference. The most important subject which came up for consideration related to analytical methods. The international conference for the unification of the formulæ of potent drugs, held at Brussels in 1902, defined standards for a number of drugs and galenical preparations, but different methods of standardisation give different results, and it was one of the objects of the pharmaceutical congress to consider what steps could be taken to bring about the approximation of analytical methods. After a long discussion it was unanimously resolved, on the motion of Prof. Bourquelot, representing the French Government, to ask the Belgian Government to convene an interational conference, composed largely of practising pharmacists, for the purpose of unifying the methods of estimating potent drugs, with the recommendation that, for the estimation of alkaloidal preparations, preference should be given to gravimetric methods. The congress also agreed that it was desirable that pharmacopœias should indicate the precise methods of determining physical constants, and that in the case of chemical tests the reactions should not be capable of giving rise to any difference of interpretation. The related topic of the international unification of analytical reagents also received consideration, and the congress resolved to request pharmacopœiæ commissions to adopt as far as possible normal reagents or some multiple of the normal. The decisions on these two questions constitute the most useful part of the work of the congress.

Next in importance was the discussion on the sale of proprietary disinfectants, and the congress unanimously resolved to recommend that the sale of proprietary antiseptic products and disinfectants should be officially regulated. No such products should be sold unless the manufacturers of them shall have obtained a licence from the Government, only to be granted after the products shall have been officially examined both chemically and bacteriologically with the view of ascertaining if they possess the properties claimed for them. It was also resolved to recommend that all such products should be labelled with the name and address of the seller as well as the manufacturer, and that the bactericidal strength and the date of manufacture should be stated on the label.

Among other subjects discussed were:—(1) The desirability of a large representation of pharmacists on the commission charged with the preparation of an international pharmacopœia; the congress expressed approval of the principle. (2) The advisability of pharmacists making their own galenical preparations; the congress agreed that this was desirable where possible. (3) The limitation in each country by the State of the number of pharmacies; the congress approved of the principle of limitation and agreed on a method of limitation. (4) The desirability of instituting in schools of pharmacy courses on the macroscopy, microscopy, and chemistry of natural and pathological secretions; the congress agreed that such a course of study might with advantage be instituted.

In addition to the discussion on topics of general and pharmaceutical interest, several communications of purely scientific interest were presented. Prof. Bourquelot made a further contribution to the biochemical method of examination of vegetable glucosides hydrolysed by emulsin. He pointed out the relation between the optical properties and reducing power of the products of hydrolysis by emulsin, and suggested as an index of enzymolytic reduction the weight of reducing substances, calculated as glucose, formed in 100 c.c. by the action of emulsin corresponding to a rotation of 1° observed in a 2 dcm. tube. After showing the different uses of this method, he gave a list of medicinal plants in which the presence of glucoside had been shown by this means, but which had fallen into disuse, as no active principle had been separated formerly.

Prof. Herissey explained a chemical method of obtaining the true glucoside arbutin, which gives glucose and hydroquinone on hydrolysis with emulsin. Commercial arbutin, extracted from *uva ursi*, is a mixture of true arbutin and methyl arbutin, and this, on being treated with alcoholic potash, gives a precipitate of the potassium salt of true arbutin, from which the glucoside can easily be obtained in a pure state. This glucoside is apparently identical with that isolated recently from the leaves of the pear tree by Prof. Bourquelot and Mlle. Fiehlenhots.

Mr. Leger described his experiments which had led to the establishment of the constitution of the aloins. These experiments show that barbaloin and isobarbaloin are glucosides which can with difficulty be split into aloemodin and α arabinose. These two aloins are stereo-isomers. Nataloin, treated with sodium peroxide, furnishes methylnanatoemodine, decomposable by hydrochloric acid into nataloemodin and methyl chloride. Nataloin appears to contain in its molecule a pentose sugar.

Prof. Perrot described the method which he, in collaboration with Mr. Goris, has devised for obtaining dried plants in which the properties of the fresh plants are preserved; the principle upon which the method is based is the destruction of the diastase.

Mr. Hercod read a paper by himself and Mr. Maben on the assay of pepsin, and the congress decided to refer the question to an international committee with a view to establishing an international standard and method of assay.

Mr. Moller read a paper dealing with the determination of colours, and the congress agreed to recommend the adoption, as an international code of colours, of the code of Klinksieck and Valette.

The above is a brief summary of the work accomplished at one of the most interesting international meetings of pharmacists which has ever been held. It should also be mentioned that a decision was arrived at to form a permanent international pharmaceutical association, the headquarters of which will probably be at the Hague.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. PHILIP WARD, who has just been appointed a Commissioner of National Education in Ireland, is the first national teacher to fill the position. He is a former president of the National Teachers' Organisation.

THE following courses of Gresham science lectures are announced for delivery at the City of London School, Victoria Embankment:—Geometry, by Mr. W. H. Wagstaff, on October 4, 5, 6, and 7; physic, by Dr. F. M. Sandwith, on October 25, 26, 27, and 28; astronomy, by Mr. S. A. Saunder, on November 7, 8, 10, and 11.

PROF. GOLDWIN SMITH, according to the Toronto correspondent of the *Times*, has bequeathed the sum of 140,000*l.* to Cornell University "to show my attachment as an Englishman to the union of the two branches of our race on this continent with each other and with our common mother"; the greater part of Prof. Goldwin Smith's library, and 1800*l.*, are left to the University of Toronto.

THE new calendar of the Battersea Polytechnic shows an increase of work in all departments. In connection with the engineering and building department, new evening classes are being commenced in pattern-making and architectural measurements, and in connection with the gun-making section a course of study extending over three years has been arranged in gun and ammunition manufacture. A course has also been arranged by request of the Institute of Certificated Grocers on subjects which appeal to the grocery and provision trade. The chemistry department is extending its work by providing more advanced instruction in paper-making and bacteriology, and new classes in soap manufacture. In the women's department, a third-year day course of science as applied to housecraft has been arranged. The new library presented by Mr. Edwin Tate, at a cost of 8000*l.*, is to be opened by the Archbishop of Canterbury on Friday, October 21.

THE Belfast University Commissioners have decided to establish a faculty of commerce within the University, to consist of the professors and lecturers in the subjects of the faculty, and in addition there will be an advisory committee. In framing the curriculum the needs of three classes of students have been borne in mind:—those who are, or expect to be, engaged in business; those who are preparing for the administrative work of the State or the municipality; and those who contemplate social or philanthropic work. It is proposed to grant a degree in the faculty to matriculated students who have pursued prescribed courses of study for at least three years and who have satisfied the examiners in certain subjects. To meet the case of students unable to devote to these subjects the time necessary for the acquisition of a degree, a diploma in commerce or a diploma in social science will be granted after a two years' course and the passing of the prescribed examinations.

THE issue of the Bulletin of Armour Institute of Technology, Chicago, for May last, which has reached us, is a general information number, which differs little in character from the calendars and prospectuses published at this time of the year by colleges and technical institutions in this country. The work of the institute in Chicago was begun in 1893. Four-year courses in mechanical and electrical engineering were first organised. A union was effected with the Art Institute of Chicago for the purpose of developing the course in architecture which that institution had maintained since 1889. The result was the establishment of the Chicago School of Architecture. In 1899 the course in civil engineering was added, in 1901 the course in chemical engineering, and in 1903 the course in fire-protection engineering. The courses in these subjects all lead now to the degree of Bachelor of Science. Each of these four-year courses represents a balanced group system of studies, combining a thorough and broad scientific training with the elements of liberal culture.

THE Department of Agriculture and Technical Instruction for Ireland has issued its programme for technical schools and science and art schools and classes for next session. The regulations which were in operation during the session 1909–10 will continue in force, with one alteration only. Small schools are to be permitted to adopt specialised courses of instruction covering a period of two years only. A prefatory note points out that the schools and classes working under this programme are mainly, though not exclusively, evening schools, and adds that instruction in evening classes cannot form a substitute for the more general and systematic education given in day schools, whether primary, secondary, or technical. The work of such evening schools and classes constitutes a specialised form of education intended to fit those receiving it for industrial or commercial pursuits, or to render those already engaged in such pursuits more efficient in their work. Attendance is purely voluntary. Those attending are for the most part engaged, or about to be engaged, in some form of industry, and are meeting problems and difficulties which the evening technical school can help them to solve. They perceive that the higher branches of their calling may be reached only by increased technical skill and knowledge; but progress is hindered by several circumstances: hitherto the previous preparation of students joining evening technical schools has in many cases not been such as to fit them for the specialised form of instruction which it is the special function of such schools to impart. An attempt is made in these regulations to remedy this defect.

THE recently issued syllabus of classes at the Sir John Cass Technical Institute, Aldgate, for the coming session shows that graded curricula of study extending over several years are provided for those engaged in chemical, electrical, and metallurgical industries. In addition, several special courses of instruction are to be given; in the chemistry department there is to be a course of work for those engaged in the fermentation industries, which includes lectures and laboratory instruction in brewing and malting and on the micro-biology of the fermentation industries, as well as a series of courses on liquid, gaseous, and solid fuels. In the metallurgical department special courses of an advanced character are provided on gold, silver, and allied metals, on iron and steel, and on metallography. The winter session at the Merchant Venturers' Technical College, which has just commenced, is the fifty-first held in connection with this institution. It will be remembered that the faculty of engineering of the University of Bristol is provided and maintained in the college. The new calendar, in addition to necessary general information, supplies full particulars of the day classes of the Bristol School of Commerce, the faculty of engineering of the University of Bristol, the extensive evening classes, and the school of art. The calendar also contains a list of gifts and loans to various departments of the college made by numerous manufacturing firms and learned societies, which shows that the college authorities are successful in securing the cooperation of employers of labour and others in the useful work they are doing in providing suitable technical instruction for the workers of the district.

THE first congress of the newly established Textile Institute, the objects of which are to promote the interests of the textile trades, was opened on Thursday last at Bradford by Lord Rotherham, who, in his inaugural address, said he looked for the institute to do its part in establishing cordial relations between men of science and practical spinners and manufacturers. The delivery of the address was followed by the reading of a paper by Mr. F. Warner on technical education in relation to the textile industries, in the course of which the author said that the existing system of education is overcrowding the office and starving the factory and workshop. Great Britain cannot afford to scrap from 5 to 7 per cent. of the working population, and the remedy for the present evil is more technical instruction and the practical training of the rising generation in industry and trade. The old apprenticeship system had manifest advantages, and its revival was suggested; but modern technical instruction, properly applied, offers advantages to the student for advancement which were impossible to the apprentice. Day classes should, by the cooperation of employers, be arranged to a far greater extent than was now the case, and in this respect England is far behind modern practice in the textile trades abroad. An essential requirement is proficient art teaching, for though in the perfection of cloth structure British goods are unsurpassed, in the class of fabric in which design and colour are required the reputation of our manufacturers is on a lower plane. Mr. Warner advocated the formation of a national department which, controlled by a council composed of captains of industry in all branches of manufacture and commerce, and of artists, designers, and educationists, could deal directly with art and technical schools. A similar system should also be put in operation in local centres. The financial difficulty should be met both by local and Government aid.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 5.—M. Bouchard in the chair.—Madame P. **Curie** and A. **Debierne**: Metallic radium. Starting with 0·106 gram of the purest radium chloride (atomic weight 226·5), the method of Guntz for the preparation of metallic barium was followed. The radium chloride in aqueous solution was electrolysed with a mercury kathode and a platino-iridium anode. After the electrolysis the solution contained 0·0085 gram of the salt. The amalgam decomposed water and was readily attacked by the air. The dry amalgam was rapidly transferred to a clean iron boat, the latter placed in a quartz tube, and was rapidly evacuated. The distillation of the mercury from the amalgam offered some difficulties; to prevent visible ebullition, which resulted in loss by projection, the tube was filled with carefully purified hydrogen, the pressure of which was kept slightly above the pressure of the mercury vapour at the temperature of the boat. At the close of the operation the metal was left in the boat, brilliantly white, and melting sharply at 700° C. The authors regard this as sensibly pure radium. The metal alters very rapidly in air, blackening immediately, probably owing to the formation of a nitride. Some particles detached from the boat, falling on white paper, produced a blackening similar to a burn. Radium energetically decomposes water going into solution, indicating that the hydroxide is soluble. Radio-active measurements showed that the increase of activity followed the usual law for the production of the emanation, the limiting activity of the metal becoming normal. Since it was found that the metallic radium was much more volatile than metallic barium, it is proposed to purify the metal by sublimation in a vacuum.—Léon **Kolowrat**: The β rays of radium at its minimum activity. The author has repeated the experiments of O. Hahn and Mlle. Meitner, and has arrived at conclusions confirming the existence of a very absorbable β radiation.—Georges **Baume** and F. Louis **Perrot**: The fusibility curves of gaseous mixtures: compounds of methyl oxide and methyl alcohol with ammonia gas. The results of these cryoscopic researches are given in graphical form.—J. B. **Senderens**: The preparation of acrolein. It has been found that potassium bisulphate reacts catalytically with glycerol, so that, instead of adding the bisulphate in the proportion of twice the weight of glycerol, as is customary, one-fiftieth of this amount of the bisulphide is sufficient.—Paul **Gaubert**: Soft crystals and the measurement of their indices of refraction. Figures are given for the refractive indices of crystals of beeswax, ammonium oleate, ozokerite, paraffin, and lecithine.—R. **Robinson**: The vessels of the fork of the median nerve. A contribution to the study of the manual dexterity of man.

THURSDAY, SEPTEMBER 22, 1910.

ANIMALS OF THE ANCIENTS.

Die Antike Tierwelt. By Otto Keller. Erster Band, Säugetiere. Pp. xii+434. (Leipzig: W. Engelmann, 1909.) Price 10 marks.

FOR many years past the author of this interesting volume has been engaged in investigating the records relating to animals known to the ancients, with the object of identifying the various species described or depicted, and working out their past history and distribution, special attention, in the case of mammals, being directed to the larger and more interesting forms, and those which have been domesticated by man. The results of this protracted study are incorporated in the work, of which the first volume is now before me, and in many respects Dr. Keller is to be congratulated on the outcome of his labours, especially in regard to his treatment of the various species of the Primates and Carnivora, although even among these he does not appear to have made himself acquainted with all the recent literature on the subject, and notably the work of Dr. Lortet on the mummified animals of Egypt, now in course of publication in the Archives of the Lyons Museum.

Even in the case of the Carnivora, I cannot, however, agree with all the author's conclusions, as, for instance, the statement on p. 72 that domesticated cats owe their origin in part to the jungle-cat (*Felis chaus*). Indeed, it is difficult to believe that he is fully acquainted with the characteristics of that species, or he would have hesitated in identifying with it the cat depicted in a fresco from Pompeii, which is reproduced on p. 72, the tail being much too long, and the ears showing no trace of the distinctive tufts.

Leaving the Carnivora with this brief mention, I pass on to the Ungulata, where there is much more room for criticism, more especially in regard to the author's identification of animals represented in the ancient sculptures and cylinders of Syria and adjacent parts of Asia Minor with species indigenous to Central Asia and other distant regions. Nor is this all, for when Dr. Keller attempts to identify animals represented in the frescoes of ancient Egypt with species inhabiting northern Africa, he is, in many cases, to say the least, far from happy in his conclusions. In the upper figure on p. 295 we find, for instance, an antelope identified as a hartebeest (Butalis), although it is much more probably a lesser kudu (*Strepsiceros imberbis*), and is identical with the fresco from the Ptahhetep Chapel, reproduced in Fig. 3 of the present writer's paper on "Some Ancient Animal Portraits" (NATURE, vol. lxx., pp. 207–209, 1904), and provisionally identified with that species. Again, the animals in the lower figure (99) on the page cited are likewise termed Bubalis, although two species are clearly portrayed, one being the presumed lesser kudu, while the other is, I think, the brindled gnu (*Connochaetes taurinus*). Further, on p. 291, Fig. 94, we find a fresco identified with the addra gazelle (*Gazella dama ruficollis*),[1] although it clearly represents *G. soemmerringi*, as does Fig. 2 in my above-cited article. The white oryx (*Oryx leucoryx*), Fig. 95, the addax (*Addax nasomaculatus*), Fig. 97, and the Nubian ibex (*Capra nubiana*), Fig. 101, are, on the other hand, correctly identified.

Leaving animals indigenous to Egypt and the neighbouring countries, attention may be directed to Fig. 93A, which is the one reproduced in NATURE for September 2, 1909, in a review of Countess Cesaresco's "Man and Animals in Human Thought." In that work the animals shown in this Assyrian relief are described as goats, but it was pointed out in the review that they are much more probably gazelles, although I was wrong in suggesting the addra, in which the females are horned. Dr. Keller is likewise of opinion that they are gazelles, but identifies them with the Tibetan goa (*G. picticaudata*), a species with which the ancient Assyrians cannot, I conceive, have been acquainted. Such an identification is, moreover, perfectly unnecessary, seeing that in the goitred or Persian *Gazella subgutturosa* we have a practically local species which agrees in all respects—notably the hornless females—with the relief.

Having shown that the animals in this sculpture are of a local type, attention may be directed to Fig. 102, p. 301, which reproduces the figures on part of a cylinder brought by Sir H. Layard from Constantinople. One of the ruminants on this is identified by Dr. Keller with the Himalayan markhor (*Capra falconeri*), and the other with the Central Asian argali sheep (*Ovis ammon*). Both species, be it noted, are represented as being in captivity, under the charge of apparently Syrian attendants, and the female of the supposed markhor carries horns as long as those of the male, and has a kid. This renders it, I think, clear that both kinds were seen by the artist in the living condition, and if this be so, it is perfectly evident that they were not, respectively, markhor and argali; animals, the very existence of which could not, I submit, have been even known to the ancient Assyrians. It is no argument to state, as the author does on another page, that the Assyrians were in the habit of bringing two-humped Bactrian camels from Afghanistan, seeing that these animals now come as far south as the Crimea and the Caucasus. Moreover, the long horns of the female are fatal to the markhor theory. In my opinion there is every reason to regard the supposed markhor as Circassian domesticated goats, in which both sexes carry long spiral horns.

As to the supposed argali, I am less confident but unless they be domesticated sheep, it may be suggested that they are Pallas's tur (*Capra cylindricornis*), of the eastern Caucasus, and in any case there can be little or no hesitation in regarding them as representing a more or less strictly local species. In connection with sheep, it must suffice to mention that there is great doubt as to the identification of those in the Negadah plate, B.C. 6000–5000 (Fig. 106, p. 310), with the domesticated Hausa sheep of Nigeria, as they appear to represent the wild udad, or Barbary sheep (*Ovis lervia*, or *tragelaphus*), of North Africa generally.

[1] *Antilope damma* of the author.

In place, therefore, of foreign species, with which it seems impossible for the ancient Egyptians and Assyrians to have been acquainted, it seems to me that all the ruminants referred to by Dr. Keller are local forms, well known to the artists and sculptors by whom they were painted or chiselled. The same remark will, I believe, apply to the representations of the Indian elephant, like the one on the obelisk of Salmanassar II. (Fig. 130, p. 375), although the author regards these animals as of foreign origin. He appears, however, to be unacquainted with the definite record that at an early date the Assyrian kings hunted the Indian elephant in the Euphrates valley, this record being confirmed by the occurrence of fossilised remains of the so-called *Elephas armeniacus*, which may have been merely a local race of the former species, in Armenia.

The Indian elephant being thus shown to have been a local, instead of an imported, species in ancient Assyria, it may be suggested that if the unicorn animal on the obelisk of Salmanassar ii. be, as Dr. Keller suggests (p. 386, Fig. 133), the Indian *Rhinoceros unicornis*, which is known to have had formerly a much wider distribution than at the present day, that species may likewise have ranged in Assyrian times into Mesopotamia; and, if this be the case, it will be practically certain that all the animals represented by the artists of ancient Egypt and Assyria were more or less local species.

More criticism of much the same nature might be added, but sufficient has been stated to show that while the volume under review contains a very large amount of valuable information concerning the early history of well-known animals, at least the portion relating to ungulates stands in need of revision by a writer with a fuller knowledge of that group than the author appears to possess. R. L.

THE DESIGN OF REINFORCED CONCRETE STRUCTURE.

(1) *A Concise Treatise on Reinforced Concrete.* By C. F. Marsh. Pp. viii + 225. (London: Constable and Co., Ltd., 1909.) Price 7*s*. 6*d*. net.

(2) *Concrete-Steel Construction.* By Prof. Emil Mörsch. Authorised translation from the third (1908) German edition, revised and enlarged by E. P. Goodrich. Pp. ix + 368. (New York: The *Engineering News* Publishing Co.; London: Messrs. Constable and Co., Ltd., 1909.) Price 21*s*. net.

(3) *Il Cemento Armato e la sua applicazione practica.* By Cesare Presenti. Pp. 141. (Milan: Ulrico Hoepli, 1910.)

(4) *Le prove dei materiali da costruzione e le costruzioni in Cemento Armato.* By Giulio Revere. Pp. xii + 541. (Milan: Ulrico Hoepli, 1910.) Price 11 lire.

THE employment of reinforced concrete in connection with engineering and architectural structures has now become so general that a text-book on somewhat simpler and more condensed lines than those of Mr. Marsh's well-known treatise on "Reinforced Concrete" will be gladly welcomed by many engineers and architects. The present volume (1) has been, to a certain extent, based upon a series of lectures delivered by the author in the winter of 1908–9 at the Central Technical College, London; hence, in all cases the derivation of important formulæ has been fully dealt with, but lengthy and detailed descriptions of the various systems of construction have been omitted; this latter portion of the subject was fully dealt with in the author's manual.

The first two chapters deal respectively with the properties and the behaviour under bending of reinforced concrete, the important question as to the value of the modulus of elasticity (E_c) for the concrete which should be adopted in the calculations required in connection with the design of struts and beams is very fully discussed, and Mr. Marsh shows that we may safely assume it to be 2,000,000 pounds per square inch when the concrete is two or three months old, or, in other words, that the ratio of E_s/E_c may be taken as 15. In the third chapter the various assumptions which have to be made for purposes of calculation are briefly explained, and their validity discussed; it is shown that, when calculations are based on the safe working stress for concrete, it is sufficiently accurate for all purposes to assume a straight line stress-strain relation for the concrete as well as for the steel.

The rest of the book is devoted to methods of calculation; after a short discussion of the bending moments of beams and slabs partially built in at the supports, direct compression is taken up, and then the longitudinal, bond, and shearing stresses in rectangular section and T section beams with single or double reinforcement; pipes and similar structures subjected to either internal or external pressure are then dealt with; a very thorough and complete investigation is next given of the calculations which are necessary in the design of small, and large, span arches, and other pieces which are subjected to both direct stresses and to bending stresses. The design of reinforced concrete arches is always admittedly a difficult piece of work, and there is no doubt that the treatment which Mr. Marsh gives of this branch of reinforced concrete work will prove of great service to those who only occasionally have to deal with such structures, as the methods explained and discussed are simple and direct.

In the last chapter a brief description is given of the general methods of reinforcement which should be adopted in structural work.

Mr. Marsh, by his well-known treatise, established his position as a trustworthy guide in this important field of engineering and architectural design, and the present volume is quite worthy of the reputation thus acquired.

(2) Prof. Mörsch, in his capacity as director of the technical bureau of the well-known firm of Wayss and Freytag, has been responsible for the design and erection of the reinforced structures built by this firm during the past fifteen years; he has, therefore, in

part ii. of this book, which deals with the applications of reinforced concrete, confined himself entirely to work done by Messrs. Wayss and Freytag, and there is justification in regard to this choice, since the whole of the examples described have been designed in accordance with the rules and formulæ given by Prof. Mörsch in the first half of the book, and many of them, in accordance with the recommendations for the design and construction of reinforced concrete structures, issued by the Verbands Deutscher Architekten und Ingenieur Vereine, and the Deutscher Beton Verein in 1904.

The theory of reinforced concrete is fully and thoroughly discussed in part i. of this book, and it is this section which will be of great service to English and American designers, because it includes a mass of experimental data not hitherto readily accessible to those who wished to make use of these results in connection with any new piece of design work.

In an investigation as to the flexure of reinforced columns, Prof. Mörsch shows that a special calculation of their safety against rupture by flexure will only be required in exceptional cases; for the strength of reinforced columns with spiral reinorcement, the author accepts the conclusions of Considère, who showed that the carrying capacity would be 2·4 times as great with such a system as when the same amount of reinforcement was employed in the shape of longitudinal rods.

For calculations connected with simple bending, Prof. Mörsch adopts the usual hypothesis that the tensile strength of the concrete should be ignored; the gradual shifting upwards of the position of the neutral axis as the loading is increased is clearly shown by the plotted results of a series of careful tests made at the testing laboratory at Stuttgart. A valuable chapter is that devoted to the calculations necessary when bending is combined with axial forces; circular and annular sections are discussed, as well as those of rectangular form.

In rectangular metal beams the shearing stresses are unimportant, and may usually be neglected, but in reinforced concrete they are of great importance in considering the arrangement of the reinforcement, and Prof. Mörsch devotes several chapters to the consideration of this branch of the subject, which is often inadequately treated in works on reinforced concrete design; after a mathematical investigation, he deals fully with the results obtained in numerous experimental investigations, which he has himself carried out on T beams, both when simply supported and when continuous; the results obtained from the latter tests are exceedingly interesting and of great importance to designers of structures in which such continuous members are largely used.

In part ii. there are excellent illustrations of the use of reinforced concrete, examples having been selected from all the various types of buildings or structures for which this material has up to the present time been employed.

The recommendations of the German societies, already referred to, and the regulations of the Royal Prussian Ministry of Public Works, for the construction of reinforced concrete buildings, are printed as an appendix.

The translator, Mr. Goodrich, and the publishers are to be congratulated on the result of their labours. The illustrations, on the whole, are satisfactory, in spite of the difficulties connected with their reproduction, referred to in the publishers' note.

(3) The author adopts the usual hypotheses in order to obtain fairly simple formulæ for the design of beams, both smple and continuous; he takes E_s/E_c as equal to 15, and deals fully with both simple rectangular cross sections and T sections. The various formulæ are illustrated by numerous fully worked out examples.

In the second part of the work is given a number of graphical and numerical tables for facilitating the rapid calculation of the dimensions of beams of various classes for certain lengths of span under known loads, and examples are given to show how much labour is saved by the use of such tables; the maximum stresses permitted are those usually adopted in practice.

(4) The first half of this book is devoted to the subject of the testing of the materials of construction—stone, wood, metals, cements, &c. There is nothing novel or exceptional in this section in the method of treatment of a subject to which so many text-books have now been devoted. A special chapter is given to the subject of the microscopical investigation of the structure of metals, and to the application of this method to commercial testing.

The standard conditions for carrying out commercial tests of materials, as approved by the Italian Government, are printed in the form of appendices to the appropriate chapters, and will prove of interest to engineers who may have to carry out contracts for the Italian Government, or for local authorities in that country.

The second half of the book treats of constructional work in reinforced concrete; here the usual order adopted in text-books is inverted; the first ninety pages of this section are occupied with illustrations and descriptions of works of all classes—buildings, bridges, silos, harbour works, &c.—which have been constructed in ferro-concrete, and then follow several chapters devoted to the theories underlying the design of such structures. Most of the works illustrated have been carried out in Italy, where ferro-concrete work has developed much more rapidly than in Great Britain, and this section of the book will prove useful to designers of similar works in this country, especially as many of the reproduced working drawings are fairly fully dimensioned.

The mathematical treatment adopted in the chapter devoted to the design of columns and beams of all classes is that which has now become more or less stereotyped in text-books dealing with reinforced concrete. There is only a brief treatment of the arch, but continuous beams are very fully discussed.

T. H. B.

TEXT-BOOKS OF CHEMISTRY.

(1) *Practical Chemistry.* By Dr. James Bruce and Harry Harper. Pp. viii+240. (London: Macmillan and Co., Ltd., 1910.) Price 2s. 6d.

(2) *Qualitative Analysis. Tables for Use at the Bench.* By E. J. Lewis. (Cambridge: University Press, 1910.) Price 2s. 6d. net.

(3) *Outlines of Organic Chemistry. A Book Designed especially for the General Student.* By Dr. F. J. Moore. Pp. x+315. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1910.) Price 6s. 6d. net.

(4) *The Calculations of General Chemistry, with Definitions, Explanations, and Problems.* Second edition. By Prof. William J. Hale. Pp. xii+175. (London: George Bell and Sons, 1910.) Price 4s. 6d.

(5) *A.B.C. Five Figure Logarithms and Tables for Chemists, including Electrochemical Equivalents, Analytical Factors, Gas Reduction Tables, and other Tables useful in Chemical Laboratories.* By C. J. Woodward. Pp. iv+70. (London: E. and F. N. Spon, Ltd.; Simpkin, Marshall and Co., Ltd.; New York: Spon and Chamberlain; Birmingham: Cornish Bros., 1910.) Price 2s. 6d. net.

(1) THE first of these books contains in the space of 240 pages an account of the manipulative methods of chemical experiment, a selection of inorganic and organic preparations, instructions for physical measurements, such as the densities of liquids and vapour densities, qualitative analysis of simple salts, and a selection of volumetric and gravimetric methods. In spite of the large amount of ground which is covered, the work is excellently done, and it is a great advantage to find in a single small volume nearly all that is needed in the way of text-book instruction for the practical work of a course passing well beyond the standard of an intermediate B.Sc. course, and almost up to the standard of the final examination. Such criticisms as may be made refer only to matters of detail, and are not intended to detract from the value of a book which is undoubtedly one of the best that has appeared. It may, however, be noted that the method of making ethylene by means of phosphoric acid, as described by Newth in the Journal of the Chemical Society, is much superior to the older method, in which sulphuric acid was used, and should be generally adopted. The gas-regulator shown on p. 5 is less efficient than those in which toluene is used, and the pyknometer (Fig. 42) shown on p. 98 has been improved by the use of two bulbs instead of one, as recently described by Mr. W. R. Bousfield. In the volumetric work it is to be regretted that only one method of preparing a standard solution (normal Na_2CO_3 from $NaHCO_3$) is given, as the checking of these methods against one another forms an excellent test of the accuracy of the work, and is of far greater value than the estimation of acids and alkalis in variable commercial samples; moreover, the estimation of acids is far more accurate if carried out with the help of a standard acid and intermediate alkali than when a standard alkali is used, as in the former case all the errors which arise from uncertainty as to "end-point," &c., are eliminated.

Amongst the omitted methods are the preparation of standard caustic soda by weighing out sodium, dissolving in alcohol and diluting, and the preparation of standard acid by measuring the density of sulphuric acid of 80 to 90 per cent. strength, and diluting, as described by Marshall in the Journal of the Society of Chemical Industry. In the experience of the present writer these methods, in the hands of students as well as in work of the highest attainable accuracy, lead to exact results more readily than most of those that have been described. In the use of permanganate it is doubtful how far it is safe to rely on the purity of the crystals, and as the solutions are not altogether permanent, it would be well to treat them from the beginning as only approximately correct.

(2) The best guarantee of the quality of the material printed on these cards is the name of the author, whose "Inorganic Chemistry" has almost created a new ideal in elementary text-books. How far the idea of using printed and varnished cards will prove superior to the system of practical text-books is a matter that can only be worked out by actual experience in the laboratory.

(3) In comparison with the majority of text-books of organic chemistry, this volume starts with one great advantage—that the authors have not attempted to make it into a dictionary or table of physical constants. They have, therefore, been enabled to deal in a small volume with an unusually large amount of interesting and "advanced" material, usually reserved for works of a more pretentious character. This is in many respects a distinct advantage. On the other hand, they have omitted almost entirely the details of methods of preparation, and so have conferred on the subject with which they deal a certain impression of unreality, which might easily have been removed. If, however, the student who reads the book is at the same time carrying out a course of organic preparations, the risk that he may come to regard the subject as one of algebra and geometry—only loosely attached to experiment by the necessities of verification—will be removed, and the book may then prove both useful and suggestive.

(4) The use of numerical examples is an excellent way of impressing upon a student the meaning of equivalents, vapour densities, molecular and atomic weights; it is also necessary in order to secure accuracy in the calculation of analytical results, especially if this is to be done correctly under the hurried and somewhat unpractical conditions of a "practical examination." This need the author has attempted with some measure of success to supply. The chief fault of the book arises from the fact that most of his examples appear to have originated in the study instead of in the laboratory. No chemist would be likely to use in actual work the bewildering array of standard solutions referred to in chapter x., 2N, N, N/2, N/4, N/5, N/6, N/8, N/10, N/20, &c.; neither would anyone who had experience of the subject expect to obtain a theoretical yield of nitric oxide from 7N nitric acid and copper. These and other calculations of a similar character suggest that the author

is merely attempting to teach chemical arithmetic with no regard for the opportunities which arise of teaching chemistry at the same time. The figures actually resulting from the best experiments are so readily accessible that a book which fails to make use of them and substitutes obvious fictions is scarcely to be recommended.

(5) This book of tables is well compiled, and should prove useful, but the printing and binding are not as good as might be desired in view of the small size of the book and the price at which it is issued.

MINERAL SPRINGS AND WELLS OF ESSEX.

A History of the Mineral Waters and Medicinal Springs of the County of Essex. By Miller Christy and Miss May Thresh, with a critical note by W. H. Dalton. Essex Field Club Special Memoirs, vol. iv. Pp. vi+73. (Stratford, Essex: Essex Field Club; London: Simpkin, Marshall and Co., Ltd., 1910.) Price 2*s.* 6*d.* net.

THIS work forms vol. iv. of the Essex Field Club Special Memoirs, and has been reprinted from the *Essex Naturalist*, with additions. As in most other English counties, there are in Essex a number of springs and wells that have attained notoriety as mineral or medicinal waters, and the authors have done well to prepare a full and precise account of them.

The earliest record is of a spring at Wanstead, which was regarded as a spa in 1619, but has long been lost to sight. Witham, Chigwell Row, and Upminster had mineral waters that were formerly reputed to be of medicinal value. No information is available concerning the particular constituents of the Witham Spa; the water of Chigwell Row was purgative, but of no importance; while that of Upminster contained Epsom salts. Tilbury water, obtained from a well, appears to have been most famous in Essex, but, as the authors remark, the saline ingredients were insufficient to justify its being considered a mineral water. Dr. Richard Russel, however, remarked in 1769 that the water "makes excellent Punch, and is extremely good for Tea." The only genuine mineral waters acknowledged in the present work are those of South Weald, Upminster, and Hockley, which contain as the more prominent ingredient magnesium sulphate. As the authors admit, every so-called mineral spring in Essex, with one exception, is now neglected, and almost forgotten; and as regards the waters in general they consider "that 'faith' was an important, if not the chief, element in the 'cures' they are credited with." Dovercourt Chalybeate Spa, discovered about 1852, is the sole remaining spa, and in a sample of the water sent in 1897 to Dr. J. C. Thresh, he reported that it contained under one grain of iron salts per gallon.

The authors express their indebtedness to Dr. Thresh for assistance in dealing with the Essex waters from a chemical point of view, and to Mr. W. H. Dalton for notes on the strata whence the waters are derived. Reference should have been made to the Bagshot Sands on p. 63, as the waters of Hockley, as well as those of South Weald, are derived from that formation or the passage-beds above the mass of London Clay. There are no deep-seated mineral waters in Essex, but the subject, as shown by the authors, is one of considerable interest, and by no means devoid of scientific importance.

H. B. W.

OUR BOOK SHELF.

(1) *Edible and Poisonous Fungi.* Board of Agriculture and Fisheries. Pp. 28. With 25 coloured plates. (London: His Majesty's Stationery Office, 1910.) Price 1*s.*

(2) *Guide to Mr. Worthington Smith's Drawings of Field and Cultivated Mushrooms and Poisonous or Worthless Fungi often Mistaken for Mushrooms, Exhibited in the Department of Botany, British Museum (Natural History).* Pp. 24. (London: Printed by Order of the Trustees of the British Museum, Natural History, 1910.) Price 1*s.*

(1) THE publication of this pamphlet by the Board of Agriculture and Fisheries is intended doubtless to broaden the "mushroom" diet of country dwellers. Whether this object will be attained depends primarily on the doubtful possibility of creating an interest in a lethargic public, and further, in making quite clear the somewhat abstruse differences between the clean and the unclean. With regard to means of discrimination, reliance is placed on coloured plates and short descriptions, to which are added a few hints on preparation for table. What is distinctly lacking is an attractive general account, with information regarding the kinds exposed for sale in foreign market places, where there is often a considerable variety. The list of edible species does not include either the chantarelle or the truffle, while another notable omission is a warning that individuals vary greatly in their power of digesting fungal ferments.

(2) The pamphlet issuing from the British Museum (Natural History) is valuable both as a scientific exposition by one of our most eminent fungologists and also as an authoritative guide for the use of those interested in mushroom cultivation. The descriptions are semi-popular, and the coloured figures are artistic, accurate and well rendered. The setting of the text, as also the plain directions for detecting the poisonous species, add to the practical utility of the pamphlet, which fulfils one of the chief objects of the Trustees, inasmuch as it provides accurate and useful information for the benefit of the general public.

Fractures and Separated Epiphyses. By A. J. Walton. Pp. vii+288. (London: E. Arnold, 1910.)

IN a short preface the author explains that this book is intended for the use of students and those first commencing hospital appointments, but there is every reason to believe it will prove of great value to practitioners in general. Mr. Walton does not confine himself to advising any one method of treatment, but concisely places before the reader the various treatments advocated, with an open-minded criticism of their several points.

The chapters dealing with the etiology and general methods of treatment are, considering the largeness of the subject, both clearly and shortly dealt with, yet nothing of importance has been omitted. In describing the fractures peculiar to each bone, with their treatment, special attention is given to the dates of union in the various epiphyses, and the injuries which they are liable to sustain. The accompanying illustrations, reproduced from radiographs of fractures seen at the London Hospital, are typical and excellent. The book show great care in preparation, and can be recommended to all who need a short, practical work on this subject.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Gauss and Non-Euclidean Geometry.

PROBABLY someone will before this have directed your attention to a statement in NATURE of June 30 regarding Gauss's share in the discovery of non-Euclidean geometry; but in case this may have escaped notice, even after the lapse of three months, I venture to bring it again before your readers. Speaking of Mannoury's book—"Methodologisches und Philosophisches zur Elementar-mathematik"—"G. B. M." says "there is one remarkable statement made which deserves mention. Dr. Mannoury says that in December, 1818, F. K. Schweikart sent to Gauss a note asserting the existence of a geometry in which the sum of the angles of a triangle is less than two right angles, and in which the altitude of an isosceles triangle with a finite base has a finite upper limit. This goes far to demolish the claim made for Gauss that he was the first to assert the possibility of a consistent system of geometry distinct from Euclid."

The story of Gauss and the non-Euclidean geometry will probably always be incomplete, as he never published his investigations on this subject, and what is known of them has been gleaned from his correspondence and some notes only recently found among his papers (cf. Gauss, "Werke," Bd. viii., Leipzig, 1900). But neither Engel nor Stackel—to whom we owe much of what has been written on the theory of parallels—nor any of the other writers on this phase of non-Euclidean geometry, have asserted that Gauss ever published any statement of his theory, large or small. The most that has been claimed for Gauss is that before Lobatschewsky, in 1826, and Bolyai, in 1832, published their statement of the geometry which will always be associated with their names, also even before Schweikart in 1818 had drawn up the note to which reference is made above, Gauss himself was convinced of the logical possibility of a geometry independent of the fifth postulate, and had mentioned many of his conclusions to his friends, verbally or in writing.

What happened with reference to Schweikart is well known. The whole story is to be found in Gauss's letter of 1819 to Gerling, by whom the memorandum had been submitted to Gauss at the request of the author. Like the subject of a recent political controversy, it could be written on half a sheet of notepaper; and it called forth from Gauss the warmest praise. With it he fully agreed. In fact, his results were exactly the same as those he had already obtained. His own work, he added, he had developed so far as to have fully solved all the problems of the new geometry. Some of his results he sent to Gerling to be communicated to Schweikart himself.

It is not of much importance whether before this date we have any reference to these investigations; but such is actually forthcoming in Wachter's letter to Gauss two years earlier, where he speaks of their conversation at Göttingen, and wonders "whether the anti-Euclidean geometry or your geometry is true."

And more valuable, as showing Gauss's real position, is his well-known letter to Wolfgang Bolyai in 1832, when he had received from him a copy of Johann's famous work:—"If I begin by saying that I cannot praise this work [of Johann's] you will assuredly be surprised for a moment. But I cannot say anything else. To praise it would be to praise myself. In fact, the whole contents of this work, the path which your son has followed, and the results to which he has been led, agree almost completely with my own meditations on this subject, some of them as old as thirty to thirty-five years."

This is but one of several statements of the same kind which we find in the correspondence of Gauss now available. Still, he would have been the last person to assert any claim for himself in the matter. Indeed, it was "a very great pleasure to him that it was actually the son of his old friend who had made this advance upon him in such a remarkable fashion." Yet there is ample evidence that the ideas contained in Schweikart's memorandum were already known to him, and that with much of the work of Lobatschewsky and Bolyai he was familiar long before they themselves had made these discoveries. To them belongs the independent discovery of their geometry, and its complete and systematic development. By their names it will always be called. To Schweikart, to a small extent, to Gauss to a much larger, can be given the credit of having realised that, along the path which Lobatschewsky and Bolyai travelled, complete success was bound to be achieved.

H. S. CARSLAW.

The University, Sydney, August 10.

An Oblique Belt on Jupiter.

OWING in the main part to the swift axial rotation of the planet Jupiter, it is usual to find the dark belts, which constitute the principal configuration of his visible surface, lying both parallel to one another and to the planet's equator. An instance of obliquity of one of the bands relatively to the others is rare, and a most definite and striking example of the kind was recorded in the northern hemisphere in 1860. A recent phenomenon akin to this was observed in the spring months of the present year. Although in this case the band was a faint one, yet the marked trend which it exhibited called for special notice, and the more important facts relating to it might be briefly recorded here.

It attracted my attention, when engaged in a systematic study of the planet, first on April 1, and was subsequently observed on the following nights:—April 6, 8, 23, 28, May 2 and 7. After the last-mentioned date it was not seen again, partly on account of its growing faintness, and partly because the prevailing telescopic seeing was not inducive to a close scrutiny of the planet. During this observed interval a number of careful drawings of the region in question were executed, as well as a series of central-meridian transits of spots situated in and around the slanting belt. Some of these spots had been watched several months[1] prior to the appearance of this belt, so that the rotational velocity of the surface matter in this particular region was, on the whole, fairly accurately ascertained.

The oblique belt, which was a new formation, stretched itself across the white zone between the S. temperate and S.S. temperate belts. Nowhere, however, did it coalesce with these two belts, a point which can be better understood from the accompanying drawings than from a description alone. Its separate existence was due, evidently, to a repulsive action exerted upon it by the belts, which seemed to form a barrier against any further displacement in latitude.

The region of the oblique belt could always be readily recognised, even under poor definition, by reason of an abnormal dark patch of matter which occupied the site where the oblique belt crossed over the central part of the zone in which it was situated. This patch presented a concave outline both east and west, and the oblique belt passed uninterruptedly through it. A white spot (*c*) preceded it, and a fainter one was at times seen on the following side. This curious patch became visible earlier than did the oblique belt, and its greater durability enabled it to remain in view long after the belt had ceased to be visible.

The quicker drift of the spots A and B relatively to E, F, and G will be noticed in the drawings. The dark patch, with its condensation D, was carried along at about the same rate of velocity as A and B, and all, therefore, participated in one and the same current. The white spot C drifted at the same rate as the spots E, F, G, and, as will be noted, it was being gradually overtaken by the dark patch. Thus we observe the relative movements of two independent currents. They disclosed the noteworthy fact that the dark patch was in reality a distended part of the current about A and B, having evidently forced its way northwards across the slower current round C to the spots E, F, G. The condensation D formed part of the oblique belt. Whether the rest of this belt participated in the quick current of A and B is not known; but if such was really the case, we have here at least a clue as to the cause of the curious trend of the belt. The material of a

[1] Opposition of Jupiter occurred on March 31, 1910.

quick current often trespasses upon a slower moving one, a fact which is manifested by wispy shadings and spots protruding considerably into an adjacent current. Such an intrusion of matter might have occurred in the region of the S.S. temperate belt, and by continuing its northerly course slowly but interruptedly, its rapid westerly drift combined would cause it to drift in a W.N.W. direction. The result would be for the matter to form a slanting streak across the disc, and it is possible, and not improbable, that the oblique belt under discussion has found its origin through a similar cause.

An Oblique Belt in Jupiter, 1910.

The movements of the seven spots lettered in the drawings are tabulated as under:—

Name of spot	First and last date of observation	Average monthly drift (3 days)[1]	Rotation period h. m. s.	
A	1910, Feb. 9 / 1910, May 7	+28·5	9 55 2·8	Current I.
B	1910, April 1 / 1910, May 7	+31·0	9 54 59·5	Current I.
D	1910, April 1 / 1910, May 7	+28·5	9 55 2·8	Current I.
C	1910, Jan. 16 / 1910, April 23	+17·0	9 55 18·1	Current II.
E	1910, March 5 / 1910, April 23	+15·8	9 55 19·7	Current II.
F	1909, Dec. 13 / 1910, April 23	+14·3	9 55 21·7	Current II.
G	1909, Dec. 30 / 1910, April 1	+17·5	9 55 17·4	Current II.

The oblique belt was situated on the opposite side of the planet to the red spot, and the longitudes of the condensation D might be given here:—

1910	1910
April 1 = 169°·2	April 23 = 146°·9
„ 6 = 161·6	May 2 = 140·2
„ 8 = 156·1	„ 7 = 133·4

Tests for Colour-vision.

AN article in NATURE for August 18 deals aptly with the question of testing for colour-vision. It is to be hoped that the committee at present inquiring into the matter will advocate that testing should be carried out in future in conditions resembling as nearly as possible those on which seamen ordinarily follow their calling. It does not seem quite practical or fair to test indoors a man's ability to pick up lights in the open. The conditions of light inside and outside vary so much, as do those of inside and outside darkness. A sailor's business is not to match colours, but to pick up and distinguish instantly lights that may be seen, far or near, through varying conditions of atmosphere.

The sight of the average seaman, from practice, is probably much keener than that of the average landsman. The sailor's eyes are trained to adapt themselves to varying conditions of outside darkness.

The suggestion of spectrum tests is good, provided that such testing is made supplementary only to the practical open-air tests with flags by day and sidelights by night. The object of the tests is to ascertain the candidate's faculty for instant recognition of a flag or light, and there is no difficulty whatever in providing efficient practical tests. It is unnecessary, and even mischievous, to try to puzzle a candidate with combinations of lights and shades such as never occur in the course of his practical work.

It is to be hoped that the committee which is investigating the matter will allow common sense and practical ability to rule its recommendations for future examinations. D. WILSON-BARKER.

Fireball of September 2.

THE remark in NATURE of September 8 (p. 318), as to the necessity of further observations for determining the height and velocity of meteors encourages me to send the following note:—

At 9.5 p.m. on September 2, from Earlstone Common, four miles south of Newbury, I had a good view of the meteor described by the Rev. J. C. W. Herschel as seen from near Wellington College. I have seen brighter meteors, but never one that remained so long in sight, and its course was marked for a long way by a streak of light, showing very clearly the route it had taken. When I first caught sight of it, it appeared to be rising in the sky, through the Camelopard, and it passed almost exactly over β and γ of the Little Bear, over η Draconis, between π and ρ Herculis, and over α Ophiuchi, vanishing perhaps 15 degrees further south in the Serpent. Rising and falling in its flight like a thrown cricket-ball, it seemed to be quite close at hand.

EDMUND J. WEBB.

Burghclere, Newbury, September 9.

MR. EDMUND J. WEBB's highly interesting account of the fireball of September 2, in conjunction with other descriptions which have now come to hand, enable the real path to be well determined.

The radiant point of the meteor was near β Aurigæ, or at about $87°+41°$, and the height of the object from about 98 to 44 miles from over the North Sea to S.S.W. coast of England. The meteor had an unusually long flight right across the country from N.N.E. to S.S.W., and its visible course of 352 miles was probably traversed at a velocity of 40 miles per second. It is only rarely that a fireball is seen in this country with such an extended trajectory. Most of the observers only saw a part of the path. The radiant was near the horizon in N.N.E.

The fireball was seen by the Rev. F. C. Lees, Sutton, Surrey; Rev. C. L. Tweedale, Otley, Yorks; Col. E. E. Markwick, Boscombe, Hants; and many other observers.

W. F. DENNING.

The Law of Definite Proportions.

PERHAPS a reader of NATURE will be good enough to solve the following question.

If an amount of heat is supplied to a volume of ice, water, and vapour *at* the triple point, and *remaining at* the triple point, and the same volume, while the heat is being supplied, are water and vapour formed in definite relative proportions from the ice? That is, is the ratio of vapour to water independent of the amount of heat supplied, or of the original proportions of the three phases?

C. E.

King Edward VII. School, Sheffield.

FIRE TESTS WITH TEXTILES.[1]

THE frequent accidents caused by the ignition of highly inflammable wearing apparel have directed wide attention to the possibility, by suitable treatment, of rendering materials like flannelette non-inflammable. The interest aroused by the subject is further increased by the fact that most of the fatal accidents occur to very young children, and apparently the number of such accidents is not diminishing.

Thanks must be given to the British Fire Prevention Committee for the efforts being made to investigate the subject in a thoroughly scientific manner, and for the report before us, which contains the results of experiments on 456 samples of cloth. These were divided into the five following groups:—(*a*) Flannelette ("non-flam," commercial); (*b*) flannelette ("non-flam," special); (*c*) flannelette (ordinary); (*d*) "union" (a mixture of cotton and wool); (*e*) flannel; (*f*) flannelette (fine finish). The method of testing employed was briefly as follows:—A yard of the cloth was suspended from three hooks fixed in a beam, the lower edge was kindled by the flame of a wax taper or spirit lamp. At the end of sixty seconds any flame was extinguished, and the portion of material burned carefully measured. In many cases photographs were taken before and after the ignition, and these supply more vivid illustrations of the results than the pages of statistics which follow. In some cases made-up garments were suspended on wire frames and tested as before. The different samples were also tested before and after repeated washings. Manifestly this is a point of great importance, and it was proved that in the case of "non-flam" materials there was practically no difference as regards fire resistance between samples washed once and those washed twenty times.

The general nature of the results may be briefly stated. Unquestionably the flannelette known as "non-flam" justifies its name. Samples of this material are only charred where they have been in contact with the flame; they are non-inflammable.

Ordinary flannelette as received from the manufacturer burned up through the centre of the sample,

(*a*) (*b*)

Demonstration Tests with Garments: (*a*) Flannelette ("Non Flam Commercial) at 120 seconds. (*b*) Flannelette (Ordinary) at 60 seconds.—From "Fire Tests with Textiles."

and from 25 to 40 per cent. of the material was consumed, while after *one washing* from 92 to 100 per cent. was destroyed. The material known as "union," a mixture of cotton and wool, as might be expected, is less inflammable than flannelette; from 57 to 66 per cent. of the material, after one washing, was burnt.

In the case of flannel the charring only reached as far as the power of the flame extended. Lastly, the flannelette (fine surface) is shown to be very like the ordinary, and in many cases the sample was completely consumed. This investigation appears to have been carefully conducted, and the report should be widely circulated. The illustrations explain themselves: (*a*) a "non-flam," made-up garment, after 120 seconds; (*b*) a made-up garment, ordinary flannelette, after 60 seconds.

[1] Fire Tests with Textiles. Flannelette known as "Non-Flam" Flannelette, Ordinary Flannelette, "Union" Flannelette submitted for test by Messrs. Whipp Bros. and Tod, Ltd., Manchester. The Committee's Report, pp. 48 ("Red Books" of the British Fire Prevention Committee, No. 148.) (London: The British Fire Prevention Committee, 1910.) Price 5s.

THE CASTES AND TRIBES OF SOUTHERN INDIA.[1]

THIS, if not quite the most workmanlike, may justly claim to be the most voluminous contribution to the publications of the Ethnographical Survey of India. The facts for which Mr. Thurston is personally responsible were collected in a series of tours throughout the Madras Presidency, in which he was able to combine the collection of specimens for the museum under his charge with a considerable amount of original work. He gives a lively account of the difficulties which he experienced in examining and measuring the shy jungle folk in whom he was most deeply interested; and the combined tact and enthusiasm with which he conducted these inquiries deserve hearty recognition. With his own personal investigations he has combined contributions from other writers, among whom the work of Mr. F. Fawcett, much of which is already familiar to students of the periodical bulletins of the Madras Museum, is the most valuable. To these have been added numerous extracts from census reports, district manuals, and similar literature; and the large series of excellent photographs adds largely to the interest and value of the work.

It is, however, to be regretted that, apparently from pressure of other duties, Mr. Thurston has been unable to arrange this great mass of material in a form suited to the needs of students. The articles contain much undigested material, and little has been done to classify this in a series of well-ordered paragraphs, each provided with a marginal heading, and bringing together the accounts of tribal organisation, domestic ceremonies, religious beliefs, and the like. It is obvious that the bulk of the work might have been much reduced by judicious compression; and, as native States like Mysore and Cochin are engaged in ethnographical surveys of their own population, it was unnecessary to give more than references to their preliminary bulletins. There is nothing in the shape of a subject-index; and though a good start was made by Mr. W. Francis in his report on the census of 1901 to compile a bibliography of the literature of the subject, Mr. Thurston has done nothing to supplement it. A protest must also be made against the habit of the writer, which has already greatly impaired the value of his useful "Ethnographic Notes on Southern India," published four years ago, of giving in the notes merely the names of his authorities without precise references. This gives a slovenly appearance to the work which it otherwise does not deserve.

We might also have expected from the author an exposition of his views on the prehistoric ethnology of the province. The Dravidian question is always with us, and though he supplies some facts which may assist in its solution, his personal views on the subject are nowhere definitely stated; and he seems to have abandoned in despair any attempt to indicate how far the existing jungle tribes are related to that remarkable people who reared the great series of megalithic monuments which abound on the Nilgiri plateau, the relics from which, excavated by Mr. Breeks and others, form the most interesting collection in the museum under his charge. Two important facts, however, can be gathered from his notes on the physical characteristics of the people; first, that the primitive Negrito element is not so widely distributed as some authorities have assumed. It is not apparent among the Kotas and Badagas, who seem to be later immigrants into the hill country from the plains, and it is found only among the more primitive tribes, like the Irulas and Kurumbas. Even among them it is important to note that prognathism and wooliness of hair appear as aberrant characters. In the second place, when we speak of the Dravidian head form, we must remember that it is not consistently uniform throughout the Presidency. Whatever may be the causes of this variance of type—the influence of environment or miscegenation—about which Mr. Thurston, with his characteristic caution, declines to express an opinion, it is certain that the type in the northern district is subbrachycephalic or mesaticephalic, while it is only in the Tamil and Malayalim countries that we find it to be dolicho- or subdolicho-cephalic.

The chief interest in the ethnography of southern India lies in the startling variances of culture which appear throughout the population. For an example of what is apparently the lowest type, we may turn to the Yānādis, a dark-skinned, platyrhine, under-

FIG. 1.—Toda Woman. From "Castes and Tribes of Southern India."

sized tribe inhabiting the Telugu country. Their religion is a crude form of animism; they make fire by friction; eat their food almost raw, merely scorching or warming the flesh of the animals which they kill; and yet, with the curious inconsistency which pervades the Hindu social system, they are regarded by the higher classes as gentlemen of the forest, are allowed to draw water from wells used by high-caste people, and may carry it to Brahmans. In direct contrast to them we may refer to the Nāyādis, a tribe in the plains little higher in culture than the Yānādis, who live by collecting jungle products, and are regarded as so impure that in their begging rounds they are compelled to stand at a distance from respectable houses, and to make their appeals for charity in stentorian tones.

A higher type of culture is reached in the Badagas, the agriculturists of the hills, where the pastoral element is represented by the Todas, and the industrial

by the Kotas. Mr. Thurston's account of these people forms one of the best articles in his work. They live in dread of the more savage Kurumbas, by origin

FIG. 2.—Nāyādis making Fire. From "Castes and Tribes of Southern India."

Negritos, who, like many other secluded races, are supposed to possess the power of necromancy. Every Badaga family pays them a sort of retaining fee in the shape of an annual tax and special dues at funeral and pregnancy rites, in return for which the Kurumba is bound to treat cases of diabolical possession or of the evil eye by means of appropriate spells. But the Kurumba needs to be cautious in exercising these uncanny powers, for instances are quoted of cases in which he has been suspected of unfair dealing, and "his hut is surrounded at night, and the entire household massacred in cold blood and their houses set on fire."

At the head of the social system stand the Brahman and the Toda. The entry of both into the social system of south India is comparatively modern. Mr. Lewis Rice, in his recent summary of the epigraphical evidence from Mysore and Coorg, finds that there is no record of Brahmans in those regions before the second century of our era; and other authorities, like that great scholar, the late Dr. Burnell, fix their migration from the north at even a later date. This fact accounts for two interesting characteristics of religious and social life. The Brahman being a newcomer, and not, as in northern India, evolved from the family priests of the invading tribes from Central Asia, reached the south with all his tabus and restrictions well established, and these were intensified by contact with the non-Aryan tribes, who were regarded as quite outside the pale of orthodoxy. The result was twofold. In the first place, the line of distinction between the Brahman and the outcast was more clearly marked than in the north; and, secondly, south Indian Brahmanism, affected by its environment, and saved from the disturbing influences of cataclysms to which it was exposed in north India from the successive invasions of foreign tribes like Scythians, Huns, and Mongols, was permitted to develop on lines peculiar to itself, and thus assumed a character very different from that which it displays in the Panjab, the Gangetic Valley, and the Delta of Bengal.

The special characteristics of south Indian Brahmanism are most effectively illustrated by Mr. Fawcett's excellent account of the Nambutiris of Malabar, with their intense craving after what they deem personal purity, their elaborate system of tabus, and their placid, reflective life spent in an endless round of elaborate ceremonial and devotion to the study of the Sanskrit Scriptures. In these respects they hold a position unique among the Brahmans of India, and the remarkable phase of religious and social life illustrated by them deserves attentive study.

Even more interesting is that remarkable race, the Todas. Mr. Thurston has wisely referred his readers to the exhaustive monograph on this tribe by Dr. W. H. R. Rivers, an excellent example of the successful application of the intensive methods of study

FIG. 3.—Yānādis. From "Castes and Tribes of Southern India."

applied to one of the smaller groups. Mainly on the ground of the exceptional hairiness observable in the Nambutiri Brahmans, he is inclined to accept the brilliant suggestion made by Dr. Rivers from a study of their emigrations preserved by the tribe, that the Todas are comparatively new arrivals in the Nilgiri plateau, and that they are connected in race with the Malabar group of Brahmans. Mr. Thurston records a curious fact which escaped the observation of Dr. Rivers, that their extreme reverence for the herd of sacred buffaloes is shown by the rule that when the animals are driven from one grazing ground to another, the women of the tribe are not permitted to tread upon the track of the holy beasts, but must be lifted over it by the men of the tribe.

In spite of the imperfections in the literary arrangement of his work, to which we have directed attention, Mr. Thurston's volumes constitute a monumental record of varied phases of south Indian tribal life, the traditions, manners, and customs of the people. Though in some respects it may be corrected or supplemented by future research, it will long retain its value as an example of out-of-door investigation, and will remain a veritable mine of information, which will be of value to his fellow-officers in acquiring a knowledge of the people, and a storehouse from which the armchair ethnologist will draw abundant facts of the highest value and interest.

A HISTORY OF BIRDS.[1]

OF the series of four volumes to be published under the title of "Animal Life: an Evolutionary Natural History," the editor, Mr. Pycraft, has himself contributed that on birds. The reader will at once be struck by two facts, first, that the subject is treated from the point of view of the evolutionist, as opposed to that of the systematist, and, secondly, that the author is never satisfied until he has inquired into, and, if possible, explained, the various phenomena that meet the eye of the ornithologist. As he tells us in his preface, and as we gather from the excellent introduction by Sir Ray Lankester, which practically summarises the whole work, the study of birds is here presented as one of living organisms, moulded in part by an inherent constitution, and in part by the struggle for existence.

A great array of facts is marshalled in order before us, and presented in attractive fashion, while Mr. Pycraft's well-known skill is particularly evident in the osteology and pterylography; but we must confess that he seems to us somewhat hard upon the "field-naturalist," the results of whose labours he terms "a pitifully small gain to science." It is true that such an one often lacks the training or opportunity necessary for scientific research, but his province is more especially to supply material for the work of his fellows, and must never forget that Darwin and Wallace—not to mention later instances—were essentially field-naturalists.

[1] "A History of Birds." By W. P. Pycraft. With an introduction by Sir Ray Lankester, K.C.B., F.R.S. Pp. xxx+458. (London: Methuen and Co., 1910.) Price 10s. 6d. net

The volume begins with a brief but sufficient summary of the general structure of birds, and proceeds to consider their phylogeny, their relationship to reptiles, and their development from climbing arboreal forms to those endowed with full powers of flight. The writer's views on this part of the subject are clearly shown by a "genealogical tree," while a woodcut is given of one of the hypothetical primitive types, or pro-aves.

From the ancestral forms of birds we pass on to a sketch of their present distribution and of the generally accepted zoo-geographical regions. Mr. Pycraft accepts the theory that the entire class originated in the northern hemisphere, with the possible exception of the Sphenisci; but the close connection of the latter in his tree of descent with the decidedly northern Colymbi seems to run counter to this contention.

Environment and its effects next come under discussion, with selected examples of adaptation to the surroundings. Here we find the view definitely adopted that a moist atmosphere leads to darker pigmentation and a dry atmosphere to lighter tints, but we are not inclined to follow our author implicitly here without further proof.

Emperor Penguin brooding its Young. From "A History of Birds."

Migration is always an interesting subject, and we concur with Mr. Pycraft in paying little attention to very precise "lines of flight"; whether, however, he is right in holding that the trend of migration is due north and south, apart from physical obstructions, is a much more debatable question.

The interrelations of birds and other animals, and their connections with plants, form the subject-matter of three well-written chapters, while an account of the relations between the sexes is not only instructive in itself, but naturally leads us on to the theory of sexual selection. The "displays" of various species, the pugnacity of the males, and so forth, are set forth at due length; but, on the whole, our author minimises the importance of sexual as opposed to natural selection, and believes that the latter, working on the discontinuous variations which undoubtedly occur, tends to preserve those varieties which finally persist.

Nidification and incubation, eggs and young, and the care of the latter, are next considered, while Mr. Pycraft has much to tell us of what we may learn from the immature bird, whether in the embryonic stage or otherwise, of its precocity or helplessness, its downy condition, its seasonal changes, and its differences from the adult. We notice that he thinks that nest-building is "a product of selection and is instinctive," and that all eggs were perhaps originally white and assumed protective coloration only where necessary.

Artificial varieties and the question of inheritance of acquired characters are treated by the author at some length, while his natural bent towards anatomy enables him to deal fully and successfully with the interesting and important subjects of structural and functional adaptations, and to conclude a work, which we heartily commend to our readers, with a detailed account of various instances of homoplasy.

The numerous illustrations, some of which are new, add much to the value of the book.

REFORMS OF THE CALENDAR.

IN the August number of *Himmel und Erde*, Prof. Förster has a paper on calendar reform, on which, though it is rather discursive, a few words may be of interest. The main point of the paper is to suggest that the International Congress of Chambers of Commerce should take up the question of altering the rule for keeping Easter, which has, from the beginning of the Christian Church, been regulated by luni-solar chronology. That sort of chronology was observed over a large part of Asia, and is by the Jews to the present day, making the year consist of twelve and thirteen months alternately, the months following the moon. But, of course, this does not make the correspondence exact, and other intercalations were necessary. The old Roman calendar was also luni-solar, the months being made to contain twenty-nine and thirty days alternately, which would give only 354 days in a year, so that an additional or intercalary month had to be inserted in alternate years of varying length.

As Dr. Förster remarks, the old Roman calendar had degenerated into a true monster of chronological complication ("zu einem wahren Monstrum von chronologischer Verwirrung"), when it occurred to Julius Cæsar that it would be best to discard the moon altogether as a time-measurement and regulate the calendar by the sun, as had been done in the old Egyptian chronology, a country in which the annual overflow of the Nile was of surpassing importance, and, of course, depended on the solar season.

Cæsar had no occasion to trouble about the days of the week in his calendar. All European nations have followed in the main his calendar, but have had to make a special case of the great Easter festival and the ecclesiastical dates depending on it. But there is no real necessity for falling back upon a Jewish or luni-solar method of reckoning in this respect.

In the years 1872 and 1873 the Rev. J. Newland Smith, of Greenwich, published and distributed two pamphlets on "Eastertide," pointing out that the present complicated rule for keeping Easter was not fixed by any Church regulation; the Council of Nicæa having only decided that it should always be kept on a Sunday. Had Mr. Newland Smith lived (he died in 1880) he hoped that a Bill would have been introduced into Parliament on the question. The proposal in his first pamphlet was that Easter should be kept either on April 9 (that being one probable date of the first Easter day), if that day were a Sunday, or, if not, on the following Sunday; in the second, that it should be always kept on the second Sunday in April, which would include the 9th.

Dr. Förster, in the article before us, makes a similar proposition, which he commends to the International Congress of Chambers of Commerce, that Easter should be kept on the Sunday following April 4, so that it would always fall between the 5th and 11th.

He hopes that other changes may be effected in the calendar, and particularly that the congress may be the means of inducing the Russians and the Greek Church generally to follow the Western usage and replace the Julian by the Gregorian calendar, or some modification of it.

Perhaps we may be allowed the suggestion that the dropping of a leap year each 128th year would be both more convenient and more accurate than the existing Gregorian rule.

W. T. L.

THE DYNAMICS OF FÖHN.[1]

MUCH has been written about the dynamics of Föhn, and the general principles involved in it are well understood, yet the processes by which an air current descends and displaces potentially colder air are still somewhat obscure. As in his previous studies of the same subject, Dr. Ficker has followed the method of examining in detail a large number of individual cases. The process is a laborious one, but we agree with the author that it is essential to follow out individual cases if we wish to arrive at a clear understanding of the processes involved. Average results may be very misleading; very probably the condition of things represented by averages never actually occurs.

In all cases examined, Föhn was preceded by typical anticyclonic conditions, with a very stable stratification of the atmosphere. In many instances the valley temperatures were actually lower than those observed simultaneously on the summits. Special attention was given to the time of commencement of Föhn at different stations, which can be accurately determined from thermograph traces. Föhn sets in earliest at the high stations at the head of the valleys, and makes its way gradually to lower levels. Stations at the same altitude experience the onset of Föhn approximately simultaneously, even though they be in different valleys. In a few instances, Föhn made its appearance at Hachlaching, a station near Munich, on the Bavarian plateau, but on all such occasions the outbreak occurred there long after Föhn had established itself in the higher valleys. The suggestion that barometric minima skirting the north-west coast of Europe exert an aspirating action on the lower strata of the atmosphere, and so cause the Föhn, thus falls to the ground.

Local conditions determine the outbreak of Föhn. During the continuance of anticyclonic conditions the valleys become filled with a mass of more or less stagnant air, cold, at any rate in winter, by reason of its contact with the mountain sides, which are chilled by radiation. Above this we find a region of potentially warmer air, and at the junction of the two layers there is often a sudden actual increase of temperature with altitude. The cold air drains away to lower levels. This process is accompanied by a gradual rise of temperature, but the winds associated with it cannot be regarded as true Föhn, because the vertical temperature gradient in them is much less

[1] "Innsbrucker Föhnstudien IV. Weitere Beiträge zur Dynamik der Föhns." By Dr. H. v. Ficker. Pp. 61. (Wien: Alfred Holder, 1910.)

than the adiabatic for dry air. The air removed by drainage is replaced by air from above, which flows down the mountain valleys like a river, often with a tumultuous rush. In this descending current, which is the true Föhn, the temperature gradient is that of the dry adiabatic. The onset of Föhn at a given station occurs when the upper level of the cold air sinks to the level of the station.

In their early stages all Föhns are fed by air which has travelled horizontally to the mountain ridges, and then descended on the northern side. There is no evidence of ascent of air on the southern side of the range during this first, or "anticyclonic," stage. If Föhn persists, a condition of things often develops in which there is heavy rain, and a marked absence of diurnal range of temperature on the south side of the Alps, and simultaneously the temperatures are much lower to the south than to the north of the range. We have then unmistakable evidence of the ascent of air on the south and of its subsequent descent on the north of the range. The conditions which determine whether an "anticyclonic" Föhn shall develop into this second or "stationary" stage need further investigation. R. G. K. L.

RESPIRATION AT HIGH ALTITUDES.[1]

PROF R. F. FUCHS, with Dr. Deimler, has confirmed the statement of Zuntz and his co-workers and of Durig, that the oxygen use of the human body during work is greatly increased at altitudes above 3000–4000 metres. While on the Colle d'Olen the O_2 use of Fuchs was only 3 per cent. more than at Erlangen; it was 36 per cent. more on the Capana Regina Margherita.

Fuchs and Deimler lived in the hut on the top of Monte Rosa for some weeks, and proved this point conclusively. This increased use of oxygen explains why most tourists are taken with mountain sickness at altitudes above 3000–4000 metres.

The oxygen needs cannot be supplied by the respiratory and circulatory mechanisms in the face of the falling partial pressure of oxygen, and the high oxygen use. Training and acclimatisation economise the oxygen use, increase the oxygen combining power of the blood, the power of the respiratory and circulating mechanisms.

The respiratory quotient sinks to a very low level, *e.g.* 0·53 after work, while the resting value is only 0·6–0·7 at these high altitudes. To explain this, it is supposed either that glycogen is built out of fat and protein in the body, or that substances are not completely burnt in the body, but are given off as lactic acid in the urine. We know that lactic acid is excreted in the urine after a hard run, when the oxygen used is greater than the supply.

A. Loewy and Franz Müller recently have found that the respiratory quotient is reduced by sea-bathing, *e.g.* from 0·88 at Berlin to 0·73 at the North Sea. The diet was the same. There is some evidence that the protein metabolism is different both in high altitudes and after the sea-bathing, but further work is required to explain the low quotients. Under the special conditions substances, such as proteins and their derivatives, may be oxidised, which share but little in the combustion process of the body. Fuchs suggests that the new building of hæmoglobin may explain partly the high oxygen use and the low respiratory quotient. It is generally agreed that a stay in high altitudes does increase the hæmoglobin of the body. LEONARD HILL.

[1] "Physiologische Studien im Hochgebirge: Versuche über den repiratorischen Stoffwechsel im Hochgebirge." By R. F. Fuchs and T. Deimler. Sitzungsberichte der Physikalish-medizinischen Sozietät in Erlangen. Band 41, 1909.

NOTES.

THE ninth meeting of the International Meteorological Committee will be held in Berlin on Monday next, September 26, and following days. It will be preceded by meetings of the Commission for Terrestrial Magnetism and Atmospheric Electricity, of which General Rykatcheff is president and Dr. A. Schmidt is secretary, and by meetings of the Magnetic Observations Committee of the International Association of Academies. Of other commissions which originated with the International Meteorological Committee, those concerning scientific aëronautics, the correlation of solar and terrestrial changes, a proposed *Système Mondial*, weather telegraphy, and maritime weather signals have held meetings in the past year, and their reports will come up for consideration at Berlin. Among new proposals to be considered is one by Prof. V. Bjerknes, of Christiania, for the organisation and publication of strictly synchronous meteorological hourly observations of the air at the surface and above at a large number of stations, with the view of studying in detail the precise changes that take place. Since the last meeting of the International Meteorological Committee, at Paris in 1907, many changes have taken place in the *personnel* of the committee. Death has removed MM. Lancaster, Pernter, and Eliot, while M. Hepites has resigned his directorship of the Roumanian Meteorological Service, and consequently ceases to be a member of the committee. The new members appointed to fill the vacancies are MM. van Everdingen (Holland), Ryder (Denmark), Trabert (Austria), and G. T. Walker (India). Dr. W. N. Shaw, director of the Meteorological Office, is the president of the committee, and Prof. G. Hellmann, director of the Royal Prussian Meteorological Institute, is the secretary.

MR. R. NEWSTEAD, of the University of Liverpool, who, it will be remembered (see NATURE, June 30, p. 530), was dispatched three months ago to Malta by the Liverpool School of Tropical Medicine to investigate the relation of sand-flies to public health, has now returned. It is understood that in the forthcoming report upon the expedition practical measures for dealing with the various disease-carrying insects in the island will be suggested, Mr. Newstead having brought back a considerable amount of material, not only with reference to sand-flies, but also to other carriers of disease.

THE National Fund Airship, which has just been completed, made its first successful flight at Moisson on September 14. It is a little more than a year ago since Mr. Eric Stuart Bruce, the late honorary secretary of the Aëronautical Society of Great Britain, was asked to visit France to make an exhaustive examination into the various types of dirigibles in connection with the national airship, with the result that the Lebaudy type was selected. This latest Lebaudy airship may certainly be said to be the finest semi-rigid dirigible in the world. It is 337 feet 10 inches long, 39 feet $5\frac{1}{2}$ inches in diameter, and has a gas capacity of 353,165·8 cubic feet. It contains three ballonets. The motive power is derived from two four-cylinder Panhard-Levassor petrol motors of 135 horse-power each. The two propellers are made of wood. Mr. Bruce is now acting as honorary secretary to the test committee of the National Fund Airship.

ATTENTION has from time to time been directed to the flower gardens upon vacant land in the neighbourhood of the Strand. The Selborne Society has been investigating a still more interesting building site in Farringdon Street, scarcely removed from the heart of the city. Although this plot has only been cleared for about two years, no fewer than twenty-eight species of flowering plants and ferns have established themselves upon it. Mosses, liverworts, and others of the more simple plants are also represented. Mr. J. C. Shenstone is preparing a detailed list, which will be published in the October number of the *Selborne Magazine*.

THE council of the Concrete Institute has decided to offer a medal annually for the best paper submitted relating to concrete and its applications.

THE Royal Philosophical Society of Glasgow announces that its Graham medal, awarded for original research in any branch of chemical science, is now open to competition. Particulars as to the award are obtainable from the secretary of the society, 207 Bath Street, Glasgow.

THE Incorporated Institution of Automobile Engineers will hold its opening meeting for the present session on October 12, when the president, Mr. F. W. Lanchester, will deliver an address on "Factors that have Contributed to the Advance of Automobile Engineering, and which Control the Development of the Self-propelled Vehicle."

DR. FREDERICK A. GENTH, jun., a prominent American toxicologist, died on September 1 at Lansdowne, Pennsylvania, at the age of fifty-five. He was a member of several foreign chemical societies, and had held official positions at home in connection with the University of Pennsylvania, the Medico-chirurgical Hospital of Philadelphia, and the State Department of Agriculture.

MR. JOSEPH A. HOLMES, director of the technological branch of the U.S. Geological Survey, has been appointed by President Taft to the directorship of the newly established Bureau of Mines. The functions of the new office will be to investigate and report upon safety appliances, and to inquire into the improvement of the methods of mining in general. Mr. Holmes, who is now in his fifty-first year, was professor of geology and natural history in the University of North Carolina from 1881 to 1891, and State geologist of North Carolina from 1891 to 1904, when he entered the service of the national geological survey. He was chief of the department of mines and metallurgy at the St. Louis Exposition in 1904.

THE death is announced of Prof. William H. Niles, who was professor of geology and geography in the Institute of Technology at Massachusetts from 1871 to 1902, and head of the department of geology at Wellesley College since 1888. Although perhaps best known as a teacher and public lecturer, he was author of papers on glacial phenomena and on the physical geology and geography of Massachusetts. In 1874 he directed attention to natural disturbances which occurred in quarries, whereby anticlinal structures were produced, owing to lateral pressure and the relief caused by the removal of rock. Prof. Niles was president of the Boston Natural History Society from 1892 to 1897. He was born on May 18, 1838, and died on September 13 of this year.

THE death is reported, at the ripe age of eighty-three, of Dr. Charles A. Goessmann, for nearly forty years professor of chemistry at the Massachusetts Agricultural College. A native of Naumburg, he graduated at Göttingen, where he was a favourite student, and afterward the assistant, of Wöhler. A report he had made on the value of sorghum as a source of sugar led to his invitation by a former American fellow-student to become scientific director of a sugar refinery in Philadelphia. After occupying that post from 1857 to 1861, he spent eight years as chemist of the Onondaga salt works, where he made important contributions to the chemistry of brines, meanwhile devoting part of his time to the professorship of chemistry at the Rensselaer Polytechnic Institute at Troy, N.Y. The most valuable part of his life-work was done at the Agricultural College at Amherst, which he made a training ground for agricultural and technical chemists. The State of Massachusetts appointed him also director of its agricultural experiment station and analyst to its board of health. He is credited with having exerted, directly and through his pupils, a powerful influence over the attitude of American agriculturists to scientific education.

WRITING in the *Times* of Friday last, Prof. R. Meldola says that it appears to have been overlooked that Erasmus Darwin, the grandfather of Charles Darwin, besides prophesying the introduction of steam as a motive power, foretold, in the following lines, the advent of aërial navigation :—

"Soon shall thy arm, unconquered steam, afar,
Drag the slow barge and drive the rapid car;
Or on wide waving wings expanded bear
The flying chariot through the streams of air;
Fair crews triumphant leaning from above
Shall wave their fluttering kerchiefs as they move;
Or warrior bands alarm the gaping crowd,
And armies shrink beneath the shadowy cloud."

THE first Universal Races Congress, "to discuss, in the light of modern knowledge and the modern conscience, the general relations subsisting between the peoples of the West and those of the East, between so-called white and so-called coloured peoples, with a view to encouraging between them a fuller understanding, the most friendly feelings, and a heartier cooperation," is to be held, under the presidency of Lord Weardale, in London on July 26–29, 1911. We notice that among the papers to be brought before the congress are the following :—Definition of race, tribe, and nation, by Brajendranath Seal; anthropological view of race, by Prof. v. Luschan; sociological view of race, by Prof. A .Fouillée; the problem of race equality, Mr. G. Spiller; differences in customs and morals and their resistance to rapid change, by Prof. G. Sergi; intellectual standing of different races and their respective opportunities for culture, by Mr. J. Gray; inter-racial marriage, by Dr. J. Deniker.

THE report for the past year of the Madras Government Museum, so long associated with the reports and bulletins issued by Mr. E. Thurston, now appears under the signature of his successor, Mr. J. R. Henderson. The most important addition during the year was the establishment of the marine aquarium, of which a description appeared in these columns (February 3). This is now stocked with fish and other marine forms of life collected on the coast, and forms a most attractive exhibit. Numerous accessions to the numismatic cabinet are recorded, the most important being a Roman *denarius* attributed to Quintus Cassius Longinus (B.C. 60), and a second to the Emperor Augustus. These furnish additional corroboration of the importance of the sea trade between Rome and southern India during this period. The present specimens were unearthed in the Coimbatore district.

THE last issue (vol. v., part v.) of the Archæological Publication of the University of California is devoted to an account of the Chimariko tribe of Indians inhabiting Trinity County, in north California. They first came into contact with the whites early in the last century; but their final destruction began with the sudden eruption of gold miners in the early 'fifties, by whom they were overwhelmed and dispersed. The information now collected was obtained by Mr. R. B. Dixon from a woman, the sole survivor of the tribe, and from a male member of a neighbouring group who was well acquainted with their language and customs. They seem never to have assimilated their culture to that of the neighbouring powerful Huba tribe, and it has been suggested, with some degree of probability, that they were a branch of the Shastan stock, which advanced from the north in a south-westerly direction, and with which they exhibit in their mythology certain resemblances. All the scanty available information about their culture and language has now been adequately collected by Mr. Dixon.

MESSRS. DULAU AND CO., LTD., have published in the series of Drapers' Company Research Memoirs a study of the mortality of the tuberculous in relation to sanatorium treatment, by Mr. W. Palin Elderton and Mr. S. J. Perry. The method adopted is to compare the number of deaths observed amongst the tuberculous with the number that would be expected on the basis of the English life-table (1) for patients of certain sanatoria, (2) for Pollock and Williams's cases, which were observed before the days of sanatorium treatment. The authors show that the mortality of tuberculous patients who are undergoing or have undergone treatment is much heavier than that of the general population, and the mortality even of the apparently cured cases is about twice as heavy. The mortality of sanatorium patients does not show any improvement on that of Williams and Pollock's cases, but comparison is difficult, owing to the way in which the older figures were given. It is precisely this comparison, however, which is of importance. The fact that the mortality of sanatorium patients is greater than that of the general population has no bearing on the real question at issue, for even a perfect cure of tuberculosis could surely not be expected, as an incidental result, to turn a weakling into a strong man, nor to render the mortality of the highly selected population in question the same as that of the population at large.

IN the report of the Warrington Museum for the year ending on June 30 last, attention is directed to the large number of donations received, which included 2436 specimens, as against 1645 in the previous twelvemonth.

IN the September number of the *Selborne Magazine* Mr. E. G. Woodd states that an additional protected area for birds has recently been established by the County Council in east Sussex. The area extends from Eastbourne to Hastings, and inland so far as Lewes, and within these limits such birds and their eggs as specially need protection have been scheduled.

WE have received the report of the Sarawak Museum for 1908–9, in which it is announced that Mr. J. Hewitt has been succeeded as curator by Mr. J. C. Moulton. Collecting expeditions have been made to neighbouring districts, which resulted in the addition of interesting specimens, and a catalogue of the birds in the collection was completed during the period under review.

THE International Commission on Zoological Nomenclature has issued through the Smithsonian Institution (Publication No. 1938) a series of twenty-five opinions in regard to matters of dispute in nomenclature. Among many cases, it will perhaps suffice to mention that the committee are in favour of retaining the generic name Simia for the orang-utan.

THE *Entomologists' Monthly Magazine* for September contains a beautifully coloured plate of nine species of rare British beetles, all of small size. According to the authors—Messrs. Champion and Lloyd—of the accompanying notes, one of the most interesting of these is the species named by Dr. Sharp *Eudectus whitei*, of which the single known example was captured by its describer on the summit of Ben-a-Bhuid, Braemar, in the summer of 1871.

A USEFUL catalogue of Danish zoological literature, compiled by Mr. Svend Dahl, has been published by J. B. Lybecker at Copenhagen under the title of "Bibliotheca Danica, 1876–1906." It comprises 262 pages of text, of which 186 are devoted to a list of authors and their works. The manner in which this list is arranged is, however, difficult to understand, as the names are given neither in alphabetical order nor according to date of birth. A specific and subject index to the various papers and books occupies 68 pages, and the volume concludes with an index of authors.

To vol. xii., part ii., of the Proceedings and Transactions of the Nova Scotian Institute of Science, Prof. G. H. Perkins communicates a fully illustrated memoir on cetacean remains from the superficial deposits of Canada. The main object of the communication is a skeleton in the museum at Halifax, discovered about 1873 on the Jacquet River, New Brunswick, which is identified as that of a narwhal (*Monodon monoceros*). Other skeletons, respectively in the museums of MacGill University, Montreal, and Montpelier, belong to the white whale described by Thompson as *Delphinapterus vermontanus*. Whether this is more than a large race of the existing *D. leucas* the author is doubtful.

THE third number of vol. ii. of the Journal of the College of Agriculture, Imperial University of Tokyo, is devoted to entomological subjects, such as Japanese Arctianæ, Panorpidæ, and Mantispidæ, mainly of interest to specialists. Mr. R. Inoue communicates, however, a paper on experiments with silkworms, in which the quantity of mulberry-leaves consumed by the larvæ at different periods of their existence is recorded. Other experiments show that "carbon dioxide, even when pure, has no influence upon the silkworms, and does not act as poison; but when the worms are reared in air containing more than 5 per cent. of the gas they lose their appetite, and their growth is more or less retarded, especially in the earlier stages."

SOME interesting observations on the eyes of trilobites are published by Prof. C. D. Walcott in a paper on Olenellus and other genera of the Mesonacidæ (forming the sixth of a series on Cambrian geology and palæontology), published as No. 6 of vol. liii. of the Smithsonian Miscellaneous Collections. Dr. Lindström expressed the opinion some years ago that all Cambrian trilobites were blind, as he was unable to detect eyes on the upper surface of the cephalon. Such eyes have, however, been detected in one of the American forms by the author, and show the facetted outer surface. It is also suggested that maculæ may occur on the under surface—hypostoma—of the Mesonacidæ, as these have been detected by Lindström in other types. After quoting Prof. A. Agassiz to the effect that trilobites are frequently found lying on their backs, and that young king-crabs (Limulus) often swim and feed in an inverted position, Prof. Walcott suggests that "in all probability the eyes of the hypostoma were of service when the trilobite was lying on its back on the sand or mud, and it was on this account that they were thus developed. It is highly probable that the adult trilobite crawled about the bottom and did not swim freely in the water to the extent that it would be necessary for it to see the bottom. Its habits must have been very much like those of Limulus when in search of food."

WE have received from Mr. J. Wrench Towse, clerk to the Fishmongers' Company, two notices which give useful summaries of the regulations made by Parliament and by the Fisheries Local Committees relative to the seasons for fishing with respect to salmon, trout and char, crabs and lobsters.

A SCHEME for the cultivation in Dalmatia of the spineless variety of cactus raised by Burbank is advocated with considerable reason by Dr. C. C. Hosseus in *Adria* (August), the object being to supply cattle fodder, of which there is a deficiency. The author points out that the natural conditions are favourable, and indicates how the scheme should be inaugurated.

THE details of a Rhododendron producing double flowers in its wild state are given by Dr. M. Miyoshi in the Journal of the College of Science, Imperial University, Tokyo (vol. xxvii., art. 11). The species *Rhododendron brachycarpum* grows in the mountains of central and northern Japan. The anmalous plants shower a second partial or complete corolla whorl. The author notes that double flowers have also been recorded for *Rhododendron ferrugineum* in the Tyrolese Alps, and for *Rhododendron albiflorum* in North America.

MR. C. J. CHAMBERLAIN continues to provide original information regarding the lesser known cycads, his latest contribution, in the *Botanical Gazette* (December, 1909), being a general description of *Dioon spinulosum*, based upon observations made in southern Mexico, where the plants grow in such profusion as to form almost a forest, and the largest specimens attain a height of 16 metres; this species, therefore, in contrast to the short-stemmed *Dioon edule*, supplies the tallest cycads known, with the exception of *Cycas media*. The leaves of an average specimen are about 20 cm. long, and bear more than a hundred pinnæ on either side. The ovulate cones are the largest known for any gymnosperm, as they may weigh as much as 15 kilos, and measure 50 cm. in length by 27 cm. in diameter. No staminate cones were collected in Mexico, but the author describes a specimen received from the Missouri Botanical Garden.

ONE of the most interesting articles in the Transactions of the Scottish Arboricultural Society (vol. xxiii., part ii.) is a contribution by Sir John Stirling-Maxwell giving early results of trials in Inverness-shire with the Belgian system of tree planting on turfs. Intended primarily for afforestation on moors, but also suitable for rough, grass-covered ground, the system consists in turning over turfs, leaving them to dry and sweeten for some months, and then planting in the centre in a heap of soil enriched with a small proportion of basic slag. The young plants take a year to become established, and then grow on quickly. The author also recommends the Sitka spruce, *Picea sitchensis*, for planting at an elevation of about 1000 feet, in which there is agreement with the conclusions communicated in an article by Mr. H. M. Cadell, who considers that it is superior to larch, Scots pine, and Norway spruce for growing in an exposed situation.

DR. A. WILMORE, in a paper in the *Geological Magazine*, 1910, p. 357, has carefully reviewed what is known of the relations of uralite and other secondary amphiboles to their parent minerals. He accepts the possibility of an interchange of material between permeating liquids and an original pyroxene, and does not regard uralite as necessarily an exact paramorph of a pyroxene.

THE geological section of the Belfast Naturalists' Field Club has issued its report for 1909–10 in the Proceedings of the club, and it is clear that a large amount of educational work results from its meetings and excursions. The interesting volcanic neck at Scawt Hill, and a selected series of Cretaceous exposures, have been studied, and a class has been formed under Dr. Dwerryhouse for petrological work. The section is fortunate in continuing to include several members whose contributions involve sound original research.

WE have received the *Bibliotheca Geographica*, issued by the Berlin Gesellschaft für Erdkunde, for the year 1906. This volume, the fifteenth of the series, has been prepared under the editorship of Dr. Otto Baschin; it contains no important changes in general arrangement, but, like all works of the kind, tends to grow in bulk with the ever-increasing volume of the annual output of geographical literature. One of the most characteristic features is the steady increase in the proportion of publications dealing with geographical principles and methods as distinct from purely regional and descriptive matter.

IN vol. xxiii. of the *Annalen des k.k. Naturhistorischen Hofmuseums* Prof. Friedrich Berwerth describes in full detail the meteoric iron which fell on August 1, 1898, near Quesa (39° N., 0° 40′ W.), in the province of Valencia, Spain, and makes an important contribution to the study of the structure of such bodies. Thanks to the generosity of Kommerzialrat J. Weinberger, the entire mass, with the exception of a small piece weighing 30 grams, which had been previously broken off in Spain for use in the investigation of the character of the meteorite, has been added to the fine collection in the Vienna Museum. A slice weighing 375 grams has been cut from it, and the total weight of the mass is now 10,370 grams, 300 grams being lost in cutting. Thanks to its excellent state of preservation, Prof. Berwerth is able to determine that the wedge-like shape of the iron is due to the large development of an octahedron and an icositetrahedron face, the remaining surfaces being three small octahedron faces. He discusses at some length the nature of the depressions—rhegmaglypts (ῥῆγμα, fracture; γλύφειν, engrave) as he terms them—caused by the fierce heat generated by the meteorite's swift rush through the earth's atmosphere; they must not be confused with the hollows due to weathering which are ordinarily seen in irons. The paper is illustrated by reproductions of several excellent photographs.

THE meteorological chart of the North Atlantic for October, issued by the U.S. Weather Bureau, contains an instructive account of the great tropical storm of October, 1909, known as the Key West Hurricane, accompanied by synoptic charts showing the weather conditions over the North Atlantic from October 10–15. The Weather Bureau records verify the general laws of cyclonic movements in the West Indies, announced by the late Father Viñes, that the storms reach further westward as the season advances; they also show that averages of tracks can be given but little weight in forecasting those of individual hurricanes. Observations indicated that a disturbance was developing in the Caribbean Sea on October 2, but the probable course of the storm could not be determined until October 6. On October 9, during its passage over the western part of that sea, a destructive wave swept from the Gulf of Mexico over the low-lying islands and coast of Yucatan. On October 10 the centre of the disturbance had curved and began to move north and north-east, and on October 11 the barometer at Key West (Florida Channel) fell to 28·50 inches, the lowest ever recorded there, and more than 6 inches of rain fell in $2\frac{1}{4}$ hours, the damage being estimated at nearly a million dollars. The Weather Bureau duly warned the seaports of the progress of the storm, and thereby effected great saving of life; on the Florida East Coast Railway, for instance, 3000 workmen were withdrawn from dangerous points; and the vice-president of the line writes:—"Positively not a life was lost in the storm. . . . Warning by the Weather Bureau enabled us to fully protect all employés and equipment."

THE Central Weather Bureau at Melbourne has recently issued an average rainfall map and isohyets of New South Wales, the first of a series now in course of preparation which will include all the States. These maps will be of great economic value in connection with corn-growing and the keeping of all kinds of stock, for which a knowledge of the rainfall is of prime importance. The map in question clearly shows that the greatest rainfall occurs on and adjacent to the Pacific coast, where the annual amounts range from 30 inches in the south to 60 and even 70 inches in the north. The isohyets and grades of shading plainly show the decrease of the rainfall to the westward. If a 15-inch rainfall is sufficient to ensure payable wheat-growing, the map shows that it can safely be done practically as far west as long. 146°, and even further in the south; but, generally speaking, over the country further to the westward, embracing an area of some 122,000 square miles, the rainfall does not reach 15 inches, and is under 10 inches over an area of about 45,000 square miles in the extreme west of the colony. Mr. Hunt points out that the most remarkable feature of the map is the comparatively light rainfall in the district extending from Delegate, in the south, to Yass, about 2° to the northward, owing to the condensation of moisture by the ranges of mountains by which it is enclosed.

DR. H. FRITSCHE, emeritus director of the Pekin Observatory, in a recent work ("Die saecularen Aenderungen der Erdmagnetischen Elemente," Riga, 1910) makes an attempt, to which boldness at least must be conceded, to extend our knowledge of terrestrial magnetism to epochs prior to direct observation. He starts with the assumption that during the last several thousand years there have been no outstandingly large changes in the earth's magnetism—a hypothesis for which much may be said in spite of the deductions drawn by Folgheraiter from the magnetism of Etruscan vases—and that such changes as have occurred can be represented by periodic terms. For these periods he assumes 500, 700, and 900 years, but his reasons for this choice of periods are rather obscure. He attacks the problem by taking as his knowns the values he has calculated from observations for the Gaussian coefficients for the epochs 1575, 1675, 1811, and 1892. Regarding the Gaussian coefficients as expressed by periodic terms with unknown coefficients, he determines the coefficients by reference to the four epochs just mentioned. He thus obtains general expressions from which Gaussian constants are derivable for any given epoch, and he makes use of these for the construction of isogonal charts for the epochs 1200, 1300, 1400, and 1500 A.D. Tables are given for the values of the Gaussian constants extending back to 2700 B.C. Dr. Fritsche's work must have entailed an enormous amount of onerous calculation, but it must be regarded as of an exceptionally speculative character.

IN a communication made to the Institution of Electrical Engineers in April last, which appears in the August number of the Journal of the institution, Mr. W. P. Digby directs attention to the advantages to engineers of tests of the electrical conductivity of the water with which they have to deal. He shows how, with a simplified conductivity tube and a form of "megger" with its scale graduated to give conductivity directly, an engineer may detect immediately a change in the nature of the feed-water for a boiler, or the amount of priming, or the development of a leak in the condensers, and may control with much greater certainty water-softening or oil-eliminating plants. It is only by actual work with the apparatus under workshop conditions that its utility in practice can be tested and established, and it seems well worthy of a thorough trial by engineers.

THE *Engineer* for September 9 contains an illustrated article on the new armoured concrete viaduct at Rotterdam. This viaduct measures 1600 m.—very nearly a mile—in length, and was commenced in 1904, and is composed of many normal bays and bridges of various types. Each pier of a normal bay is composed of four columns supporting the four armoured concrete girders which go to make up the arch. The lower faces of these girders are curved or arched, while the upper faces are flat. The concrete used was composed, for the most part, of 450 kilos. of Portland cement to half a cubic metre of river sand and one cubic metre of gravel, the sizes of the stones in which varied between 5 mm. and 30 mm. in diameter. Under test loads, a 20 m. arch was deflected 3·26 mm., or 1/6140 of the span. A 15 m. arch was deflected 1·57 mm., or 1/9550 of the span. Normal bays not resting on abutments were deflected, as an average, 1 mm., or 1/9770 of the span; normal bays resting on abutments were only deflected 0·6125 mm., or 1/12600 of the span.

AN article in *Engineering* for September 9 contains an interesting discussion on the progress of aviation during the past year. The progress on the more practical side has been much more striking than in the records achieved. The number of machines which will actually fly is enormously greater, and they do so with much less uncertainty. The greatest advance has been made in cross-country flight, and this is of the utmost importance. While flight may now be looked upon as a fair certainty when the weather is really calm, such weather is rare, in this country at all events. Hence the greatest interest attaches to the progress of flight in a wind, and in this direction the advance has been considerable. Cross-country flights are now undertaken in quite strong winds. The aëroplane has, in the last year, ceased to be a mechanical curiosity, which could do little save make exhibition flights in exceptional weather over a prepared track, and has become a practical machine for progress across country. We have therefore now got to the stage when the aëroplane must be reckoned with as a machine which is a practical factor in human life, and, if progress is as rapid in the future as in the past, it will very soon be a most serious factor. Even in its present state, a machine which can travel seventy miles an hour, and fly at such a height that hitting it would be extremely difficult, must have its uses in war, and with increase in the lifting power, speed, and radius of action, these uses must very rapidly augment. Its useful capabilities in time of peace are less easy to foresee; but that a machine which can travel in any direction with the speed of an express train is destined to have an important influence on civilised life is obvious.

OUR ASTRONOMICAL COLUMN.

FURTHER OBSERVATIONS OF HALLEY'S COMET.—In Bulletin No. 20 of the Kadaikánal Observatory Messrs. Michie Smith and John Evershed give an account of the observations of Halley's comet made with various instruments during April and May. A number of photographs, which may fill in the blanks between those taken in America and in Europe, were secured with a 5-inch Grubb portrait lens of 33·8 inches focal length. On certain of these there are many distinct tails and a number of fine details; other plates were exposed in a half-plate Ross camera giving a scale of 1 mm. = 17·5′. Mr. Evershed used a 9¼-inch reflector, of 74 inches focal length, fed by a 16-inch cœlostat, and secured a number of photographs showing the intricacies of the structure in the head, the scale being 1 mm. = 110″.

Spectrograms were also secured, and show the differences between the radiations from the head and those from the tail observed in Daniel's comet 1907*d*; the continuous spectrum of the nucleus shows, faintly, a considerable number of Fraunhoferic lines attributable to reflected sunlight. In the head, the pair of "cyanogen" radiations at λ 3871 and λ 3883 appear to account for at least two-thirds of the total emission, and the preliminary examination shows no essential variation in the spectrum between April 19 and May 15. In the very strong band at λ 4645–4744, five or six separate lines can be distinguished on some of the spectrograms. Visual observations showed that the very bright comet lines in the green and blue could be traced a long distance into the tail and to some considerable distance on the other side of the nucleus.

Notwithstanding the small dispersion (1 mm. = 73 A. at 4227), measurable displacements of the cometary lines, as compared with lines in the spectrum of Venus, were found, and on May 2 gave a relative approach of 77 km. per sec., the ephemeris value being 68 km. per sec.; but to this must be added the recessional velocity of Venus.

The programme for the detection of the comet during transit was very complete, and is described in detail, but, as has been stated before, no trace was found.

Observations of the tail were made by Mr. Evershed, who describes its appearance during May 18–21. He suggests that the persistence of the phenomenon in the east may be explained by supposing the tail to have been very broad in the direction of its motion, although relatively narrow in the direction at right angles to this; with a strong curvature, this would account for the apparent length of time for the earth to make the complete passage.

In the September number of the *Bulletin de la Société astronomique de France* there are reproduced some excellent photographs taken by M. Mascart at Teneriffe, as well as a number of drawings and accounts by various other observers.

Dr. C. D. Perrine, director of the Observatorio Astronómico of the Argentine Republic, writing from Córdoba on August 18, says:—"It will be of interest to your readers to know that we are still observing Halley's comet. It is some 2′ or 3′ in diameter, of about the ninth magnitude, with a nucleus of eleventh magnitude. It is getting so low in the west, however, that we will not be able to follow it much longer."

THE DISTANCES OF RED STARS.—Another contribution to the question of the correlation between spectral type and parallax, in the form of an abstract of a paper read by Dr. H. Norris Russell, appears in No. 195 (vol. xlix.) of the Proceedings of the American Philosophical Society. Dr. Russell compared the parallaxes of stars measured by Mr. Hinks and himself at Cambridge with the spectral types determined at Harvard, and found that the percentage of orange and red stars increases steadily as the distance from our system decreases. Further, a comparison of the observed parallaxes of stars having large proper motions with the parallaxes computed from Kapteyn's formula shows that while the formula stands for the stars of all classes taken together, there are marked deviations when spectra types are considered separately; the observed parallax of the red stars is nearly twice the computed value. As all the stars considered are similar in apparent brightness, it follows that redness is attended by intrinsic faintness, the reddest stars averaging one-fiftieth the brightness of the sun. On the other hand, some bright-red stars, such as Arcturus and Antares, are known to be at great distances, and are probably at least one hundred times as bright as the sun.

This conclusion confirms the important hypothesis (now well established on other grounds) that there are two classes of red stars, one class getting hotter, the other cooling. In the intermediate stages the stars would be hotter, passing through orange and yellow to white, and back to red as it approached extinction.

"MOCK SUNS" AT EASTBOURNE.—From Mrs. A. M. Butler, of Reigate, we have received further particulars of the "mock suns" phenomena referred to in these columns last week as having been seen at Eastbourne on September 10. Mrs. Butler and her daughters watched the phenomena from 12.45 p.m., and saw everything described by Mr. Ronca except the fainter small circle to which the brilliant chromatic curve was tangential. In addition they saw, to the S.E. of the sun, part of another coloured curve, having its convex side turned towards the actual sun. From an effective coloured sketch of the phenomena, drawn by Mrs. Butler, it would appear that this second curve, which was seen at 1.20 p.m., was of about the same radius as the former, and would have barely intersected it had both been continued.

ASTRONOMY IN INDIA.—From the *Pioneer Mail* of August 26 we are pleased to learn that an association for the promotion of astronomy has been formed in India. It is to be known as the Astronomical Society of India, and has its headquarters at Calcutta.

The special objects of the society will be to assist observers by holding meetings, whereat papers will be read and discussed, and by disseminating astronomical news. It is proposed also to found a library of astronomical literature and to publish a journal for each month of the session. The president is Mr. H. G. Tompkins, Treasury Buildings, Calcutta, to whom all communications should be addressed.

THE CRUSADE AGAINST CONSUMPTION.

FOR many years the National Association for the Prevention of Consumption worked away unostentatiously but pertinaciously. The experience gained during these years must now be to them of great value in the educational crusade they have undertaken. During the past year an educational exhibition has been going the round of London, into the provinces, east and west and north, to Oxford, Cambridge, Liverpool, Edinburgh, &c. Nothing has been more gratifying or more promising for the ultimate success of this crusade than the keen interest that has been taken in this exhibition, and in the lectures and conferences by all sorts and conditions of men—and women, too, for that matter. We should, naturally, expect public health authorities to be interested, but all who have seen the audiences gathered together at these lectures and conferences cannot but have been impressed by the intelligent interest taken, even by the very poor, in the question of the prevention of the spread of tuberculosis. Some of the work undertaken by the association at one time appeared to come dangerously near interfering with or overlapping the work of the local medical authorities, and with hospitals and associations already in existence; but through the good sense of those who, though working in different directions, are mutually interested in putting a check on the spread of consumption, the danger of such overlapping is gradually being minimised.

The class amongst which tuberculosis is most prevalent, the badly housed and badly fed, has, up to the present, and very naturally, entertained a suspicion that those who looked upon tuberculosis as an infective disease might interfere too much with the liberty of the tuberculous worker, and by isolating him deprive him of his means of subsistence. Nowhere has the educational campaign done better work than in bringing home to these people the immense importance of observing certain fundamental principles of hygiene, not only in their own immediate interest, but in the interests of those with whom they are most closely associated. It is now well known what precautions tuberculous patients should take, and as soon as this knowledge can be brought to the patient and his friends there will be some chance of getting these precautions adopted. There seems to be little doubt that the National Association for the Prevention of Consumption has the power to help and cooperate with similar organisations already in existence, and that it may even be of assistance to the authorities working with and under the Local Government Board, but what they are best qualified to undertake is, undoubtedly, that national educational movement to which Mr. John Burns has given his official approval.

The carrying on of this movement requires funds, large funds, and a special appeal committee has been formed, which, acting under the presidency of the Earl of Derby, is setting about to collect, in the first instance, a sum of 5000*l.* annually to be devoted to this work. That the necessary fund will be obtained can scarcely be doubted, especially as a most elaborate system of collecting small sums has been organised; moreover, those who will be most immediately benefited are already taking a very keen interest in making this scheme a success, and the committee have announced that they have already received offers of assistance from working-men's clubs and institutes affiliated to the Institute Union, and the Billposters' Association of Great Britain; whilst the post-office authorities have promised assistance, or have granted facilities which will help to form the nucleus of a fund such as could be obtained in no other way. Further, those endowed with a larger share of this world's goods have manifested an equal willingness to help, but the object is such a good one, the outlet for expenditure is so wide, and the promise of such an enormous return is so great, that if five times the sum asked for be subscribed it may be advantageously spent. The time has come when the annual loss of 50,000 or 60,000 lives from consumption—a preventable disease—is a blot on our civilisation. When we *knew not* we could not be blamed for our want of initiative and lack of energy, but now that we *know*, inaction is criminal.

RECENT PAPERS ON PETROLOGY.

UNDER this head may be included work on the minerals that build up rocks, since modern petrology depends on the understanding of the causes that have brought certain mineral constituents into association. This is true even of the fragmental rocks, where the correct appreciation of a detrital mineral may lead up to the source and the relative age of the deposit. Experimental work on minerals has, moreover, almost always a geological aim, though compounds have a way of arising artificially under conditions that seem improbable in nature.

Improvements in methods of research will be found in Mr. F. E. Wright's paper on the "Measurement of Extinction Angles in Thin Section" (*Amer. Journ. Sci.*, vol. xxvi., p. 349), where the intensity of light for different positions of a crystal-plate between crossed nicols is dealt with mathematically. The methods of observation in general use are critically discussed, and the principle of the twinned selenite plate, introduced by Sommerfeldt in 1907, is further developed by the author in his artificial quartz twin plate (p. 374). Since the eyes of observers differ in regard to their sensitiveness to certain tints, this plate may be made wedge-shaped, so that the most serviceable tint may be selected. Mr. Wright also introduces (p. 377) a bi-quartz wedge-plate. A plate of right-handed quartz, cut normal to the optic axis, is fixed side by side with a left-handed one of the same thickness. Above each is set a wedge of quartz of the opposite sign of rotary polarisation, the two wedges tapering in the same direction. Except where the wedge and the plate below it are of the same thickness, the two similar wedges will show colours of similar intensity. If a crystal-plate lies beneath the wedge-plate, and is not in a position of extinction, a difference of intensity appears in the two wedges, and a thickness can be selected that gives, by the rotation produced, the most sensitive effect to meet the case of each experiment.

Dr. J. W. Evans (Proc. Geol. Assoc., vol. xxi., p. 79) gives a useful paper for students on the systematic examination of a thin section of a crystal with an ordinary petrological microscope, in which his double quartz-wedge, described in 1905, is effectively introduced for determining the relative retardation of the rays in a section of a doubly refracting crystal.

Messrs. Allen, White, Wright, and Larsen (*Amer. Journ. Sci.*, vol. xxvii., p. 1) provide a characteristic synthetic study of diopside and its relations to calcium and magnesium metasilicates, in which the minerals produced at various temperatures are subjected to a thorough optical examination. Etch-figures are used to show minute crystallographic changes that result from dissolving one member of the metasilicate series in another, the resulting minerals being shown to be actual solid solutions (p. 39). Some of the substances produced are as yet unknown in nature, and a rhombic $MgSiO_3$ mineral arises at about 1365°, which resembles olivine in form, and which is quite distinct from enstatite (p. 30). The stable form of $MgSiO_3$ is, curiously enough, that known from meteorites only, and is styled clinoenstatite.

Messrs. Wright and Larsen also introduce us to new views on quartz (*ibid.*, p. 421). In treating of quartz as a geologic thermometer, they make use of Le Chatelier's observation in 1890 that quartz undergoes a reversible change at about 575°, as indicated by a sudden change in its expansion-coefficients, birefringence, and circular polarisation. Mügge regards the low temperature α-quartz as trapezohedral-tetartohedral, and the high temperature β-form as probably trapezohedral-hemihedral. "At ordinary temperatures all quartz is α-quartz, but if at any time in its history a particular piece of quartz has passed the inversion point and been heated above 575°, it bears ever afterward marks potentially present which on proper treatment can be made to appear" (p. 425). Quartz formed on the low temperature side, such as that of veins and geodes, shows trigonal trapezohedra, more regular twinning than the β-form (as discovered on etching), more frequent intergrowths of right- and left-handed forms, and an absence of the effects of shattering that appear in quartz cooled down from the high-temperature form. The authors verify these points by an examination of quartz from ordinary veins and from pegmatites.

M. Borisov (*Trav. Soc. imp. des. Nat. de St.-Pétersbourg*, vol. xl., p. 46) describes quartz in druses from the Government of Olonetz; the form is the rhombohedron, with a polar angle reading 85° 47′, so that we have a rare type resembling cubes. Mr. R. S. Bassler (Proc. U.S. Nat. Mus., vol. xxxv., p. 133) traces the remarkable changes by which fossils in the carboniferous limestone of Kentucky have been converted into geodes of chalcedony and quartz, and his photographs alone would claim the attention of petrologists and palæontologists alike.

Students of silicates will note the paper by Messrs. Shepherd, Rankin, and Wright (*Amer. Journ. Sci.*, vol. xxviii., p. 293), on the binary systems of alumina with silica, lime, and magnesia, in which andalusite and sillimatrite receive experimental treatment. A very useful statement is included (p. 322) as to the six phases of crystallised silica now known, the α and β forms, respectively, of quartz, tridymite, and cristobalite. Mr. Larsen (*ibid.*, p. 263) examines the refractive indices and densities of some of his artificially prepared silicates and their glasses. Incidentally, he finds that glasses rich in lime and magnesia cannot be prepared, owing to their strong tendency to produce crystals—a tendency well recognised among basic igneous rocks. Messrs. Washington and Wright (*ibid.*, vol. xxix., p. 52) discover, in a felspar from the Mediterranean islet of Linosa, a molecule corresponding to soda-anorthite, and look forward (p. 70) to naming the actual $Na_2Al_2Si_2O_8$ felspar, when forthcoming, Carnegieite. Since the felspar that they really possess is a new species, and receives the name of Anemousite, it seems quite grasping to look so far ahead, even from the very open windows of the Carnegie Institution.

Mr. F. Cornu (*Verhandl. k. k. Reichsanstalt*, 1909, p. 41), in a preliminary and slightly polemical demonstration, promises an important work on the importance of "Hydrogelen im Mineralreiche" which will need to be considered by all who deal with soils and products of decay. The author claims that our method of heating thin slices in Canada balsam removes the water from essential substances in the case of weathered rocks, and he here opens up a new field, which will, we hope, be promptly cultivated.

M. G. Césaro (*Bull. classe des Sci., Acad. roy. de Belgique*, 1909, p. 435) has made a comprehensive study of the mesotype group of zeolites, including a mesolite from Kenbane Head, co. Antrim (p. 447), once alleged to be galactite. The author (p. 492) ultimately concludes that galactite is a mixture of natrolite and scolezite.

A new light is thrown on nephrite by Prof. Steinmann (*Sitzungsber. niederrhein. Gesell. Nat. u. Heilkunde in Bonn*, 1908, pub. 1909, p. 1), who concludes that the Ligurian examples were originally dykes in the surrounding olivine-rocks, and had the composition of websterite or diopside-rocks. The expansion of the peridotites, due to serpentinisation, caused pressures throughout the mass, and the dykes became converted into the schistose nephrites that now remain. The brecciated and slickensided character common in serpentine-rock is aptly accounted for by this chemical expansion. "Schwellungsmetamorphose" (p. 13) is introduced as an appropriate term, and Steinmann holds that the Ligurian serpentines received their main mineral characters before the occurrence of the great movements that folded them in among the Alps.

This paper, connecting mineral changes and large rock-masses, may lead us on to igneous rocks in general. Mr. R. A. Daly (Proc. Amer. Acad. Arts and Sci., vol. xlv., 1910, p. 211) has sought to establish the average chemical compositions of igneous-rock types, and his results, largely based on Osann's collection of modern analyses, are likely to serve as standards for all who use ordinary rock-names. The number of analyses employed is shown in each case, and we are naturally left to presume that no very widely differing types are included here under the same name. A second series of averages is generously given, in which the figures are re-calculated with water omitted. Mr. Daly (p 236) urges that Rosenbusch's classification, as here emphasised, is objective and natural in a highly useful degree. Comparisons can now be easily made, by using these tables, between rocks of different grain, and the author points out that dacite is the effusive type of "granodiorite," rather than of the far less siliceous quartz-diorites of our ordinary terminology. On p. 240 we find a characteristic suggestion as to the cause of the similarity of composition of rocks of various degrees of antiquity, since "in general, differentiation in batholiths, when well advanced, restores the condition temporarily disturbed by magmatic assimilation."

Mr. G. P. Merrill (*Amer. Journ. Sci.*, vol. xxvii., p. 469) concludes from averages of analyses of stony meteorites, compared with those of terrestrial rocks, that magmatic differentiation could not have produced our rocks from planetesimal material of meteoritic composition. But he does not quite touch the main question, though he goes near it (p. 470). Surely the rocks of our crust are an extremely thin film on an interior of unknown composition. A planet like the earth, when duly disrupted, would supply exceedingly little material of the kind familiar to the geologist, and a vastly preponderating mass of far more basic character. Æons might go by before a chip of the crust fell upon another planet. Moreover, have not the glassy globules found in the superficial deposits of Bohemia (Bouteillenstein and Moldavite) been claimed by a high authority as of meteoritic origin?

Mr. R. T. Chamberlin, while keeping his eye on planetesimals, has published through the Carnegie Institution a paper on "The Gases in Rocks," in which a large amount of new material is made available. In the course of experiments, most gas arises from rocks that contain the greatest proportion of ferromagnesian minerals (p. 27). The discussion of the condition of the gases that are found to exist in rocks covers ground of great interest to geologists. The author affirms, with Suess, that the water and gases of the interior (p. 69) "form an integral part in the magmas, having been vital factors in their development from the primitive planetary matter." Lavas, it is urged, originate far below the possible reach of surface-waters (p. 73), and thus bring up original water with them. On the other hand, Dr. Johnston-Lavis ("Mechanism of Volcanic Action," *Geol. Mag.*, 1909, p. 437) continues to urge that the water found in lavas is absorbed by them as they rise into the moist layers of the upper regions of the crust. Mr. R. A. Daly (*Journ. of Geology*, vol. xvi., p. 401), in a paper on the origin of augite-andesite, supports the views of Scrope and Darwin on the differentiation of an igneous magma by fractional crystallisation. His views are quoted several times, under the name of Daley, in a remarkable paper by Dr. H. I. Jensen, on the distribution, origin, and relationships of alkaline rocks (Proc. Linn. Soc. N.S.W., vol. xxxiii., p. 491). The rather dubious term "alkaline" is here used to denote "rich in combined alkalies," and the rocks discussed are those that might be conceived to originate by differentiation from a foyaite-magma. Dr. Jensen examines their distribution in space and time, and concludes that they are almost all associated with Cainozoic earth-movements. The Christiania series (p. 502) is merely known to be post-Silurian, and may therefore be Eocene. "Alkaline rocks are continental and occur in areas of normal faulting above and possibly shear below" (p. 515). They are attributed to the melting and assimilation of sediments rich in alkalies (such as were formed when our earth's surface first cooled below 100° C.), as they gradually sank under the weight of Palæozoic and Mesozoic deposits. The crustal re-adjustments of the Eocene period allowed them to be expelled within the low-pressure regions, *i.e.* the continents, towards which they had gradually flowed. There is much more in this paper than might appear from so generalised a summary. Dr. Jensen's thorough study of the types of rock with which he deals is evidenced by several papers on their occurrence in eastern Australia, published in the last two years (Linn. Soc. N.S.W. and Australasian Association for the Advancement of Science, 1908–9).

Messrs. A. Boudariat and Johnston-Lavis (*Bull. Soc. Belge de Géol.*, tome xxii., 1909, p. 103) describe the occurrence of a basalt in the volcanic cone of Tritriva in central Madagascar, which has enriched itself with abundant grains of quartz at the expense of an underlying gneiss. The quartz-grains show the aureole of augite that is so common round inclusions of quartz in basic rocks. At Tritriva the volcanic chimney that was blown through the gneiss is clearly visible, and Dr. Johnston-Lavis makes some just remarks on the analogy with the so-called quartz-basalts of other areas, and on the modification of lavas by absorption.

Mr. C. B. Travis (Proc. Liverpool Geol. Soc., vol. x., p. 311) has examined the Ordovician rhyolites of Nant Ffrancon, Carnarvonshire, and gives good reason for agreeing with Iddings and Parkinson that lithophysal cavities, such as those traceable in the large Welsh spherulites, were original features of the lavas. The view that all such cavities are due to decomposition of solid structures was abandoned, however, by its supporters so far back as 1892.

The petrology of sedimentary rocks still attracts few workers. Dr. Woolacott (Univ. Durham Phil. Soc., Memoir i., 1909) describes a brecciated magnesian limestone in a paper illustrated by views of the rock as it occurs in the open field. Experiment (p. 5) leads to an estimate of the thrust concerned as having generated a pressure of 300 tons to the square foot. Mr. G. Linck, so well known for his researches on chemically deposited limestones, contributes a lucid paper on these rocks to the *Naturwissenschaftliche Wochenschrift*, 1909, p. 689. The Canadian Mining Institute publishes (Journ., vol. xii., 1909) a general paper by Mr. E. Coste on petroleums and coals, strongly supporting the "solfataric" view of the origin of petroleum. Mr. A. J. Cox (*Philippine Journ. Sci.*, vol. iii., p. 301) investigates the Philippine coals as fuels, and concludes that they may compete successfully with those of Australia. This subject is also dealt with by Mr. W. D. Smith ("Mineral Resources of the Philippine Islands," Bureau of Science of Manila, 1909). Barytes is so frequent as a cementing material in rocks that Dr. Trener's discussion of its origin in mineral waters rising from below is of general petrological interest (*Jahrb. k.k. Reichsanstalt*, Bd. lviii., p. 439).

As regards the petrography of special areas, we may note the excellent "Introduction to Petrography and the Collections of Rocks" published by the Royal Scottish Museum, Edinburgh (1909, price 1*d*.). Emphasis is here laid on Scottish examples. Dr. W. F. Hume, in his "Notes on the Petrography of Egypt" (*Geol. Mag.*, 1908, p. 500) gives a concise sketch that ought to be reprinted for the use of travellers. Mr. F. Kretschmer (*Jahrb. k.k. Reichsanstalt*, Bd. lviii., p. 527) describes the "Kalksilikatfelse" near Mahrisch-Schönberg in the Sudetic, and shows them to have become mineralised by the granite of the chain, while (p. 571) certain dyke-like pyroxene-pegmatites have arisen from the absorption of limestone into the invading igneous material. Dr. Hinterlechner and Mr. C. von John, in an elaborate paper on the eruptive rocks of the Bohemian Eisengebirge (*ibid.*, Bd. lix., p. 127), show that the alteration of the sediments into crystalline schists is not here dependent on the amount of dynamic influence. Where pressure has been least, the crystallisation is most marked, and is due to the intrusion of a mass that was once regarded as a primitive core. This, the earliest granite of the area, is later than Lower Silurian sediments, and Dr. Hinterlechner believes that it was intruded after the folding of the district. Since Devonian beds are here involved, this red gneiss may be of Upper Devonian or Carboniferous age. A paper of this kind emphasises the fact that in true petrology the laboratory merely subserves the work done in the open field.

G. A. J. C.

REPORTS ON CLIMATES.

THE results of the meteorological observations at the principal stations in the system of the Deutsche Seewarte for the five-year period 1901–5, and for the ten-year period 1896–1905, recently published, complete the series of these valuable statistics for the thirty years 1876–1905. They include the mean monthly, seasonal, and annual values, and extremes or other data relating to the various elements, deduced from observations generally made three times daily, and in practically the same form as in previous instalments. The heights of some of the barometers above sea-level have changed from time to time, but in order to permit easier comparison of one period with another, this inconvenience has been minimised by reducing the observations to agree with the levels given in previous publications. Otherwise, as usual in the case of barometrical observations at climatological stations, the readings are not reduced to sea-level.

The meteorology of Peru is discussed by Dr. J. Hann in the *Sitzungsberichte* of the Vienna Academy of November 4, 1909. The observations of the various stations on which the discussion is based have been published in the Annals of the Harvard College Observatory, to which we have previously referred; the tables were carefully prepared for publication under the direction of Prof. S. J. Bailey, of Arequipa, and are mostly printed *in extenso*, with mean values, but without discussion. In the present work Dr. Hann has submitted the results of the various elements to minute investigation by the laborious process of harmonic analysis. This brings out many interesting points; we propose here only to make a few general remarks on the most important station, on the summit of the Misti (lat. 16° 16′ S., long. 71° 25′ W.), at the great elevation of 5850 metres above sea-level. Dr. Hann points out that the agreement of the daily range of the barometer with that of the highest stations in Europe and America is very noteworthy; the principal maximum occurs between noon and 1h. p.m., and the minimum about 5h. a.m. The mean annual temperature (1893–5) was −7·8° C.; January, −6·0°; May, June, and August, −9·7°. The thermometer, even on very fine days, rarely rose above freezing point. Above 4600 metres, only snow or hail was observed; a certain amount of snow remains during nearly the whole year, but a few clear days suffice to clear off the greater part of a heavy snowfall.

A valuable paper on the climate of the Lower Guinea coast and hinterland, by Dr. R. Sieglerschmidt, appears in vol. xxiii., part i., of *Mitteilungen aus den deutschen Schutzgebieten*; it is the more important from the fact that, with the exception of a short discussion of the rainfall of the Cameroons by Fitzner in 1907, no general paper on the climate of that district has been published for some years. Among the earlier papers may be specially mentioned the results of the Loango expedition (published in 1878), observations at Vivi and other places by Freiherr v. Danckelman (1884), and the reports by Lancaster and Meuleman on the climate of the Lower Congo (1897). Dr. Sieglerschmidt's article deals exhaustively with each of the meteorological elements, and the general results confirm those given by Dr. Hann in his "Klimatologie," that the air-pressure on the Lower Guinea coast has a single yearly range, and that the yearly means decrease from south to north, while the temperature (reduced to sea-level) increases considerably towards the interior, except in the extreme north. Rainfall increases along the coast from almost complete rainlessness to that of the second wettest district of the globe. The oceanic air-current, which from June to September (or October) extends from the north of Angola to the Cameroons far into the interior, has a great influence on the yearly range of temperature, rainfall, &c., while in the hinterland of the north and south districts the yearly range is determined by the alternation of summer warmth and winter cold of higher latitudes.

The climate of Berlin, part ii., air-temperature, by Prof. G. Hellmann (with the assistance of Messrs. G. v. Elsner and G. Schwalbe), forms part No. 6, vol. iii., of the *Abhandlungen* of the Royal Prussian Meteorological Institute. In this valuable and laborious investigation the observations are dealt with in great detail and for various periods from the year 1701. In the following table we quote the maximum and minimum readings for 1830–1907, and the mean monthly and yearly values for 1822–1907, in centigrade degrees:—

	Jan.	Feb.	March	April	May	June
Mean max. ...	1·4	3·3	7·0	12·9	18·5	22·5
Mean min. ...	−3·2	−2·0	0·2	4·3	8·8	12·8
True mean ...	−1·1	0·5	3·4	8·6	13·6	17·5
	July	August	Sept.	Oct.	Nov.	Dec.
Mean max. ...	23·8	22·8	19·0	12·9	6·3	2·7
Mean min. ...	14·3	13·9	10·5	6·4	1·6	−1·4
True mean ...	18·9	18·1	14·6	9·5	3·9	0·7

Yearly mean, 9·0; absolute maximum, 37·0 (July 20, 1865); absolute minimum, −25·0 (January 29, 1830, January 22, 1850).

The author points out that the earlier period was somewhat colder than the later; this was noticeable in all the winter months, especially in January, while greater heat in summer, especially in May and August, was observed, but he considers that it would be premature to assume that a permanent change of climate has taken place. The principal anomalies in the yearly range are the cold periods in the middle of February and June, and the warm periods near the end of September and middle of December. The cold spell of May 11–13, popularly known as the days of the Ice Saints, is not specially noticeable. The chief cause of these anomalies in the annual range of temperature is the distribution of air-pressure in Eurasia, especially the position of the barometric maximum.

A comprehensive discussion of the rainfall of northern Spain and Portugal, by Dr. W. Semmelhack, is contained in *Aus dem Archiv der Deutschen Seewarte* (1910, No. 2). It deals with many aspects of the subject, including horizontal and vertical distribution of amount and frequency, isohyets and tabular means of years and seasons, thunderstorms, &c., embracing a period extending from 1861 to 1900. The rainfall is affected chiefly by conditions of pressure over the Atlantic, Mediterranean, and the Continent, and its yearly distribution is therefore subject to considerable fluctuation. To give details would require much space, but a rough idea may be gained from the fact that about 4 per cent. of the area in question receives an amount not exceeding 12 inches; 53 per cent., approximately 12–27½ inches; 17 per cent., 27½–39½ inches; 23 per cent., 39½–59 inches; 3 per cent., more than this amount. The extreme values are 9·6 inches at Palencia (Old Castile) and 113 inches at Sierra d'Estrella. The monthly extreme values vary very greatly; the highest are met with on the N., N.W., and W. coasts. In March, 1886, 48·7 inches were recorded at Sierra d'Estrella, but in the dry districts of the central plateau the greatest monthly amounts are little above 6 inches; rainless months occur at times at nearly all the stations.

BIRD NOTES.

To the July issue of the *Quarterly Review* Dr. H. Gadow communicates an instructive article on the nature and meaning of the colours of birds. After pointing out the fallacy of the idea that the colouring of such birds as the scarlet ibis or white egret can be in any sense protective, the author discusses the diverse means by which colour is produced in birds, showing that while black and the red and yellow group are pigmentary, blues and greens are so-called structural tints, due to the reflection from the surface of the feathers of an undue proportion of short light-rays. Metallic colouring, which usually occurs in black feathers, is due, of course, to another cause. Dr. Gadow next proceeds to describe the sequence in which various colours replace one another with the advance of specialisation. As regards the cause of colour-specialisation, the author rejects both natural and sexual selection, remarking that if the latter were the inducing factor, every group and species would have its own taste, and each individual would strive to develop its yellow patches into orange and then into red. For the explanation offered in place of natural and sexual selection, we must refer our readers to the article itself.

In the August number of Witherby's *British Birds* the editor congratulates his readers on the satisfactory response which has been made this season to his appeal for assistance in marking birds. Nearly 11,000 rings were distributed, and schedules recording the marking of between 5000 and 6000 birds have been already received. The cooperation is invoked of all into whose hands ringed birds may fall. In the same issue Mr. W. Frohawk describes and illustrates the feeding habits of the razorbill, remarking that all the specimens which have come under his special notice fed on sand-launces. These fish, to the number in some cases of so many as half a dozen at a time, are held transversely in the beak, and the marvel is how the bird manages to capture and hold one after the other without losing those previously caught. Possibly each is killed when caught; but even then it is difficult to see how the catch is procured and retained.

To the August number of the *Popular Science Monthly* Prof. F. H. Herrick contributes the third and final instalment of an article on instinct and intelligence in birds. It is concluded that many of the alleged cases of intelligence are really due to habit, and that "all the intelligence which birds may on occasion exhibit seems to give way under the spell of any of the strange instincts. . . . They seldom meet emergencies by doing the intelligent act, and, in spite of the anecdotes, probably but seldom come to the effective aid of their companions in distress. On the other hand, I have more than once seen a mother bird try to pluck a hair or piece of grass from the mouth of a nestling."

Another instance of intelligence is afforded, in the author's opinion, when a gull, after feeding its young for three weeks on partially digested fish, offers them entire squids to swallow. The practice displayed by young kingfishers of arranging themselves in a row and showing a tendency to walk backwards is, however, attributed to habit formed underground; while the time it takes for hole-nesting birds to change their place of entrance when a more convenient access has been afforded is an instance of the dominance of habit over intelligence.

THE BRITISH ASSOCIATION AT SHEFFIELD.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY PROF. G. C. BOURNE, M.A., D.Sc., F.R.S., PRESIDENT OF THE SECTION.

In choosing a subject for the address with which it is my duty, as President of this Section, to trouble you, I have found myself in no small embarrassment. As one whose business it is to lecture and give instruction in the details of comparative anatomy, and whose published work, *qualecunque sit*, has been indited on typical and, as men would now say, old-fashioned morphological lines, I seem to stand self-condemned as a morphologist. For morphology, if I read the signs of the times aright, is no longer in favour in this country, and among a section of the zoological world has almost fallen into disgrace. At all events, I have been very frankly assured that this is the case by a large proportion of the young gentlemen whom it has been my fate to examine during the past two years; and, as this seems to be the opinion of the rising generation of English zoologists, and as there are evident signs that their opinion is backed by an influential section of their elders, I have thought that it might be of some interest, and perhaps of some use, if I took this opportunity of offering an apology for animal morphology.

It is a sound rule to begin with a definition of terms, so I will first try to give a short answer to the question "What is morphology?" and, when I have given a somewhat dogmatic answer, I will try to deal in the course of this address with two further questions: What has morphology done for zoological science in the past? What remains for morphology to do in the future?

To begin with, then, what do we include under the term morphology? I must, first of all, protest against the frequent assumption that we are bound by the definitions of C. F. Wolff or Goethe, or even of Haeckel, and that we may not enlarge the limits of morphological study beyond those laid down by the fathers of this branch of our science. We are not—at all events we should not be—bound by authority, and we owe no allegiance other than what reason commends to causes and principles enunciated by our predecessors, however eminent they may have been.

The term morphology, stripped of all the theoretical conceptions that have clustered around it, means nothing more than the study of form, and it is applicable to all branches of zoology in which the relationships of animals are determined by reference to their form and structure. Morphology, therefore, extends its sway not only over the comparative anatomy of adult and recent animals, but also over palæontology, comparative embryology, systematic zoology and cytology, for all these branches of our science are occupied with the study of form. And in treating of form they have all, since the acceptance of the doctrine of descent with modification, made use of the same guiding principle—namely, that likeness of form is the index to blood-relationship. It was the introduction of this principle that revolutionised the methods of morphology fifty years ago, and stimulated that vast output of morphological work which some persons, erroneously as I think, regard as a departure from the line of progress indicated by Darwin.

We may now ask, what has morphology done for the advancement of zoological science since the publication of the "Origin of Species"? We need not stop to inquire what facts it has accumulated: it is sufficiently obvious that it has added enormously to our stock of concrete knowledge. We have rather to ask what great general principles has it established on so secure a basis that they meet with universal acceptance at the hands of competent zoologists?

It has doubtless been the object of morphology during the past half-century to illustrate and confirm the Darwinian theory. How far has it been successful? To answer this question we have to be sure of what we mean when we speak of the Darwinian theory. I think that we mean at least two things. (1) That the assemblage of animal forms as we now see them, with all their diversities of form, habit, and structure, is directly descended from a precedent and somewhat different assemblage, and these in turn from a precedent and more different assemblage, and so on down to remote periods of geological time. Further, that throughout all these periods inheritance combined with changeability of structure have been the factors operative in producing the differences between the successive assemblages. (2) That the modifications of form which this theory of evolution implies have been rejected or preserved and accumulated by the action of natural selection.

As regards the first of these propositions, I think there can be no doubt that morphology has done great service in establishing our belief on a secure basis. The transmutation of animal forms in past time cannot be proved directly; it can only be shown that, as a theory, it has a much higher degree of probability than any other that can be brought forward, and in order to establish the highest possible degree of probability, it was necessary to demonstrate that all anatomical, embryological, and palæontological facts were consistent with it. We are apt to forget, nowadays, that there is no *a priori* reason for regarding the resemblances and differences that we observe in organic forms as something different in kind from the analogous series of resemblances and differences that obtain in inanimate objects. This was clearly pointed out by Fleeming Jenkin in a very able and much-referred to article in the *North British Review* for June, 1867, and his argument from the *a priori* standpoint has as much force to-day as when it was written forty-three years ago. But it has lost almost all its force through the arguments *a posteriori* supplied by morphological science. Our belief in the transmutation of animal organisation in past time is founded very largely upon our minute and intimate knowledge of the manifold relations of structural form that obtain among adult animals; on our precise knowledge of the steps by which these adult relations are established during the development of different kinds of animals; on our constantly increasing knowledge of the succession of animal forms in past time; and, generally, on the conviction that all the diverse forms of tissues, organs, and entire animals are but the expression of an infinite number of variations of a single theme, that theme being cell-division, multiplication, and differentiation. This conviction grew but slowly in men's minds. It was opposed to the cherished beliefs of centuries, and morphology rendered a necessary service when it spent all those years which have been described as "years in the wilderness" in accumulating such a mass of circumstantial evidence in favour of an evolutionary explanation of the order of animate nature as to place the doctrine of descent with modification on a secure foundation of fact. I do not believe that this foundation could have been so securely laid in any other way, and I hold that zoologists were actuated by a sound instinct in working so largely on morphological lines for forty years after Darwin wrote. For there was a large mass of fact and theory to be remodelled and brought into harmony with the new ideas, and a still larger vein of undiscovered fact to explore. The matter was difficult and the pace could not be forced. Morphology, therefore, deserves the credit of having done well in the past: the question remains, What can it do in the future?

It is evident, I think, that it cannot do much in the way of adding new truths and general principles to zoological science, nor even much more that is useful in the verification of established principles, without enlarging its scope and methods. Hitherto—or, at any rate, until very recently—it has accepted certain guiding principles on faith, and, without inquiring too closely into their validity, has occupied itself with showing that, on the assumption that these principles are true, the phenomena of animal structure, development, and succession receive a reasonable explanation.

We have seen that the fundamental principles relied upon during the last fifty years have been inheritance and variation. In every inference drawn from the comparison of one kind of animal structure with another, the morphologist founds himself on the assumption that different degrees of similitude correspond more or less closely to degrees of blood-relationship, and to-day there are probably few persons who doubt that this assumption is valid. But we must not forget that, before the publication of the "Origin of Species," it was rejected by the most influential zoologists as an idle speculation, and that it is imperilled by Mendelian experiments showing that characters may be split up and reunited in different combinations in the course of a few generations. We do not doubt the importance of the principle of inheritance, but we are not quite so sure as we were that close resemblances are due to close kinship and remoter resemblances to remoter kinship.

The principle of variation asserts that like does not beget exactly like, but something more or less different. For a long time morphologists did not inquire too closely into the question how these differences arose. They simply accepted it as a fact that they occur, and that they are of sufficient frequency and magnitude, and that a sufficient proportion of them lead in such directions that natural selection can take advantage of them. Difficulties and objections were raised, but morphology on the whole took little heed of them. Remaining steadfast in its adherence to the principles laid down by Darwin, it contented itself with piling up circumstantial evidence, and met objection and criticism with an ingenious apologetic. In brief, its labours have consisted in bringing fresh instances, and especially such instances as seemed unconformable, under the rules, and in perfecting a system of classification in illustration of the rules. It is obvious, however, that, although this kind of study is both useful and indispensable at a certain stage of scientific progress, it does not help us to form new rules, and fails altogether if the old rules are seriously called into question.

As a matter of fact, admitting that the old rules are valid, it has become increasingly evident that they are not sufficient. Until a few years ago morphologists were open to the reproach that, while they studied form in all its variety and detail, they occupied themselves too little—if, indeed, they could be said to occupy themselves at all—with the question of how form is produced, and how, when certain forms are established, they are caused to undergo change and give rise to fresh forms. As Klebs has pointed out, the forms of animals and plants were regarded as the expression of their inscrutable inner nature, and the stages passed through in the development of the individual were represented as the outcome of purely internal and hidden laws. This defect seems to have been more distinctly realised by botanical than by zoological morphologists, for Hofmeister, as long ago as 1868, wrote that the most pressing and immediate aim of the investigator was to discover to what extent external forces acting on the organism are of importance in determining its form.

If morphology was to be anything more than a descriptive science, if it was to progress any further in the discovery of the relations of cause and effect, it was clear that it must alter its methods and follow the course indicated by Hofmeister. And I submit that an inquiry into the causes which produce alteration of form is as much the province of, and is as fitly called, morphology as, let us say, a discussion of the significance of the patterns of the molar teeth of mammals or a disputation about the origin of the cœlomic cavities of vertebrated and invertebrated animals.

There remains, therefore, a large field for morphology to explore. Exploration has begun from several sides, and in some quarters has made substantial progress. It will be of interest to consider how much progress has been made along certain lines of research—we cannot now follow all the lines—and to forecast, if possible, the direction that this pioneer work will give to the morphology of the future.

I am not aware that morphologists have, until quite recently, had any very clear concept of what may be expected to underlie form and structure. Dealing, as they have dealt, almost exclusively with things that can be seen or rendered visible by the microscope, they have acquired the habit of thinking of the organism as made up of organs, the organs of tissues, the tissues of cells, and the cells as made up—of what? Of vital units of a lower order, as several very distinguished biologists would have us believe; of physiological units, of micellæ, of determinants and biophors, or of pangenes; all of them essentially morphological conceptions; the products of imagination projected beyond the confines of the visible, yet always restrained by having only one source of experience—namely, the visible. One may give unstinted admiration to the brilliancy, and even set a high value on the usefulness, of these attempts to give formal representations of the genesis of organic structure, and yet recognise that their chief utility has been to make us realise more clearly the problems that have yet to be solved.

Stripped of all the verbiage that has accumulated about them, the simple questions that lie immediately before us are: What are the causes which produce changes in the forms of animals and plants? Are they purely internal, and, if so, are their laws discoverable? Or are they partly or wholly external, and, if so, how far can we find relations of cause and effect between ascertained chemical and physical phenomena and the structural responses of living beings?

As an attempt to answer the last of these questions, we have the recent researches of the experimental morphologists and embryologists directed towards the very aim that Hofmeister proposed. Originally founded by Roux, the school of experimental embryology has outgrown its infancy and has developed into a vigorous youth. It has produced some very remarkable results, which cannot fail to exercise a lasting influence on the course of zoological studies. We have learnt from it a number of positive facts, from which we may draw very important conclusions, subversive of some of the most cherished ideas of whilom morphologists. It has been proved by experiment that very small changes in the chemical and physical environment may and do produce specific form-changes in developing organisms, and in such experiments the consequence follows so regularly on the antecedent that we cannot doubt that we have true relations of cause and effect. It is not the least interesting outcome of these experiments that, as Loeb has remarked, it is as yet impossible to connect in a rational way the effects produced with the causes which produced them, and it is also impossible to define in a simple way the character of the change so produced. For example, there is no obvious connection between the minute quantity of sulphates present in sea-water and the number and position of the characteristic calcareous spicules in the larva of a sea-urchin. Yet Herbst has shown that if the eggs of sea-urchins are reared in sea-water deprived of the needful sulphates (normally 0·26 per cent. magnesium sulphate and 0·1 per cent. calcium sulphate), the number and relative positions of these spicules are altered, and, in addition, changes are produced in other organs, such as the gut and the ciliated bands. Again, there is no obvious connection between the presence of a small excess of magnesium chloride in sea-water and the development of the paired optic vesicles. Yet Stockard, by adding magnesium chloride to sea-water in the proportion of 6 grams of the former to 100 c.c. of the latter, has produced specific effects on the eyes of developing embryos of the minnow *Fundulus heteroclitus*: the optic vesicles, instead of being formed as a widely separated pair, were caused to approach the median line, and in about 50 per cent. of the embryos experimented upon the changes were so profound as to give rise to cyclopean monsters. Many other instances might be cited of definite effects of physical and chemical agencies on particular organs, and we are now forced to admit that inherited tendencies may be completely overcome by a minimal change in the environment. The nature of the organism, therefore, is not all important, since it yields readily to influences which at one time we should have thought inadequate to produce perceptible changes in it.

It is open to anyone to argue that, interesting as experiments of this kind may be, they throw no light on the origin of permanent—that is to say, inheritable—modifications of structure. It has for a long time been a matter of common knowledge that individual plants and animals react to their environment, but the modifications induced by these reactions are somatic; the germ-plasm is not affected, therefore the changes are not inherited, and no permanent effect is produced in the characters of the race or species. It is true that no evidence has yet been produced to show that form-changes as profound as those that I have mentioned are transmitted to the offspring. So far the experimenters have not been able to rear the modified organisms beyond the larval stages, and so there are no offspring to show whether cyclopean eyes or modified forms of spicules are inherited or not. Indeed, it is possible that the balance of organisation of animals thus modified has been upset to such an extent that they are incapable of growing into adults and reproducing their kind.

But evidence is beginning to accumulate which shows that external conditions may produce changes in the germ-cells as well as in the soma, and that such changes may be specific and of the same kind as similarly produced somatic changes. Further, there is evidence that such germinal changes are inherited—and, indeed, we should expect them to be, because they are germinal.

The evidence on this subject is as yet meagre, but it is of good quality and comes from more than one source.

There are the well-known experiments of Weismann, Standfuss, Merrifield, and E. Fischer on the modification of the colour patterns on the wings of various Lepidoptera.

In the more northern forms of the fire-butterfly, *Chrysophanus (Polyommatus) phlaeas*, the upper surfaces of the wings are of a bright red-gold or copper colour with a narrow black margin, but in southern Europe the black tends to extend over the whole surface of the wing and may nearly obliterate the red-gold colour. By exposing pupæ of caterpillars collected at Naples to a temperature of 10° C. Weismann obtained butterflies more golden than the Neapolitan, but blacker than the ordinary German race, and conversely, by exposing pupæ of the German variety to a temperature of about 38° C., butterflies were obtained blacker than the German, but not so black as the Neapolitan variety. Similar deviations from the normal standard have been obtained by like means in various species of Vanessa by Standfuss and Merrifield. Standfuss, working with the small tortoiseshell butterfly (*Vanessa urticae*), produced colour aberrations by subjecting the pupæ to cold, and found that some specimens reared under normal conditions from the eggs produced by the aberrant forms exhibited the same aberrations, but in a lesser degree. Weismann obtained similar results with the same species. E. Fischer obtained parallel results with *Arctia caja*, a brightly coloured diurnal moth of the family Bombycidæ. Pupæ of this moth were exposed to a temperature of 8° C., and some of the butterflies that emerged were very dark-coloured aberrant forms. A pair of these dark aberrants were mated, and the female produced eggs, and from these larvæ and pupæ were reared at a normal temperature. The progeny was for the most part normal, but some few individuals exhibited the dark colour of the parents, though in a less degree. The simple conclusions to be drawn from the results of these experiments is that a proportion of the germ-cells of the animals experimented upon were affected by the abnormal temperatures, and that the reaction of the germ-cells was of the same kind as the reaction of the somatic cells and produced similar results. As everybody knows, Weismann, while admitting that the germ-cells were affected, would not admit the simple explanation, but gave another complicated and, in my opinion, wholly unsupported explanation of the phenomena.

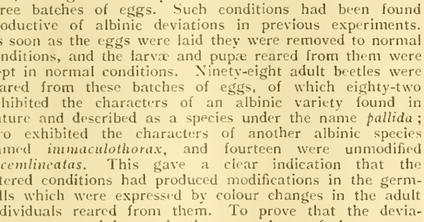
In any case this series of experiments was on too small a scale, and the separate experiments were not sufficiently carefully planned to exclude the possibility of error. But no objection of this kind can be urged against the careful and prolonged studies of Tower on the evolution of chrysomelid beetles of the genus Leptinotarsa. Leptinotarsa—better known, perhaps, by the name Doryphora—is the potato-beetle, which has spread from a centre in North Mexico southwards into the isthmus of Panama and northwards over a great part of the United States. It is divisible into a large number of species, some of which are dominant and widely ranging; others are restricted to very small localities. The specific characters relied upon are chiefly referable to the coloration and colour patterns of the epicranium, pronotum, elytra, and underside of the abdominal segments. In some species the specific markings are very constant, in others, particularly in the common and wide-ranging *L. decemlineata*, they vary to an extreme degree. As the potato-beetle is easily reared and maintained in captivity, and produces two broods every year, it is a particularly favourable subject for experimental investigation. Tower's experiments have extended over a period of eleven years, and he has made a thorough study of the geographical distribution, dispersal, habits, and natural history of the genus. The whole work appears to have been carried out with the most scrupulous regard to scientific accuracy, and the author is unusually cautious in drawing conclusions and chary of offering hypothetical explanations of his results. I have been greatly impressed by the large scale on which the experiments have been conducted, by the methods used, by the care taken to verify every result obtained, and by the great theoretical importance of Tower's conclusions. I can do no more now than allude to some of the most remarkable of them.

After showing that there are good grounds for believing that colour production in insects is dependent on the action of a group of closely related enzymes, of which chitase, the agent which produces hardening of chitin, is the most important, Tower demonstrates by a series of well-planned experiments that colours are directly modified by the action of external agencies—viz., temperature, humidity, food, altitude, and light. Food chiefly affects the subhypodermal colours of the larvæ, and does not enter much into account; the most important agents affecting the adult coloration being temperature and humidity. A *slight* increase or a *slight* decrease of temperature or humidity was found to stimulate the action of the colour-producing enzymes, giving a tendency to melanism; but a large increase or decrease of temperature or humidity was found to inhibit the action of the enzymes, producing a strong tendency to albinism.

A set of experiments was undertaken to test the question whether colouration changes induced by changed environmental conditions were inherited, increased, or dropped in successive generations. These experiments, carried on for ten lineal generations, showed that the changed conditions immediately produced their maximum effect; that they were purely somatic and were not inherited, the progeny of individuals which had been exposed to changed conditions through several generations promptly reverting when returned to normal conditions of environment. So far the results are confirmatory of the well-established proposition that induced somatic changes are not inheritable.

But it was found necessary to remove the individuals experimented upon from the influence of changed conditions during the periods of growth and maturation of the germ-cells. Potato-beetles emerge from the pupa or from hibernation with the germ-cells in an undeveloped condition, and the ova do not all undergo their development at once, but are matured in batches. The first batch matures during the first few days following emergence, then follows an interval of from four to ten days, after which the next batch of eggs is matured, and so on. This fact made it possible to test the effect of altered conditions on the maturing germ-cells by subjecting its imagos to experimental conditions during the development of some of the batches of ova and to normal conditions during the development of other batches.

In one of the experiments four male and four female individuals of *L. decemlineata* were subjected to very hot and dry conditions, accompanied by low atmospheric pressure, during the development and fertilisation of the first three batches of eggs. Such conditions had been found productive of albinic deviations in previous experiments. As soon as the eggs were laid they were removed to normal conditions, and the larvæ and pupæ reared from them were kept in normal conditions. Ninety-eight adult beetles were reared from these batches of eggs, of which eighty-two exhibited the characters of an albinic variety found in nature and described as a species under the name *pallida*; two exhibited the characters of another albinic species named *immaculothorax*, and fourteen were unmodified *decemlineatas*. This gave a clear indication that the altered conditions had produced modifications in the germ-cells which were expressed by colour changes in the adult individuals reared from them. To prove that the deviations were not inherent in the germ-plasm of the parents, the latter were kept under normal conditions during the periods of development and fertilisation of the last two batches of eggs; the larvæ and pupæ reared from these eggs were similarly subjected to normal conditions, and gave rise to sixty-one unmodified *decemlineatas*, which, when bred together, came true to type for three generations. The *decemlineata* forms produced under experimental conditions also came true to type when bred together. Of the *pallida* forms produced by experimental conditions all but two males were killed by a bacterial disease. These two were crossed with normal *decemlineata* females, and the result was a typical Mendelian segregation, as shown by the following table:—



This is a much more detailed experiment than those of Standfuss, Merrifield, and Fischer, and it shows that the changes produced by the action of altered conditions on the maturing germ-cells were definite and discontinuous, and therefore of the nature of mutations in De Vries' sense.

In another experiment Tower reared three generations of *decemlineata* to test the purity of his stock. He found that they showed no tendency to produce extreme variations under normal conditions. From this pure stock seven males and seven females were chosen, and subjected during the maturation periods of the first two batches of ova to hot and dry conditions. Four hundred and nine eggs were laid, from which sixty-nine adults were reared, constituted as follows:—

Twenty (12 ♂, 8 ♀) . .	apparently normal *decemlineata*.
Twenty-three (10 ♂, 13 ♀).	*pallida*.
Five (2 ♂, 3 ♀) . . .	*immaculotho. a.x.*
Sixteen (9 ♂, 7 ♀) . .	*albida*.

These constituted lot A.

The same seven pairs of parents subjected during the second half of the reproductive period to normal conditions gave 840 eggs, from which were reared 123 adults, all *decemlineatas*. These constituted lot B. The *decemlineatas* of lot A and lot B were reared side by side under normal and exactly similar conditions. The results were striking. From lot B normal progeny were reared up to the tenth generation, and, as usual in the genus, two generations were produced in each year. The *decemlineatas* of lot A segregated into two lots in the second generation. A^1 were normal in all respects, but A^2, while retaining the normal appearance of *decemlineata*, went through five generations in a year, and this for three successive years, thus exhibiting a remarkable physiological modification, and one without parallel in nature, for no species of the genus Leptinotarsa are known which produce more than two generations in the year. This experiment is a sufficient refutation of Weismann's argument that the inheritance of induced modifications in *Vanessa urticae* is only apparent, the phenomena observed being due to the inheritance of two kinds of determinants—one from dark-coloured forms which are phyletically the oldest, and the other from more gaily coloured forms derived from the darker forms. There is no evidence whatever that there was ever a species or variety of potato-beetle that produced more than two, or at the most, and then as an exception, three broods in a year.

The modified albinic forms in this last experiment of Tower's were weakly; they were bred through two or three generations, and came true to type, but then died out. No hybridisation experiments were made with them, but in other similar experiments, which I have not time to mention in detail, modified forms produced by the action of changed conditions gave typical Mendelian characters when crossed with unmodified *decemlineatas*, thus proving that the induced characters were constant and heritable according to the regular laws.

I have thought it worth while to relate these experiments at some length, because they seem to me to be very important, and because they do not appear to have attracted the attention in this country that they deserve.

They are confirmed to a very large extent by the experiments of Prof. Klebs on plants, the results of which were published this summer in the Croonian Lecture on "Alterations of the Development and Forms of Plants as a Result of Environment." As I have only a short abstract of the Croonian Lecture to refer to, I cannot say much on this subject for fear of misrepresenting the author; but, as far as I can judge, his results are quite consistent with those of Tower. *Sempervivum funckii* and *S. acuminatum* were subjected to altered conditions of light and nutrition, with the result that striking variations, such as the transformation of sepals into petals, of petals into stamens, of stamens into petals and into carpels, were produced. Experiments were made on *Sempervivum acuminatum* with the view of answering the question whether such alterations of flowers can be transmitted. The answer was in the affirmative. The seeds of flowers artificially altered and self-fertilised gave rise to twenty-one seedlings, among which four showed surprising deviations of floral structure. In two of these seedlings all the flowers were greatly altered, and presented some of the modifications of the mother plant, especially the transformation of stamens into petals. These experiments are still in progress, and it would perhaps be premature to lay too much stress upon them if it were not for the fact that they are so completely confirmatory of the results obtained by similar methods in the animal kingdom.

I submit to you that evidence is forthcoming that external conditions may give rise to inheritable alterations of structure. Not, however, as was once supposed, by producing specific changes in the parental soma, which changes were reflected, so to speak, upon the germ-cells. The new evidence confirms the distinctions drawn by Weismann between somatic and germinal variations. It shows that the former are not inherited, while the latter are; but it indicates that the germ may be caused to vary by the action of external conditions in such a manner as to produce specific changes in the progeny resulting from it. It is no more possible at the present time to connect rationally the action of external conditions on the germ-cells with the specific results produced in the progeny than it is possible to connect cause with effect in the experiments of Herbst and Stockard; but when we compare these two kinds of experiments, we are no longer able to argue that it is inconceivable that such and such conditions acting on the germ-plasm can produce such and such effects in the next generation of adults. We must accept the evidence that things which appeared inconceivable do in fact happen, and in accepting this we remove a great obstacle from the path of our inquiries, and gain a distinct step in our attempts to discover the laws which determine the production of organic form and structure.

But such experiments as those which I have mentioned only deal with one aspect of the problem. They tell us about external conditions and the effects that they are observed to produce upon the organism. They give us no definite information about the internal changes which, taken together, constitute the response of the organism to external stimuli. As Darwin wrote, there are two factors to be taken into account—the nature of the conditions and the nature of the organism, and the latter is much the more important of the two. More important because the reactions of animals and plants are manifold; but, on the whole, the changes in the conditions are few and small in amount. Morphology has not succeeded in giving us any positive knowledge of the nature of the organism; and in this matter we must turn for guidance to the physiologists, and ask of them how far recent researches have resulted in the discovery of factors competent to account for change of structure. Perhaps the first step in this inquiry is to ask whether there is any evidence of internal chemical changes analogous in their operation to the external physical and chemical changes which we have been dealing with.

There is a great deal of evidence, but it is extremely difficult to bring it to a focus and to show its relevancy to the particular problems that perplex the zoologist. Moreover, the evidence is of so many different kinds, and each kind is so technical and complex, that it would be absurd to attempt to deal with it at the end of an address that has already been drawn out to sufficient length. But perhaps I may be allowed to allude to one or two generalisations which appear to me to be most suggestive.

We shall all agree that, at the bottom, production and change of form is due to increase or diminution of the activities of groups of cells, and we are aware that in the higher animals change of structure is not altogether a local affair, but carries with it certain consequences in the nature of correlated changes in other parts of the body. If we are to make any progress in the study of morphogeny, we ought to have as exact ideas as possible as to what we mean when we speak of the activities of cells and of correlation. On these subjects physiology supplies us with ideas much more exact than those derived from morphology.

It is, perhaps, too sweeping a generalisation to assert that the life of any given animal is the expression of the sum of the activities of the enzymes contained in it, but it seems well established that the activities of cells are, if not wholly, at all events largely, the result of the actions of the various kinds of enzymes held in combination by their living protoplasm. These enzymes are highly susceptible to the influence of physical and chemical media, and it is because of this susceptibility that the organism responds to changes in the environment, as is clearly illustrated in a particular case by Tower's experiments on the production of colour changes in potato-beetles. Bayliss and Starling have shown that in lower animals, protozoa and sponges, in which no nervous system has been developed, the response of the organism to the environment is effected by purely chemical means. In protozoa, because of their small size, the question of coadaptation of function hardly comes into question; but in sponges, many of which are of large size, the mechanism of coadaptation must also be almost exclusively chemical. Thus we learn that the simplest and, by inference, the phyletically oldest mechanism of reaction and coordination is a chemical mechanism. In higher animals the necessity for rapid reaction to external and internal stimuli has led to the development of a central and peripheral nervous system, and as we ascend the scale of organisation this assumes a greater and greater importance as a co-ordinating bond between the various organs and tissues of the body. But the more primitive chemical bond persists, and is scarcely diminished in importance, but only overshadowed, by the more easily recognisable reactions due to the working of the nervous system. In higher animals we may recognise special chemical means whereby chemical coadaptations are established and maintained at a normal level or in certain circumstances altered. These are the internal secretions produced by sundry organs, whether by typical secretory glands (in which case the internal secretion is something additional and different from the external secretion), or by the so-called ductless glands, such as the thyroid, the thymus, the adrenal bodies, or by organs which cannot strictly be called glands, namely, the ovaries and testes. All these produce chemical substances which, passing into the blood or lymph, are distributed through the system, and have the peculiar property of regulating or exciting the specific functions of other organs. Not, however, of all the organs, for the different internal secretions are more or less limited and local in their effects, one affecting the activity of this and another the activity of that kind of tissue or organ. Starling proposed the name hormones for the internal secretions because of their excitatory properties (*ὁρμάω*, to stir up, to excite).

Hormones have been studied chiefly from the point of view of their stimulating effect on the metabolism of various organs. From the morphologist's point of view, interest chiefly attaches to the possibility of their regulating and promoting the production of form. It might be expected that they should be efficient agents in regulating form, for, if changes in structure are the result of the activities of groups of cells, and the activities of cells are the results of the activities of the enzymes which they contain, and if the activities of the enzymes are regulated by the hormones, it follows that the last-named must be the ultimate agents in the production of form. It is difficult to obtain distinct evidence of this agency, but in some cases, at least, the evidence is sufficiently clear. I will confine myself to the effects of the hormones produced by the testes and ovaries. These have been proved to be intimately connected with the development of secondary sexual characters, such, for instance, as the characteristic shape and size of the horns of the bull; the comb, wattles, spurs, plumage colour, and spurs in poultry; the swelling on the index finger of the male frog; the shape and size of the abdominal segments of crabs. These are essentially morphological characters, the results of increased local activity of cell-growth and differentiation. As they are attributable to the stimulating effect of the hormone produced by the male organ in each species, they afford at least one good instance of the production of a specific change of form as the result of an internal chemical stimulus. We get here a hint as to the nature of the chemical mechanism which excites and correlates form and function in higher organisms, and, from what has just been said, we perceive that this is the most primitive of all the animal mechanisms. I submit that this is a step towards forming a clear and concrete idea of the inner nature of the organism. There is one point, and that a very important one, upon which we are by no means clear. We do not know how far the hormones themselves are liable to change, whether by the action of external conditions or by the reciprocal action of the activities of the organs to which they are related. It is at least conceivable that agencies which produce chemical disturbances in the circulating fluids may alter the chemical constitution of the hormones, and thus produce far-reaching effects. The pathology of the thyroid gland gives some ground for belief that such changes may be produced by the action of external conditions. But, however this may be, the line of reasoning that we have followed raises the expectation that a chemical bond must exist between the functionally active organs of the body and the germ-cells. For if, in the absence of a specialised nervous system, the only possible regulating and coadapting mechanism is a chemical mechanism, and if the specific activities of a cell are dependent on the enzymes which it holds in combination, the germ-cells of any given animal must be the depository of a stock of enzymes sufficient to insure the due succession of all its developmental stages as well as of its adult structure and functions. And as the number of blastomeres increases, and the need for coordination of form and function arises, before ever the rudiments of a nervous system are differentiated, it is necessary to assume that there is also a stock of appropriate hormones to supply the chemical nexus between the different parts of the embryo. The only alternative is to suppose that they are synthesised as required in the course of development. There are grave objections to this supposition. All the evidence at our disposal goes to show that the potentialities of germ-cells are determined at the close of the maturation divisions. Following the physiological line of argument, it must be allowed that in this connection "potentiality" can mean nothing else than chemical constitution. If we admit this, we admit the validity of the theory, advanced by more than one physiologist, that heritable "characters" or "tendencies" must be identified with the enzymes carried in the germ-cells. If this be a true representation of the facts, and if the most fundamental and primitive bond between one part of an organism and another is a chemical bond, it can hardly be the case that germ-cells—which, *inter alia*, are the most primitive, in the sense of being the least differentiated, cells in the body—should be the only cells which are exempt from the chemical influenees which go to make up the coordinate life of the organism. It would seem, therefore, that there is some theoretical justification for the inheritance of induced modifications, provided that these are of such a kind as to react chemically on the enzymes contained in the germ-cells.

One further idea that suggests itself to me and I have done. Is it possible that different kinds of enzymes exercise an inhibiting influence on one another; that germ-cells are "undifferentiated" because they contain a large number of enzymes, none of which can show their activities in the presence of others, and that what we call "differentiation" consists in the segregation of the different kinds into separate cells, or perhaps, prior to cell-formation, into different parts of the fertilised ovum, giving rise to the phenomenon known to us as prelocalisation? The idea is purely speculative; but, if it could be shown to have any warrant, it would go far to assist us in getting an understanding of the laws of the production of form.

I have been wandering in territories outside my own province, and I shall certainly be told that I have lost my way. But my thesis has been that morphology, if it is to make useful progress, must come out of its reserves and explore new ground. To explore is to tread unknown paths, and one is likely to lose one's way in the unknown. To stay at home in the environment of familiar ideas is no doubt a safe course, but it does not make for advancement. Morphology, I believe, has as great a future before it as it has a past behind it, but it can only realise that future by leaving its old, home, with all its comfortable furniture of well-worn rules and methods, and embarking on a journey, the first stages of which will certainly be uncomfortable, and the end is far to seek.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY A. J. HERBERTSON, M.A., PH.D., PROFESSOR OF GEOGRAPHY IN THE UNIVERSITY OF OXFORD, PRESIDENT OF THE SECTION.

GEOGRAPHY AND SOME OF ITS PRESENT NEEDS.

Geographical Progress in the Last Decade.

AT the close of a reign which has practically coincided with the first decade of a new century, it is natural to look back and summarise the progress of geography during the decade. At the beginning of a new reign it is equally natural to consider the future. Our new Sovereign is one of the most travelled of men. No monarch knows the World as he knows it; no monarch has ruled over a larger Empire or seen more of his dominions. His advice has been to wake up, to consider and to act. This involves taking existing geographical conditions into account. It will be in consonance with this advice if I pay more attention to the geography of the present and future than to that of the past, and say more about its applications than about its origins. Yet I do so with some reluctance, for the last decade has been one of the most active and interesting in the history of our science.

Among the many geographical results of work in the past decade a few may be mentioned. The measurement of new and the remeasurement of old arcs will give us better data for determining the size and shape of the Earth. Surveys of all kinds, from the simple route sketches of the traveller to the elaborate cadastral surveys of some of the more populous and settled regions have so extended our knowledge of the surface features of the Earth that a map on the scale of 1 : 1,000,000 is not merely planned, but actually partly executed. Such surveys and such maps are the indispensable basis of our science.

The progress of oceanography has also been great. The soundings of our own and other Admiralties, of scientific oceanographical expeditions, and those made for the purpose of laying cables, have given us much more detailed knowledge of the irregularities of the ocean floor. An international map of oceanic contours, due to the inspiration and munificence of the Prince of Oceanographers and of Monaco, has been issued during the decade, and so much new material has accumulated that it is now being revised. A comparison of the old and new editions of Krümmel's "Ozeanographie" shows us the immense advances in this subject.

Great progress has been made on the geographical side of meteorology and climate. The importance of this knowledge for tropical agriculture and hygiene has led to an increase of meteorological stations all over the hot belt—the results of which will be of value to the geographer. Mr. Bartholomew's "Atlas of Meteorology" appeared at the beginning, and Sir John Eliot's "Meteorological Atlas of India" at the end, of the decade. Dr. Hann's "Lehrbuch" and the new edition of his "Climatology," Messrs. Hildebrandsson and Teisserenc de Bort's great work, and the recent studies of the Upper Atmosphere, are among the landmarks of progress. The record is marred only by the closing of Ben Nevis Observatory at the moment when its work would have been most necessary. To appreciate the progress of climatology it is only necessary to compare the present number and distribution of meteorological stations with those given in Bartholomew's Atlas of 1899. I have not time to recapitulate the innumerable studies of geographical value issued by many meteorological services, observatories, and observers—public and private—but I may direct attention to the improved weather maps and to the excellent pilot charts of the North Atlantic and of the Indian Ocean published monthly by our Meteorological Office.

Lake studies have also been a feature of this decade, and none are so complete or so valuable as the Scottish Lakes Survey—a work of national importance, undertaken by private enthusiasm and generosity. We have to congratulate Sir John Murray and Mr. Pullar on the completion of a great work.

In Geology, I might note that we now possess a map of Europe on a scale of 1 : 1,500,000 prepared by international cooperation, and also one of North America on a smaller scale; both invaluable to the geographer. The thanks and congratulations of all geographers are due to Prof. Suess on the conclusion of his classical work on the Face of the Earth, the first comprehensive study of the main divisions and characteristics of its skeleton. English readers are indebted to Prof. and Miss Sollas for the brilliant English translation which they have prepared.

A new movement, inspired mainly by Prof. Flahault in France, Prof. Geddes in this country, Profs. Engler, Drude, and Schimper in Germany, has arisen among botanists, and at last we have some modern botanical geography which is really valuable to the geographer. I wish we could report similar progress in zoological geography, but that, I trust, will come in the next decade.

I pass over the various expensive arbitrations and commissions to settle boundary disputes which have in many cases been due to geographical ignorance, also the important and fascinating problems of the growth of our knowledge of the distribution of economic products and powers, existing and potential, and the new geographical problems for statesmen due to the political, economic revolutions in Japan and China.

It is quite impossible to deal with the exploration of the decade. Even in the past two years we have had Peary and Shackleton, Stein and Hedin, the Duke of the Abruzzi, and a host of others returning to tell us of unknown or little known parts of the globe. We hope to hear soon from Dr. Charcot the results of the latest investigations in the Antarctic.

Further work is being undertaken by Scott and his companions, by Bruce, Amundsen, Filchner, and others in the South or North Polar ice worlds; by Longstaff, Bruce, and others in the mountains of India and Central Asia; by Goodfellow and Ryder in New Guinea; and by many other expeditions.

One word of caution may perhaps be permitted. There is a tendency on the part of the public to confuse geographical exploration and sport. The newspaper reporter naturally lays stress on the unusual in any expedition, the accidental rather than the essential, and those of us who have to examine the work of expeditions know how some have been unduly boomed because of some adventurous element, while others have not received adequate popular recognition because all went well. The fact that all went well is in itself a proof of competent organisation. There is no excuse for us in this section if we fall into the journalist's mistake, and we shall certainly be acting against the interests of both our science and our section if we do so.

The Position of Geography in the Association.

It was not my intention in this address to raise the question of what is Geography, but various circumstances make it desirable to say a few words upon it. We are all the victims of the geographical teaching of our youth, and it is easy to understand how those who have retained unchanged the conceptions of geography they gained at school many years ago cavil at the recognition of geography as a branch of science. Moreover, the geography of the schools still colours the conceptions of some geographers who have nevertheless done much to make school geography scientific and educational. Many definitions of geography are consequently too much limited by the arbitrary but traditional division of school subjects. In schools, tradition and practical convenience have, on the whole rightly, determined the scope of the different subjects. Geography in schools is best defined as the study of the Earth as the home of Man. Its limits should not be too closely scrutinised in schools, where it should be used freely as a coordinating subject.

The present division into sections of the British Association is also largely a matter of practical convenience; but we are told that the present illogical arrangement of sections distresses some minds. No doubt there are some curious anomalies. The most glaring, perhaps, is that of combining mathematics with physics—as if mathematical methods were not used in any other subject.

There is undoubtedly a universal tendency to subdivision and an ever-increasing specialisation; but there is also an ever-growing interdependence of different parts of science. The British Association is unquestionably bound to take the latter into account as well as the former. At present this is chiefly done by joint meetings of sections: a wise course, of which this section has been one of the chief promoters. It is possible that some more systematic grouping of sections might be well advised, but such a reform should be systematic, and not piecemeal. It is one which raises the whole question of the classification of knowledge. This is so vast a problem, and one on which such divergent opinions are held, that I must apologise for venturing to put forward some tentative suggestions.

It might be found desirable to take as primary divisions the Mathematical, Physical, Biological, Anthropological, and Geographical groups. Mathematical applications might also be considered in each of the sections which use mathematical notations. In the Physical Group there should be the subdivisions Physics and Chemistry. Each would devote a certain proportion of time to its applied aspects, or these might be dealt with in sub-sections, which would include Engineering and Applied Chemistry. In the Biological Group there would be Botany, Zoology, in both cases including Palæontology and Embryology, and Applied Biology, which would be dealt with in one or other of the ways I have suggested, and would include Agriculture, Fisheries, &c. (Medicine we leave out at present.) In the Anthropological Group, in addition to the present Anthropology and Economics, there should be a section on Psychology, which might or might not be attached to Physiology, and have the Education Section as a practical appendage. In the Geographical Group there would be Geography and Geology, the practical applications of Geography and Geology being considered in joint meetings with other sections or else in sub-sections—for instance, Geography and Physics for questions of Atmospheric and Oceanic Circulation, Geography and Economics for questions of Transportation, &c.

The Need for Classification and Notation in Geomorphology, &c.

So much, then, for the classification of Geography with reference to the other sciences. I should like to say a few words about the subdivisions of geography and the vexed question of terminology.

In the scheme of the Universe it is possible to consider the Earth as a unit, with its own constitution and history. It has an individuality of its own, though for the astronomer it is only one example of a particular type of heavenly bodies. As geographers, we take it as our unit individual in the same way that an anatomist takes a man. We see that it is composed of different parts, and we try to discover what these are, of what they are composed, what their function is, what has been their history.

One fundamental division is into land, water, and air. Each has its forms and its movements. The forms are more obvious and persistent in the land. They are least so in the atmosphere, though forms exist—some of which are at times made visible by clouds, and many can be clearly discerned on isobaric charts. The land is the temporarily permanent; the water and atmosphere the persistently mobile, the latter more so than the former. The stable forms of the land help to control the distribution and movements of the waters, and to a less extent those of the atmosphere. How great the influence of the distribution of land and water is on the atmosphere may be seen in the monsoon region of eastern Asia.

The study of the land, the ocean, and the atmosphere has resulted in the growth of special branches of knowledge—Geomorphology, Oceanography, and Climatology. Each is indispensable to the geographer, each forms an essential part of the geographical whole. Much research work is and will be carried on in each by geographers who find their geographical studies hampered for the lack of it. As geographical progress is to a considerable extent conditioned by progress in these subjects, it would be legitimate to examine their needs. Time, however, will admit only a note on one of the barriers to progress in geomorphology—the lack of a good classification and notation.

Geomorphology deals with the forms of the land and their shaping. Three things have to be kept clearly in view: (1) The structure, including the composition, of the more permanent substance of the form; (2) the forces which are modifying it; and (3) the phase in the cycle of forms characteristic of such structure acted on by such forms. We may say that any form is a function of structure, process, and time. The matter is even more complicated, for we have instances, *e.g.* in antecedent drainage systems, of the conditions of a previous cycle affecting a subsequent one—a kind of heredity of forms which cannot be neglected.

The geomorphologist is seeking for a genetic classification of forms, and in the works of Betrand, Davis, de la Noë and de Margerie, Penck, Richthofen, Suess, and Supan and their pupils are being accumulated the materials for a more complete and systematic classification of forms. As you all know, the question of terms for the manifold land-forms is a difficult one, and apt to engender much more controversy than the analysis of the forms themselves. I believe that we shall find it advantageous to adopt some notation analogous to that of the chemists. I have not yet had time to work such a notation out in detail, but it might take the form of using different symbols for the three factors noted above—say, letters for different kinds of structure, Arabic figures for processes and Roman figures for the stage of a cycle the form has reached.

Take a very simple set of structures and indicate each by a letter:—

			Undisturbed	Faulted
Structure ...	homogeneous ...		... A	A′
	layered	horizontal ...	B	B′
		tilted...	... C	C′
		folded	... D	D′
	mixed		... E	E′

If pervious or impervious, a *p* or an *i* could be added—*e.g.* a tilted limestone with faults would be $C'p$.

Next, indicate the commoner erosion processes by Arabic numerals:—

Process ..	moving water	1
	ice	2
	wind	3
	sea	4

One process may have followed another, *e.g.* where a long period of ice erosion has been followed by water erosion we might write 2·1, where these alternate annually, say 21.

The phase of the cycle might be denoted by Roman figures. A scale of V might be adopted, and I, III, and V used for youthful, middle-aged, and old-aged, as this has been called, or early, middle, and late phases, as I prefer to term them. II and IV would denote intermediate phases.

A scarped limestone ridge in a relatively mature phase like the Cotswolds would be, if we put the process first, 1 C^1 III.; a highland like the Southern Uplands of Scotland would be denoted by the formula 1. 2·1 E^1 III.

This is the roughest suggestion, but it shows how we could label our cases of notes and pigeon-hole our types of forms—and prevent for the present undue quarrelling over terms.[1] No doubt there would be many discussions, for example, about the exact phase of the cycle, whether ice, in addition to water, has been an agent in shaping this or that form, and so on. But, after all, these discussions would be more profitable than quarrels as to which descriptive term, or place-name, or local usage should be adopted to distinguish it.

The use of such notations in geographical problems is not unknown. They were employed by Köppen in his classification of climate; and now, in the case of climatology, there is coming to be a general consensus of opinion as to what are the chief natural divisions, and the use of figures and letters to indicate them has been followed by several other authors. This should also be attempted for oceanography.

If any international agreement of symbols and colours could be come to for such things it would be a great gain, and I hope to bring this matter before the next International Geographical Congress.

[1] What I wish to make clear is that it is not necessary to invent a new term for every new variety of land form as soon as it is recognised. It will suffice at first to be able to label it. The notation will also stimulate the search for and recognition of new varieties.

The Need for Selecting Natural Geographical Units.

We have still to come to Geography proper, which considers land, water, and air, not merely separately but as associated together. What are the units smaller than the whole Earth with which our science has to deal?

When we fix our attention on parts of the Earth and ask what is a natural unit, we are hampered by preconceptions. We recognise species, or genera, families, or races as units—but they are abstract rather than concrete units. The reason for considering them as units is that they represent a historical continuity. They have not an actual physical continuity such as the component parts of an individual have. Concrete physical continuity in the present is what differentiates the geographical unit. Speaking for myself, I should say that every visible concrete natural unit on the Earth's surface consisting of more than one organic individual is a geographical unit. It is a common difficulty not to be able to see the wood for the trees; it is still more difficult to recognise that the wood consists of more than trees, that it is a complex of trees and other vegetation, fixed to a definite part of the solid earth and bathed in air. We may speak of a town or State as composed of people, but a complete conception of either must include the spacial connections which unite its parts. A town is not merely an association of individuals, nor is it simply a piece of land covered with streets and buildings; it is a combination of both.

It is true that in determining the greater geographical units, man need not be taken into account. We are too much influenced by the mobility of man, by his power to pass from one region to another, and we are apt to forget that his influence on his environment is negligible except when we are dealing with relatively small units. The geographer will not neglect man; he will merely be careful to prevent himself from being unduly influenced by the human factor in selecting his major units.

Some geographers and many geologists have suggested that land forms alone need be taken into account in determining these larger geographical units. Every different recognisable land form is undoubtedly a geographical unit. A vast lowland, such as that which lies to the east of the Rocky Mountains, is undoubtedly a geographical unit of great importance, but its geographical subdivisions are not necessarily orographical. The shores of the Gulf of Mexico could not be considered as geographically similar to those of the Arctic Ocean, even if they were morphologically homologous. The lowlands of the polar regions are very different from those at or near the tropics. The rhythm of their life is different, and this difference is revealed in the differences of vegetation.

I wish to lay great stress on the significance of vegetation to the geographer for the purposes of regional classification. I do not wish to employ a biological terminology nor to raise false analogies between the individual organism and the larger units of which it is a part, but I think we should do well to consider what may be called the life or movement going on in our units as well as their form. We must consider the seasonal changes of its atmospheric and of its water movements, as well as the parts of the Earth's crust which they move over and even slightly modify. For this purpose a study of climatic regions is as necessary as a study of morphological regions, and the best guides to the climatic regions are the vegetation ones.

By vegetation I mean not the flora, the historically related elements, but the vegetable coating, the space-related elements. Vegetation in this sense is a geographical phenomenon of fundamental importance. It indicates quality—quality of atmosphere and quality of soil. It is a visible synthesis of the climatic and edaphic elements. Hence the vast lowlands of relatively uniform land features are properly divided into regions according to vegetation—tundra, pine forest, deciduous forest, warm evergreen forest, steppe, and scrub. Such differences of vegetation are full of significance even in mountainous areas.

The search after geographical unity—after general features common to recognisable divisions of the Earth's surface, the analysis of these, their classification into types, the comparisons between different examples of the types—seem to me among the first duties of a geographer.

Two sets of studies and maps are essential—topographical and vegetational—the first dealing with the superficial topography and its surface irregularities, the latter relating to the quality of climate and soil.

Much has been said in recent years—more particularly from this Presidential chair—on the need for trustworthy topographical maps. Without such maps no others can be made. But when they are being made it would be very easy to have a general vegetational map compiled. Such maps are even more fundamental than geological maps, and they can be constructed more rapidly and cheaply. Every settled country, and more particularly every partially settled country, will find them invaluable if there is to be any intelligent and systematic utilisation of the products of the country. Possessing both sets of maps, the geographer can proceed with his task.

This task, I am assuming, is to study environments, to examine the forms and qualities of the Earth's surface, and to recognise, define, and classify the different kinds of natural units into which it can be divided. For these we have not as yet even names. It may seem absurd that there should be this want of terms in a subject which is associated in the minds of most people with a superfluity of names. I have elsewhere suggested the use of the terms major natural region, natural region, district, and locality to represent different grades of geographical units, and have also attempted to map the seventy or eighty major natural regions into which the Earth's surface is divided, and to classify them into about twenty types. These tentative divisions will necessarily become more accurate as research proceeds, and the minor natural regions into which each major natural region should be divided will be definitely recognised, described, and classified. Before this can be done, however, the study of geomorphology and of plant formations must be carried far beyond the present limits.

The value of systematic and exhaustive studies of environment such as those I suggest can hardly be exaggerated. Without them all attempts to estimate the significance of the environment must be superficial guesswork. No doubt it is possible to exaggerate the importance of the environmental factor, but it is equally possible to undervalue it. The truly scientific plan is to analyse and to evaluate it. Problems of the history of human development, as well as those of the future of human settlements, cannot be solved without this. For the biologist, the historian, the economist, the statesman, this work should be carried out as soon and as thoroughly as is possible in the present state of our knowledge.

A beginning of systematic geographical studies has also been made at the opposite end of the scale in local geographical monographs. Dr. H. R. Mill, one of the pioneers of geography in this country and one of my most distinguished predecessors in this chair, has given us in his study of south-west Sussex an admirable example of the geographical monograph proper, which takes into account the whole of the geographical factors involved. He has employed quantitative methods so far as these could be applied, and in doing so has made a great step in advance. Quantitative determinations are at least as essential in geographical research as the consideration of the time factor. At Oxford we are continuing Dr. Mill's work. We require our diploma students to select some district shown on a sheet of this map for detailed study by means of map measurements, an examination of statistics and literature which throw light on the geographical conditions, and, above all, by field work in the selected district. Every year we are accumulating more of these district monographs, which ought, in their turn, to be used for compiling regional monographs dealing with the larger natural areas. In recent years excellent examples of such regional monographs have come from France and from Germany.

The geomorphologist and the sociologist have also busied themselves with particular aspects of selected localities. Prof. W. M. Davis, of Harvard, has published geomorpholngical monographs which are invaluable as models of what such work should be. In a number of cases he has passed beyond mere morphology and has directed attention to the organic responses associated with each land form. Some of the monographs published under the supervision of the late Prof. Ratzel, of Leipzig, bring out very clearly the relation between organic and inorganic distributions, and some of the monographs of the Le Play school incidentally do the same.

The Double Character of Geographical Research.

To carry on geographical research, whether on the larger or the smaller units, there is at present a double need—in the first place, of collecting new information, and, in the second place, of working up the material which is continually being accumulated.

The Need for the Systematic Collection of Data.

The first task—that of collecting new information—is no small one. In many cases it must be undertaken on a scale that can be financed only by Governments. The Ordnance and Geological Surveys of our own and other countries are examples of Government departments carrying on this work. We need more of them. The presidents of the Botanical and Anthropological Sections are, I understand, directing the attention of the Association to the urgent necessity for complete Botanical and Anthropological Surveys of the kingdom. All geographers will warmly support their appeal, for the material which would be collected through such surveys is essential to our geographical investigations.

Another urgent need is a Hydrographical Department, which would cooperate with Dr. Mill's rainfall organisation. It would be one of the tasks of this department to extend and coordinate the observations on river and lake discharge, which are so important from an economic or health point of view that various public bodies have had to make such investigations for the drainage areas which they control. Such research work as that done by Dr. Strahan for the Exe and Medway would be of the greatest value to such a department, which ought to prepare a whether by government departments or by private We shall see how serious the absence of such a department is if we consider how our water supply is limited, and how much of it is not used to the best advantage. We must know its average quantity and the extreme variations of supply. We must also know what water is already assigned to the uses of persons and corporations, and what water is still available. We shall have to differentiate between water for the personal use of man and animals, and water for industrial purposes. The actualities and the potentialities can be ascertained, and should be recorded and mapped.

The Need for the Application of Geographical Methods to already Collected Data.

In the second direction of research—that of treating from the geographical standpoint the data accumulated, whether by Government departments or by private initiative—work has as yet hardly been begun.

The topographical work of the Ordnance Survey is the basis of all geographical work in our country. The Survey has issued many excellent maps, none more so than the recently published half-inch contoured and hill-shaded maps with colours "in layers." Its maps are not all above criticism; for instance, few can be obtained for the whole kingdom having precisely the same symbols. It has not undertaken some of the work that should have been done by a national cartographic service—for instance, the lake survey. Nor has it yet done what the Geological Survey has done—published descriptive accounts of the facts represented on each sheet of the map. From every point of view these are great defects; but in making these criticisms we must not forget (1) that the Treasury is not always willing to find the necessary money, and (2) that the Ordnance Survey was primarily made for military purposes, and that the latest map it has issued has been prepared for military reasons. It has been carried out by men who were soldiers first and topographers after, and did not necessarily possess geographical interests.

The ideal geographical map, with its accompanying geographical memoir, can be produced only by those who have had a geographical training. Dr. Mill, in the monograph already referred to, has shown us how to prepare systematised descriptions of the one-inch map sheets issued by the Ordnance Survey.

The preparation of such monographs would seem to fall within the province of the Ordnance Survey. If this is impossible, the American plan might be adopted. There the Geological Survey, which is also a topographical one, is glad to obtain the services of professors and lecturers who are willing to undertake work in the field during vacations. It should not be difficult to arrange similar cooperation between the universities and the Ordnance Survey in this country. At present the Schools of Geography at Oxford and at the London School of Economics are the only university departments which have paid attention to the preparation of such monographs, but other universities will probably fall into line. Both the universities and the Ordnance Survey would gain by such cooperation. The chief obstacle is the expense of publication. This might reasonably be made a charge on the Ordnance Survey, on condition that each monograph published were approved by a small committee on which both the universities and the Ordnance Survey were represented.

The Geological Survey has in recent years issued better and cheaper one-inch maps, and more attention has been given to morphological conditions in the accompanying monographs; but it is necessary to protest against the very high prices which are now being asked for the older hand-coloured maps. The new quarter-inch map is a great improvement on the old one, but we want "drift" as well as "solid" editions of all the sheets. The geographer wants even more than these a map showing the quality of the solid rock, and not merely its age. He has long been asking for a map which would indicate the distribution of clay, limestone, sandstone, &c., and when it is prepared on the quarter-inch, or better on the half-inch, scale the study of geomorphology and of geography will receive a very great stimulus and assistance.

The information which many other Government departments are accumulating would also become much more valuable if it were discussed geographically. Much excellent geographical work is done by the Admiralty and the War Office. The Meteorological Office collects statistics of the weather conditions from a limited number of stations; but its work is supplemented by private societies which are not well enough off to discuss the observations they publish with the detail which these observations deserve. The Board of Agriculture and Fisheries has detailed statistical information as to crops and live stock for the geographer to work up. From the Board of Trade he would obtain industrial and commercial data, and from the Local Government Board vital and other demographic statistics. At present most of the information of these departments is only published in statistical tables.

Statistics are all very well, but they are usually published in a tabular form, which is the least intelligible of all. Statistics should be mapped, and not merely be set out in columns of figures. Many dull Blue-books would be more interesting and more widely used if their facts were properly mapped. I say *properly* mapped, because most examples of so-called statistical maps are merely crude diagrams, and are often actually misleading. It requires a knowledge of geography in addition to an understanding of statistical methods to prepare intelligible statistical maps. If Mr. Bosse's maps of the population of England and Wales in Bartholomew's Survey Atlas are compared with the ordinary ones, the difference between a geographical map and a cartographic diagram will be easily appreciated.

The coming census, and to a certain extent the census of production, and probably the new land valuation, will give more valuable raw material for geographical treatment. If these are published merely in tabular form they will not be studied by any but a few experts. Give a geographer with a proper staff the task of mapping them in a truly geographical way, and they will be eagerly examined even by the man in the street, who cannot fail to learn from them. The representation of the true state of the country in a clear, graphic, and intelligible form is a patriotic piece of work which the Government should undertake. It would add relatively little to the cost of the census, and it would infinitely increase its value.

The Need of Reorganising the Geographical Factor in Imperial Problems.

With such quantitative information geographically treated and with a fuller analysis of the major natural regions it ought to be possible to go a step further and to attempt to map the economic value of different regions at the present day. Such maps would necessarily be only approximations at first. Out of them might grow other maps prophetic of economic possibilities. Prophecy in the scientific sense is an important outcome of geographical as well as of other scientific research. The test of geographical laws, as of others, is the pragmatic one. Prophecy is commonly but unduly derided. Mendeléeff's periodic law involved prophecies which have been splendidly verified. We no longer sneer at the weather prophet. Efficient action is based on knowledge of cause and consequence, and proves that a true forecast of the various factors has been made. Is it too much to look forward to the time when the geographical prospector, the geographer who can estimate potential geographical values, will be as common as and more trustworthy than the mining prospector?

The day will undoubtedly come when every Government will have its Geographical-Statistical Department dealing with its own and other countries—an Information Bureau for the administration corresponding to the Department of Special Inquiries at the Board of Education. At present there is no geographical staff to deal geographically with economic matters or with administrative matters. Yet the recognition of and proper estimation of the geographical factor is going to be more and more important as the uttermost ends of the Earth are bound together by visible steel lines and steel vessels or invisible impulses which require no artificial path or vessel as their vehicle.

The development of geographical research along these lines in our own country could give us an Intelligence Department of the kind, which is much needed. If this were also done by other States within the Empire, an Imperial Intelligence Department would gradually develop. Thinking in continents, to borrow an apt phrase of Mr. Mackinder's, might then become part of the necessary equipment of a statesman instead of merely an after-dinner aspiration. The country which first gives this training to its statesmen will have an immeasurable advantage in the struggle for existence.

The Need for the adequate Endowment of Geography at the Universities.

Our universities will naturally be the places where the men fit to constitute such an Intelligence Department will be trained. It is encouraging, therefore, to see that they are taking up a new attitude towards geography, and that the Civil Service Commissioners, by making it a subject for the highest Civil Service examinations, are doing much to strengthen the hands of the universities. When the British Association last met in Sheffield geography was the most despised of school subjects, and it was quite unknown in the universities. It owed its first recognition as a subject of university status to the stimulus and generous financial support of the Royal Geographical Society and the brilliant teaching of Mr. Mackinder at Oxford. Ten years ago Schools of Geography were struggling into existence at Oxford and Cambridge, under the auspices of the Royal Geographical Society. A single decade has seen the example of Oxford and Cambridge followed by nearly every university in Great Britain, the University of Sheffield among them. In Dr. Rudmose Brown it has secured a scientifically trained traveller and explorer of exceptionally wide experience, who will doubtless build up a Department of Geography worthy of this great industrial capital. The difficulty, however, in all universities is to find the funds necessary for the endowment, equipment, and working expenses of a Geographical Department of the first rank. Such a department requires expensive instruments and apparatus, and, since the geographer has to take the whole World as his subject, it must spend largely on collecting, storing, and utilising raw material of the kind I have spoken of. Moreover, a professor of geography should have seen much of the World before he is appointed, and it ought to be an important part of his professional duties to travel frequently and far. I have never been able to settle to my own satisfaction the maximum income which a department of geography might usefully spend, but I have had considerable experience of working a department the income of which was not very far above the minimum. Until now the Oxford School of Geography has been obliged to content itself with three rooms and to make these suffice, not merely for lecture-rooms and laboratories, but also for housing its large and valuable collection of maps and other materials. This collection is far beyond anything which any other university in this country possesses, but it shrinks into insignificance beside that of a rich and adequately supported Geographical Department like that of the University of Berlin. This fortunate department has an income of about 6000*l.* a year, and an institute built specially for its requirements at a cost of more than 150,000*l.*, excluding the site. In Oxford we are most grateful to the generosity of Mr. Bailey, of Johannesburg, which will enable the School of Geography to add to its accommodation by renting for five years a private house, in which there will temporarily be room for our students and for our collections, especially those relating to the geography of the Empire. But even then we can never hope to do what we might if we had a building specially designed for geographical teaching and research. Again, Lord Brassey and Mr. Douglas Freshfield, a former President of this Section, have each generously offered 500*l.* towards the endowment of a professorship if other support is forthcoming. All this is matter for congratulation, but I need hardly point out that a professor with only a precarious working income for his department is a person in a far from enviable position. There is at present no permanent working income guaranteed to any Geographical Department in the country, and so long as this is the case the work of all these departments will be hampered and the training of a succession of competent men retarded. I do not think that I can conclude this brief address better than by appealing to those princes of industry who have made this great city of Sheffield what it is to provide for the Geographical Department of the University on a scale which shall make it at once a model and a stimulus to every other university in the country and to all benefactors of universities.

IONISATION OF GASES AND CHEMICAL CHANGE.[1]

THE term "catalytic" was introduced by Berzelius to describe a number of chemical actions which would only take place in the presence of a third substance, which itself was apparently unchanged throughout the reaction. The first cases of such actions were investigated by Sir Humphry Davy in 1817. He showed that many mixtures of gases were caused to unite in the presence of finely divided platinum at temperatures far below those at which union ordinarily took place. Some years afterwards Faraday investigated similar actions, and attempted to explain them by a supposed condensation of the gases on the surface of the metal.

Thirty years ago Prof. H. B. Dixon investigated the behaviour of carbon monoxide and oxygen when they were dried as completely as possible, and he discovered that in these circumstances electric sparks caused no explosion. Some years before Wanklyn had discovered that purified chlorine did not act on sodium, but he did not identify the impurity, now known to be a trace of water, which causes the vigorous action which takes place in ordinary circumstances.

In 1882 Cowper investigated the action of dried chlorine on several metals, and found that the removal of moisture in many cases inhibited the reaction.

In the following year, working in Prof. Dixon's laboratory at Balliol College, I found that purified carbon could be heated to redness in dried oxygen, and that sulphur and phosphorus could be distilled in the same gas without burning. In the investigations which followed, some thirty simple reactions have been tried by myself and others. It has been shown that hydrogen and chlorine can be exposed to light without explosion, ammonia and hydrogen chloride mixed without union, sulphur trioxide can be crystallised on lime, ammonium chloride and mercurous chloride give undissociated vapours, hydrogen and oxygen can be exposed to a red heat without explosion, and lastly, in 1907, nitrogen trioxide was obtained as an undissociated gas for the first time by carefully drying the liquid and evaporating into a dried atmosphere.

The amount of water necessary to carry on these chemical reactions is extremely small, certainly less than 1 mg. in 300,000 litres. There is no accepted explanation of its catalytic effect, and in the same way the catalytic power of platinum is still a mystery. Dr. Armstrong's theory, that only water which is capable of conducting an electric current is capable of bringing about these chemical actions, seems to be supported by the fact that water can be formed in heated tubes containing very pure hydrogen and oxygen without the explosive combination of the gases taking place. That great purity does affect the chemical activity of water was proved by an experiment shown during the lecture. Two tubes, one containing water of a very high degree of purity and the other containing ordinary distilled water, were placed side by side in the lantern. Into each was filtered some liquid sodium amalgam, and while vigorous effervescence was seen in the less pure water, the very pure specimen was apparently without action for some minutes, and even at the end of the lecture its action had not attained the same vigour as that in the other tube.

In 1893 Sir J. J. Thomson (*Phil. Mag.*, xxxvi., 321) showed that if the combination of atoms in a molecule is electrical in its nature, the presence of liquid drops of water, or drops of any liquid of high specific inductive capacity, would be sufficient to cause a loosening of the tie between the atoms, and this might result in chemical combination of the partially freed atoms to form new molecules. He showed in the same paper that drying a gas very completely stopped the passage of a current of 1200 volts. In the same year I was able in the same way to prevent the passage of discharge from an induction coil, a discharge which would traverse a spark gap of three times the distance in undried gas.

Shortly after the discovery of Röntgen rays, it was found that they would ionise a gas through which they passed. At the time it was thought that this ionisation was similar to that taking place in electrolysis. If this were so the rays would probably cause chemical union to take place even in a dried gas, and accordingly Prof. Dixon and I undertook some experiments on the subject, which were published in a joint paper (Chem. Soc. Jour., 1896). The results were negative; no chemical action could be detected. Since that time the ionisation of gases has been shown to be of quite a different nature. The negative ion has been shown to be a particle of the mass of about 1/1500th that of the hydrogen atom, and the positive ion is the residue. Since the ionisation of gases is different from that in electrolysis, the retention of this term is much to be deprecated. It is suggested that the term ionisation should be retained for electrolytic dissociation, and for the different process which takes place in gases under the action of Röntgen rays, &c., a new name, electromerism, should be adopted. The electron would thus be the negative electromer.

It is probable that electrolysis and true ionisation may take place in gases, as in the decomposition of steam by electric sparks of a particular length. An experiment recently devised seems to show that in mercury vapour, which ordinarily consists of atoms, something of the nature of ionisation without electrolysis can take place. If oxygen be admitted to the interior of a mercury lamp from which the current has just been cut off, a considerable quantity of mercuric oxide is produced, although the temperature of the lamp (about 150°) is far lower than would suffice to bring about the union of ordinary mercury vapour with oxygen.

In order to test further the question as to whether electromerism can bring about chemical change, I have investigated the action of radium bromide on very pure and dry hydrogen and oxygen. The gases were sealed up with some radium bromide contained in an open silica tube. The containing vessel was provided with a vacuum gauge, by means of which the combination of 1/5000th

[1] Discourse delivered at the Royal Institution on Friday, March 11, by Dr. H. Brereton Baker, F.R.S.

part of the gases could be easily detected. No action whatever was observed, although the substances were left in contact for two months. A further experiment showed that, as was to be expected, very dry air undergoes electromerism when subjected to the action of radium. Two more tubes were then set up, similar to the first, containing mixtures of carbon monoxide and oxygen, one very dry and the other containing traces of moisture, and although the radium bromide was in contact with them for more than three months, not the slightest contraction could be observed. In these cases, therefore, electromerism produces no chemical change.

There was, however, a possibility that electromerism might bring about a chemical action in a mixture of gases which was under conditions which were nearly, but not quite, suitable for chemical action to take place. The gaseous mixtures mentioned only combine, even when moist, at a red heat. Since the experiments were done at 20°, they only show that electromerism does not produce chemical action in gases which are otherwise unable to combine.

There remained the possibility that if gases were just on the point of combining, increasing the electromerism might accelerate the rate of action. I sought for a case of simple chemical union which would proceed at a manageable temperature, and at a rate which could be measured. Of those tried, the reaction between hydrogen and nitrous oxide was found to be the most suitable. The gases used were as pure as possible, but dried only by passing through phosphorus pentoxide tubes. They were found to combine with great uniformity when heated in clean Jena glass tubes to 530°. An electric resistance furnace was used, consisting of a wide silica tube which formed the heated chamber. It is known that many substances when heated produce electromers in a gas; lime is fairly efficient, thoria more so, and, of course, radium bromide most of all. In the first experiment two tubes of the same Jena glass, containing the hydrogen and nitrous oxide mixture, were heated side by side. One contained some lime, and in order to make the conditions as similar as possible an equal quantity of powdered Jena glass was introduced into the other. As soon as the requisite temperature was reached, the action proceeded rapidly in the tube containing lime, the rate in the first five minutes being five times the rate of combination in the tube containing only powdered glass. After fifteen minutes the second tube had caught up the first, and the rates of union were equal up to the completion of the action. With thoria the effect was still more marked, the rate increasing to twenty times the rate in the tube containing the glass. Finally, about 2 mg. of radium bromide was heated in the mixture of gases. As soon as the combining temperature was reached, the gases in the radium bromide tube exploded.

From these three experiments it is seen that, as the amount of electromerism was increased, there was a rapid increase in chemical action.

I have recently been able to show that if the union of carbon monoxide and oxygen takes place in a strong electric field, which has the effect of removing electromers, the chemical action is diminished. Similar experiments are in progress with the mixture of hydrogen and chlorine, combining under the influence of light.

The next experiment tried illustrates one way in which the electromerism of a gas may bring about chemical change. Hydrogen sulphide and sulphur dioxide can be mixed at the ordinary temperature in presence of traces of moisture, but in presence of liquid water decomposition takes place into sulphur and water. The gases were dried before mixing by calcium chloride, which leaves about 4 mg. of water vapour per litre in the gas. After mixing, a small open silica tube containing about 2 mg. of dried radium bromide was introduced. After six hours no apparent change had taken place in the gas; there was no deposit of sulphur on the sides of the jar, and it seemed at first as if no action had been produced. On opening the jar, however, an inrush of air was noticed, and the contents were almost odourless. On heating the radium tube a large quantity of water was driven off, and a copious sublimate of sulphur was seen. The whole of the gaseous contents of the jar had condensed in the small tube containing the radium bromide. The explanation of this action of radium bromide is probably simple. Water vapour condenses on the electromers emitted, liquid drops are formed, and in them the chemical action takes place.[1]

Prof. Townsend has recently published an account of some experiments in which he has shown that there is a very marked decrease in the mobility of negative electromers in the presence of an amount of water vapour represented by a pressure of 1/10th mm. The air, in his experiments, was subjected to the action of Röntgen rays.

It is concluded that water in a form approaching to that of a drop is condensed on the electron even when a very small quantity is present. If this deposition of water molecules on electromers goes on when the amount of water present is still smaller, the theory of Sir J. J. Thomson affords a satisfactory explanation of the influence of moisture on chemical change, since some electromers are always present in ordinary gases.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE *Lancet* states that the University of Bristol is to receive the sum of 1000*l.* from the estate of the late Miss J. L. Woodward for the foundation of a scholarship in music or botany, to be known as the "Vincent Stuckey Lean Scholarship."

IT is proposed that the Congress of the Universities of the Empire shall be held in London in June, 1912, and a meeting of the Vice-Chancellors of the British universities is to take place in November next with the object of drawing up a provisional scheme of subjects to be discussed at the congress, which scheme will then be submitted to the overseas universities for suggestions.

AN Institute of Colonial Medicine has been established in connection with the faculty of medicine of the University of Paris. The first session will begin on October 13 and end at the close of the year. The following courses of instruction are announced:—Technical bacteriology and hæmatology, by Prof. Roger; parasitology, by Prof. Blanchard; surgery in tropical countries, by Dr. Morestin; ophthalmic affections, by Dr. Lapersonne; general epidemiology, by Prof. Chantemesse; tropical pathology and tropical hygiene, by Dr. Wurtz; and dermatology, by Prof. Gaucher in collaboration with Dr. Jeanselme.

ATTENTION has been directed here from time to time to the movement in this country to establish universities in China. We learn from the *Times* of September 13 that the success of the proposed Hong Kong University seems assured. Sir Frederick Lugard, the Governor of Hong Kong, has taken a prominent part in demonstrating the advantages likely to accrue from the undertaking, and he has been generously assisted by large contributions from the leading Chinese and others in the colony. Sir Hormusji Mody has offered to erect the buildings, whatever their cost (estimated at about 30,000*l.*), in accordance with the approved plans. Dr. Ho Kai, C.M.G., has given 18,000*l.*; Mr. J. H. Scott, senior partner of Messrs. Butterfield and Swire, has announced a gift of 40,000*l.* on behalf of his own and allied firms; and the Central Government at Peking has sent a substantial contribution. The bare minimum sum required has now been practically raised, and Sir Frederick Lugard and his helpers are appealing to the British public for the amount required to make the University worthy of British prestige. It may be pointed out that though there is no antagonism between them, there is no connection between this scheme and that associated with Oxford and Cambridge for the establishment of a university at Hankau, on the Yangtsze.

THE annual meeting of the Institution of Mining Engineers was held at the University College, Nottingham, last week. In welcoming the members, Sir Joseph Bright, chairman of the council of the college, said they hoped in the near future to establish a chair of mining

[1] I have invariably noticed that water collects in tubes containing radium preparations exposed to undried air. The salts are not at all deliquescent, the crystals appearing quite sharp-edged under the microscope. I found that 10 mg. of radium bromide exposed to an atmosphere saturated at 0° for two days caused a deposition of water on its surface weighing 1·5 mg.

engineering at the college. A paper was read at the meeting by Prof. H. Louis on the Mining School at Bochum, Westphalia, in the course of which he said that in Germany there are schools devoted to the better education of miners and the elementary training of colliery officials. The course lasts two years, and the men attend for eight hours weekly for a year and a half, and for ten hours weekly during the last six months. It cannot, he said, be imagined that the Germans would have continued those institutions for nearly a century had they not found that it paid them to do so. Surely it is high time to abandon our insular policy of not profiting by the experience of our neighbours in matters of such vital importance. In Prof. Louis's opinion it would be easy enough for the various British coalfields to form miners' funds like that raised in Westphalia for the same purpose. Future legislation should, he suggested, enact that in any coalfield where a large majority—say two-thirds—of the producers decide to take advantage of its provisions power shall be given to constitute a fund, and a levy upon the entire output of the field should thus be legalised, the fund to be administered and applied very much as the Westphalian miners' fund has been.

An examination of the calendars, prospectuses, and announcements of the London polytechnic institutions for the session which is now commencing serves to show how well the metropolitan area is provided with facilities for technical and scientific instruction. The encouragement which is extended by the authorities to the plan of giving a distinguishing character to the curricula of certain of these colleges is well brought out by an inspection of the announcements in connection with the winter's work at the Northampton Institute. We can only give a few examples. The classes in submarine cable work are being continued, and more advanced classes are projected in radio-telegraphy. The success of the pioneer courses in aëronautics given last winter has been so marked that the subject is being developed. The instruction in electroplating is being brought more into line with the actual requirements of the trade, and arrangements have been made to extend the advanced work in sight-testing and physiological optics. The South-Western Polytechnic at Chelsea continues to provide courses of study suited for a great variety of technological purposes, and also for university students. We notice from the calendar of the day work at this college that students are informed that those who enter for technical instruction should have received previously a sound English education, and should have acquired an elementary knowledge of mathematics and, if possible, of physics and chemistry. The courses are arranged to occupy three years. On entering the student states whether he wishes to be trained as a mechanical or electrical engineer, or as a consulting or industrial chemist. In any of these cases he has mapped out a complete course of study. Students who have completed a three years' course should be in a position to obtain situations in important industrial firms. Birkbeck College, too, continues its excellent work. The new calendar has again to point out that the usefulness of the college is curtailed by its limited accommodation, and its pressing need is for increased space. More spacious college buildings, with additional class-rooms and larger laboratories better adapted to modern requirements, would give a great stimulus to the work of the college and add to its public utility. We notice that 1293 students attended its classes last winter, and that about a quarter of them were women.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 12.—M. Bouchard in the chair.—J. **Guillaume** and J. **Merlin**: Occultation of η Geminorum by Venus, July 26, 1910, observed at Lyons. As the planet was only 9° above the horizon, the images observed were unsteady. The data are given in full, and calculations made of the diameter of Venus.—Carl **Störmer**: Theorems on the general equations of motion of a corpuscle in a magnetic and electric field superposed.—Paul **Floquet**: A comparison of the different methods of measuring the dielectric constant. Paraffin extracted from ozokerite has been shown by M. Malclès to possess no residual charge and to be without any appreciable conductivity. This paraffin has been utilised for comparing at the same instant the values of the dielectric constant obtained by two different static methods. The results agreed within 1 per cent., and a similar concordance was obtained for measurements based on the relative velocities in air and in paraffin of Hertzian waves.—Philippe **de Vilmorin**: Researches on Mendelian heredity.—J. **Athanasin** and J. **Dragoin**: The association of elastic and contractile elements in muscle.—E. **Roubaud**: The evolution of instinct in Vespides. Remarks on the social wasps of Africa, genus Belonogaster.—Joseph **Roussel**: The existence of three horizons of calcium phosphate in Algeria and Tunis.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), parts ii. and iii. for 1910, contain the following memoirs communicated to the society:—

February 26.—R. **König**: Conformal representation of the surface of a solid angle.—B. **Dürken**: The behaviour of the nervous system after extirpation of the limb-rudiments in the frog.—O. **Berg**: The Thomson effect in copper, iron, and platinum.

March 12.—Kurt **Wegener**: Aërological results obtained at the Samoa Observatory in 1909.

April 30.—R. **Fuchs**: Linear homogeneous differential equations of the second order with four essentially singular points.

THURSDAY, SEPTEMBER 29, 1910.

HISTORY OF BOTANY.

A History of Botany, 1860–1900, being a Continuation of Sachs' "History of Botany, 1530–1860." By Prof. J. Reynolds Green, F.R.S. (Oxford: Clarendon Press, 1909.) Price 9s. 6d. net.

BOTANICAL science has been fortunate in having had as historian a botanist of such wide knowledge and mature judgment as the late professor of botany in the University of Würzburg. Sachs' "History of Botany," which covers the period from the sixteenth century up to 1860, will always rank, not only as a standard history of botany, but also as the model of a critical study of the growth and progress of scientific thought. Botanists will be grateful to the delegates of the Clarendon Press for their decision to arrange for the continuation of the history of botany up to the close of the nineteenth century, the latter half of which has witnessed such a surprising development of the biological sciences under the stimulus of Darwin's "Origin of Species," published a year before the date at which Sachs' "History of Botany" stops. Sachs himself lays the greatest stress upon the change in outlook in morphological and systematic botany produced by Darwin's epoch-making work; but though he frequently refers to the new conception of evolution, he does not deal in detail with the Darwinian theory of evolution, owing, no doubt, to his conviction that it marked the beginning of a new era, rather than the close of the period under his consideration.

Dr. Green, who has undertaken the honourable task of continuing Sachs' history, has therefore had, as he recognises in his introduction, a very clear starting point for his survey of botanical progress during the latter half of the nineteenth century. Yet he does not commence his history, as might have been expected, with an account of the Darwinian theory of evolution. The fact that the publication of the "Origin of Species" took place a year prior to 1860, the date at which Dr. Green takes up the history, should not have been allowed to stand in the way of his dealing fully with the subject, since it received no detailed treatment in the earlier history. Even if this omission is technically justifiable, one would at least have expected a chapter dealing with such botanical work as has confirmed, elaborated, or modified the Darwinian theory of evolution. Yet Darwin's own amplifications of his theory as detailed in his "Variation of Animals and Plants under Domestication," published in 1868, are not recorded, nor is the theory of pangenesis, put forward by Darwin in 1868, and elaborated by De Vries, either mentioned or criticised. One cannot help feeling that the omission of all discussion of the theory of evolution is a serious blemish to this history of botany. It would indeed have been legitimate to have included a consideration of the work of Weismann and other zoologists who have contributed to the establishment of the theory of evolution. Some discussion, it is true, bearing on evolutionary principles is to be found in the chapters dealing with the morphology of plants, but the importance of the subject warrants a more special treatment.

In general, Dr. Green has adhered to the lines on which Sachs founded the original work, and commences with a consideration of the advances in our knowledge of the morphology of plants. In the first chapter, dealing with the nature of the alternation of generations, he discusses the classic work of Hofmeister, who first clearly established the homologies in the various groups of the Archegoniatæ, and formulated the theory of the alternation of generations obtaining in these plants. Then follows a careful and critical account of the later and divergent views as to the antithetic or homologous nature of these alternating generations, a divergence of opinion which continues to the present time. Dr. Green gives us also an excellent and impartial summary of the opposing views on morphology, on one hand the school of organographers led by Goebel, which considers that physiological requirement is the main factor affecting changes of structure, while the rival school of Naegeli and Celakovsky attributes differentiation to some inherent tendency of the protoplasm to develop in the direction of increasing complexity. In this field of thought, too, the close of the century found active difference of opinion. The difficulties, on the other hand, which had arisen with regard to the proper interpretation of the flower were, as is shown in the chapter on the morphology of the flower, largely overcome by the general acceptance of Goebel's view of the independent morphological value of the sporangium.

To the chapter on taxonomy is added a brief account of the various Floras published during the latter half of the nineteenth century, but this somewhat cursory treatment of the subject of geographical distribution of plants as an annex to systematic botany does not do justice either to the general importance from an evolutionary point of view of the distribution of plants, nor does it allow of an adequate consideration of the physiological and ecological bearing of the more recent work on plant geography. The publication of the "Origin of Species," it has been said, "placed botanical geography on an entirely new basis," yet no one would gather this from the meagre treatment accorded it in this new history of botany. Sir Joseph Hooker's great memoir on the "Distribution of Arctic Plants" is dismissed in two lines, and yet, in conjunction with his "Introductory Essay to the Flora of Tasmania," it probably did more than any other publication to win the support of botanists for the Darwinian theory of evolution. The total omission of any mention of Warming's "Ecology of Plants" and of Schimper's "Plant Geography on Physiological Basis," which represent the trend of modern studies in plant distribution, seems most unfortunate. It is equally regrettable that the series of monographs which have appeared in Engler's "Jahrbücher" and the important work of Drude on plant geography have been left out of consideration.

An interesting feature of the history is the inclusion of a special chapter on palæobotany, a branch of study conspicuously absent from Sachs' history, for before 1860 our knowledge of fossil plants, based mainly on plant impressions, was too inexact and too uncertain to be of much value in the discussion of the relationship of plants.

But with the publication of the classic memoirs of Renault and of Williamson a precise knowledge of the extinct vegetation of at least one geological period led to striking advances in our knowledge of the extinct vascular cryptogams, and the discovery, at the beginning of the present century, of the seed-bearing nature of many of the fern-like plants of the Carboniferous period, led to a remarkable advance in our conception of the course of evolution of plants and an unexpectedly complete vindication of Hofmeister's views. There is no more striking testimony of the stimulus given to the study of palæobotany by Renault and Williamson than the band of still active workers in France and England, the work of which is passed in review in chapter v.

It is perhaps in consonance with the general trend of advance in botanical science that physiology should receive a fairly lengthy treatment, but a perusal of book iii. certainly gives the reader the impression that the author has given a somewhat more detailed account of the problems of this branch of botany, and that subjects of equal importance connected with the anatomy of plants have been less generously treated.

One must take into consideration that none of the chapters on physiology deal with the physiology of the reproductive processes. These are dealt with partly in connection with the alternation of generations, and partly in connection with the morphology of the flower. But the physiology of reproduction really merits a chapter to itself, in which the modern views of the nature of fertilisation might have been more fully set forth, and the splendid work of Darwin and Müller on self- and cross-fertilisation might then have received ampler treatment.

Grateful as we feel to Dr. Green for the summaries of work done in the various fields of botany, and recognising fully their usefulness, we close the book with a feeling that it lacks the breadth of treatment and the perspective of Sachs' history. But in making this somewhat invidious comparison, we do not wish to detract from the careful and painstaking work of the author, which is shown by the very large number of books and papers which he passes under review. His task has been doubly difficult, partly owing to the fact that he has had to deal with innumerable memoirs rather than with a smaller number of great works, and partly owing to the fact that he has been called upon to write the history of a comparatively short period of scientific advance, a period, moreover, so recent as to make it difficult to get a proper perspective. These difficulties might have daunted the most courageous, and we feel duly indebted to Dr. Green for undertaking the onerous task and providing us with so useful a summary of the work done during the latter half of the nineteenth century in so many fields of botanical research.

FUELS AND FURNACES.

Fuel and Refractory Materials. By Prof. A. H. Sexton. Second edition. Pp. x+364. (London: Blackie and Son, Ltd., 1909.) Price 5*s*. net.

THIS work deals generally with natural and prepared fuels, with coal-washing, recovery of by-products, the types of furnaces for metallurgical purposes, with the working of these furnaces in regard to the economical use of fuel, with the measurement of the high temperatures produced, and the commercial testing and calorimetry of fuels, as well as with the natural refractory materials and the apparatus made from these.

The book is packed with information on this very extensive subject, although it is a little loose in places, sometimes in expression, at others with regard to information given.

On p. 39 calorific power is defined as the heat evolved, which is ambiguous. On p. 59 coal is stated to be the only important fuel except natural gas and oil, but for much special Government work and for the higher class Sheffield steels, the irons made with charcoal fuel in Sweden and elsewhere are of the greatest importance; also, later, it is stated that charcoal *has* been used in blast-furnaces, whereas at least quite recently there was charcoal pig-iron being made in one blast-furnace in Cumberland, and it is also extensively made in such countries as Sweden.

The time-honoured diagrams of charcoal burning in piles remind one how they shocked the commercial sensibilities of a former student, who was also a Swedish ironmaster, as all the beautifully arranged trunks shown would, according to him, have been cut up into planks for sale, and visits to several charcoal-burning districts confirmed the statement.

Coalite, the product of the coking of coal at a barely visible red-heat, is just mentioned, and as this new departure in coking is creating such an amount of interest in the hope that it may help in the future to reduce the smoke produced in those worst of offenders, domestic fire-grates, one would have liked a little more said about coalite.

A good account is given of fuels generally, but the cost of illuminating gas is stated as varying from 2*s*. 6*d*. to 8*s*. per 1000, whereas in Sheffield it varies from 1*s*. 4*d*. to 1*s*. per 1000 cubic feet.

The description of the use of steam in producers is very well done, but the statement that no producer is satisfactory that allows any sensible amount of CO_2 to pass into the gas is too severe, as in ordinary works practice it is not feasible to reduce the CO_2 below 4 to 6 per cent. by volume, and there is no advice given on the important matter of the thickness of the bed of fuel that should be kept for normal working.

Silicon, manganese, &c., important fuels in metallurgical operations, are not mentioned.

In dealing with standards of temperature it is not clearly enough stated that the present accepted standard is the gas thermometer, and in the description of the Wanner pyrometer, the statement that

"W" is a Nicols prism will be apt to confuse the student. The resistance pyrometer is said to give the correct temperature to a tenth of a degree at 1000° C., but owing to the coating required to protect the platinum wire for most work, nothing like this accuracy will be obtained in practice. In speaking of the useful Féry spiral pyrometer, it is indicated that one of its objections is that it will only give "black body" temperatures, but surely this limitation applies to the other radiation pyrometers also.

The account of the manufacture of Sheffield steel-melting crucibles is not correct, nor is the statement (p. 346) that the crucible is "put to dry, after which it is used without firing," as these crucibles are subjected to a very careful firing, or annealing, on a very ingeniously designed annealing grate. Also, amongst the addition of non-plastic material added to enable the crucible to be made without cracking, are mentioned burnt clay, silica, and graphite; but in Sheffield work the material used is the best ground coke-dust, which not only has this effect, but by forming a solid skeleton to the material of the crucible at temperatures at which the fireclay material is quite soft, enables the crucible to stand the necessarily rough usage to which it is subjected during the making of crucible steel, without losing its shape. If from any little accident in the annealing of the crucible air has been allowed to impinge on any part of it so as to burn out the coke-dust, the crucible loses its shape at these portions, and is exceedingly difficult to manipulate.

The whole subject-matter of the book covers a very wide field, and these critical observations are not intended to indicate that the work will not be a useful one for students, but are only intended to set them on their guard in cases where it will be necessary for them to know the exact state of practical work, or to compare with other authorities where their own experience seems to differ from the statements made in the book.

A. McWilliam.

MEDICAL PARASITOLOGY.

A Handbook of Practical Parasitology. By Prof. Max Braun and Dr. M. Lühe. Translated by Linda Forster. Pp. viii+208. (London: J. Bale, Sons and Danielsson, Ltd., 1910.) Price 10*s.* 6*d.* net.

THIS is a handy and very useful work by two extremely competent authorities, and well worth translating into English for the benefit of medical men and others to whom the German language may present difficulties. The book is divided into three parts—(i.) Protozoa, (ii.) Helminthes, and (iii.) Arthropoda. Each of these sections begins with an introductory portion, in which, after a general account of the group, very full directions are given for its practical study, with an excellent summary of the most important and useful methods of technique. The group is then dealt with systematically, those forms most important for the purposes of the book being described in their place in the classification, and for each main subdivision a common and easily obtained type is described in detail with directions for procuring and studying it. The information given is in general accurate and up-to-date—the date, that is to say, of the German edition—and the figures are clear and well executed.

In the Protozoa the step is taken of abolishing the class Sporozoa and elevating its two principal subdivisions, Neosporidia and Telosporidia, to the rank of independent classes. The Neosporidia are placed immediately after the Rhizopoda, while the Telosporidia follow the Flagellata, but with subtraction of the Hæmosporidia, which are classified with the Trypanosomidæ amongst the Flagellata as the third order, Binucleata, of that class. In their treatment of these organisms the authors take up an advanced neo-Schaudinnian standpoint with regard to certain highly controversial questions.

The term Helminthes has no zoological significance, but is used in a sense convenient for medical requirements to comprise the Trematodes, Cestodes, Nematodes, and Acanthocephala; not, however, the leeches. In the section Arthropoda, which is a brief one, an account is given of the mites, Linguatulids, lice, fleas, and parasitic Diptera. The Arthropods which transmit parasites, such as ticks and "stinging-flies" (*sic*), are dealt with under the Protozoa.

The translation is, in general, clear, but some curious results arise from the translator's desire to anglicise scientific terms. It appears to be a rule with her to convert the termination "-idium," plural "-idia," into "-ide," plural "-ides," and the consequences are in many cases very puzzling. "Coccide," for instance, suggests a cochineal insect, but means in this book a coccidian parasite. No zoologist would ever guess the meaning of "Myxides," used to denote individuals of the common parasite of the bladder of the pike, *Myxidium lieberkühni*. Most zoologists, and many people who are not zoologists, are familiar with chromidia, disguised here as "chromides." In these and many other cases the meaning of the term used can only be inferred from the context or deduced from analogy. It is also very misleading to use the term "carnivori" to denote birds of prey (p. 60); "small-pox" on p. 32 should be carp-pox; and *Trypanosoma*, in the description of Fig. 14, should be *Trypanoplasma*. It is to be regretted that the eminent zoologists and others, to whom the translator expresses her indebtedness for assistance, did not correct these vagaries.

E. A. M.

POPULAR ASTRONOMY.

(1) *Astronomy, a Handy Manual for Students and Others.* By Prof. F. W. Dyson, F.R.S. Pp. vii+247. (London: J. M. Dent and Sons, Ltd., 1910.) Price 2*s.* 6*d.* net.

(2) *Chats about Astronomy.* By H. P. Hollis. Pp. vi+226. (London: T. Werner Laurie, n.d.) Price 3*s.* 6*d.* net.

MANY signs point to the fact that the popular interest in astronomy grows from day to day. Perhaps in revolt against the merely utilitarian the world will not willingly let die the least obviously practical of the sciences. The production of books, urged by this increased interest, and rendered necessary by the extraordinary modern progress of the science, is not behind the demand. That diverse tastes and capacities have to be catered for is clearly seen in the characters of the above books. The first, condensed, but logical and lucid, will appeal essentially to the lover of astronomy having a mind comparatively trained to precise thinking, while the second frankly provides for the reader who needs spoon-feeding, and likes printed talk.

(1) A simple account of the methods and results in astronomy, without unnecessary detail, and clearly stated for the student and general reader, is the aim and in great part the achievement of this handy little manual. Such faults as the book possesses spring mostly from a too great conciseness. In such subjects as the finding of the solar parallax and the estimation of the distance of the Milky Way, it is better to keep in mind the weaker brethren than the resolute student. Too great economy of words ceases to be a virtue. Jumps, however, requiring undue intellectual effort on the part of the reader are not of frequent occurrence, while the general precision and clarity are ample compensations.

The work is comprehensive in scope, embracing the ancient astronomy and its development through the Copernican system to the most modern outlook on the universe. Recent work on astrophysics, the more intimate study of suns, near and far, is effectively presented. Very few mistakes have been noticed, though what seems an erroneous inference from diagram lxxxiv. leads to the inversion of the relative masses of Sirius and its companion, while it might be inferred from a statement on p. 116 that a magnetic field is a property of all sun-spots. This certainly is not proven.

The reproductions are effective and well chosen, and the diagrams, while efficient, have a home-made look about them which is quite pleasant, though the practice of using Roman numerals to indicate them seems wholly without virtue. An efficient and tasteful binding and handy format are further recommendations for a remarkably cheap book.

(2) Though dealing somewhat discursively with such parts of astronomy as are of most popular appeal, the common sense and individuality of the writer prevent the treatment from becoming banal. To the man in the street interested in the phenomena of the skies, the book may be recommended, and he will no doubt read it with interest and profit. In great part the author restricts himself to the realm of naked-eye astronomy. Both the manner and matter and the definiteness with which the subject is treated suggest and encourage a practical acquaintance with the phenomena on the part of the reader. The earth and its movements, stars and planets, sun-spots and comets, and the changes of the moon are among the subjects informingly and chattily dealt with. A brigbtly and amusingly written chapter on astronomers and their work gives an excellent account of a much misunderstood profession. The inset reproductions are sufficiently good, but the general appearance of the book might certainly be improved.

MARINE BIOLOGICAL RESEARCH IN BRITISH SEAS.

(1) *Bulletin Trimestrie: Conseil Permanent International pour l'Exploration de la Mer. Résumé des Observations sur le Plankton des Mers explorées par le Conseil pendant les Années,* 1902–1908. Edited by H. M. Kyle. Part i. Pp. xxxiv+79, and 10 plates. (Copenhague: And. Fred Høst et Fils, 1910.)

(2) *The Decapod Natantia of the Coasts of Ireland.* By Stanley M. Kemp. Scientific Investigations, 1908, Department of Agriculture and Technical Instruction for Ireland, Fisheries Branch. Pp. 190+23 plates. (Dublin: 1910.) Price 3*s.* 6*d.*

(3) *Report of a Survey of the Trawling Grounds on the Coasts of Counties Down, Louth, Meath, and Dublin.* By E. W. L. Holt. Part I., Record of Fishing Operations. Scientific Investigations, 1909, No. 1, Department of Agriculture and Technical Instruction for Ireland. Pp. 538+2 plates. (Dublin: 1910.) Price 3*s.*

(1) IN 1908 the International Council resolved to prepare a report on the plankton work carried out by tbe countries participating in the international fisheries investigations, and the present bulletin contains the first instalment of tbis report. The bulletin begins with lists of the stations and times of investigation, and of the kinds of nets employed and the occasions on which they were worked. Special reports are then given, in which various specialists deal with the annual and seasonal abundance of the main groups of animal and plant organisms represented in the catches. The groups so far summarised are the Tintinnoidea, Halosphæra and Flagellates, Cladocera, Pteropoda, and Copepoda. Following these special reports are synoptical charts representing the abundance and seasonal distribution of the commoner species contained in the groups studied. The material thus summarised is very considerable; 332 stations in all were worked, some 14,000 hauls were made, and altogether about 800 species of planktonic organisms were identified. It is evident, however, that the deduction of general results from this mass of material has been a difficult task. The coordination of the observations has been imperfect from the first; many changes have been made, and there has been confusion in the choice of methods of investigation. Nevertheless the results obtained are of very great value, and general facts of distribution in relation to the physical changes taking place in the sea emerge clearly from the study of tbe data. The report provides a concise and valuable summary of this extensive investigation.

(2) This is a minute and careful account of forty-seven species of decapod natant Crustacea (fifty-four in all are recorded from the entire British sea-area) collected by the Irish Fishery cruiser *Helga* off the coasts of Ireland, the main localities investigated being Rathlin Deep, the Irish Sea between Dublin and the Isle of Man, the deep water of Counties Cork and Kerry, and the region near the Porcupine Bank. The report, which is a valuable addition to our knowledge of the British marine fauna, includes full details of

the localities fished, as well as the physical conditions of the sea during the operations. The economic aspect of the research is not neglected.

(3) This is the first instalment of the results of an extensive survey of the Irish fishing-grounds, which is now being carried on by Mr. Holt and his colleagues. It is well known to those engaged in actual fishery administration that mere statistics of the quantities of fish landed at the ports afford, in themselves, information of very little value for a rational regulation of the industry. Fishery authorities competent to their work must obviously obtain at first hand a knowledge of the natural conditions of the sea areas under their control, and this has been the object of the Irish survey. The observations recorded are those of fishing operations carried on by the cruiser *Helga* at such times as her attention was not being directed to the detection of predatory trawlers; they include lists of the fishes present on the fishing-grounds visited, with the numbers taken per haul, and the individual measurements of those caught. It is quite impossible to summarise the results here stated, but one may say with confidence that the report is a contribution of essential value for a real understanding of the natural conditions of the British fisheries. J. J.

OUR BOOK SHELF.

Science in Modern Life. Prepared under the editorship of J. R. Ainsworth Davis. Vol vi., Engineering. By J. W. French. Pp. vi+225. (London: The Gresham Publishing Co., 1910.) Price 6s. net.

THE first half of this book is devoted to the various systems of power production, and the other half to the application of such power to the manifold needs of mankind; there is also a short account of the properties of, and the modern methods of manufacturing on a large scale, the chief materials used in constructional work.

In a book of this nature, which is evidently intended to give non-technical readers an intelligent idea of the remarkable work done by the engineer in providing for the varied daily needs of communities living under the complex conditions of civilised life, it is a pity that space should have been given to descriptions of machines and methods which are obsolete, and are only interesting from the historical point of view. In dealing with high-speed engines, there are two illustrations and some amount of letterpress devoted to the Willans and Robinson central valve engine, which is no longer made, though, of course, such engines are still to be found in generating stations and factories where they were installed some years ago, and where they will remain until unfit for further service; it is, however, an obsolete type. In discussing water-tube boilers Mr. French states that "of these types the most extensively adopted in the navies of the world is the Belleville water-tube boiler." This is incorrect; no recent British warship has been fitted with this steam generator, which did not prove altogether satisfactory.

That the section which deals with the applications of power is well up to date is shown by the chapter dealing with aërial navigation and hydroplanes. The latest types of machines are described and discussed. The cable-way illustrated on p. 127 was used in connection with the building of the new low-level lighthouse at Beachy Head, and not, as stated, for the Eddystone Lighthouse.

There are a dozen excellent plates, and about 600 other illustrations, which will greatly increase the utility of the book to those readers who are not familiar with such technical matters. T. H. B.

Vegetationsbilder. Edited by Prof. Dr. G. Karsten and Prof. Dr. H. Schenck. Eighth series. Part 1. Trockensteppen der Kalahari. F. Seiner. Part 2. Von den Juan Fernandez Inseln. Carl Skottberg. Part 3. Die schwäbische Alp. Otto Feucht. Part 4. Aus Bosnien und der Herzegovina. L. Adamovič. Parts 5–6. Die Flora von Irland. Prof. T. Johnson. With six plates in each part. (Jena: Gustav Fischer, 1910.) Price 4 marks each part.

THE eighth series has progressed rapidly, as six parts have been published within the year. For the first time the British Islands is represented, namely, in the double part dealing with the flora of Ireland, arranged by Prof. Johnson. It would be difficult to improve on the subjects chosen, which include *Arbutus unedo*, one of the original forest trees, *Erica mackaii*, *Erica mediterranea*, *Daboecia polifolia*, *Euphorbia hibernica*, *Eriocaulon articulatum*, and *Eryngium maritimum*. All the photographs are excellent, and the number takes rank among the best. European countries are also represented in the pictures of the plant associations of Bosnia and Herzegovina, contributed by Prof. L. Adamovič, and those illustrating the Swabian Alps, provided by Mr. O. Feucht. Naturally the magnificent spruce, *Picea omorika*, endemic to Bosnia, is selected by Prof. Adamovič for illustration, and another subject is *Pinus leucodermis*; other photographs portray associations on the chalk, serpentine, and screes. The slopes and cliffs of the Swabian Jura are rich in calcicolous plants, of which *Saxifraga aizoon* and *Saxifraga decipiens* are two of the most prominent; the illustrations of *Laserpitium Siler* and of Juniper trees about eight feet high also attract attention. The part devoted to the Kalahari desert contains photographs of the well-known trees *Copaifera mopane*, *Copaifera coleosperma*, *Kigelia pinnata*, and *Acacia haematoxylon*, in their natural habitats; a remarkable large shrub, *Sesothamnus Seineri*, discovered by the author, presents striking xerophytic characters. Dr. C. Skottsberg illustrates a number of endemic plants. *Boehmeria excelsa*, a tree growing to a height of eighteen feet, *Juania australis*, a pinnate-leaved palm, *Gunnera palmata*, and a strong root-climbing fern, *Arthropteris altescendens*, are confined to the island of Masatierra; scenes from the island of Masafuera show forest of *Myrceugenia Schultzei* and the tree fern, *Dicksonia berteroana*.

Light Visible and Invisible. By Silvanus P. Thompson, F.R.S. Second edition, enlarged. Pp. xiii+382. (London: Macmillan and Co., Ltd., 1910.) Price 6s. net.

THE first edition of Prof. Thompson's popular book was reviewed at length in NATURE of March 31, 1898 (vol. lvii., p. 506). To the new edition have been added chapters on radium and the manufacture of light, the latter being the lecture given to a popular audience at the meeting of the British Association at York in 1906. We have little doubt that with these additions the volume will continue to be read widely.

A Home-work Atlas of Maps in Black and White. Edited by Prof. L. W. Lyde. Pp. 15. (London: A. and C. Black, 1910.) Price 1s.

THESE simple maps, showing in a striking way the essential facts of the geography of each of the continents, should prove of real use in schools to give pupils guidance as to how, when answering questions, long verbal descriptions may be saved by judicious diagrams.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

British Marine Zoology.

PROF. MACBRIDE'S letter in NATURE of September 15 does not require a detailed answer, as some of his statements are merely matters of opinion; but there are a few points on which I should like to comment..

(1) Prof. MacBride says we are unable to support properly one biological station, and that he does not see how we "could be expected to support two"—the second being evidently that proposed by Mr. Pace. But why does he try to ignore the three or four other existing stations? They are all supported; some of them, so far as regards students and researchers, are very well supported indeed.

(2) When he refers to some biological station as an "expensive toy," which in his experience its local friends "soon tire of supporting," one would like to ask of what station he is writing? The statement does not seem to apply to any of those mentioned.

(3) It is difficult for one who has followed the work of the U.S. Bureau of Fisheries Laboratory at Wood's Hole to understand Prof. MacBride's words in regard to it. He says it is "devoted entirely to economic work." A moment's thought of the scientific researches issued from that laboratory by Sumner and others shows the inadequacy of such a description.

(4) As to the Canadian stations, again I think Prof. MacBride does but scant justice to praiseworthy efforts. The western station at Nanaimo was visited last September by a party of biologists from the British Association, who were, to say the least, more appreciative than Prof. MacBride.

But the main thing I want to say is that Prof. MacBride, both in his original article and in his reply to my criticism, has, it seems to me, a false ideal. Expensive equipment, large funds, increased support—these are his keynote; and not a word is said as to a rich and varied fauna, physical features affording natural facilities for research and sympathetic personal service—the factors in the case that give character and tradition to a biological station.

W. A. HERDMAN.

IT would be interesting to know what biological stations Prof. MacBride had in mind when writing the letter which appeared in NATURE of September 15.

Prof. MacBride states that it would be better to concentrate scientific support on one station than to have it spread over a number of stations poorly provided with funds and with staff, and, *ipso facto*, incapable of really first-class work. Surely there is more than one station in Great Britain which is capable of affording opportunities of first-class work, and I venture to think that the number of workers attending some of the smaller stations is ample proof of their usefulness.

The case cited by Prof. MacBride, of Chicago students travelling 1000 miles to Wood's Hole, will, I am afraid, not help many of our Liverpool students to attend vacation courses other than those held now at Port Erin, and Chicago students would have to travel nearly 1000 miles in any case to reach the sea.

There is, to my mind, a great advantage in having biological stations near to our universities, so that it is possible to reach them quickly and frequently. Such stations would serve the departments of zoology, botany, physiology, and biochemistry, and the staff of these departments would feel more at home there than at some station which was only visited at odd times, and in the control of which they would not be so immediately concerned. As a result there would be more encouragement for students to work at these laboratories, and little time lost in preparation.

With regard to the economic side of the controversy, one might quote from a paper by the director of the Fisheries Laboratory at Wood's Hole:—"But the life of the sea is an interrelated whole. Hence the futility of endeavouring, even on economic grounds, to restrict our investigations to food fishes or other animals of obvious commercial importance."

WM. J. DAKIN.

Port Erin Biological Station, September 19.

THERE are one or two matters alluded to in Prof. Herdman's and Mr. Dakin's letters on which I should like to say a word or two.

(1) I had no desire to ignore existing biological stations other than Plymouth, but, until Mr. Pace's circular appeared, I think I am correct in saying that the Marine Biological Association was alone in making its appeal for support to all the zoologists in the United Kingdom. The other stations depend on local support.

(2) The curiosity of Mr. Dakin and Prof. Herdman as to the particular station which "local friends tired of supporting" is, I think, uncalled for. Prof. Herdman's unrivalled acquaintance with biological institutions in this country surely includes acquaintance with a station which has been closed.

(3) I held up the station at Wood's Hole as an example of a laboratory devoted to purely scientific ends, and supported solely by professional biologists. That valuable scientific work of general interest occasionally issues from the laboratory of the U.S. Bureau of Fisheries, which was founded and is maintained for research on economic lines, is totally irrelevant.

(4) As to my want of appreciation of "praiseworthy efforts" in Canada, is Prof. Herdman aware that every cent of expense in connection with all three stations in Canada is borne by the Federal Government, which also pays the travelling expenses of workers?

Finally, in regard to "ideals," I would in all modesty oppose my experience to that of Prof. Herdman. For the last twenty years I have been engaged in zoological research. On a good many occasions I have visited small biological stations, but the only stations where I have been able to bring research to a successful issue are those of Naples and Plymouth, which in the matter of boats and apparatus are thoroughly equipped, and which in the matter of "sympathetic personal service" are very near perfection. A biological station where senior students can handle living animals is one thing, and one where advanced research can be done is another. In Plymouth we possess a station of the second kind, certainly, to say the least, better equipped than any other in the kingdom. It will be a thousand pities if it has to curtail its usefulness for lack of support. It was this strong feeling of the absolute necessity of a well-equipped laboratory which led me in 1906, after several summers of futile attempts to utilise the small movable laboratory, to make the motion at the meeting of the Biological Board in Ottawa which resulted in the building of the permanent station at St. Andrews, New Brunswick.

E. W. MACBRIDE.

The Spotted Kudu.

IN the *Times* of September 23 and the *Field* of September 24 (vol. cxvi., p. 607) I have given preliminary notices of the skull and skin of a hitherto unknown kudu shot by Mr. Ivor Buxton to the west of the Arusi plateau of Gallaland, in the Sahatu Mountains, and south-east of Lake Zwei, at an estimated height of 9000 feet above sea-level. As the owner has promised to present the specimen to the British Museum, I take this opportunity of making it the type of a new species.

The specimen is an adult bull, its full age being indicated by the worn condition of the cheek-teeth. The head, neck, and body are covered with coarse dark-brown hair, much more like that of a Kashmir stag or a mule-deer than that of either of the striped kudus, and the fronts of the legs are dark greyish-brown, and the remainder grey. The throat and chest lack the abundant fringe of long hair characteristic of the typical kudu, but are marked by two broad patches of white, one above the other, while the body-skin shows large white spots on the flanks and hindquarters, but no kudu-like stripes. The face has the usual tragelaphine white markings. The horns are of the kudu-type, but with a much more outward direction, and are greatly inferior in length to those of the typical species, their tips being worn to a yellow straw-colour, as in the nyala and situtunga. They have also a more distinct back ridge than in other kudu horns, and thereby again approximate to those of the two last-named species; while the bony cores have no ridge corresponding to that on the sheaths. The skull has a transverse diameter of $4\frac{1}{2}$ inches across the orbits, and a contour length of $15\frac{1}{2}$ inches, the corresponding dimensions in a skull of the typical species with horns of the same length being $5\frac{1}{2}$ inches and $14\frac{3}{4}$ inches.

The spotted kudu, as I have called the new species, is in great degree intermediate between other kudus and the situtunga and nyala. It agrees approximately in size with the typical kudu, but in horn-characters is to a certain extent intermediate between that species and the situtunga or nyala. In the presence of a white patch on the throat and a second on the chest it resembles the lesser kudu and situtunga, as it also does in the absence of a neck frill; but in its long, coarse, dark, and white-spotted coat it comes much nearer male situtungas and nyalas than to either of the striped kudus. The ears are rather narrower and more pointed than in the typical kudu.

I propose to name the species *Strepsiceros buxtoni*, reserving for future consideration the question whether this species does not render it advisable to merge the genus Strepsiceros in Tragelaphus. If that course were adopted, the typical kudu would become *Tragelaphus strepsiceros*, the lesser kudu *T. imberbis*, and the spotted kudu *T. buxtoni*.

R. Lydekker.

The Habits of Worms.

So little is known about the habits of worms that it seems desirable to place on record any new observation calculated to throw light on the subject. On September 17 I received from Mr. Edwards, curator of the Worcester Museum, a small tube containing about half a score of living worms. The letter which accompanied the tube informed me that the worms were found in a lavatory basin. It was assumed that they had found their way up through the waste-pipe, as none had been found when the plug was fixed in the bottom of the basin. The worms were taken in the morning when the plug was not inserted, and when the water had been very slowly dripping all night. They were found singly, but when placed in a tube coiled themselves into a ball, and were difficult to separate. Each worm was about three-quarters of an inch in length, possessed of red blood, and having five to eight setæ in each bundle. These features, together with the shape of the brain and spermathecæ, show the species to be *Pachydrilus subterraneus*, Vejdovsky. It was first described in 1889, and on April 8, 1892, I received it from the late Dr. Plowright, of King's Lynn. This was the first British record; but it has since been found by Mr. Southern and myself in various parts of the British Isles. It was obtained by Prof. Vejdovsky from the underground waters of Lille and Prague, and has more than once been sent to me by irate persons who complained that it had been found in their drinking water.

Pachydrilus (Lumbricillus) belongs to the large and important order of enchytræids, some of the species of which are parasitic upon plants, while others feed on decaying leaves and vegetable matter, and yet others live in the water. As I am preparing a monograph of British annelids for the Ray Society, I am exceedingly anxious to obtain information and materials for making the work complete, and shall be grateful if observers will submit specimens of annelids of all kinds for identification, together with observations of their habits.

Hilderic Friend.

Swadlincote, Burton-on-Trent.

Erasmus Darwin on Flying Machines.

Prof. Meldola's reference to Erasmus Darwin's prophecy of flying machines (p. 370) omits the most remarkable proof, as it seems to me, of his insight into the future. The verses which he quotes are from Canto I., lines 289–96, of the "Botanic Garden"; on line 254 there is a note in which occurs the following passage (the italics are mine):—

"As the specific levity of air is too great for the support of great burthens by balloons, there seems no probable method of flying conveniently but by the power of steam, *or some other explosive material*, which another half-century may probably discover."

University College, London. Arthur Platt.

CAUSAL GEOLOGY.[1]

In science there can be no orthodoxy, and consequently there are no heresies. Prof. Schwarz's book will be read and circulated, instead of being burnt as a danger to established modes of thought. It will bring, in consequence, a freshness to those who have repeated, year after year, the same explanations of phenomena in their courses of instruction. They will feel much like the humdrum banker, who thinks that he really understands his business, until his son takes him one evening to the theatre, and he meets for the first time with the ideal villains of finance. The planetesimal hypothesis of Chamberlin is held by the present author to enable "one to build up a system of geology without an appeal to the unknown and the unknowable" (p. v). "Unknowable" is a rash word; but there is a good deal more of the unknown than of the known in the explanations of earth-structure put forward by Prof. Schwarz. We remember a paper of his, in which the former boundaries of continents and oceans were ingeniously deduced from a rock-fragment discovered in a southern isle. The present work includes speculations of a similar order of magnitude, but the underlying facts are marshalled more strategically, and far bigger battalions are brought into the field.

The planetesimal hypothesis, as developed by Prof. Schwarz, leads him to the conception of a cold earth, steadily growing in bulk by the accretion of meteoritic, or, as he prefers to write it, meteoric matter. The phenomena of the surface cannot, then, be caused by shrinkage of the interior, nor can volcanic action be ascribed to general internal heat. Earth-movements (p. 189) are said to develop sufficient heat to vaporise water in the crustal layers affected by them; all this water has crept down by capillary action from the surface, and may form outbursts of steam, shattering the sedimentary rocks around the orifice. If the heat generated is sufficient to melt the sediments, the product, with the water in it, appears as an ordinary upwelling of lava.

From the author's point of view, all gneisses and granites are derived from sediments by metamorphism in dissolving waters, or by actual melting (pp. 40, 221, &c.). The ultrabasic vents of Kimberley and Pretoria, so well known as the diamond-pipes, contain "meteoric matter of the centrosphere" (p. 198), since here faulting was sufficiently profound to melt up the ferriferous masses that underlie the ordinary crust. The faulting is accounted for by the transference of sedimentary matter from one part of the surface to another, the overladen rocks flowing away under the pressure; and we are given to understand that melting, with production of granite domes, or of lava ready to arise in fissures, takes place where water is present, and where the pressure is most intense, instead of where pressure is relieved. A fine instance of revivalism in geology appears on p. 227, where Prof. Schwarz, rejecting Darwin's observations in South Africa, and *lit par lit* injection generally, urges that "thin laminæ of granite substance bedded in between metamorphosed sediments" may result

[1] "Causal Geology." By Prof. E. H. L. Schwarz. Pp. viii+248. (London: Blackie and Son, Ltd., 1910.) Price 7s. 6d. net.

from the sediments "changing into granite in the ultimate expression of metamorphism."

It would be unfair, however, to judge the author's powers of observation from this or by his more startling propositions, such as that of the reconstitution of sand-grains on p. 140. The fact that he has seen so much throughout South Africa, in a country laid bare by nature for the geologist, entitles him to a serious hearing. The emphasis that he lays on the descent of ore-material from the surface (p. 11), and on the ascent of calcium carbonate from below, recalls at once the tropical rains, and the "pans" upon the desiccating surface. But surely, as Mr. Mennell has lately pointed out in his "Petrology," there is abundant evidence of the accumulation of iron-ores under African conditions at the surface. The whole siliceous crust, however, according to Prof. Schwarz, is a residue from the leaching-out and down-sinking of iron and magnesium from the primitive meteoritic matter. The silica was first set free from this matter in a colloidal form which consolidated as chert. Quartz arose only by metamorphic action in the depths (p. 39). When we are told that chert is not crystalline, and when we reflect on the quartz deposited in cavities from solution, as is the case in limestones which retain all their fossils, we cannot help thinking that our author's earlier studies have been temporarily overcast by a cloud of planetesimals. The careless writing of some sentences suggests that the work has been pushed forward with something of the heat of a new gospel. The word "meteorite" is thus missing in the middle of p. 10; cubes of salt are said to be present (p. 57) in the "bubbles in granitic quartz"; to most field-workers the Archæan masses (p. 69) cannot seem "characterised by the enormous development of limestone"; when carbon dioxide is included in an analysis of the air, the omission of argon and its allies can hardly be excused (p. 93) by their "minute proportions"; Fig. A, a lunar area, opposite p. 22, should surely be inverted to agree with its description; and, to come to smaller matters, grammar is imperfect on pp. 3, 131, 145, and 200.

Boulder in Dwyka Conglomerate, Prieska, illustrating lateral flow in rocks under pressure. From "Causal Geology."

Yet we again and again respect Prof. Schwarz's grasp of geological literature, writing as he does in a small South African town, and his preface shows that he is still to be ranked among the inquirers, and not as the apostle of a dogma. Probably we also have been the gainers, if, after reading his well-printed and well-illustrated book, we feel that we know less than before concerning the constitution of the globe.

GRENVILLE A. J. COLE.

THE BRITISH SECTION OF THE BRUSSELS EXHIBITION.

THE importance of a Government department to deal with exhibitions could not have been better exemplified than when the King of the Belgians opened the new British section of the Brussels Exhibition on September 19. Exactly five weeks previously the section which had cost so much in thought, time, and money was reduced to a smoking mass of ruins. For a moment everyone was stunned by the extent of the loss, but within a few hours it had been determined to rebuild the section provided the reply received from previous exhibitors was satisfactory. The replies were not only satisfactory, but almost overwhelming; in fact, more space was applied for than the Commission had at its disposal.

But the rebuilding of the section was only rendered possible by the Belgian Commission placing at the disposal of the British organisers the *Salle des Fêtes*. This building was originally used for holding large congresses and meetings, and had a platform and a sloping auditorium, the side alleys being divided up into reception and cloak rooms. All the internal fittings of this building have been removed, and it has been divided up into courts in a most artistic fashion, the various courts radiating out from a central transept.

The space of the original building was 150,600 square feet; the present space is only 35,500 feet; but this fact made it difficult rather than easy to design and fit up the new section, owing to the large number of exhibitors who desired space. How rare is it for an exhibition to be ready for the opening day, even after months have been spent in collecting the exhibits! But although the work was enormous, the new section arose from the ashes in the space of five weeks, and the whole exhibit, with the exception of one or two cases, was absolutely finished when the King of the Belgians opened it. Not only was the exhibit finished, but the new catalogue, "Catalogue Officiel de la nouvelle Section Britannique," was ready on the same day for distribution. Without the machinery of the committees organised by the Royal Commission of the Board of Trade it would, however, hardly have been possible to have accomplished this feat.

In declaring the new section open, and replying to Sir Arthur Harding, the King said: "Your Excellency has associated the British and Belgian people in the eulogy which you have made in such happy terms of the work of repairing the disaster caused by the fire. Certainly the Belgians have displayed in that work their fine qualities of courage and perseverance which no misfortune can daunt, and I congratulate them upon it highly. But what shall I say of the English—of the Government as of the exhibitors—who, in reconstructing in the space of a few weeks a section as beautiful and interesting as anyone could possibly wish for, have once more shown of what that unconquerable tenacity, the characteristic of the British Empire, is capable. I find no words to express to Your Excellency my admiration and my gratitude."

One of the most interesting exhibits is that of the Thermal Syndicate. The articles are manufactured at the high temperature of the electric arc, and it is of particular interest to notice that even the intense heat of the conflagration had no effect upon the silica ware. In the new section, tubes and pipes which had been through the fire are exhibited alongside of articles freshly manufactured. These tubes have glass fused to them, but, except for slight discoloration, are absolutely uninjured by the ordeal through which they have passed.

Although Messrs. Johnson and Matthey have not been able to exhibit again, it should be mentioned that the transparent silica shown by them in the original section was also in no wise injured by the heat, although much of it was broken by the falling *débris*. The writer found pieces of platinum exhibited by the same firm absolutely embedded in fused glass, which gives a good idea of the intense heat to which everything in the burning building was subjected.

As showing the resource of energy of some of the exhibitors, mention should be made of the pottery exhibit of Mr. Bernard Moore. A large vase is shown which has been designed and manufactured since the fire and bears a commemorative design—a phœnix rising from the flames with the motto *Quod ignis debit incendium abstulit*. The Pilkington Tile and Pottery Co. also shows a commemorative vase. This is of particular interest, because it shows a new lustre which has not been discovered more than three months.

The International Salt Co., Ltd., shows salt purified by a new process. The salt is fused and air blown through it, the impurities separate out, and the pure salt is run off. Whether this process will be able to compete against the older process remains to be seen, but at least it is interesting.

Owing to the exigencies of time and of space, it has not been found possible to instal again completely the very fine display of scientific instruments and of chemical products which was shown in the original section, but the chemical court makes quite a good display. The section, as a whole, is a splendid example of what can be done by organisation and the courage which knows no defeat.

It should be mentioned in closing that the advances due to recent science have been found to be of the utmost value in the cutting and removal of the tangled mass of iron-work which is all that remains of the burnt-out parts of the exhibition. The cutting of even thick girders is done entirely by burning with the oxyhydrogen flame, and it is extremely interesting to notice how rapidly it is possible to work by means of this method.

F. MOLLWO PERKIN.

MATHEMATICS IN AUSTRIA.

AS the result of an educational conference, convened at Vienna in 1908, changes of considerable importance have been made in the curriculum of the secondary schools of Austria. At the instance of the Board of Education, the mathematical syllabus issued in 1909 for the Austrian Gymnasien has been translated into English, and it deserves the thoughtful consideration of all those who are interested in the efficiency of our own educational system. It comes at an opportune moment and forms a useful contribution to all the discussions and experimental investigations of the last few years, which should provide a sound foundation for the work of the International Commission on Mathematical Teaching, which will report to the congress at Cambridge in 1912. We do not propose to examine this pamphlet in detail, but it may be useful to note some of its salient features.

Although in recent years the theoretical has been replaced by the practical in our secondary schools to a degree which many have considered dangerous, it is clear that far more drastic measures have been adopted by the Austrian authorities. The course of arithmetic is limited to multiplication and division of decimals, contracted methods, proportion and interest. There are few who will not admit that the time spent on mixtures, discount, stocks, and the various other specialised arithmetical problems, which occupy so large a space in our text-books, might be employed to far greater advantage. At present only a small proportion of boys ever obtain a working knowledge of the elements of trigonometry and the calculus. Reform in this direction is badly needed, but it is almost impossible for changes to be made in the school curriculum so long as the various examining bodies, and in particular the Oxford and Cambridge joint board and the Civil Service Commissioners, continue to require a standard in arithmetic, which can only be attained by a large expenditure of time. There is much to be said for omitting altogether the arithmetic paper from these examinations, but, if this should be regarded as too extreme a measure, we are profoundly convinced of the desirability of restricting it to simple questions on the laws of the subject; the time thus saved would be devoted to numerical trigonometry, and consequently it would be reasonable to expect from candidates for such examinations as the leaving certificate or army qualifying an elementary practical knowledge of trigonometry. It would be difficult to exaggerate the benefits which would result from such a change as this, and we do not doubt that it will come, although not in the near future.

The next feature of interest is the importance which is attached to the idea of functionality.

"The notion of Function is recognised as the idea which differentiates higher from elementary mathematics, and a full grasp of it is held to be the proper aim of school teaching . . . the habit of looking at variable quantities as varying *continuously* and in obedience to *law* is to be fostered from the beginning."

Experience shows how slow is the growth of appreciation of this conception, but the sphere of its operation is so extensive and its application so stimulating that it well repays the effort required. If the graphical work in algebra is not designed to illustrate this principle, it is reduced to a valueless mechanical operation.

The last noteworthy variation is the combination of plane and solid geometry throughout. The cultivation of the power of thinking in three dimensions receives far more attention on the Continent than in England. Many even of those who win mathematical scholarships at our universities have no knowledge of the rudiments of practical solid geometry. There are signs, however, of change in this direction, and the value of an elementary course on plan and elevation of simple solids is being gradually realised.

Enough has been said to show that the guiding principles of this syllabus are progressive and eminently practical, and the Board of Education have done well to render it accessible.

NOTES.

The Thomas Young lecture of the Optical Society will be delivered in the lecture hall of the Chemical Society this evening by Prof. R. W. Wood, of the Johns Hopkins University, Baltimore, U.S.A. The subjects will be "The Echelette Grating" and "The Mercury Telescope."

Lieut. Filchner, the German explorer, in an address at the meeting of German naturalists and physicians at Königsberg, announced, says Reuter, that the start of his Antarctic expedition could with a certainty be fixed for the spring of 1911. He has agreed with Captain Scott, who starts from the Ross Sea for the Pole, while Lieut. Filchner's base will be the Weddell Sea, that, if the expeditions meet in the centre of the Antarctic, some of Captain Scott's party shall join his and accompany him to the Ross Sea, and that some of his party shall go with Captain Scott to the Weddell Sea.

We learn from the *British Medical Journal* that the fifth International Dairy Congress, which will be held in Stockholm in 1911, offers a prize of 20*l.* for the best essay on the nutritive value of raw milk as compared with that of pasteurised, sterilised, or evaporated milk, determined, at least in part, by experiments made upon infants. In case the raw milk is found to give the better results, it is requested that the *rôle* played by the enzymes of the milk be determined if possible. The papers, which may be written in German, French, or English, and typewritten, should be sent before April 1, 1911, to the Secrétariat-général de la Fédération internationale de Laiterie, 23 rue David Desvachez, Bruxelles, Belgium.

The observatory of the Hampstead Scientific Society is now in full working order. It is equipped with an 8-inch equatorially mounted reflector telescope, which may be used by members of the society on any evening by arrangement with the secretaries, and by the public on Saturday evenings. A special meeting of the astronomical section of the society will be held on October 5, at 8.30 p.m., at Stansfeld House, Prince Arthur Road, Hampstead, when a paper on Saturn will be read. For several successive evenings following the observatory will be devoted to demonstrations on Saturn. Inquiries may be addressed to Mr. P. H. Hepburn, one of the honorary secretaries of the astronomical section, 49 Downshire Hill, Hampstead.

The Marconi Wireless Telegraph Company announces that it has received a Marconigram from the Italian Lloyd steamship *Principessa Mafalda* stating that Mr. Marconi, who was on board, has been successful in obtaining wireless messages from Clifden, Ireland, and Glace Bay, Canada, stations up to a distance of 3500 miles, in broad daylight. A kite was used for the support of the aërial wire on the vessel, and, except for encountering high wind, which stopped kite-flying, Mr. Marconi is confident that a greater distance would have been achieved. The distance easily excels all accomplishments in the reception of wireless messages on shipboard in the daytime, the greatest previous distance at sea being 1750 miles.

The Berlin correspondent of the *Times* announces the death, in his sixty-fourth year, of Prof. Theobald Fischer, professor of geography in the University of Marburg. Prof. Fischer made valuable contributions to the knowledge of the structure of the plateau of the Atlas; and the results of most of his researches are to be found in *Petermann's Mitteilungen* and in the Proceedings of the Hamburg Geographical Society. He was the author of a work on the peninsulas of southern Europe in Kirchhof's "Länderkunde Europas," and of books on the date palm (1881) and the olive (1904).

M. G. Chavez was successful on Friday, September 23, in making a flight with a Blériot monoplane across the Alps from Brigue to Domo d'Ossola, but he had the misfortune to meet with a severe accident when landing, from the effects of which he died on Tuesday, September 27. To traverse by aëroplane a distance of about thirty miles of snow-covered mountain, including the Simplon, which reaches a height of 6600 feet, is a notable achievement, even though it has a sensational aspect. M. Chavez started at 1.30 p.m., and reached Domo d'Ossola at 2.19; over the Simplon Pass he encountered a very high wind, which caused him to take the route over the Gorge of Gondo instead of going by the shorter route over the Mousoera Pass. When quite near the landing place at Domo d'Ossola the wings of the monoplane appear to have broken, and the machine fell to the ground with M. Chavez beneath. Everyone will regret that the remarkable feat of crossing the Alps by aëroplane should have had such a melancholy termination. M. Chavez is the fifteenth airman who has been killed by flying accidents this year.

We record with regret the death, on September 16, of Mr. Hormuzd Rassam, at the age of eighty-four years. Mr. Rassam in 1845 joined Mr. (afterwards Sir) A. H. Layard to assist him in his Assyrian researches. He was sent out again by the trustees of the British Museum in 1849 to take part in Layard's second undertaking, and carried on work for the British Museum until 1854. In 1864 he was selected by the British Government to proceed to Abyssinia to try to persuade King Theodore to release Consul Cameron and other prisoners. Though at first he met with success with King Theodore, he was, after a few months, thrown into prison with the original prisoners, who had been retaken, and he was kept in chains for nearly two years. The occurrences led to the war with Abyssinia in 1868. Mr. Rassam conducted further Assyrian explorations from 1876 to 1882, and during the Turko-Russian war he was sent to Asia Minor, Armenia, and Kurdistan by the British Foreign Office. Among his published works may be mentioned "British Mission to Theodore, King of Abyssinia, with Notices of the Country Traversed from Massowah through the Soudan, the Amhara, and back to Annesly Bay from Magdala," two vols., and "Asshur and the Land of Nimrod."

The second International Congress of Alimentary Hygiene will be held in Brussels on October 4–8. In addition to the usual meetings of sections, the following lectures are included in the provisional programme:—Tuesday, October 4: Prof. Dastre, "The Ultra-violet Rays and their Application to Alimentary Hygiene"; October 5: Prof. Paterno, "The Chemical Sciences"; October 6: M. Bordet, "Hygiene and Bacteriology." Various social functions and visits to the exhibition, to the Colonial Museum, and to the Institut au Parc Leopold have also been arranged. Members and associates (subscription, 20 francs and 10 francs respectively) are admitted free to the Universal Exhibition during the time of the congress. Further information may be obtained of the honorary secretary, Mr. Cecil H. Cribb, 136 Shaftesbury Avenue, London, W.

The annual foray of the mycological section of the Yorkshire Naturalists' Union was held at Sandsend, near Whitby, on September 17–22. The magnificent old woods at Mulgrave, with their deep, well-watered ravines invariably produce a rich fungus flora independent of season, which to a very great extent determines the presence or absence of fungi in less favoured districts. Notwithstanding four previous visits, six agarics new to the British flora were met with, in addition to a species only previously recorded from Jersey. *Mycena flavipes*, a beautiful fungus with a pink cap and a bright yellow stem, was met with in some quantity. This fungus was first recorded as a British species from specimens collected in Mulgrave Woods about twenty-five years ago, and has not been met with elsewhere in this country. A considerable number of rare and interesting British species were also collected. Several parasitic fungi were also noted. The total number of species collected amounted to between four and five hundred. During the evenings, discourses on mycological subjects were given by Mr. Harold Wager, F.R.S., Mr. A. Clarke, Mr. T. Gibbs, and Mr. Geo. Massee. Mr. Cheesman exhibited a collection of Myxogastres collected in the Rocky Mountains, and Mr. A. Clarke exhibited an extensive series of coloured drawings of fungi. Much of the success of the meeting was due to the facilities kindly afforded by the Rev. the Marquis of Normanby.

PROF. FLINDERS PETRIE in *Man* for September records the discovery in the neighbourhood of the Pyramid of Sneferu (B.C. 4600) of a stone tomb dating from a time before the construction of the pyramid, the earliest private tomb in Egypt to which a date can be assigned. This burial is of the highest interest, as it shows that the body was completely unfleshed before it was wrapped in linen. It lies in a sarcophagus of red granite, the oldest stone sarcophagus known. It has long been known that in prehistoric burials the corpse was stripped of the flesh, the bones even being broken to extract the marrow. In the present case each bone was separately wrapped in linen; and the present discovery proves that the dissevering of the skeleton was the custom among the higher classes at the beginning of the Pyramid period.

IN the last progress report of work at Knossos Dr. A. J. Evans records a remarkable discovery of what he calls the "Tomb of the Double Axes," which has produced more definite evidence regarding the sepulchral cult and the conception of the after-world than any grave yet opened in Crete or prehistoric Greece. Here the double axes were socketed in sacral horns of plaster, and it would seem that the tomb, besides being a place of sepulture, was also a chapel, where the protection of the Great Mother of the prehistoric Cretan cult was sought for the shade of the departed warrior, the stone benches round the shrine being probably arranged for some memorial function in which the family took part. Inside the tomb was found a bronze axe, not of the thin ritual type, but a real prehistoric implement, probably used by the workmen at some early reopening of the sepulchral chamber to admit of the presentation of offerings to the dead.

AN interesting recent addition to the Maidstone Museum is a model of the fine dolmen situated at Coldrum, some 2¼ miles north of West Malling. The dolmen itself stands on the edge of a well-marked prehistoric cultivation terrace at the foot of the chalk escarpment and faces east, towards Kits Coty House, which is some six miles distant. It was in this dolmen that Mr. F. J. Bennett recently found some remains of prehistoric man, and it is to Mr. Bennett, assisted by Mr. Filkins, of Maidstone, that the model is due. It is built to scale, the model of each stone having been made and fixed at the site of Coldrum itself, thus ensuring an accurate representation. Mr. Bennett has also had prepared plans of the Coldrum and Addington megaliths, together with a photographic survey of the former and a tracing of the 25-inch map showing additional sarsens, so that visitors to the museum may more clearly understand the relations of the various parts and their surroundings. With so many of our megalithic remains being neglected or wilfully despoiled, it is an urgent necessity that similar models, plans, &c., should be made of the few which still remain intact.

A MEMOIR on "Factors in the Transmission and Prevention of Malaria in the Panama Canal Zone," by Dr. S. T. Darling, in the *Annals of Tropical Medicine and Parasitology*, vol. iv., No. 2, describes a number of very interesting observations and experiments on the development of the parasites of simple and malignant tertian malaria in mosquitoes, and on the infectivity of different species of anopheline mosquitoes in the region in question. *Cellia albimana*, the common white-hind-footed mosquito, a very hardy species, was found to be the most efficient transmitter of malaria, *C. tarsimaculata* scarcely less so; on the other hand, *Arribalzagia malefactor* belies its name, since it was not found possible to infect it. Incidentally, the author comes to a conclusion which will perhaps be a surprise to many—that the characteristic musical note of the mosquito is caused by the vibration of the proboscis, not by the wings in flight.

A RECENT number of the *Philippine Journal of Science* (vol. v., No. 1, Section B) contains seven papers by different investigators on the subject of the etiology of beriberi, together with a report of the discussion which followed the reading of these papers at the first biennial meeting of the Far-Eastern Association of Tropical Medicine, held at Manila in March. It was generally agreed, and a resolution was passed by the meeting to the effect, that "beriberi is associated with the continuous consumption of white (polished) rice as the staple article of diet." Evidence, experimental and otherwise, was brought forward to prove that in the process of polishing the rice the grains are deprived of certain outer layers, the pericarp and sub-pericarpal tissue, which appear to contain some substance or substances essential for the maintenance of the normal metabolism of nerve-tissues. On this view, beriberi is a disorder of metabolism, due to deficiencies of diet. The chief obstacle to the acceptance of this theory, it is pointed out, is that it does not explain the occurrence of beriberi in some tropical countries and its absence in others, such as Ceylon, where white rice is equally the staple diet of the natives. Some experts consider, therefore, that the diet is only the predisposing condition, and that the true cause of the disease has yet to be found.

A SYNOPSIS of the Silurian fossils of the South Yarra district forms the subject of a paper by Mr. F. Chapman, palæontologist to the Melbourne Museum, in the August number of the *Victorian Naturalist*. The presence of an eurypterid of the genus Pterygotus, of the peculiar brittle-star described by the author as a new genus, Gregoriara, and of the bivalve *Cardiola cornucopiae*, is stated to link the fauna with that of the British and Bohemian Silurian.

THE September issue of the *Irish Naturalist* is devoted to a report of the sixth triennial conference and excursion of the Irish Field Club, held at Rosapenna, County Donegal, on July 8–13. Notes on the natural history and archæology of the district are contributed by a number of members of the club, among which reference may be made to Mr. Ussher's announcement of the discovery of five specimens of the humerus of the great auk.

Dr. A. C. Günther, with the assistance of Mr. Tate Regan, has (in the *Journal des Museum Godeffroy*, Heft xvii., Hamburg, 1910) completed the description of the collection of fishes made in the Indian Ocean and South Pacific by Andrew Garrett. Four new species, *Trygon panapensis*, *Tetrodon regani*, *Opichthys macrops*, and *O. garretti*, are described. The report is very beautifully illustrated by twenty coloured plates.

Attention has previously been directed in Nature to the need for uniform orthography of geographical names in Government departments; this need is exemplified by the "Return" of the British Museum for 1910. In 1909 Mrs. J. A. Brooke presented to the museum a series of specimens sent from China by her son, the late Mr. J. W. Brooke, some of which went to Bloomsbury and others to Cromwell Road. Those at Bloomsbury are entered (p. 77) as having been obtained in Szechuan, while those at Cromwell Road are recorded (p. 123) as coming from Sze-chuen.

We have received copies of several papers on human skulls and skeletons and supposed evidence of human work, read by Dr. F. Ameghino before the Congreso Científico Internacional Americano, held at Buenos Aires in July last. In one he describes a skull from a cave in Cuba as a new species, under the name of *Homo cubensis*. Skeletons from the Moro district, on the Atlantic coast of Argentina, are described in a second paper under the name of *H. sinemento*, and stated to be of a more primitive type than the Neanderthal *H. primigenius*. These remains are stated to be of Lower Pampean age; in a third paper the author describes another skeleton, from the Upper Pampean, which is regarded as representing a third species, *H. caputinclinatus*. The other four papers relate to supposed evidence of man's presence in various formations, the oldest of which is classed as Upper Eocene.

To vol. xxviii., pp. 197–239, of the Bulletin of the American Museum of Natural History Dr. R. Broom contributes an important article on the relationship of the Permian reptiles of North America to those of South. After reviewing the leading types of each, he concludes that in the Upper Carboniferous northern South America was the home of a primitive vertebrate fauna from which originated both the North American Pelycosauria and the African Anomodontia (in the wider sense of the term). In the Permian this fauna invaded North America, where it soon became isolated. Early in the same epoch the Brazilian Mesosaurus reached Africa by a land-bridge, and later on appeared other types, which probably developed in the area now occupied by the South Atlantic. When sundered, the North American and African faunas underwent great development in divergent directions, the former undergoing many strange specialisations—notably in vertebral spines—while the latter showed a tendency to a great increase in the size of the limbs. This limb-lengthening, accompanied by the alteration of the phalangeal formula of the toes from 2.3.4.5.4 to 2.3.3.3.3, started the mammalian line of evolution, for directly the more specialised anomodonts raised their bodies above the ground they were well on the way to become mammals. Birds, in fact, "are reptiles that became active on their hind limbs; mammals are reptiles that acquired activity through the development of all four."

An article entitled "Hunting Birds with the Camera," contributed by Mr. W. Bickerton to the October number of the *Royal Magazine*, gives a good idea of the great patience required by anyone who desires to photograph birds. The article is accompanied by several striking illustrations, including two of a reed-warbler feeding a young cuckoo. Mr. Bickerton says that, of all our summer visiting birds, the reed-warbler has its nest used most frequently by the cuckoo to deposit her eggs. He remarks, "In the area I am describing no fewer than seven different eggs of the cuckoo lay each in a different reed-warbler's nest, left there for the latter bird to hatch out."

The second number of the botanical section of the current volume of the Philippine Journal of Science contains the latter portion of the critical enumeration of Philippine Leguminosæ prepared by Mr. E. D. Merrill, a third set of bryological determinations by Dr. V. F. Brotherus, and a short list of indigenous fungi compiled by Messrs. H. and P. Sydow.

An investigation into the causes underlying a serious loss of gooseberry bushes in Cambridgeshire is recorded by Mr. T. F. Brooke and Mr. A. W. Bartlett in *Annales Mycologici* (vol. vii., No. 2). Two fungi fell under suspicion, but definite proof in the shape of infection experiments was only obtained for *Botrytis cinerea*, although good reason is adduced for finding a second cause of disease in *Cystoporina ribis*. The diseases are not in any way connected and distinct macroscopic and microscopic characters are defined for each fungus; further, it is noted that in no case were both fungi discovered on the same plant.

A new and peculiar type of resin collector that has been tried in the pine forests of Florida, U.S.A., is described by Mr. J. S. Woolsey, jun., in the *Indian Forester* (August). The tree is tapped by two small tunnels, about an inch in diameter and five inches long, bored from a common opening or mouth tangentially through the sap wood. The collector consists of two metal caps set at right angles, and connected by a hollow angle piece. One metal cap is fitted over the mouth, while a glass jar, into which the resin flows, is fitted to the other horizontal cap. It is claimed that the method gives an increased yield and a clean gum, and that evaporation is avoided.

Systematic articles are prominent in the latest issue of the *Kew Bulletin* (No. 7), as, in addition to a long series of new species of Protea and other African diagnoses, Mr. J. S. Gamble contributes a second list of new Lauraceæ from the Malayan region, principally additions to the genera Cinnamomum, Alseodaphne, and Notophœbe, and Dr. O. Stapf presents a revision of the Australian plant *Epacris heteronema*. Also Mr. G. Massee describes several new exotic fungi, including a Sphærulina and a Phoma, both discovered on *Welwitschia mirabilis* in Damaraland. More important from an economic aspect is *Eutypa caulivora* (Sphæriaceæ), a parasite collected on rubber trees in Singapore, that kills its host by blocking up the water channels with mycelium.

The Australian Commonwealth Bureau of Meteorology has commenced the issue of a monthly report from January last. It is intended to embody, *inter alia*, discussions on current weather, daily observations at each of the capital cities, and extracts, or brief articles, on matters of general scientific interest, and, judging from the first number, it gives promise of taking a prominent place among the leading weather bulletins. The principal article in the

January number deals with the disastrous flood during that month in the Upper Darling tributaries, owing to abnormally heavy rains, attributed by Mr. H. A. Hunt to the joint action of an anticyclonic area over the southern half, and a monsoonal depression operating in the northern half, of the continent. In the Namoi basin several places recorded more than 12 inches of rain between January 11 and 15, and at Bingara, in the area of the river Gwydir, 19·44 inches were registered, the normal for the whole month being $3\frac{1}{4}$ inches. The report states that, generally speaking, the amount of damage was inestimable, but the deposit left by the subsidence of the water has rendered the soil fertile over a vast area.

We have received copies of several papers which have been published recently by members of the staff of the Reichsanstalt at Charlottenburg, amongst them one on the thermal expansion of metals, by Dr. E. Grüneisen, which appeared in the *Annalen der Physik* for August 5. The first part of the paper deals with the observations of expansion of platinum, palladium, copper, silver, aluminium, iron, nickel, and iridium made previously at the Reichsanstalt by Holborn, Day, Scheel and others, and the second part with observations made by the author on magnesium, zinc, cadmium, antimony, iridium, gold, lead, and bismuth by comparison of the expansion of a bar of each metal with that of a platinum standard bar by a method analogous to the double-mirror method of determining the bending of a beam. With the exception of zinc, cadmium, and possibly tin, the whole of the metals which have regular expansions confirm Thiesen's law that the rate of expansion is proportional to a power of the absolute temperature. The author finds that the power lies between 0·06 and 0·5, and is a periodic function of the atomic weight of the metal.

Engineering for September 23 contains a photograph of submarine "D 1," which is the largest vessel of its class belonging to the British Navy. An interesting development in this vessel consists in the application of wireless telegraphy to submarine work. Successful experiments have been carried out recently with this vessel in Torbay, the crusier *Bonaventure* establishing and maintaining communication with the "D 1" when submerged. The "D 1" replied from below the surface. The installation was tested when the submarine was submerged to a depth just sufficient to keep the periscope above water, *i.e.* about one-half of the telegraphy mast was below water. The possibilities of such a development are considerable, as not only could the actions of submarines be directed by these means from larger vessels, but a flotilla of submarines will be able to use the system for the purpose of communicating among themselves when submerged, their value in naval warfare being thus considerably improved.

The progress of the great Barren Jack dam in Australia is described in the *Engineer* for September 23. This dam will be one of the largest in the world when finished. The design in plan gives a length of 784 feet, curved to a radius of 1200 feet, and a maximum height of 240 feet. The structure is of cyclopean concrete; the base is 163 feet wide and 20 feet high, with vertical sides, and this level has now been reached. The catchment area embraces 5000 square miles, mostly of hard shale formation, and much of it mountainous, which is snow-fed in winter. The maximum depth of water behind the dam will be 224 feet, and the capacity will be 33,380 millions of cubic feet. Nature has furnished a gorge in hills of granite, providing the best site and best materials for a dam, behind which is an unfailing supply of rainfall; a natural 220-mile channel, and, at the proper place, a foundation for a distributing weir. That advantage is now being taken of this almost ready-made but long neglected irrigation opportunity is a matter for congratulation. It is not intended to wait for the completion of the work before putting it to use. The building contract provides for the wall reaching a height of 110 feet in August, 1911, when storage will be started, so as to ensure irrigation in the summer of 1911–12. The remainder of the dam is to be finished in August, 1913.

We have received from Ozonair, Ltd., of 96 Victoria Street, a catalogue of apparatus suitable for laboratory and research work. Four arrangements are described ranging in cost from 15*l.* to 100*l.* for alternating, and from 25*l.* to 110*l.* for direct current, for a complete installation operated from the street mains. It is claimed that the yield of ozone is greater than that of any other generator, and that the purity of the effluent is unapproached.

A report on recent progress in the chemistry of the sugars, by Mr. J. S. Hepburn, appears in the Journal of the Franklin Institute for August. This paper reviews the work of Emil Fischer upon sugars and ferments, describes the synthesis of monoses, disaccharides, and glucosides, and discusses the fermentation of the sugars, the action of the various inverting enzymes, and the lock-and-key theory of enzyme action. The splitting of racemic sugar derivatives into their active components and asymmetric syntheses within the sugar are also considered. References are given to original papers, of which no fewer than seventy-four are by Prof. Emil Fischer and his colleagues or pupils.

A supplement of eighty-four pages to the *Columbia University Quarterly* gives an account of the Charles Frederick Chandler testimonial, presented on the occasion of his retirement from the positions of head of the department of chemistry and dean of the School of Mines of Columbia University. Prof. Chandler has been a college teacher during fifty-four years, and his retirement marked the close of his forty-sixth year of service at Columbia. A bibliography of fifty publications testifies to the fact that his keen interest in pure science was allied with much work of a public and philanthropic kind. His work on behalf of public health in New York was of the utmost value, and the story of his midnight raid upon the cattle stalls of Washington Market, as set forth in the *Columbia Quarterly*, will form a fascinating feature in some future history of municipal cleansing; the ingenious methods by which in the following years he overcame the prejudice of the poorer people against the isolation of small-pox cases is an eloquent testimony to his versatile ability.

Two important crystallographic papers, by Prof. Armstrong and Messrs. Colgate and Rodd, have recently appeared in the Journal of the Chemical Society. The investigation has been in progress since 1892. The work now described includes the crystallographic examination of no fewer than twenty-nine derivatives of the *p*-dihalogenbenzenesulphonic acids; but considerable progress has already been made in the study of the five similar series of isomeric acids in which the two halogens occupy the *ortho* and *meta* positions relatively to one another. The series now described is comparatively simple in its crystallographic properties; almost all the compounds belong to one of the two types of close-packed arrangement which Barlow and Pope have indicated for the benzene molecule, namely, the rhombohedral arrangement, in which (*a*) one parameter has a value slightly below 2·780, or (*b*) two of the parameters are nearly equal. Amongst the sulphonic chlorides and bromides two isomorphous series are seen, the second series being restricted to compounds in which an iodine atom is present; it is noteworthy that the two chloriodobenzenesulphonic chlorides are found in different series, and that one of them was on one occasion obtained in a labile form, the crystals becoming cloudy and opaque when removed from the solvent from which they had separated. This behaviour indicates clearly that certain members of the series are actually dimorphous, and the whole series may therefore be regarded as isodimorphous. Isodimorphism was also detected amongst the anilides and toluides. It is remarkable that two other series, containing the halogen atoms in the *meta* position, which were examined by Dr. E. C. Jee in 1900, proved to be isotrimorphous and isotetramorphous respectively. The completion of the work on these series will be awaited with interest.

A SECOND edition of "A Text-book of Zoology," by Profs. T. Jeffrey Parker and W. A. Haswell, is announced as nearly ready by Messrs. Macmillan and Co., Ltd. The work has been subjected to careful revision throughout; some parts have been to a great extent rewritten, and a considerable number of new illustrations have been added.

OUR ASTRONOMICAL COLUMN.

VELOCITIES AND ACCELERATIONS OF THE EJECTA FROM HALLEY'S COMET.—Profs. Barnard and Lowell and Senor J. Comas Sola all deal with the velocities and accelerations of the matter ejected from the body of Halley's comet, during May and June, in No. 4441 of the *Astronomische Nachrichten* (pp. 11–16).

From measures of photographs taken at the Yerkes Observatory (Y), Honolulu (H), and Beirut (B) on June 6, Prof. Barnard found the velocities of recession, of a well-marked feature in the tail, given in the following table:—

Stations	Interval between photographs	Hourly motion	Recession per second			
			From comet		From sun	
	Hours	′	Miles	km.	Miles	km.
Y–H	4·25	3·60	23·1	37·2	39·7	63·9
Y–B	15·15	5·17	33·1	53·3	49·7	80·0
H–B	10·90	5·78	37·3	59·7	53·9	86·4

These results show a strong acceleration in the mass measured, which was about 1·5° from the head; from the last two photographs this acceleration was about 14 miles (22 km.) per second.

Similar results are obtained by Prof. Lowell from the measures of two photographs taken, with rather less than an hour's interval, on May 23. On these photographs are shown four knots in the tail, at distances varying from 1° 28′ to 6° 15′ from the head, and the measures give for the velocities of the particles composing the knots 13·6, 17·2, 19·7, and 29·7 miles per second respectively, thus showing an acceleration of the velocities as the particles receded further from the head.

Senor Sola, dealing with the velocities of the gaseous globes ejected from the nucleus on June 4, shown on photographs taken on June 4, 6, and 7, finds that between June 4 and 6 the acceleration of these ejecta was 0·148 metre per second, and between June 6 and 7 was 0·248 metre per second.

OBSERVATIONS OF COMETS.—New observations of three comets are published in No. 4441 of the *Astronomische Nachrichten*. A number of observers give positions, determined during August, of Metcalf's comet, 1910*b*, and generally describe it as a faint object, magnitude about 11·0, having a central condensation and a suspicion of a tail.

D'Arrest's comet was observed at the Algiers Observatory on August 26 and 29 and September 1 by M. Gonnessiat. The correction to Leveau's ephemeris was an increasing quantity, and on September 1 had the value −1m. 19·39s., +6′ 16·2″; the comet is described as a diffuse nebulosity of 2′ or 3′ diameter, with a feeble, central condensation of about magnitude 14·5.

With a 9-inch refractor Mr. Innes found that, on August 11 and 12, Halley's comet was a most difficult object, and was, therefore, much fainter than the magnitude (7·4) given in No. 4423 of the *Astronomische Nachrichten*. Observations made between July 26 and August 11 indicate a correction of about −11s. to the ephemeris given in the same place; the ephemeris is nearly correct in δ. When last seen the comet was a nebulous object, of 1′ diameter, showing a slight condensation.

THE SOLAR PHYSICS OBSERVATORY, SOUTH KENSINGTON.—From the report published by the Board of Education, dealing with the work done at the Solar Physics Observatory, South Kensington, during 1909, we learn that spectroheliograms of the solar disc were obtained on 147 days during the year; of the 286 negatives secured, 231 have been selected for the measurement of flocculic areas in pursuance of the scheme for establishing a cooperative daily record of such areas. Fifty-seven photographs showing the calcium prominences at the limb were also secured with the spectroheliograph. Visual observations of the sun were possible on 232 days, and "no spots" was recorded on five occasions. The spectra of 138 spots were observed visually, and show that the lines chiefly affected, in the region F–D, are due to V, Ti, Sc, and Mg, associated with H. A powerful instrument for the photographic recording of sun-spot spectra cannot be used owing to the vibration occasioned by traffic in the vicinity. Work with the 36-inch reflector on Halley's comet and other objects was also restricted by the poor observing conditions. A large number of photographs of stellar spectra were secured with various prismatic cameras, those obtained with a calcite-quartz optical system being employed for the temperature-comparisons of various stars.

THE DETERMINATION OF LONGITUDE.—In an interesting brochure of sixty-two pages, now published as an extract from the journal *L'Horloger*, Dr. Jean Mascart recounts the history of the determination of longitudes, with a special chapter on the invention and development of marine chronometers, and an account of the voyage of the *Flore*, which had for its purpose the actual testing of the different methods of determination, in 1771–2. The brochure is well illustrated with portraits and cuts of historical instruments and their parts, and contains numerous references to the literature of the subject with which it deals.

THE ROYAL COMMISSION ON WELSH MONUMENTS.

THE first report of the commission contains a general account of work already done, and an outline of the work proposed to be done. The first volume of classified information the commission hopes to publish in the course of the present year, in the form of an inventory of monuments in the county of Montgomery.

The task undertaken is truly immense. No type of monument nor available source of information seems to have been overlooked in the outline given. There are, of course, inevitable limitations to be considered, but it is not likely that the work in value and extent will ever be a subject for serious adverse criticism. As, however, the commission's plan of campaign has been published at a time when that plan may be reconsidered in some details before the information collected has been cast into a final form, one may venture to direct attention to a class of facts which is not even mentioned in the report, but which may be shown to be by far the most important within the scope of the inquiry.

The most important documents are the monuments themselves. Whatever facts may be directly elicited from them take precedence of all facts elicited from "finds," folklore, and documentary information. They may be called structural facts, and they are to be regarded as facts irrespective of any theory. So long as such facts may be gathered, as a rule, at every ancient site, there seems to be no valid reason why they should not be treated as of first importance in any examination of ancient monuments. Opinions may differ greatly as to the value of deductions from the facts, but no difference of opinion can possibly justify a policy of turning a deaf ear to the positive testimony of the monuments themselves.

The sharpest distinction should be made between the testimony of a structure and that of any "finds," and the commission's chief object is to make an inventory of structures. Judging a structure by the finds alone, the popular epithet "sepulchral" is often tolerable, but the epithet does not explain the structure even of a hermetically closed cist, which everybody would regard as sepulchral. Now, "grave goods" have been given a place in the commission's schedule, and for that reason alone one would claim recognition of the structural facts. The relation of a burial to the surface soil is particularised, and such details show that the structural facts, in a way, are included in the schedule. The facts I have chiefly in mind are measures, both angular and linear. Some measures of the sort, of course, are given in ordinary reports and plans of monuments, but measures made on the lines of a working theory, based on the sum of knowledge already gained by measurements, must be much more to the point than any measures made with absolutely no theory in view. Even when a working theory is adopted, some technical knowledge is indispensable for making the required measures.

The subject, I understand, has been considered by the commission. Some information bearing on the astronomical inquiry, which I had the honour of submitting at the Cardiff meeting, was accepted. I understand, further, that some arrangements have been, or are being, made for making measures. The report, however, gives us no light on the matter. There is not even a recommendation of the inquiry. We are told what features of ancient churches are to be observed, but not a word about the one feature which usually gives character to the whole, orientation.

If measures of monuments have any meaning—and if they were and likely to remain meaningless, to ignore them would be a reckless accommodation to our ignorance—that meaning must be the vertebral column of any body of information about them. In most, if not all, branches of scientific inquiry measurements take precedence of any other data. If such a commission were appointed to gather anthropological data, is it likely that anthropometry would be given a second place in the inquiry? A similar method for archæological research has been devised in which measurement forms the first and best basis for a classification of monuments, all apart from any theory as to the significance of the measures. To those who are in the habit of regarding measures as constituting the very soul of a monument, the preservation of measures is the best possible preservation of a monument.

One can easily understand why a representative body of archæologists should hesitate a little before giving its endorsement to a line of inquiry which has to make its own way into favour. Probably at a mixed gathering of archæologists a majority might be found in favour of keeping it in abeyance. The commission might justify its silence, if not inaction, in such a matter, to such an audience, by referring to the element of prejudice which unfortunately is not confined to non-scientific bodies. There is, however, no evidence, so far as the commission is concerned, of such a slavish subjection of what should be a free, open, and thorough inquiry to the idiosyncrasies of the human equation. Just as the commission seeks the sympathetic cooperation of the Welsh public in its work, it is to be hoped that a representation of this kind will receive an equally sympathetic treatment by the commission itself.

The task of sifting and sorting the contents of the vast drag-net which the commission has cast over Wales is not an enviable one, but a better master of method in handling such materials could hardly be found than the secretary, Mr. Edward Owen.

John Griffith.

ANNUAL REPORT OF THE GOVERNMENT LABORATORY.

The report of the principal chemist of the Government Laboratory, London, upon the work of the department during the last fiscal year, contains, as usual, a mass of information respecting the chemical examinations and inquiries made for the various branches of the executive. On former occasions we have described the general work of the laboratory in some detail, and will therefore, in the present instance, merely note a few of the many miscellaneous points of interest mentioned in the report.

Conformably to the provisions of the White Phosphorus Matches Prohibition Act, 1908, which came into operation on January 1 this year, a number of samples of imported matches were examined in order to ascertain whether they were free from the white or poisonous form of phosphorus. In only seven instances, however, out of 647, was white phosphorus found to be present. The importation of the matches in these consignments was prohibited. They were but an insignificant proportion of the total matches imported. Only doubtful cases are dealt with in the laboratory, as the absence of white phosphorus is shown in the great majority of cases by simple tests which have been devised for application by the local customs officials. The effect of the Act already has been to stamp out the use of white phosphorus in imported matches; and as regards matches made in the United Kingdom, samples of the paste used for "tipping" have been taken from the factories, but in no case has the use of white phosphorus been detected.

A number of samples of beer and brewing materials were found to contain arsenic in excess of the limits laid down by the Royal Commission on Arsenical Poisoning. One sample of malt contained as much as one-eighth of a grain of arsenic per lb., and the beer brewed from it showed a considerable excess of the poison. The brewers were immediately warned of the danger of allowing such beer to go into consumption. On investigation, the presence of the arsenic was traced to the fuel used for kiln-drying the malt.

Articles of food taken from the canteens on board naval vessels were not in all cases free from objection. Thus, of four samples of "lard," one consisted of cocoa-nut oil, one was considerably adulterated with cotton-seed oil and beef stearine, and the remaining two gave evidence of slight contamination with cotton-seed oil; and out of four samples of condensed milk, one was found to be a "skimmed" product and another was deficient in fat. The general Admiralty supplies, however, were found to be usually satisfactory.

The tendency of makers of foodstuffs to work down to a "standard," when one has been fixed, is exemplified by a remark which the principal chemist makes in regard to the proportion of water in imported colonial butter. Since the fixing of the limit of water at 16 per cent., "the quantity of water in colonial butter, formerly exceptionally low, is now nearer the limit, and occasionally exceeds it." Two samples of imported "pastry margarine" were found to contain solid paraffin, in one case as much as 10 per cent. Amongst miscellaneous samples analysed may be mentioned certain feeding-meals which were examined in connection with alleged poisoning of cattle; in some instances the meal was found to contain Java or Rangoon beans, which, on digestion with water, produce prussic acid through the influence of an enzyme. In another case of cattle poisoning, the food was found to have been contaminated with an arsenic-paste sheep dip.

In connection with lead poisoning in the pottery industry, a large number of samples were examined. From works in which cases of plumbism had occurred, thirty-six specimens of glaze were taken. The proportion of lead oxide in these glazes varied from 12·6 to 47·5 per cent., and it is noteworthy that, with one exception, the lead was almost wholly present as a soluble compound.

Samples of air from certain mines in Scotland were found to be very impure, proportions of carbon dioxide as high as $3\frac{1}{2}$ per cent. being shown, and as much as 16 per cent of methane; whilst the oxygen in one sample had been reduced to $15\frac{1}{2}$ per cent.

Arising out of suspected frauds in connection with claims for old age pensions, the Government chemists were asked if possible to ascertain the date of entries made in family Bibles, old letters, and certificates. In some cases they were able to show, from the nature of the ink employed, that the writing was comparatively recent, and that the entries had been made for the purpose of manufacturing evidence in support of the claim.

The total number of analyses and examinations made during the year at the two main laboratories (Clement's Inn and Custom House) was 170,033, the greater number being in connection with dutiable articles. Legal proceedings were taken in 223 cases for contraventions of revenue laws, and the total amount of fines paid was 2877*l*.

THE ARCHÆOLOGICAL SURVEY OF NUBIA.

THE last Bulletin of the Archæological Survey of Nubia describes excavations in the cemeteries and buildings of the ancient district of Pselchis, which will become submerged when the new Nile barrage is completed. The results are to some degree unsatisfactory, owing to the prevalence, even from ancient times, of the practice of *sebakh*-digging by agriculturists in order to obtain fresh supplies of rich soil to re-fertilise the land, which is periodically covered by a layer of fine sand drifted by the prevailing wind. This results in the destruction of many interesting remains; and treasure hunters have also done much damage, but the operations of the latter can be easily distinguished from the ruder methods adopted by the farmers.

The anatomical reports by Prof. G. Elliot Smith and Dr. D. E. Derry are, as usual, exhaustive, and present much valuable information. They disclose the advance in the Byzantine-Pagan period, between the second and fourth centuries A.D., of a group of negroes from the south with distinctive physical characteristics, customs, and arts. Their occupation of these new settlements was certainly not altogether peaceful, many skeletons showing evidence of death by wounds, and one, in particular, with such extensive cranial injuries that it is difficult to understand how the victim could even for a short time have survived. One of the negresses whose remains were discovered in this cemetery displays an extremely abnormal type of prognathism. While the alveolar index of adult Europeans is 96·2, and that of African negroes 104·4, this specimen gives an index of 123·3, which is little below that of the chimpanzee, 128·8. It would be interesting to identify this abnormal type with that of some modern race; and a clue may be found in the fact that the negroes whose remains were found here practised the custom of filing the teeth, which, with removal of some of the incisors, still prevails among the Masai and some of the Kavirondo Bantus.

It seems to be generally believed that the latter races derived this custom from the Dinka and other allied Nilotic peoples, some of whom may have supplied the individuals whose remains have now, in such strange circumstances, been subjected to scientific examination. The question of the ancient prevalence of tuberculosis is also advanced by the fact that many of these people suffered from spinal disease due to this malady. It must have been common among them, because the high average of cases found in these cemeteries cannot be accounted for by the supposition that this site was used as a sanatorium for this class of disease.

MANGANESE-ORE DEPOSITS.

THE paper referred to below[1] gives an elaborate and interesting account of the occurrence of manganese ore in Sandur, one of the States of the Presidency of Madras; its value lies mainly in the abundance of detail given respecting this one particular occurrence, and it thus lacks the broader economic interest that attaches to that recent admirable memoir dealing with the manganese deposits of the whole of India, "The Manganese-ore Deposits of India," by Dr. L. L. Fermor, Mem. Geol. Surv. India, xxxvii., which appeared at the commencement of the present year, and which has given so much valuable information regarding the occurrence and distribution of this ore. Mr. Ghose gives no figures at all to show the output of manganese from the State of Sandur, and thus avoids directing attention to its relative unimportance; it may therefore be as well to make up here for his shortcomings in this respect:—

Production of manganese ore during 1908 in the State of Sandur, 23,413 tons.

Production of manganese ore during 1908 in the Presidency of Madras, 513,845 tons.

Production of manganese ore during 1908 in the whole of India, 2,584,525 tons.

The production of ore, of which the paper treats, is therefore less than 1 per cent. of the output of India, and may be looked upon as economically negligible; it would accordingly be difficult to justify the concluding sentence of Mr. Ghose's paper, in which he characterises these Sandur deposits as "among the largest and most remarkable manganese-ore deposits of the world." Such exaggeration of language is out of place in a scientific paper, especially seeing that, as a matter of fact, the Sandur deposits are considerably smaller than those of Nagpur or Balaghat, whilst the ore is also apparently of inferior quality. In the same way, the estimates of the probable ore reserves may be dismissed as resting on very slight foundation.

The interest of the paper centres essentially in the geological description of the occurrences, and in the author's views as to their formation, which differ entirely from those put forward by the India Geological Survey authorities. Dr. Fermor looks upon these manganese deposits as having "been formed by the replacement at the surface of Dharwar schists, phyllites, and quartzites" in such a manner as to form a capping approaching to laterite in its character, and he accordingly designates these ores as "*lateroid* replacement masses"; this view appears, moreover, to be endorsed by Sir Thomas Holland. Mr. Ghose, on the other hand, considers that these "deposits primarily owe their origin to sedimentary deposition from magmatic solution. Their economic value has been enhanced by secondary enrichment." It should be noted that he does not use the term "magmatic solution" in the sense in which it has generally been employed by writers on ore deposits, but means in this case hot solutions containing iron and manganese, flowing in horizontal currents over the floor of an ocean.

Apart from all other considerations, it is obvious that these two theories would assign widely different economic values to the ore deposits in question. If the former is correct, the extension of the ore bodies in depth is strictly limited, whereas the latter theory, according to which the deposits are syngenetic, would impose no such limits upon their extension, and the suspicion cannot be avoided that the author's promulgation of his theory may have been unconsciously influenced by his desire to magnify the economic value of ore deposits, in the opening up of which he has taken a leading part. Seeing that the result of future mining operations will demonstrate without doubt which of these two conflicting theories is the correct one, whilst at present decisive evidence is lacking, it is hardly worth while to examine critically the bases upon which they rest, and the question may well be left for the future to settle, it being sufficient to record here that, whether his theories are right or wrong, the author has produced a full and interesting description of this system of deposits, and has thus contributed to our knowledge of the occurrences of ores of manganese.

H. L.

[1] "Manganese-ore Deposits of the Sandur State." By A. Ghose. Excerpt from the Transactions of the Mining and Geological Institute of India, vol. iv., pp. 155–204+21 plates. Part 3, February, 1910.

ZOOLOGICAL WORK IN INDIA.

IN vol. ii., No. 8, of the entomological series of the Memoirs of the Department of Agriculture, the Government entomologist, Mr. H. Maxwell-Lefroy, commences a lavishly illustrated account of the life-history of Indian insects, dealing in this instance with beetles. Hitherto, it is stated, little definite information has been recorded with regard to the life-histories of the beetles of India, and entomologists will therefore welcome the particulars given by the author in the case of eight of the commoner species. In seven out of the eight, the egg, larva, pupa, and imago are illustrated by coloured plates, executed in first-class style by the Calcutta Phototype Company.

Three out of five numbers of the Records of the Indian Museum, recently to hand, contain articles on biting flies and gnats. In the first of these, vol. iv., No. 1, Mr. F. V. Theobald describes certain new genera and species of Culicidæ, typified by specimens in the Indian Museum. It is stated, however, that in the case of the Culices with banded proboscis, some at least of the determinations must be regarded as provisional, since certainty cannot be attained until both sexes have been bred in captivity and the generative organs of the males and the larvæ carefully examined. In No. 3 of the same volume Mr. E. Brunetti records a protest against what he considers unnecessary subdivision and splitting in the Culicidæ, remarking that specialists in the Diptera must regard the present state of affairs as absurd, and that Prof. Williston appears to be the only systematic dipterologist who has attempted to stem the tide. The plea of the unwieldiness of big genera cannot be upheld, it is added, since the systematist is quite accustomed to such genera: a similar protest, it may be mentioned, seems called for in the case of the excessive generic splitting now in vogue in the squirrel and mice family. Mr. Brunetti concludes by stating that the subject will be more fully discussed in the supplement to the catalogue on which he is now engaged.

An article forming part ii. of the fourth volume, by Dr. Annandale, on Indian sand-flies (Phlebotomus), will be read with interest, since not only are these minute insects some of the greatest torments to Europeans in India, but, as may be inferred from the investigations made on their south European representatives, it is practically certain that they are also carriers of certain types of fever.

Finally, in the fourth and last part of vol. iv., Mr. Brunetti publishes a systematic revision of the Oriental blood-sucking flies of the family Muscidæ, with the description of a new genus.

From among a dozen articles in the first and second parts of the fifth volume of the Records, it must suffice to direct attention to one by Dr. R. E. Lloyd, on variation in Indian rats. In a previous paper the author has adduced evidence in favour of discontinuous variation having played a prominent part in the production of races. Individual rats from any particular towns, for instance, sometimes show more or less marked differences from their fellows, and the evidence they afford for discontinuous evolution lies in the manner in which these are distributed among the multitude of whole-coloured specimens. In the present paper it is stated that, among the thousands of normally coloured rats infesting Poona, there is found a colony of about one hundred individuals characterised by the presence of a white breast-patch, these having apparently originated in the city itself. Again, it was found that the rats of Naini Tal differ from the normal type of plains-rat by their shorter tails, longer and greyer fur, and a more or less well-defined white breast-patch. Some rats in the district differ, however, from this type by the under side of the tail being white. Accordingly, we find that in a single limited area there live, under apparently similar conditions, two phases of a widely distributed species, differing from one another solely in one obvious feature, these two phases living apart from each other. Obviously, any explanation as to the origin of the white-tailed phase will apply equally to the case of the white-breasted Poona rats, and the author concludes by endeavouring to explain each instance by the light of the theory of gametic factors. R. L.

THE BRITISH ASSOCIATION AT SHEFFIELD.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY PROF. W. E. DALBY, M.A., M.INST.C.E., PRESIDENT OF THE SECTION.

British Railways: Some Facts and a Few Problems.

It is remarkable how few among us really realise the large part that railways play in our national life. How many of us realise that the capital invested in the railway companies of the United Kingdom is nearly twice the amount of the national debt; that the gross income of the railway companies is within measurable distance of the national income; that to produce this income every inhabitant of the British Islands would have to pay annually 3*l.* per head; that they employ more than six hundred thousand people; and that about eight million tons of coal are burnt annually in the fire-boxes of their locomotives? I hope to place before you in the short time which can be devoted to a presidential address a few facts concerning this great asset of our national life and some problems connected with the recent developments of railway working—problems brought into existence by the steady progress of scientific discovery and the endeavour to apply the new discoveries to improve the service and to increase the comfort of the travelling public.

A great deal of interesting information is to be found in the Railway Returns issued by the Board of Trade. I have plotted some of the figures given, in order to show generally the progress which has been made through the years, and at the same time to exhibit the rates of change of various quantities in comparison with one another.

Consider, in the first place, what the railways have cost the nation. This is represented financially at any instant by the paid-up capital of the companies. The total paid-up capital in 1850 was 240 millions sterling. In 1908 this amount had increased to 1310 millions. The curve marked "Total" in Fig. 1 shows the total paid-up capital plotted against the year. It will be noticed that

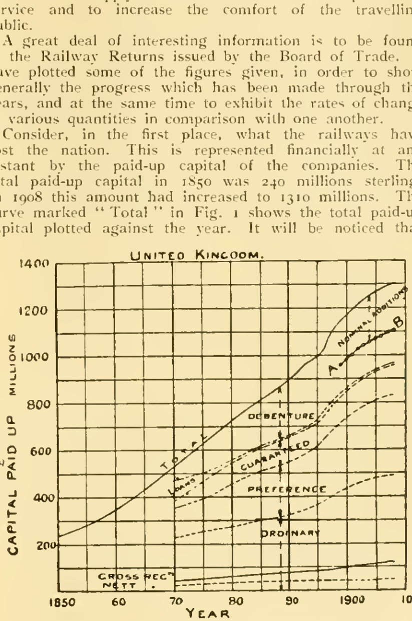

FIG. 1.

the increase per annum is remarkably regular up to about 1896, and is at the rate of not quite 100 millions per annum. After this date the capital increases at a somewhat greater rate, but in 1900 the rate drops with a tendency to a gradually decreasing value. Part of the increase immediately after 1896 is, however, due to nominal additions to the capital. The extent to which this process of watering the stock has been carried is indicated over the period 1898 to 1908 by the curve AB. In the year 1908 the nominal additions to capital amounted to 196 millions of pounds.

Curves are also plotted showing the amounts of the different kinds of stock making up the total. It will be noticed that the ordinary stock is a little more than one-third of the total paid-up capital in 1908, viz. 38 per cent. In 1870 it was about 43 per cent.

The lower curve on the diagram shows the gross receipts, which amounted to 120 millions of pounds in 1908. The dotted line indicates the net revenue after deducting from the total receipts the working expenditure. This, for 1908, was $43\frac{1}{2}$ millions, corresponding to 3·32 per cent. of the total paid-up capital. If the net receipts are reckoned as a percentage of the paid-up capital after deducting the nominal additions, the return is increased to 3·9 per cent. These figures practically represent the average dividend reckoned in the two ways for the year 1908.

Fig. 2 shows by the upper curve the number of miles open for traffic plotted against the year. This curve indicates great activity of construction during the period 1850 to 1870, with a regular but gradually decreasing addition of mileage from year to year afterwards.

At the end of 1908 there were 23,205 miles open, corresponding to 53,669 miles of single track, including sidings. Of this, 85 per cent. was standard 4 feet 8½ inches gauge, 12·3 per cent. 5 feet 3 inches, and 2·2 per cent. 3 feet gauge. The remainder was made up of small mileages of 1 foot 11½ inches, 2 feet 3 inches, 2 feet 4 inches, 2 feet 4½ inches, 2 feet, 2 feet 9 inches, 4 feet, and 4 feet 6 inches gauges.

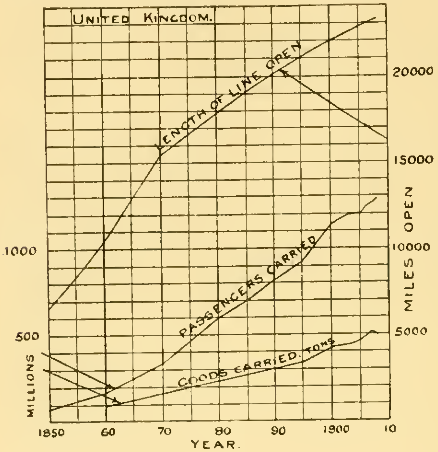

FIG. 2.

The two lower lines of the diagram show, respectively, the number of passengers carried and the tons of goods carried from year to year.

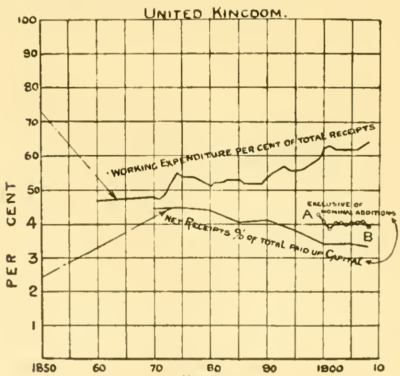

FIG. 3.

The curves of mileage, passengers carried, and goods carried increase regularly with the increase of capital, indicating that up to the present time the possibility of remunerative return on capital invested in railway enterprise in this country is not exhausted. It is true that there is a maximum of goods carried in the year 1907; but the sudden drop in the curve between the years 1907 and 1908 suggests that the drop is only of a temporary character, and there is every reason to believe that the curve will resume its upward tendency with time. In 1908 the railways of the United Kingdom carried 1278 millions of passengers, exclusive of season-ticket holders, and 491 million tons of goods; the quantity of goods carried in 1907 was nearly 515 millions of tons. It is curious that, very approximately, the companies carry per annum one passenger and about 0·4 ton of goods for every pound sterling of paid-up capital.

The proportion of the gross receipts absorbed in carrying out this service is shown by the upper curve of Fig. 3. The proportion has increased, on the whole regularly, from 47 per cent. in 1860 to 64 per cent. in 1908.

The lower curve shows the net receipts as a percentage of the paid-up capital. From 1899 onwards the curve AB shows the net receipts reckoned on the paid-up capital exclusive of the nominal additions. It will be observed that the net receipts have not declined more than half a per cent. since 1870, notwithstanding the increase in working expenditure.

Fig. 4 indicates the cost of working the traffic calculated in terms of the train-mile, no data being available regarding the actual work done as represented by the ton-mile or the passenger-mile. In some respects the train-

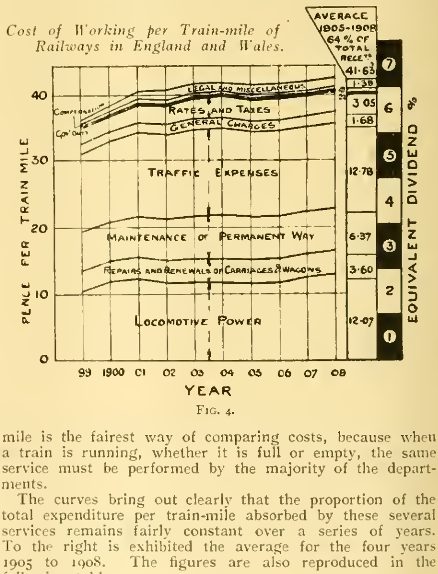

FIG. 4.

mile is the fairest way of comparing costs, because when a train is running, whether it is full or empty, the same service must be performed by the majority of the departments.

The curves bring out clearly that the proportion of the total expenditure per train-mile absorbed by these several services remains fairly constant over a series of years. To the right is exhibited the average for the four years 1905 to 1908. The figures are also reproduced in the following table:—

TABLE I.

Average Working Costs per Train-mile of the Railways in England and Wales taken over the Years 1905 to 1908.

	Pence per train-mile.
Locomotive power	12·07
Repairs and renewals of carriages and waggons	3·60
Maintenance of permanent-way	6·37
Traffic expenses	12·78
General charges	1·68
Rates and taxes	3·05
Government duty	0·22
Compensation	0·47
Legal and miscellaneous	1·39
Total	41·63

Locomotive power absorbs an amount about equal to the traffic expenses; and companies actually pay in rates and taxes a sum nearly equal to the whole amount required to maintain the rolling-stock in an efficient state.

To the right is shown a scale, the divisions of which represent an amount estimated in pence per train-mile corresponding to 1 per cent. of the average dividend. This shows that if the whole of the locomotive power could be obtained for nothing, the average dividend would only be increased by $1\frac{3}{4}$ per cent. Reckoned on the ordinary stock alone, however, the increase would be about three times this amount.

It may be of interest at this stage to compare the financial position and the cost of the working of railways in their earlier days with the state of things now. For this purpose the position of the old London and Birmingham Railway is compared with the position of the London and North-Western Railway, the system into which it has grown. The years selected are 1840 and 1908.

I have taken out the cost per mile of working the traffic of the London and Birmingham Railway from some accounts given in Winshaw's "Railways." The details are grouped somewhat differently in the list just given, but in the main the various items may be compared.

The number of train-miles on the London and Birmingham Railway recorded for the year January to December, 1839, is 714,998. The accounts given are for the year June, 1839, to June, 1840. The mileage record is thus not strictly comparable with the expense account, but it may be regarded as covering the same period with sufficient accuracy for our purpose.

The costs work out as follows:—

TABLE II.

Cost per Train-mile for the Year ending June, 1840, *London and Birmingham Railway.*

	Pence per mile.
Locomotive power	23·2
Maintenance of way	27·2
Traffic expenses, including repairs to waggons	25·9
General charges, including legal charges ...	4·5
Rates and taxes...	4·5
Government duty	7·65
Accident account	0·35
Total	93·30

The receipts amounted to 231*d.* per train-mile. Hence the working expenditure was 40 per cent. of the gross receipts.

The gross receipts for the year ending June 30, 1840, were 687,104*l.*, which, after deducting charges for loans, rents, and depreciation of locomotives, carriages, and waggons, enabled a dividend of $9\frac{1}{4}$ per cent. to be paid on the ordinary stock.

There are two noteworthy facts in these old accounts. First, the allowance for depreciation on the rolling-stock of nearly 4 per cent. of the receipts. Secondly, the fact that the cost of working the traffic is given per ton-mile. This method of estimating the cost of working has gradually fallen into desuetude on British railways. One company only at the present time records ton-mile statistics. Quite recently (in 1909) the committee appointed by the Board of Trade to make inquiries with reference to the form and scope of the accounts and statistical returns rendered by the railway companies under the Railway Regulation Acts have had the question of ton-mile and passenger-mile statistics under consideration. There was considerable difference of opinion concerning the matter, and in the end the committee did not recommend that the return of ton-mile and passenger-mile statistics should be made compulsory on the railway companies.

Returning to the London and Birmingham Railway accounts, the actual figures given by Mr. Bury, the locomotive engineer, were, for the year ending December, 1839:—

Passenger Trains.—Ton-miles, 21,159,796, giving an average of 542,533 ton-miles per engine at 0·86 lb. of coke per ton-mile costing 0·17*d.*

Goods Trains.—17,527,439 ton-miles, giving an average of 584,247 per engine at 0·57 lb. of coke per ton-mile costing 0·11*d.* per ton-mile.

Table III. shows various amounts and quantities in comparison with one another. Beneath the actual figures are placed proportional figures, the London and Birmingham item being in every case denoted by unity.

TABLE III.

Comparison of Capital, Receipts, Miles Open, Train-miles, and Cost of Working between the London and Birmingham Railway for the Year ending June, 1840, *and the London and North-Western Railway for the Year ending December,* 1908.

	Stock and Share Capital.		Loans and Debentures.		Total.	Gross Receipts.
	£	Interest per cent.	£	Interest per cent.	£	£
L. & B. Ry., 1840 . . .	3,125,000	$9\frac{3}{4}$	2,125,900	$4\frac{5}{8}$	5,250,000	687,000
L. & N. W. Ry., 1908 .	85,861,760	5 app. average on all types of stock.	39,175,374	3 average.	125,037,134	15,515,334
L. & B. Ry., 1840 . . .	1		1		1	1
L. & N. W. Ry., 1908 .	27·5		18·4		24	22·6

	Miles Open in Equivalent Single Track.	Train-miles Run.	Receipts per Train-mile.	Cost of Working per Train-mile.	Expenditure to Gross Receipts per cent.
L. & B. Ry., 1840 . .	250	714,998	231 pence	93 pence	40
L. & N. W. Ry., 1908.	5,406	48,732,644	$76\frac{1}{2}$,,	50 ,,	65
L. & B. Ry., 1840 . .	1	1	1	1	1
L. & N. W. Ry., 1908.	21·6	68·3	0·33	0·54	1·62

The comparison brings out some curious facts. For instance, it will be noticed that the gross receipts of the London and North-Western Railway in 1908 were twenty-two and a half times as much as those of the London and Birmingham Railway in 1840, and that the track mileage open was about twenty-two times as great. The money earned per mile of track open is thus practically the same after a lapse of seventy years. To earn the same amount per mile of track open, however, the trains of the London and North-Western Railway had in 1908 to run 68·3 times the number of train-miles that the trains of the London and Birmingham Railway ran in 1840. That is to say, in order to earn a sovereign a London and North-Western train has now to run three times the distance which it was necessary for a London and Birmingham train to run to earn the same amount.

Another point to notice is that although the mileage and the receipts per mile of track open have each increased in the same proportion, yet the capital has increased at a greater rate, being on the total amount twenty-four times as much as in 1840, and the stock and share capital has increased twenty-eight times. So that with the necessity of running three times the train-mileage to obtain the same return per mile of track open, there runs the obligation to pay interest on an ordinary stock which has been increased in a greater proportion than the mileage and in a greater proportion than the earning power of the line. Lower dividends are therefore inevitable. The cost of working per train-mile has decreased gradually to about half its value in 1840, but, at the same time, the receipts per train-mile have dwindled to one-third of the amount in 1840.

These figures show that a more conservative system of financing the railways might have been adopted in the earlier days with advantage. If, when the receipts per train-mile were larger, a proportion of the revenue had been used annually for the construction of new works and for the provision of new rolling-stock, instead of raising fresh capital for everything in the nature of an addition to the railway, the companies would to-day have been in a position to regard with equanimity the increasing cost of working.

It is too late in the day to recover such a strong financial position, but even now on many lines a larger proportion of the revenue could be sunk in the line with great ultimate advantage to the financial position.

The Problem of the Locomotive Department.

During the last twenty years the demand on the locomotive has steadily increased. The demand has been met, though with increasing difficulty, owing to the constructive limitations imposed by the gauge. The transference of a train from one place to another requires that work should be done continuously by the locomotive against the tractive resistance. The size of the locomotive is determined by the rate at which this work is to be done. If T represents the tractive resistance at any instant, and V the speed of the train, then the rate at which work is done is expressed by the product TV. The pull exerted by the locomotive must never be less than the resistance of the whole train considered as a dead load on the worst gradient and curve combination on the road, and it can never be greater than about one-quarter of the total weight on the coupled wheels of the engine.

Again, the tractive pull of the engine may be analysed into two parts—one the pull exerted to increase the speed of the train, the other the pull required to maintain the speed when once it has been reached. For an express train the number of seconds required to attain the journey speed is so small a fraction of the total time interval between the stops that the question of acceleration is not one of much importance. But for a local service where stops are frequent the time required to attain the journey speed from rest is so large a fraction of the time between stops that this consideration dominates the design of the locomotive, and, in fact, makes it desirable to substitute the electric motor for the locomotive in many cases.

An accurate estimate of the rate at which work must be done to run a stated service can only be made if there are given the weight of the vehicles in the train, the weight of the engine, the kind of stock composing the train, the speed and acceleration required at each point of the journey and a section of the road; and, in addition to this, allowance must be made for weather conditions.

A general idea of the problem can, however, be obtained by omitting the consideration of acceleration, gradients, and the unknown factor of weather conditions, considering only the rate at which work must be done to draw a given load at a given speed on the level. Even thus simplified the problem can be solved only approximately, because, although the tractive resistance of a train as a whole is a function of the speed, the tractive resistance per ton of load of the vehicles and per ton of load of the engine differ both in absolute value and in their rates of change for a stated speed, and, further, the ratio between the weight of the vehicles and the weight of the engine is a very variable quantity.

For our purpose, however, it will be sufficiently accurate to assume that the resistance of the whole train, expressed in pounds per ton, is given by the formula

$$T = 5\tfrac{1}{3} + \frac{V^2}{256}.$$

It follows that the horse-power which must be developed at the driving-wheels to maintain a speed of V miles per hour on the level with a train weighing W tons is

$$HP = W\left\{\frac{V}{70} + \frac{V^3}{96{,}000}\right\}.$$

Fig. 5 shows curves of horse-power plotted from this equation for various weights of train. From this diagram a glimpse of the problem confronting locomotive engineers at the present day can readily be obtained.

To illustrate the point, consider the case of the Scotch express on the West Coast route.[1] This is an historic service, and goes away back to 1844, in which year the first train left Euston for Carlisle, travelling by way of Rugby, Leicester, York, and Newcastle, and occupying $15\frac{1}{4}$ hours. It was not until 1847, however, that there was a through service to Edinburgh *via* Berwick.

In September, 1848, the West Coast service for Edinburgh was established by way of Birmingham and Carlisle, the timing being 8 hours 55 minutes to Carlisle, and 12 hours to Edinburgh.

In September, 1863, the starting time from Euston was fixed at 10 a.m., and in 1875 the train ran *via* the Trent Valley between Rugby and Stafford, thus cutting out Birmingham and shortening the journey to Carlisle from 309 miles to 299 miles, the timing being 7 hours 42 minutes to Carlisle, and 10 hours and 25 minutes to Edinburgh. The speed has gradually been increased, and in 1905 the timing was 5 hours 54 minutes to Carlisle, and $8\frac{1}{4}$ hours to Edinburgh. Now the timing is 5 hours 48 minutes to Carlisle, but is still $8\frac{1}{4}$ hours to Edinburgh.

Three specific examples are plotted on the diagram, showing the power requirements in 1864, 1885, and 1903 for this train. Typical trains in 1864, 1885, and 1903 weighed, including engine and tender, 100 tons, 250 tons, and 450 tons respectively. The average speeds were thirty-

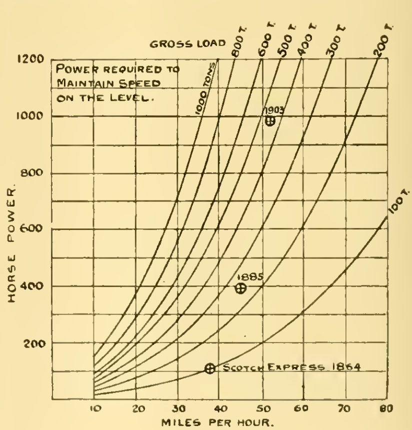

Fig. 5.

eight, forty-five, and fifty-two miles per hour respectively. A glance at the diagram will show that the power required to work this train was about 100 horse-power in 1864, 400 horse-power in 1885, and 1000 horse-power in 1903.

It must not be supposed that the increase in the weight of the train means a proportionate increase in the paying load. Far from it. On a particular day in 1903, when the total weight of the Scotch express was 450 tons approximately, the weight of the vehicles was about 346 tons. There were two dining-cars on the train, and the seating accommodation, exclusive of the seats in the dining-cars, was for 247 passengers, giving an average of 1·4 tons of dead load to be hauled by the engine per passenger, assuming the train to be full. In the days before corridor stock and dining-cars were invented the dead load to be hauled was about a quarter of a ton per passenger for a full train.

In a particular boat special, consisting of two first-class saloons, one second- and third-class vehicles, one first-class dining-car, one second and third-class dining-car, one kitchen-car, and two brake-vans, seating accommodation was provided, exclusive of the dining-cars, for 104 passengers, and the dead load to be hauled averaged 2·72

[1] I am indebted to Mr. Bowen Cooke for particulars of the Scotch Express Service.

tons per passenger. Notwithstanding this increase in the dead load of luxurious accommodation, the fares are now less than in former days on corresponding services. Similar developments have taken place in almost every important service, and new express services are all characterised by heavy trains and high speeds.

Characteristic Energy-curves of Steam Locomotives.

This steadily increasing demand for power necessarily directs attention to the problem, What is the maximum power which can be obtained from a locomotive within the limits of the construction-gauge obtaining on British railways? The answer to this can be found without much ambiguity from a diagram which I have devised, consisting of a set of typical characteristic energy-curves to represent the transference and transformation of energy in a steam locomotive, an example of which is given in Fig. 6. While examining the records of a large number of locomotive trials, I discovered that if the indicated horse-power be plotted against the rate at which heat energy is transferred across the boiler-heating surface the points fall within a straight-line region, providing that the regulator is always full open and that the power is

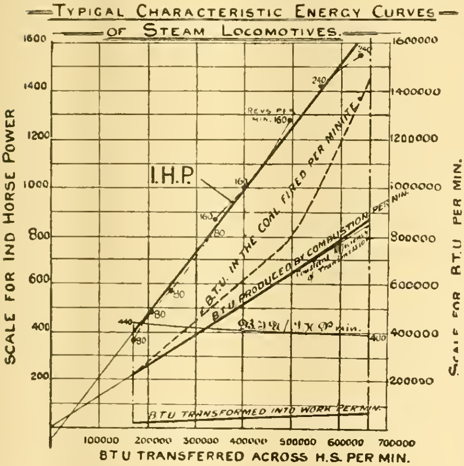

FIG. 6.

regulated by means of the reversing lever—that is to say, by varying the cut-off in the cylinders. It is assumed at the same time, of course, that the boiler-pressure is maintained constant. I have recently drawn a series of characteristic energy-curves for particular engines, and these are published in *Engineering*, August 19 and 26, 1910. A typical set is shown in Fig. 6.

The horizontal scale represents the number of British thermal units transferred across the boiler-heating surface per minute. This quantity is used as an independent variable. Plotted vertically are corresponding horse-powers, each experiment being shown by a black dot on the diagram. The small figures against the dots denote the speed in revolutions of the crank-axle per minute. Experiments at the same speed are linked by a faint chain-dotted line. A glance at the diagram will show at once how nearly all the experiments fall on a straight line, notwithstanding the wide range of speed and power.

The ordinates of the dotted curve just below the I.H.P. curve represent the heat energy in the coal shovelled per minute into the fire-box—that is, the rate at which energy is supplied to the locomotive. The thick line immediately beneath it represents the energy produced by combustion. The vertical distance between these two curves represents energy unproduced, but energy which might have been produced under more favourable conditions of combustion. Some of the unproduced energy passes out of the chimney-top in carbon monoxide gas, but the greater proportion is found in the partially consumed particles of fuel thrown out at the chimney-top in consequence of the fierce draught which must be used to burn the coal in sufficient quantity to produce energy at the rate required. The rate of combustion is measured by the number of pounds of fuel burnt per square foot of grate per hour. In land practice, with natural draft, 20 lb. of coal per square foot of grate per hour is a maximum rate. In a locomotive the rate sometimes reaches 150 lb. per square foot per hour. In the diagram shown the maximum rate is about 120 lb. per square foot, and the dotted curve begins to turn upwards at about 70 lb. per square foot per hour. The vertical distance between the curves shows what has to be paid for high rates of combustion.

I found that in almost every case the curve representing the energy actually produced by combustion differed very little from a straight line, passing through the origin, showing that at all rates of working the efficiency of transmission is approximately constant. That is to say, the proportion of the heat energy actually produced by combustion in the fire-box which passes across the boiler-heating surface per minute is nearly constant, and is therefore independent of the rate of working.

The lowest curve on the diagram represents the rate at which heat energy is transformed into mechanical energy in the cylinders of the locomotive. It seems a small rate in proportion to the rate at which heat energy is supplied to the fire-box, but it is not really so bad as it looks, because the engine actually transformed 60 per cent. of the energy which would have been transformed by a perfect engine working on the Rankine cycle between the same limits of pressure. The engine efficiency is represented in a familiar way by a curve labelled "B.T.H. per I.H.P. minute." It will be seen that the change of efficiency is small, notwithstanding large changes in the indicated horse-power.

The diagram indicates that the indicated horse-power is practically proportional to the rate at which heat is transferred across the boiler-heating surface, and as this is again proportional to the extent of the heating surface, the limit of economical power is reached when the dimensions of the boiler have reached the limits of the construction-gauge, the boiler being provided with a fire-grate of such size that, at maximum rate of working, the rate of combustion falls between 70 and 100 lb. of coal per square foot of grate per hour. A boiler of large heating surface may be made with a small grate, necessitating a high rate of combustion to obtain the required rate of heat-production. Then, although a large power may be obtained, it will not be obtained economically.

Returning now to the consideration of the type of locomotive required for a local service with frequent stops, the problem is to provide an engine which will get into its stride in the least time consistent with the comfort of the passengers. The average speed of a locomotive on local service is low. The greater part of the time is occupied in reaching the journey speed, and the brake must then often be applied for a stop a few moments after the speed has been attained. In some cases the stations are so close together that there is no period between acceleration and retardation. Without going into the details of the calculation, I may say that to start from rest a train weighing, including the engine, 300 tons, and to attain a speed of thirty miles per hour in thirty seconds requires about 1350 indicated horse-power. During the period of acceleration the engine must exert an average tractive pull of nearly fifteen tons.

Mr. James Holden, until recently locomotive engineer of the Great Eastern Railway, built an engine to produce an acceleration of thirty miles per hour in thirty seconds with a gross load of 300 tons. The engine weighed 78 tons, and was supported on ten coupled wheels, each 4 feet 6 inches diameter. There were three high-pressure cylinders, each $18\frac{1}{2}$ inches diameter and 24 inches stroke. A boiler was provided with 3000 square feet of heating surface and a grate of 42 square feet area. Boiler pressure, 200 lb. per square inch. This engine practically reached the limit of the construction-gauge.

An acceleration of thirty miles per hour in thirty seconds is considerably below what may be applied to a passenger without fear of complaint. But it is clear that it is just about as much as a locomotive can do with a train of reasonable weight. Even with a gross load of 300 tons nearly one-third of it is concentrated in the locomotive, leaving only 200 tons to carry paying load. The problem of quick acceleration cannot therefore be properly solved by means of a steam locomotive. But with electric traction the limitations imposed on the locomotive by the construction-gauge and by the strength of the permanent way are swept away.

The equivalent of the boiler-power of a dozen locomotives can be instantaneously applied to the wheels of the electric train, and every axle in the train may become a driving axle. Thus the whole weight of the stock, including the paying load, may be utilised for tractive purposes. If, for instance, the train weighed 200 tons, then a tractive force equal to one-fifth of this, namely, 40 tons, could be exerted on the train, but uniformly distributed between the several wheels, before slipping took place. The problem of quick acceleration is therefore completely solved by the electric motor.

Electric Railways.

December 18, 1890, is memorable in the history of railway enterprise in this country, for on that date the City and South London Railway was opened for traffic, and the trains were worked entirely by electricity, although the original intention was to use the endless cable system of haulage. This line inaugurated a wonderful system of traction on railways, in which independent trains, moving at different speeds at different parts of the line, are all connected by a subtle electric link to the furnaces of one central station.

Since that epoch-marking year electric traction on the railways of this country has made a gradual if somewhat slower extension than anticipated. But electrically operated trains have in one branch of railway working beaten the steam locomotive out of the field, and now reign supreme—that is, in cases, as indicated above, where a quick, frequent service is required over a somewhat short length of road. The superiority of the motor over the steam locomotive, apart from questions of cleanliness, convenience, and comfort, lies in the fact that more power can be conveyed to the train and can be utilised by the motors for the purpose of acceleration than could possibly be supplied by the largest locomotive which could be constructed within the limits of the construction-gauge. There are many other considerations, but this one is fundamental, and determines the issue in many cases.

A few facts relating to the present state of electric railways in the United Kingdom may prove of interest. At the end of 1908 there were in the United Kingdom 204 miles of equivalent single track worked solely by electricity and 200 miles worked mainly by electricity, corresponding to 138 miles of line open for traffic. Of this, 102 miles belong to the tube railways of London and 201 miles to the older system formed by the District and the Metropolitan Railways and their extensions.

It is not an easy matter to ascertain exactly how much capital is invested in these undertakings for the purpose of electric working alone, since some of the lines originally constructed for a steam locomotive service have been converted to electric working. On the converted lines there is the dead weight of capital corresponding to the locomotive power provided before electrification took place. The capital invested in the 102 miles of tube railways in London is a little more than 25,000,000*l.*

The total number of passengers carried (exclusive of season tickets) on the 138 miles of electrical track during the year 1908 was nearly 342 millions, being roughly one-third of the total number of passengers carried on all the railways of England and Wales during the same period.

The average cost of working this traffic is 22·3*d.* per train-mile. This figure includes the service of the lifts, which is presumably returned with the traffic expenses. The charges work out in this way:—

TABLE IV.

Average Working Cost per Train-mile of the Electric Railways worked wholly or mainly by Electricity in England and Wales for the Year 1908.

	Pence per train-mile.
Locomotive power	8·40
Repairs and renewals of carriages and waggons	1·50
Maintenance of permanent way	2·40
Traffic expenses	5·22
General charges	1·52
Rates and taxes	2·36
Government duty	0·088
Compensation	0·116
Legal and miscellaneous	0·75
Total	22·35

The corresponding total receipts were 38·65*d.* per train-mile. The working expenses are thus 58 per cent. of the total receipts. Comparing this with the figures given above for the whole of the lines in England and Wales, it will be seen that the cost for locomotive power on the electric railways appears to be about two-thirds of the cost on steam lines per mile run, the cost for repairs and renewals of carriages and waggons about one-half, and the cost for traffic expenses about one-half.

The two kinds of working are not, however, strictly comparable, as all the conditions of traffic in the two cases are different, and the length of the electric lines is relatively so small that the problems which arise out of the transmission of electric power over long distances are excluded. The traffic expenses and the cost of repairs and renewals of carriages and waggons, general charges, &c., are practically independent of the kind of power used for locomotive purposes, and, moreover, the difference in weight of electric trains and the steam-hauled trains is on the average so great that no comparison can be instituted without ton-mile statistics.[1]

Method of Working.

With two exceptions, the method of working the electrified lines of this country is in the main the same. A third conductor rail is laid on insulators fixed to the ordinary track sleepers, and is maintained throughout the whole of its length at as nearly as possible a pressure of 600 volts, except in a few cases where the pressure is 500 or 550 volts. Collecting shoes sliding along the rails are fixed to the trains, and through them current is supplied to the armatures fixed to or geared with the axles. The current flows through the armatures back to the stations or sub-stations through the running rails, which are bonded for the purpose, or sometimes through a fourth rail carried on insulators fixed to the track sleepers, as in the cases of the District and Metropolitan Railways.

Differences in the equipment arise out of the geographical necessities of the distribution. For a short line the power is produced at a central station, and is distributed by feeders to the conductor rail direct. For longer lines power is produced at higher voltage (11,000 volts in the case of the District Railway), and is then distributed to sub-stations conveniently placed along the line, where it is transformed to a lower voltage, converted to direct current, and then by means of feeders is distributed at 600 volts or thereabouts to the third rail.

In 1908 the Midland Railway Company opened for traffic the electrified line connecting Lancaster, Morecambe, and Heysham. The method of electrification was a departure from the general direct-current practice hitherto applied to electrified lines in this country. Power was supplied to the trains at 6600 volts, single phase, at twenty-five alternations per second, along an overhead conductor. The pressure was reduced by transformers carried on the motor-coach itself, and was then used by single-phase motors. The traffic conditions on this line are simple.

[1] Most valuable information regarding the cost of converting the line between Liverpool and Southport from steam to electric working will be found in Mr. Aspinall's presidential address to the Institution of Mechanical Engineers.

In December, 1909, the electrified portion of the London, Brighton, and South Coast Railway from Victoria, round by Denmark Hill, to London Bridge was opened for traffic. This work marks an epoch in the history of electric traction in England. For the first time the single-phase system was applied to meet the exacting traffic conditions of a London suburban service where the main condition is that the trains should be accelerated rapidly. The system has shown that it can meet all the conditions of the service perfectly. Energy is purchased, and is distributed by overhead conductors direct to the trains at 6000 volts, single phase, at twenty-five alternations per second, where it is used by the single-phase motors after suitable transformation by apparatus carried under the motor carriage. The results of this electrification will be of unusual interest, because not only has the method applied shown itself to be quite suitable for dealing with a stopping traffic where quick acceleration is the dominating condition, but it contains the germ of practicable long-distance electrification. The near future may see the extension of the system to the line between London and Brighton, giving a frequent non-stop service which would bring Brighton in point of time nearer than the suburbs on opposite sides of London are to one another.

Power Signalling.

During the last ten years a considerable number of trial installations of power-signalling apparatus have been made by the railway companies of this country. The electric lines have generally adopted power signalling, and the District Railway has installed a complete system on all its lines and branches.

The term "power signalling" is applied to any equipment in which the actual movements of the points and signals are done by power, the signalman's work being thus reduced to the movement of small light control levers or switches. Of the several systems tried and proposed, three bulk largest in the equipments applied in this country, namely, the all-electric, the low-pressure pneumatic, and the electro-pneumatic systems.

The "all-electric" system is represented by installations of the McKenzie-Holland and Westinghouse system on the Metropolitan and Great Western Railways, by installations of the "Crewe" system on the London and North-Western Railway, and by installations of Siemens Brothers on the Great Western Railway. The general feature of the all-electric system is that the points are operated by motors sunk in a pit by the side of the rails; the signals are pulled off electrically, and all the apparatus is controlled electrically.

The low-pressure pneumatic system is represented by installations on the London and South-Western Railway and the Great Central Railway. The points and signal arms are moved by air compressed to about 20 lb. per square inch, and led to cylinders connected to the points and to the signal arms. The control is also done by means of compressed air, small pipes leading from each air cylinder to the cabin.

The electro-pneumatic system has found most favour in this country up to the present time. The equipment installed includes such notable stations as the Central at Newcastle with 494 levers, and the Glasgow Central with 374 levers, and the whole of the Metropolitan District system of underground railways. In this system an air cylinder is connected to each set of points and to each signal-arm. Air compressed at 65 lb. per square inch is supplied to the cylinders from a main running alongside the railway kept charged by small air-compressors placed at convenient intervals. Each air cylinder is provided with a small three-way air-valve operated by an electromagnet. The movement of each air-valve is controlled electrically from the cabin through the electromagnet associated with it. The system grouped round any one signal-cabin may be regarded as an engine fitted with a large number of cylinders, each working intermittently by compressed air, and where in each the valve-rod has been changed to an electric cable, all the cables being led to a signal-cabin, where the operation of the valves is done by means of an apparatus which is as easily played upon as a piano, with this difference, however, that the notes are mechanically interlocked, so that a signalman cannot play any tune he pleases, but only a tune which permits of safe traffic movement. Moreover, the instrument is so arranged that the movement of the small lever determining the movement of a signal-arm cannot be completed unless the signal-arm actually responds to the intention of the signalman, thus detecting any fault in the connections between the box and the arm.

The obvious advantage of power signalling is the large reduction of physical labour required from the signalman. His energy can be utilised in thinking about the traffic movements rather than in hauling all day at signal levers. One man at a power frame can do the work of three at the ordinary frame. The claims made for power signalling, in addition to the obvious advantage of the reduction of labour, are briefly that the volume of traffic which can be dealt with is largely increased, that the area of ground required for the installation is considerably less than with the ordinary system, with its rodding, bell-crank levers, chains, and pulleys, and that where the conditions are such that power signalling is justified the maintenance cost is less than with a corresponding system of normal equipment.

Automatic Signalling.

Several of the power-signalling installations are automatic in the sense that between signal-cabins on stretches of line where there are no junctions or cross-over roads requiring the movement of points, the movement of the signal arm protecting a section is determined by the passage of the train itself. The most important equipment of this kind is that installed on the group of railways forming the "Underground" system. This includes the District Railway with all its branches. On this line the particular system installed is the electro-pneumatic, modified to be automatic except at junctions. Signal-cabins are placed only at junctions and at places where points require to be operated. The stretch of line to be automatically signalled is divided into sections, and the entrance to each section is guarded by a signal-post. Calling two successive sections A and B, the train as it passes from Section A to Section B must automatically put the signal at the entrance to B to danger, and at the same time must pull off the signal at the entrance to A. These operations require the normal position of the signal-arm to be "off" instead of at danger, as in the usual practice. The position of the arm in this system conveys a direct message to the driver. If "on" he knows that there is a train in the section; if "off" he knows that the section is clear. Each signal-arm is operated by an air motor, as briefly described above, but the cables from the valves are now led to relays at the beginning and end of the section which the signal protects. The contrivance by means of which the train acts as its own signalman is briefly as follows. One rail of the running track is bonded, and is connected to the positive pole of a battery or generator. The opposite rail is divided into sections, each about 300 yards long, bonded, but insulated at each end from the rails of the adjacent sections, and each section is connected to a common negative main through a resistance. A relay is placed at the beginning and at the end of each section, and is connected across from the positive to the negative rail. Current flows and energises the relay, in which condition the relay completes a circuit to the electromagnet operating the admission valve of the air cylinder on the signal-post, air is admitted, and the signal-arm is held off. This is the normal condition at each end of the circuit. When a train enters a section it short-circuits the relays through the wheels and axles, in consequence of which the relays, de-energised, break the circuit to the admission valve, which closes, and allows the air in the cylinder to escape, and the signal-arm, moved by gravity alone, assumes the "on" or danger position. At the same time the short circuit is removed from the section behind directly the train leaves it, the relays are at once energised, the admission valve to the air cylinder on the protecting post of the section is opened, air enters, and the signal is pulled down to the "off" position.

The speed at which traffic can be operated by this system of power signalling is remarkable. At Earl's Court junction box forty trains an hour can be passed each way—that is, eighty per hour—handled by the one signalman in the box. As the train approaches the box, both its approach to the section and its destination must be notified to the signalman. When it is remembered that with ordinary signalling, to take an express train, for example, a signalman hears some twenty-four beats on the gongs in his box, and sends signals to the front and rear box, which give altogether some twenty-four beats on the gongs in these two boxes, forty-eight definite signals in all, for every express train he passes into the section which his signals protect, it will be understood that the system must be profoundly modified to admit such a speed of operation as eighty trains per hour per man. The modification is radical. No gong signals are used at all. There is a small cast-iron box standing opposite the signalman with fifteen small windows in it, each about $1\frac{1}{2}$ inches square. Normally, each window frames a white background. A click in the box announces the approach of a train, and a tablet appears in one of the empty windows showing by code the destination of the train. The signalman presses a plug in the box, a click is heard, and a tablet is seen in a precisely similar apparatus in the next box. When the train passes the man presses another plug, and the tablet disappears.

Four wires run between the signal-boxes along the railway, and by combining the currents along the four wires in various ways fifteen definite signals can be obtained, a number sufficient for the District traffic. Each of the fifteen combinations is arranged to operate one particular tablet in the box. Current from these four wires is tapped off at intermediate stations, and is used to work a train indicator showing the passengers assembled on the platform the destinations of the next three trains. The whole equipment is a triumph of ingenuity and engineering skill, and is a splendid example of the way electricity may be used to improve the railway service, quite apart from its main use in connection with the actual driving of the trains.

The facts and problems I have brought before you will, I think, show the important influence that scientific discovery has had upon our railway systems. Scientific discovery and mechanical ingenuity have reduced the cost of locomotive working to a point undreamt of by the pioneer locomotive builders. Electric railways are the direct fruit of the discoveries of Faraday. The safety of the travelling public was enormously increased by the invention of continuous brakes and by the discovery of the electric telegraph, and is greatly increased by the development of modern methods of signalling; and the comfort of travellers is increased by modern methods of train-lighting, train-warming, and the train kitchen. Inventions of a most ingenious character have from time to time been made in order to furnish a steady and ample light in the carriages. The smoothness of travelling on our main lines is evidence of the thought which has been lavished both on the wheel arrangements of the carriages and on the permanent way. Problems in connection with the continuous brake are many and interesting. Some of the problems of modern signalling would have quite baffled the scientific electrician of a quarter of a century ago. When engineers endeavour to apply the results of scientific discovery they often find themselves confronted by new problems unperceived by the man of science. Together they may find a solution, and thus enlarge the boundaries of knowledge, and at the same time confer a practical advantage on the community. The pure man of science, the practical engineer, act and react on one another both to the advantage of pure science and to the advantage of the national welfare. The future success of our railways depends upon the closer application of scientific principle both to the economic and engineering problems involved in their working, some decrease in unprofitable competition with one another, and a more just appreciation on the part of the State of the part railway companies play in our national well-being.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY W. CROOKE, B.A., PRESIDENT OF THE SECTION.

ONE-AND-THIRTY years have passed since the British Association visited this city. At that time anthropology was in the stage of probation, and was represented by a branch of the section devoted to biology. Since then its progress in popularity and influence has been continuous, and its claims to be regarded as a science, with aims and capabilities in no way inferior to those of longer growth, are now generally admitted. Its advance in this country is largely due to the distinguished occupant of this chair at our last meeting in Sheffield. During the present year Dr. E. B. Tylor has resigned the professorship of anthropology in the University of Oxford. Before this audience it is unnecessary for me to describe in detail the services which this eminent scholar and thinker has rendered to science. His professorial work at Oxford; his unfailing support of the Royal Anthropological Institute and of this section of the British Association; his sympathetic encouragement of a younger generation of workers—these are familiar to all of us. Many of those now engaged in anthropological work at home and abroad date that interest in the study of man, his culture and beliefs, which has given a new pleasure to their lives, from the time when they first became acquainted with his "Primitive Culture" and "Researches into the History of Mankind." These works enjoy the almost unique distinction that, in spite of the constant accumulation of new material to illustrate an advancing science, they still maintain their authority; and this because they are based on a thorough investigation of all the available material and a profound insight into the psychology of man at the earlier stages of culture. He has laid down once for all the broad principles which must always guide the anthropologist: that a familiarity with the principles of the religions of the lower races is as indispensable to the scientific student of theology as a knowledge of the lower forms of life, the structure of mere invertebrate creatures, is to the physiologist. "Few," he assures us, "who will give their minds to master the general principles of savage religion will ever think it ridiculous or the knowledge of it superfluous to the rest of mankind. . . . Nowhere are broad views of historical development more needed than in the study of religion. . . . Scepticism and criticism are the very conditions for the attainment of reasonable belief." I need hardly say that his exposition of the principles of animism, as derived from the subconscious mental phenomena of dreams and waking visions, has given a new impulse and direction to the study of the religion of savage races.

Dr. Tylor, on his retirement from the active work of teaching, carries with him the respectful congratulations and good wishes of the anthropologists here assembled, all of whom join in the hope that the Emeritus Professor may be able to devote some of his well-earned leisure to increasing the series of valuable works for which we are already indebted to him.

In his address from this chair Dr. Tylor remarked that twenty years before that time it was no difficult task to master the available material. "But now," he added, "even the yearly list of new anthropological literature is enough to form a pamphlet, and each capital of Europe has its anthropological society in full work. So far from any finality in anthropological investigation, each new line of argument but opens the way to others behind, while those lines tend as plainly as in the sciences of stricter weight and measure towards the meeting ground of all sciences in the unity of nature."

Since these words were written there has been a never-ceasing supply of fresh literature, which is well represented in the publications of the present year. Every contributor to this science must now be a specialist, because he can with advantage occupy only one tiny corner of the field of humanity; and even then he is never free from a feeling of anxiety lest his humble contribution may have been anticipated by some indefatigable foreign scholar. In short, the attempt to give a general exposition of the sciences devoted to the study of mankind has been replaced by the monograph. Of such studies designed to coordinate and interpret the facts collected by workers in the field we welcome two contributions of special importance.

Prof. J. G. Frazer has given us a monumental treatise on totemism and exogamy, in which, relying largely on new Australian evidence and that collected from Melanesia by Dr. Haddon and his colleagues, Dr. Rivers and Dr. Seligmann, he endeavours to prove that totemism originated in a primitive explanation of the mysteries of conception and childbirth. As contributing causes he discusses the influence of dreams and the theory of the external soul, the latter being occasionally found connected with totemism; and he points out that one function of a totem clan was to provide by methods of mimetic or sympathetic magic a supply of the totem plant or animal on which the existence of the community depends, this function being not metaphysical or based on philanthropic impulse, but on a cool but erroneous calculation of economic interest. He has also cleared the ground by dissociating totemism from exogamy, the latter, as an institution of social life, being, he believes, later in order of time than totemism, and having in some cases accidentally modified the totemic system, while in others it has left that system entirely unaffected. The law of exogamy is, in his opinion, based mainly on a desire to prevent the union of near relations, and on the resulting belief in the sterilising effects of incest upon women in general and edible animals and plants. In dealing with totemism as a factor in the evolution of religion he gives us a much-needed warning that it does not necessarily develop, first into the worship of sacred animals and plants, and afterwards into the cult of anthropomorphic deities with sacred plants and animals for their attributes. In the stage of pure totemism totems are in no sense deities, that is to say, they are not propitiated by prayer and sacrifice; and it is only in Polynesia and Melanesia that there are any indications of a stage of religion evolved from totemism, a conclusion which demolishes much ingenious speculation. It is hardly to be expected that in a field covered by the wrecks of many controversies these views will meet with universal acceptance. But the candour with which he discards many of his own theories, and the infinite labour and learning devoted to the preparation of his elaborate digest, deserve our hearty recognition.

In his treatise on "Primitive Paternity," Mr. E. S. Hartland deals with the problems connected with the relations of the sexes in archaic society. Mother-right he finds to be due not so much to the difficulty of identifying the father as to ignorance of physiological facts; and he supposes that the transition from mother-right to father-right originated not from a recognition of the physical conditions of paternity, but from considerations connected with the devolution of property; as Prof. Frazer states the case, it arises from a general increase in material prosperity leading to the growth of private wealth.

We also record the steady progress of the great "Encyclopædia of Religion and Ethics," under the editorship of Dr. J. Hastings, which promises to provide an admirable digest of the results of recent advances in the fields of comparative religion and ethnology.

It is now admitted by all students of classical literature that the material collected from the lower races is an indispensable aid to the interpretation of the myths, beliefs, and culture of the Greeks and Romans. Most of our universities provide instruction of this kind; and Oxford has opened its doors to a special course of lectures dealing with the relation of anthropology to the classics. One of its most learned mythologists, Dr. L. R. Farnell, when about half-way through his treatise on the cults of the Greek states, admitted the increasing value of the science in elucidating the problems on which he was engaged. Even with this well-advised change of method he has left the field of peasant religion, nature-worship, and magic, which must form the starting-points for the next examination of Greek beliefs, practically unworked. The formation of a Roman Society, working in cooperation with and following the methods which have been adopted by the Society for the Promotion of Hellenic Studies, is a fresh indication of the increasing importance of the work upon which we are engaged.

In the field of archæology Dr. A. J. Evans has commenced the publication of the Minoan records, which open up a new chapter in the early history of the Mediterranean. It is now certain that the origin of our alphabet is not to be found, as De Rougé supposed, in the hieratic script of Egypt, but in the Cretan hieroglyphs; and that the influence of the Phœnicians in its development was less important than has been generally supposed. Before the full harvest of these excavations can be reaped we may have to await the discovery of some bilingual document, like the Rosetta Stone, which will solve the mysteries of the Minoan syllabary.

As regards physical anthropology, the validity of the use of the cephalic index, particularly in discriminating the elements of mixed populations, has been questioned. The recent Hunterian lectures delivered by Prof. A. Keith, as yet published only in the form of a summary, are designed to place these investigations on a more scientific basis. In particular increased attention is being given to the influence of environment in modifying a structure generally so stable as the human skull. Thus it has been ascertained that the immigrant into our towns, by some process of selection or otherwise, develops a longer and narrower head than the countryman. The recent American Commission, under the presidency of Prof. Boas, reports that "racial and physical characteristics do not survive under the new climate and social environment. . . . Children born even a few years after the arrival of their parents show essential differences as compared with their European parentage. . . . Every part of the body is influenced, even the shape of the skull, which has always been considered to be the most permanent hereditary characteristic." Similar results appear from a comparison of the American negro with his African ancestor.

I may here refer briefly to the work on folk-lore. Though in recent years it has not maintained the importance which it at one time secured in the proceedings of this section, we still regard it as an essential branch of the study of man. The Folk-lore Society, after thirty-two years' useful work, finds that much still remains to be done in these islands to secure a complete record of popular beliefs and traditions, many of which are rapidly disappearing. It has therefore formulated a scheme for more systematic investigation in those districts which have hitherto been neglected. A committee including representatives of the two allied sciences is also engaged on the necessary task of revising and defining the terminology of anthropology and folk-lore.

The materials collected by field workers in various regions of the world, and popular accounts of savage religion, customs, and folk-lore continue to arrive in such increasing numbers that the need of a central bureau for the classification of this mass of facts has become increasingly apparent. It is true that we have suffered a set-back, it is to be hoped only temporary, in the rejection of an appeal made to the Prime Minister for a grant-in-aid of the Royal Anthropological Institute. But if we persist in urging our claims to official support the establishment of an Imperial Bureau of Ethnology cannot be long deferred.

One result of this accession of fresh knowledge, largely due to improved methods of research, is to modify some of our conceptions of savage psychology. We now understand that side by side with physical uniformity there may be wide differences arising from varieties of race and environment. It is becoming generally recognised that we can no longer evade the difficulty of interpreting beliefs and usages by referring them to that elusive personality, primitive man. Between the embryonic stage of humanity and the present lie vast periods of time; and no methods of investigation open to us at present offer the hope of successfully bridging this gap in the historical record. To use the words of Prof. Frazer: "It is only in a relative sense, by comparison with civilised men, that we may legitimately describe any living race of savages as primitive." Hence the hypothesis of the unilinear evolution of culture which satisfied an earlier school will no longer bear examination.

Further, not to speak of the artistic endowments of palæolithic man, we find to our surprise that a race like the Australian Arunta, whose lowness in the scale of humanity does not necessarily connote degradation, has worked out with exceptional ability through its tribal council their complex and cumbrous systems of group marriage and totemism. They have developed a cosmogony which postulates the self-existence of the universe; they have reached a belief in reincarnation and transmigration of the soul. So far from their social system being rigid it is readily modified to suit new conditions. They live in peace with neighbouring tribes, and have established the elements of international law. On the moral side, though there is much that is cruel and abhorrent, they are not wanting in kindliness, generosity, gratitude. The savage, in short, is not such an unobservant simpleton as some are inclined to suppose; and any interpretation of his beliefs and usages which ignores this fact is certain to be misleading.

This popularisation of our science has not, however, been universally welcomed. It has been urged with much reason that this overabundance of material tends to encourage an unscientific method, particularly the comparison of isolated facts without due regard to the context of culture to which they are organically related. There is much force in this contention; and probably when the work of this generation comes to be critically reviewed we shall be rightly charged with rashly attempting a synthesis of facts not generically related, with reposing too much confidence in evidence collected in a haphazard fashion, and with losing sight of their historical relations in our quest after survivals. Those who have practical experience of work among savage or semi-savage races understand the difficulty of collecting information on subjects outside the range of their material interests. Only a skilled linguist is able to interpret their hazy religious beliefs. We fail to evolve order from what is and always must be chaotic; we fail to discriminate religion from sociology because both are from the savage point of view identical; and generally it is only the by-products of religion, such as demonology, witchcraft, mythology which reward our search. The most dogmatic among us, when they consider the divergent views of Messrs. Spencer and Gillen and Strehlow, may well hesitate to frame theories about the Arunta.

In the next place it has been objected that the scientific side of anthropology is in danger of being submerged by a flood of amateurism. It is only within recent years that a supply of observers trained in scientific methods has become available. Much of the work in India, the dominions, and other parts of the Empire has been done by amateurs, that is to say, by officers in the service of the Crown, missionaries, or planters, who understand the languages, manners, and prejudices of the people, but have not received the advantage of scientific training. Some of this work is, in its kind, useful; but there seems reason to believe that inquiries conducted by this agency have almost reached their limit. The existing material may be supplemented and corrected by workers of the same class; but from them no important additions to our knowledge can reasonably be expected.

Criticisms such as these have naturally suggested proposals for improving the qualifications of this agency by providing a course of training for public servants before they join their appointments; and excellent arrangements with this object have been made by several of our universities. In addition to this schemes are in the air for the establishment of a School of Oriental Studies in London or of a College for Civilians in Calcutta. We must, however, recollect that the college established by Lord Wellesley at the beginning of the last century with the intention, to use his own words, of promoting among junior officers "an intimate acquaintance with the history, language, customs, and manners of the people of India," failed to meet the aims of its founder. We must also remember that recruits for the Colonial services do not undergo any training in this country; and that in the case of the Covenanted Civil Service of India the period extends only to a single year, during which the candidate is expected to learn the rudiments of at least one Oriental language and to acquire some knowledge of the law and history of India. It seems obvious that this leaves little time for the scientific study of anthropology; and the most that can be expected is to excite in the young official a desire to study the native races and to define the subjects to which his attention may usefully be directed. There is, again, the obvious risk of letting loose the half-trained amateur among savage or semi-savage peoples. He may see a totem in every hedge or expect to meet a corn-spirit on every threshing-floor. He may usurp the functions of the arm-chair anthropologist by adding to his own proper business, which is the collection of facts, an attempt to explain their scientific relations. As a matter of fact, the true anthropologist is born, not made; and no possible course of study can be useful except in the case of a few who possess a natural taste for this kind of work.

Having then practically exhausted our present agency it is incumbent upon us to press upon the Governments throughout the Empire the necessity of entrusting the supervision of ethnographical surveys to specialists. This principle has been recognised in the case of botany, geology, and archæology, and it is high time that it was extended to anthropology. It is the possession of such a trained staff that has enabled the American Government to carry out with success a survey of the natives of the Philippine Islands; and it is gratifying to record that the Canadian legislature, in response to resolutions adopted by this section at the Winnipeg meeting, has recently voted funds to provide the salary of a superintendent of the ethnological survey. We may confidently expect that other Governments throughout the Empire will soon follow this laudable example. These Governments will, of course, continue to collect at each periodical census those statistics and facts of sociology and economics which are required for purposes of administration. But beyond these practical objects there are questions which can be adequately investigated only by specialists.

The duties of such a director will necessarily be threefold: First, to sift, arrange, and coordinate the facts already collected by non-scientific observers; secondly, to initiate and control special investigations, in particular that intensive study of smaller groups within a limited area which, in the case of the survey of the Todas by Dr Rivers, has so largely contributed to our knowledge of that tribe. Such methods not only open out new scientific fields, but, and this is perhaps more important, establish a standard of efficiency which improves later surveys of these or neighbouring races.

The field for inquiry throughout the Empire is so vast that there is ample room for expeditions independent of official patronage. In some respects the private traveller possesses advantages over the official—in his freedom from the bondage of red tape and from the suspicion which inevitably attaches to the servant of Government that his inquiries are conducted with the object of imposing taxation or of introducing some irksome measures of administration. He is always sure to receive the aid of local officers, whose familiarity with the native races must be of the highest value.

The third duty of the director will be to organise in a systematic way the collection of specimens for home and colonial museums. Our ethnographical museums, as a whole, have not reached that standard of efficiency which the importance of the Empire and the needs of training in anthropology obviously require; and our students have to seek in museums at Berlin and other foreign cities for collections illustrative of tribes which have long been subject to British law. It is only necessary to refer to the recent handbook of the ethnographical collections in the British Museum to see that there are wide gaps in the series which might easily be filled by systematic effort. No time is to be lost, because the tragedy of the extinction of the savage is approaching the final act, and our grandchildren will search for him in vain except perhaps in the slums of our greater cities.

Assuming then that in the near future anthropological inquiries will be organised on practical lines, I invite your attention to some special problems in India which deserve intensive study, and which can be solved in no other way. India is a most promising field for such inquiries. Here the student of comparative religion can trace with more precision than is possible in any other part of the Empire the development of animism and the interaction on it of the forces represented by Buddhism, Hinduism, Islam, and Christianity. The anthropologist can observe the most varied types of moral and material culture, from those represented by the heirs of its historic civilisation down to forest and depressed tribes little raised above the level of savagery.

The first question which awaits examination is that of the prehistoric races and their relation to the present population. Unfortunately the materials for this inquiry are still imperfect. The operations of the archæological survey, with the scanty means at its disposal, have rightly been concentrated upon the remains of architecture in stone, which starts from the Buddhist period, and upon the conservation of the splendid buildings which are our inheritance from older ruling powers. The prehistoric materials have been collected by casual workers who were not always careful to record the localities and circumstances of the discovery of their contributions to the local museums. Many links are still wanting, some altogether absent from Indian soil; others which systematic search will doubtless supply. We can realise what the position of prehistoric archæology in Europe would be if the series of Neolithic barrows, the bone carvings of the cave-dwellers, the relics from kitchen-middens and lake dwellings were absent. The caves of central India, it is true, have supplied stone implements and some rude rock paintings. But the secrets of successive hordes of invaders from the north, their forts and dwellings, lie deep in the alluvium, or are still covered by shapeless mounds. Tropical heat and torrential rain, the ravages of treasure-hunters, the practice of cremation have destroyed much of the remains of the dead. The epigraphical evidence is enormously later in date than that from Babylon, Assyria, or Egypt; and the oriental indifference to the past and the growth of a sacred literature written to subserve the interests of a priestly class weaken the value of the historical record.

Further, India possesses as yet no seriation of ceramic types such as that devised by Prof. Flinders Petrie which has enabled him to arrange the Egyptian tombs on scientific principles, or that which Prof. Oscar Montelius has established for the remains of the Bronze Age. Mr. Marshall, the Director of the Archæological Survey, admits that the Indian museums contain few specimens of metal work the age of which is even approximately known.

Though the record of the prehistoric culture is imperfect, we can roughly define its successive stages.

The palæolithic implements have been studied by Mr. A. C. Logan, whose work is useful if only to show the complexity of the problem. Those found in the laterite deposits belong to the later Pleistocene period, and display a technique similar to that of the river-drift series from western Europe. The Eoliths, which have excited such acute controversy, have up to the present not been discovered; and so far as is at present known the palæolithic series from India appears to be of later date than the European. Palæolithic man seems to have occupied the eastern coast of the peninsula, whence he migrated inland, using in turn quartzose, chert, quartzite, limestone, or sandstone for his weapons; that is to say, he seems not to have inhabited those districts which at a later time were seats of neolithic culture. Early man, according to what is perhaps the most reasonable theory, was first specialised in Malaysia, and his northward route is marked by discoveries at Johore and other sites in that region. Thence he possibly passed into India. The other view represents palæolithic man as an immigrant from Europe. At any rate, his occupation of parts of southern India was antecedent to the action of those forces which produced its present form, ere the great rivers had excavated their present channels, and prior to the deposition of the masses of alluvium and gravel which cover the implements which are the only evidence of his existence.

Between the palæolithic and the neolithic races there is a great geological and cultural gap; and no attempt to bridge it has been made except by the suggestion that the missing links may be found in the cave deposits when they undergo examination.

There is reason, however, to believe that the neolithic and the Iron Age cultures were continuous, and that an important element in the present population survives from the neolithic period. Relics of the neolithic are much more widely spread than those of the palæolithic age. They extend all over southern India, the Deccan, and the central or Vindhyan range. Up to the present they are scanty in the Punjab and Bengal; but this may be due to failure to discover or identify them. Mr. Bruce Foote has discovered at various sites in the south factories of neolithic implements associated with wheel-made pottery of a fairly advanced type, showing that the Stone Age has survived side by side with that of metal down to comparatively recent times. The Veddas of Ceylon, the Andamanese, and various tribes on the north-east frontier, in central and southern India, are, or were up to quite recent times, in the Age of Stone. In fact, when we speak of ages of stone or metal we must not regard them as representing division of time but generally continuous phases of culture.

There is no trustworthy evidence for the existence of an Age of Bronze. The single fine implement of this metal which has been discovered is probably, like the artistic vessels from the Nilgiri interments, of foreign origin; and other implements of a less defined type seem to be the result of imperfect metallurgy. This is not the place to discuss the problem of the origin and diffusion of bronze. Babylon, Asia Minor, and China have each been supposed to be a centre of distribution. The Egyptian specimen attributed to the third dynasty, say before the fourth millennium B.C., is believed by Prof. Petrie to be the result of a chance alloy; but the metal certainly appears in Egypt about 1600 B.C., and it is believed to have originated in central Europe, where the Zinnwald of Saxony or the Bohemian mines provided a supply of tin. The absence of a Bronze Age in India has been explained by the scarcity of tin and the impossibility of procuring it from its chief source in the Malay-Burman region, where the mines do not seem to have been worked in ancient times. But another view deserves consideration. Prof. Ridgeway has shown that all the sites where native iron is smelted are those where carboniferous strata and ironstone have been heated by eruptions of basalt; and iron was thus produced by the natural reduction of the ore. In Africa as well as India the absence of the Bronze Age seems to be due to the abundant supplies of iron ores which could be worked by processes simpler than those required in the case of bronze. In India iron may have been independently discovered towards the close of the neolithic period, and iron may have displaced copper without the intervention of bronze.

However this may be, the Copper Age in India, which has been carefully studied by Mr. V. A. Smith, is of great importance. Implements of this metal in the form of flat and bar celts, swords, daggers, harpoon, spear, and arrow heads, with ornaments and a strange figure probably human, have been found at numerous sites in northern India. In western Europe, according to Dr. Munro, the Copper Age was of short duration; but Mr. Smith believes that in India the variety of types indicates a long period of development.

No mention of iron occurs in the Rig-veda; but it appears in the Atharvan, which cannot be dated much later than 1000 B.C. It is now recognised that there is a still obscure stratum of Babylonian influence underlying the Aryan culture; and if, as is generally supposed, the manufacture of iron was established by the Chalybes at the head-waters of the Euphrates, who passed it down the delta, its use may have spread thence among the Indo-Aryans. It certainly appears late in the south Indian dolmen period; and we have the alternatives of believing that it was introduced there by the Dravidian trade with the Persian Gulf, which certainly arose before the seventh century before Christ, or that it was independently discovered by the Dravidians who still extract it in a rude way from the native ores.

The great series of dolmens, circles, and kistvaens which cover the hills and plateaux of the Deccan and the region to the south seem to belong to the Iron Age. Whether the construction of these monuments was due to the migration of the dolmen-building race from northern Africa, or whether the builders were a local people utilising the material on the spot must remain uncertain. The excavations conducted by Mr. Breeks and others disclose tall jars, many-storeyed cylinders of varying diameter, with round or conical bases, fashioned to rest on pottery ring-stands, like the classical amphoræ, or to be imbedded in softer soil. The lids of these vessels are ornamented with rude, grotesque figures of men, animals, or more rarely inanimate objects, depicting the arms, dress, ornaments, and domesticated fauna of the period. It has been suspected that these figurines may be of a date earlier than the implements of iron with which they are associated, and that they were deposited with the dead in a spirit of religious conservatism. At any rate, the costumes and arms represented on the older pottery present no resemblance to those depicted on the later series of dolmens and kistvaens. The pottery also seems to belong to different periods, the larger jars being of a later date than the true funereal urns which are found at a lower level, and contain a few cremated bones, gold ornaments, bronze and iron rings, with beads of glass or agate. These people clearly regarded bronze as an article of luxury, as it appears in the form of ornaments or in the series of splendid vases preserved in the Madras museum. It is difficult to suppose that these were of local origin; more probably they were imported in the course of trade along the western coast or from more distant regions.

Another and equally remarkable phase of culture, combining distinctly savage features with a fairly advanced civilisation, is illustrated by the Adittanalur cemetery in the Tinnevelli district recently excavated by Mr. Rea. Two skulls discovered here are prognathous, suggesting a mixture of the Negrito and Dravidian types. There is no trace of cremation, and in most cases the smallness of the urn openings implies that the corpses were exposed to birds of prey, and that only such bones as could be discovered after removal of the flesh were collected for interment; or, according to another interpretation of the facts, we have an instance of the custom of mourners carrying with them, like the modern Andamanese, the relics of the dead. These interments certainly extended over a long period, neolithic weapons being found in some graves, while in others iron arms were discovered fixed point downwards near the urns, as if they had been thrust into the ground by the mourners. In the richer graves gold frontlets, like those of Mycenae and other Greek interments, were fastened over the forehead of the corpse. These were, like the Greek specimens, of such a flimsy type that they could never have been used in real life. It is a remarkable instance of a survival in custom that at the present day some tribes in this region tie a triangular strip of gold on the forehead of the dead, the import of which, on the analogy of the death masks of Siam, Cambodia, ancient Mexico, and Alaska, we may interpret as an attempt to guard the corpse from the glances of evil spirits while the spirit is on its way to deathland, or to be used in processions of the corpse.

The question remains: To what races may we attribute these successive phases of culture in southern India? The Tamil literature, as interpreted by Bishop Caldwell and Mr. V. Kanakasabhai, shows the existence of an advanced type of archaic culture in this region; but the evidence to connect this with the existing remains is as yet wanting. We may reasonably assume that neolithic man survives in the existing population, because we have no evidence of subsequent extensive migrations, except the much later arrival of Indo-Aryan colonies from the north, and that of the Todas, whom Dr. Rivers satisfactorily identifies with the Nayars and Nambutiri Brahmans of Malabar. The occurrence of a short-headed strain among some tribes in western India probably represents some prehistoric migration by sea or along the coast line from the direction of Baluchistan or the Persian Gulf. The suggestion that it is the result of a Scythian or Hun retreat from northern India in the face of an advancing Aryan movement is not corroborated by any historical evidence, and is in itself improbable. The customs of dolmen and kistvaen burial still persist among some of the present tribes, and they display some reverence for the burial places of their forgotten predecessors. This feeling may, however, be due to the habitual tendency of the Hindu to perform rites of propitiation at places supposed to be the haunts of spirits, and need not necessarily connote racial identity.

The most primitive type identifiable in the population of south India is the Negrito, which appears among the Veddas of Ceylon, and among the Andamanese, who retain the Negrito skin colour and hair, but have acquired, probably from some Mongoloid stock, distinct facial characters. It has been the habit with some writers to exaggerate the Negrito strain in the south. But tribes like the Badagas and Kotas, which have been classed as representative of this type, possess none of the Negrito characters, which appear only among the more primitive Kurumbas, Malayans, Paniyans, and Irulas. In all the modern tribes the distinctive Negrito marks—woolliness of hair, prognathism, lowness of stature, and excessive length of arm—have become modified by miscegenation or the influences of environment.

The resemblances in culture of the Indian Negrito with the cognate races to the east and south-east of the Peninsula are too striking to be accidental. The Kadirs of Madras climb trees like the Bornean Dayaks, clip their teeth like the Jakun of the Malay Peninsula, and wear curiously ornamented hair combs like the Semang of Perak, among whom they serve some obscure magical purpose. The Negrito type deserves special examination in relation to the recent discovery of Pygmies in New Guinea, and the monograph on the Pygmy races in general by Dr. P. W. Schmidt, who regards them as the most archaic human type, from which he supposes the more modern races were developed, not by a process of gradual evolution, but *per saltum*. If there be any force in these speculations he is justified in expressing his conviction that the investigation of the Pygmy races is, at the present moment, one of the weightiest and most urgent, if not the most weighty and most urgent, of the tasks of ethnological and anthropological science.

This Negrito stock was followed and to a considerable extent absorbed by that which is usually designated the Dravidian. The problem of the origin of this race has been obscured by the unhappy adoption of a linguistic term to designate an ethnical group, and its unwarrantable extension to the lower stratum of the population of northern India. At present the authorities are in conflict on this, the most important question of Indian ethnology. One school denies that this people entered India from the north or north-west on the ground that the immigration of a dolichocephalic race from a brachycephalic area is impossible, and insists that the distinction between the so-called Dravidians and Kolarians is linguistic, not physical. The other theory postulates the origin of the Dravidians from the north-west, that of the Kolarians from the north-east; and avoids the difficulty of head form by referring the Dravidians to one of the long-headed races of central or western Asia or north Africa, or by suggesting that their skull form has become modified on Indian soil by environment or miscegenation.

Recent investigations, archaeological or linguistic, throw some new light on this complex problem. Sir T. Holdich, in his recent work "The Gates of India," asserts that Makrán, the sea-board division of Baluchistan, is full of what he calls "Turanian," or Dravidian remains. He explains the position of the Brahui tribe in Baluchistan, on whom the controversy mainly turns, by assuming that while they now call themselves Mingal or Mongal and retain no Dravidian physical characters, the survival of their Dravidian tongue is due to the fact that it is their mother language, preserved by Dravidian women enslaved by Turco-Mongol hordes. Relics of the original Dravidian stock, he suggests, may be found in the Ichthyophagi, or fish-eaters, whom Nearchus, the admiral of Alexander the Great, observed on the Baluchistan coast, living in dwellings made of whale-bones and shells, using arrows and spears of wood hardened in the fire, with claw-like nails and long shaggy hair, a record of the impression made upon the curious Greeks by the first sight of the Indian aborigines.

In the next place, inquiries by Dr. Grierson in the course of the Linguistic Survey prove that what is called the Mon-khmer linguistic family, which preceded the Tibeto-Burmans in the occupation of Burma, at one time prevailed over the whole of Further India, from the Irawadi to the Gulf of Tongking, and extended as far as Assam. To this group the Munda tongue spoken by some hill tribes in Bengal is allied; or, at least, it may be said that languages with a common substratum are now spoken not only in Assam, Burma, Annam, Siam, and Cambodia, but also over the whole of Central India as far west as the Berars. "It is," says Dr. Grierson, "a far cry from Cochin-China to Nimár, and yet, even at the present day, the coincidences between the language of the Korkus of the latter district and the Annamese of Cochin-China are strikingly obvious to any student of language who turns his attention to them. Still further food for reflection is given by the undoubted fact that, on the other side, the Munda languages show clear traces of connection with the speech of the aborigines of Australia." The last assumption has been disputed, and it is unnecessary to discuss this wider ethnical grouping. Though identity of language is a slippery basis on which to found an ethnological theory, it seems obvious that the intrusive wedge of dialects allied to the Mon-Khmer family implies that the Central Indian region was at one time occupied by immigrants who forced their way through the Eastern Himalayan passes, their arrival being antecedent to the migration which introduced the Tai and Tibeto-Burman stocks into Further India.

When the solution of this problem is seriously undertaken under expert guidance, the first step will be to make an exhaustive survey of the group of forest tribes, from the Santáls and Pahárias on the east, passing on to the Kols and Gonds, and ending with the Bhíls on the west. At present our information of the inter-relations of these tribes is fragmentary, and their superficial uniformity does not exclude the possibility that they represent more than one racial element. It will also be necessary to push inquiry beyond the bounds of the Indian Empire, and, like the trigonometrical surveyor, to fix the base line as a datum in India, and extend the triangulation through the borderlands. It is in these regions that the ethnological problems of India await their final solution. Many of these countries are still beyond our reach. Until the survey of the routes converging at Herat, Kabul, or Kandahar is complete, the extent of the influence of the western races—Assyrian, Babylonian, Iranian, Arab, and Greek—cannot be determined. Recent surveys in Tibet have thrown much light on that region, but it is still only very partially examined. In Nepal the suspicious native Government still bars the way to the Buddhist sites in the Tarai and the Nepal valley, and thus a wide chapter in the extension of Hindu influence beyond the mountain range remains incomplete.

The second great problem is the origin and development of caste. We have yet to seek a definition which will cover the complex phases of this institution, and effect a reconcilement between the views of Indian observers who trace it to the clash of races or colours, and that of the sociologists, who lay little stress on race or colour and rely more upon the influence of environment, physical or moral. We must abandon the insular method which treats it only in relation to India, and ignores the analogous grouping of rank and class which was prepotent in Western Europe and elsewhere, and is now slowly losing ground in the face of industrial development. It is by the study of tribes which are on the borderland of Hinduism that we must look for a solution of the problem. The conflict of the Aryan and aboriginal culture, on which the religious and social systems of Hinduism were based, is reproduced in the contact between modern Hinduism and the forest tribes. Since the Hindus are the only members of the Aryan stock among whom we find endogamous groups with exogamous sections, the suggestion of Prof. Frazer that they may have borrowed it from the non-Aryans gains probability. The Dravidians within the Indian totemic area have worked out an elaborate system of their own, which is well described in the recent survey of the Malayans by Mr. F. T. Richards. How far this is connected with their preference for mother-right and their strong family organisation, of a more archaic type than the joint family of the Aryans, is a question which deserves examination. The influence, again, of religion must be considered, and this can be done with the most hopeful results in regions like eastern Bengal, where a people who have only in a very imperfect way adopted Hinduism are now being converted wholesale to Muhammadanism.

Again, when we speak of the tribe in India, we must remember that it assumes at least seven racial types, ranging from the elaborate exogamous groups of the Rajputs to the more archaic form characteristic of the Baloch and Pathán tribes of the western frontier, attached to which are alien sections affiliated by the obligation to join in the common blood-feud, which in process of time develops into a fiction of blood-brotherhood. Thus among the Marri of Baluchistan we can trace the course of evolution: admission to participate in the common blood-feud, admission to participation in a share of the tribal land, and finally admission to kinship in the tribe.

This elasticity of structure has permitted not only the admission of non-Aryan tribes into the Rajput body in modern times, but prepares us to understand how the majority of the Rajputs were created by a similar process of fusion, the new-comers being known as the Gurjaras, who entered India in the train of the Huns in the fifth or sixth centuries of our era. The recognition of this fact, by far the most important contribution made in recent times to the ethnology of India, is due to a group of Bombay scholars, the late Mr. A. M. T. Jackson, whose untimely death at the hand of an assassin we deeply regret, and R. G. and D. R. Bhandarkar. Mr. D. R. Bhandarkar has recently proved that a group of these Gurjara Huns, possibly the tribal priests or genealogists, were admitted first to the rank of Brahmans, and then, by a change of function, of which analogies are found in the older Sanskrit literature, becoming Rajputs, are now represented by the Guhilots, one of the proudest septs. This opens up a new view of tribal and caste development. Now that we can certainly trace the blood of the Huns among the Rajput, Jat, and Gujar tribes, a fresh impulse will be given for the quest of survivals in belief and custom connecting them with their Central Asian kinsfolk.

In what I have said I have preferred to speculate on a problem for work in the future rather than dwell upon the progress which has been already made. In the sphere of religion we have passed the stage when, as Prof. Max Müller said, "the best solvent of the old riddles of mythology is to be found in the etymological analysis of the names of gods and goddesses, heroes and heroines," or when the "disease of language" theory was generally accepted. The position, in fact, has completely changed since Comparative Religion has adopted the methods of Anthropology. The study of myths has given way to that of cults, the former being often only naïve attempts to explain the latter. India offers wide fields for inquiry by these new methods, because it supplies examples of cult in its most varied and instructive phases. The examination of Hinduism, the last existing polytheism of the archaic type, is likely to explain much hitherto obscure in the development of other pantheons. It is no longer possible to refer the complex elements of this or any other group of similar beliefs to a single class of physical concepts. The sun, the dawn, the golden gates of sunset, or the dairy no longer furnish the key which unlocks the secret. It is by the study of the Animism, Shamanism, or Magic of the lower tribes that Hinduism can be interpreted. This analysis shows that behind the myths and legends which shroud the forms of the sectarian gods the dim shape of a Mother goddess appears, at once chthonic or malignant because she gives shelter to the dead, and beneficent because she nurtures the sons of men with the kindly fruits of the earth. Beside her, though his embodiment is much less clearly defined, stands a male deity, her consort, and by a process of magic, mimetic, sympathetic, or homœopathic, their union secures the fertility of the animal and vegetable creation.

Much, however, remains to be done before the problems of this complex polytheism can be fully solved. The action of archaic religions, as has been well said, "takes place in the mysterious twilight of sub-consciousness"; and the foreign observer is trammelled by the elaborate system of tabu with which the Hindu veils the performance of his religious rites. This feeling extends to all classes, and the ceremonial of the jungle shrines is as little open to examination as the *penetralia* of the greater temples. The great army of mendicant friars jealously conceals the secrets of its initiation, rites, and beliefs, and this field of Indian religious life remains practically unworked. Much may be done by the training of a body of native observers who are not subject to the tabu imposed upon the foreigner. Here the difficulty lies in the contempt displayed by the higher educated classes towards the beliefs and usages of the lower tribes. There are some indications that this feeling is passing away, and in recent years much useful ethnological work has been done by native scholars.

The problems of ethnology, so far as they are concerned with the origin of prehistoric races and their relation to the existing population, are more or less academic. Ethnography, which examines the religious, cultural, and industrial conditions of the people, has more practical uses. At the present time it is incumbent upon us to preach, in season and out of season, that the information which it is competent to supply is the true basis of administrative and social reform. If, for example, we were now in possession of the facts which an anthropometrical survey of our home population would supply, many of our social problems would assume a clearer aspect. Such, for instance, are the questions of degeneration due to slum life and malnutrition, the influence of alcoholism on industrial efficiency, the condition of dangerous and sweated industries, and that of the aliens settled in our midst. It is characteristic of the genius of the English people, that while we are not yet prepared to admit the need of such a survey, the provision of medical inspection and relief for children in elementary schools will snon render it inevitable.

This is more clearly the case in those regions where a large native population is controlled by a small European minority. The Negro question in America teaches us a useful lesson, applicable to native races in most parts of the Empire. In India, whenever the Government has made really serious mistakes, the failure has been due to ignorance or disregard of the beliefs or prejudices of the subject people. A little more than a century ago a mutiny of native troops at Vellore was due to injudicious attempts to change a form of headdress which they believed to be a symbol of their religion or caste; ignorance of the condition of the Santáls allowed them to be driven to frenzy by the extortions of moneylenders which culminated in a serious outbreak; the greased cartridges of the Great Mutiny, and the revolt against measures, adopted in defiance of native feeling to check the plague epidemic, teach a similar lesson.

In India at the present time "the old order changeth, yielding place to new"; and at no period in the history of our rule was it more necessary to effect a reconciliation between the foreigner and the native. While the tabus of marriage relations and commensality will for an indefinite period prevent the amalgamation of the races, much of the present disquiet is due to ignorance and misunderstanding on both sides. The religious and social movements now in progress deserve the attentive study of the British people. In religion various attempts are being made to free Hinduism from some of its most obvious corruptions, to harmonise Eastern and Western ideals, and to elevate the former so as to enable them to resist the pressure of the latter. Such is Vedantism, a revival of the ancient pantheistic philosophy, which not only claims supremacy in India, but asserts that its mission is to replace the dying faiths of the Western world. The spread of monotheism, as represented by Bhagavata beliefs, is equally noteworthy; and the effect of the revival of the cults of Ganpati, god of luck, and of Sivaji, the Mahratta hero, on the political situation in the Deccan deserve the most careful consideration.

The social movement is the result of that fermentation which is in progress among the subject peoples in many parts of the world. While the educated Indian claims social equality with the foreigner, he is occupied with a serious problem at his own doors. The degraded castes, popularly called the "untouchables," are revolting against the obloquy which they have long endured at the hands of the higher races. Many of them have sought relief by joining the Christian or Muhammadan communities, and the progress of conversion is so remarkable as to excite the surprise and alarm of the orthodox classes. Measures have been designed to improve their almost intolerable position. It remains to be seen how far any concessions which are likely to satisfy them can be reconciled with the ideals of the caste system.

It is true that the people of India prefer to celebrate many of their religious and social rites free from observation of the foreigner, and that there are forbidden chambers in the Oriental mind which no stranger may enter. But the experience of those best qualified to express an opinion is that a sympathetic interest in the religious and social life of the people, so far from tending to increase the existing tension, is a valuable aid towards the promotion of mutual goodwill and sympathy. Orthodox native States not only show no aversion to ethnographical inquiry, but are themselves actively engaged in such surveys. Even the Rajputs, who ordinarily display little taste for scientific work, are beginning to undertake the collection of the bardic chronicles which embody their tribal folk-lore and traditions.

When the divergencies in the beliefs and institutions of the foreigner and the indigenous races are realised and understood, a compromise must be effected, each side discarding some hereditary prejudices—the Hindu that aversion to the manners and customs of the European which is the chief barrier to the promotion of intercourse between the races; the European that insularity of thought which makes it difficult for him to understand all that is valuable in novel types of belief and culture, as well as that lack of imagination which inclines him to exaggerate what seems to him intolerable in the economical condition, the social organisation and beliefs of races whose environment differs from his own.

Anthropology has thus a practical as well as a scientific side. The needs of inquirers whose interest mainly lies in the investigation of survivals and in the stages of evolution in culture and belief can, as I have endeavoured to show, be met only by the adoption of improved methods of inquiry and a more rigorous dissection of evidence. Unfortunately the inadequate resources of the societies devoted to the study of man, as contrasted with the extent of the sphere of inquiry and the importance of the savage or semi-savage races as factors in the progress of the Empire, prove that the practical value of anthropology is as yet only imperfectly realised. If its progress is to be continuous we must convince the politician that it has an important part to play in the schemes in which he is interested. Thus it is certain that in the near future the relations between the foreigner and the native races will demand the increasing attention of statesmen at home and abroad. Here anthropology has a wide field of action in the examination of the causes which menace the very existence of the savage; of the condition of the mixed races, like the Mulatto or the Eurasian; of the relations of native law and custom to the higher jurisprudence; of the decay of primitive industries in the face of industrial competition. One of its chief tasks must be the examination of the physical and moral condition of the depressed classes of our home population, and the effect of modern systems of education on the mind and body of the child. It will thus be in a position to assist the servants of the State to meet the ever-increasing responsibilities imposed upon them; and it will help to dispel the ignorance and misconceptions which prevail even among the intelligent classes in this country in regard to the condition of the native races, who, by a strange decree of destiny, have been entrusted to their charge. By such practical contributions to the welfare of humanity it will not only secure the popular interest which is a condition of efficiency, but engage the ever-increasing attention of those to whom its scientific side is of paramount importance.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

MR. ARTHUR HALE has been appointed second demonstrator in the chemical department of the Finsbury Technical College.

AMONG the public introductory lectures to be given at University College (University of London) during October, we notice the following:—October 3, niton: one of the argon series of gases, Sir W. Ramsay; October 4, the origin of scenery, Prof. E. J. Garwood; October 6, the life and times of Sennacherib, Dr. T. G. Pinches; recent investigations into the mental growth of children, Dr. C. Spearman; October 10, climatic control, Prof. L. W. Lyde; instinct, Prof. Carveth Read; October 13, experimental phonetics, Mr. D. Jones.

WE see from the calendar of the day section of the Bradford Technical College for next session that, to meet the growing demands and necessities of the textile and other departments, a block of buildings is in course of erection in close proximity to the present college. The buildings for the textile department, when completed and equipped, will be worthy of the chief centre of the wool industry in this country. The new equipment will be of a complete character, enabling wool to be taken in the fleece and turned out, in conjunction with the dyeing and finishing department, in the dyed and finished state. In connection with this extension of the college, it has been decided to put down a plant for the department of engineering which, although primarily intended for educational purposes, will at the same time serve to supply light and power to the present building, the new extensions, and the school of art. From the point of view of both mechanical and electrical engineering students this will constitute a valuable advance. The whole of the plant has been so designed that any one set may be available for demonstration or experiment without interfering with the supply of current for lighting or power. More extended trials will be carried out during the summer months, when only a small portion of the plant is required for generating purposes. Students will thus have excellent opportunities of obtaining practical instruction in steam and electrical engineering, and of becoming acquainted with the running of a power station.

WITH what thoroughness the more recently established of the provincial universities are performing their new duties is well brought out by an examination of their calendars for the session 1910–11, which is now commencing. The calendar of the University of Leeds, for instance, runs to some six hundred pages, and gives particulars of courses of work for undergraduates wishing to take degrees in arts, science, technology, and medicine, and for other students desirous of studying for special purposes in the laboratories of the University. In the case of the University of Bristol, in addition to the necessary regulations for degrees, diplomas, and certificates, particulars are given of the university work done in associated institutions, of courses to meet particular local needs, and so on. Reference to courses of a special character brings to the mind again the work of the London polytechnics. The prospectus of the Borough Polytechnic Institute for the coming session shows that, in addition to the numerous trade classes held in previous years, special lectures and practice have been arranged in waistcoat-making and trade millinery for women, classes in masonry and lectures on the chemistry and manufacture of food-stuffs, and the analysis of laundry trade materials. At the City of London College the needs of commercial men especially are provided for, and the new syllabus is very strong in classes intended for young men engaged in offices and warehouses. The prospectus of the Belfast Technical Institute shows that, while specialising to some degree in classes intended to train men employed in textile and engineering industries, the authorities have in no way forgotten the needs of other workers. It would be difficult to find an industry in the city in which any considerable number of men and women are engaged that has not been considered in drawing up the scheme of work of the institute.

SOCIETIES AND ACADEMIES.

GLASGOW.

Institute of Metals, September 21.—Donald **Ewen** and Prof. T. **Turner**: The shrinkage of antimony-lead alloys and of the aluminium-zinc alloys during and after solidification. From the investigation of the shrinkage of the brasses it has been suggested that, for an alloy of given composition, a direct proportion exists between the amount of expansion on solidification and the distance of the solidus from the liquidus at this composition on the equilibrium diagram. The results of shrinkage tests on two further series of alloys are included in this paper; they show that the above theory is incapable of general application, and appear to indicate that it obtains only in the case of alloys containing solid solutions.—F. **Johnson**: The effect of silver, bismuth, and aluminium on the mechanical properties of "tough-pitch" copper containing arsenic. Contrary to the general belief, it was found that bismuth *increased* the tensile strength, as did silver also. It was found that silver had little effect upon the toughness of the arsenical copper, which, again by virtue of the presence of arsenic, was tougher than electrolytic copper made under similar conditions. The effect of silver on the hot-working properties was found to be negligible up to 0·3 per cent.; that of bismuth noticeable above 0·02, and serious above 0·05 per cent.; whilst that of aluminium was ruinous at 0·3 per cent. In view of the possibility of modern commercial copper containing other impurities which could modify the limiting proportion allowable of the above-mentioned impurities, it is difficult to fix a limit beyond which they should not occur. It may, however, be safely said that silver occurs in such traces that its presence may be ignored. Its influence will be beneficial rather than harmful. Bismuth should, preferably, be entirely absent, and may be expected to cause trouble in any process of mechanical treatment at a red-heat, if present above 0·01 per cent. As regards the presence of this impurity in the finished material, however, little concern may be felt, as the amount which will render arsenical copper unfit for working hot, will have no serious effects on the mechanical properties of the finished material in the cold.—A. D. **Ross**: Magnetic alloys formed from non-magnetic materials. The paper deals with investigations carried out chiefly on ternary alloys consisting of copper, manganese, and one of the elements aluminium, tin, bismuth, and antimony. All the groups show fair magnetic quality, but the most interesting are the ternary alloys containing respectively aluminium and tin. Some of the former are, under small magnetising forces, much more magnetic than cobalt, and have little coercive force. The tin alloys are less permeable, but exhibit greater hysteresis. Most of the alloys have their magnetic quality improved if they are annealed for a short time at a moderate temperature, 150°–200° C. Prolonged annealing has invariably an adverse effect, the hysteresis loss increasing rapidly with time. The behaviour of the alloys on cooling to the temperature of liquid air is peculiar and characteristic. For low and moderate fields the process results in general in a decided increase in susceptibility, whereas almost all other magnetic materials are rendered less susceptible.

September 22.—G. D. **Bengough** and O. F. **Hudson**: The heat-treatment of brass: Experiments on 70:30 alloy. The authors have studied the general effect of heat-treatment on the mechanical properties of 70:30 brass, and have paid special attention to the question of burning. Bars and wires made by different manufacturers were used in order to ascertain to what extent variations in character of the alloy and size of section influenced the results. The mechanical tests of the bars and wires after they had been annealed for half an hour show, in agreement with the results of previous workers, that the best annealing temperature is between 600° and 700° C. For this time of annealing a temperature within a few degrees of the melting point does not seriously injure 70:30 brass which is free from tin and lead, but, if maintained for a sufficiently long time, a temperature nearly 100° C. lower will burn the brass.—Dr. C. H. **Desch**: Some common defects occurring in alloys. After references to the defective state of our knowledge of the "diseases" of non-ferrous metals and alloys, as compared with that possessed by manufacturers and users of iron and steel, the importance of the equilibrium diagram as a guide in undertaking investigations of this kind is emphasised, and some of its limitations are mentioned. Some of the principal defects observed in non-ferrous alloys are then briefly reviewed, as a basis for discussion.—H. S. **Primrose**: Metallography as an aid to the brass founder. The results of a systematic investigation of the gun-metal castings in a large engineering foundry are discussed in the light of microscopical examination, in addition to the ordinary tensile testing. The reason why metallography is steadily superseding the old methods of judging by fracture is shown by comparison of photomicrographs of the internal structure. The crystalline formation being profoundly influenced by the rate of cooling as well as by the initial casting temperature, the microstructure of test bars, variously cooled and cast at different points, is contrasted to indicate how the best physical tests are got from a perfect interlocking structure. The different causes of blow-holes are described, and their detection by the microscope discussed with reference to micrographs of the various types. How these defects can be obviated or subsequently eliminated is illustrated by examples taken from actual cases.

PARIS.

Academy of Sciences, September 19.—M. Armand Gautier in the chair.—E. **Bertin**: The arrest of steamships either by reversing the engine or by allowing to slow down by friction of the water. With reciprocating engines reversal causes a rapid slowing down, but with steam turbines the reversing effect is much less. Formulæ are worked out for the reduction in velocity both with and without reversed turbines.—M. **Pougnet**: The action of the ultra-violet rays upon plants containing coumarin, and some plants the smell of which is due to the hydrolysis of glucosides. The ultra-violet rays produce the smell rapidly in coumarin plants, and also in plants the odour of which arises from the products of hydrolysis of a glucoside. The action is caused by the cells being killed by the ultra-violet light.—J. **Athanasin**: The functional mechanism of striated and non-striated muscular fibres.—J. **Deprat** and H. **Mansuy**: General stratigraphical results of the geological expedition to Yun-nan.—Ernest **van den**

Broeck and E. A. **Martel**: The conditions of effective filtration of the underground waters in certain chalk formations. In Belgium the crinoidal chalk at the base of the Carboniferous of the Dinant geological basin furnish filtered potable waters in a remarkably constant manner.

NEW SOUTH WALES.

Linnean Society, July 27.—Mr. C. Hedley, president, in the chair.—G. I. **Playfair**: Polymorphism and life-history in the Desmidiaceæ. A number of new forms described.—L. A. **Cotton**: The ore-deposits of Borah Creek, New England, N.S.W. The Borah Creek Mine is situated in the New England district of New South Wales, within two miles of the Gwydir River. The ores contained in the mine are arsenopyrite, zinc blende, chalcopyrite, stannite, and galena. They are very uniformly distributed through the mine, both along the lode and in depth. The order of deposition of the minerals, which form symmetrical zones in the fissure, is arsenopyrite, pyrite, zinc blende, chalcopyrite, stannite, galena, and finally quartz. Comparison with other occurrences indicates the probability of a genetic relationship between the silver-lead deposits and the tin deposits. It is suggested that the Borah Creek deposits have been formed later than the tin deposits by deposition from highly aqueous and siliceous magmatic extractions containing relatively large amounts of metallic sulphides.—T. G. **Sloane**: Revisional notes on Carabidæ (Coleoptera), part iii. The tribes Oodini, Chlæniini, and Sphodrini, as represented in Australia, are reviewed, and the Australian genera of these tribes, as well as the species of every genus found in Australia, are tabulated. Synonymy is dealt with, and six species are described as new (Chlænius, 1 sp.; Anatrichis, 1 sp.; Coptocarpus, 2 spp.; Platynus, 2 spp.). Certain characters not hitherto deemed of importance in classification are discussed.

CAPE TOWN.

Royal Society of South Africa, August 17.—Mr. S. S. Hough, F.R.S., president, in the chair.—H. **Bohle**: The influence of uniformity and contrast on the amount of light required. The author dealt first with the adaptability of the human eye to various daylight illuminations, and gave a new definition of glare. When the eye looks at an illuminant of great intrinsic brilliancy in front of a dark background it tries to do two things at once: to open wide for the dark background and to close up for the intrinsic brilliancy. The author then considered the physiological effects of radiation, explained overheating of the eyes due to excess light absorption, and considered the effects of the ultra-violet rays of modern illuminants and of solar radiation. In addition he treated the effects of light radiation on germs of disease, the destructive action of rays when applied excessively, and finally dealt with the effect which uniformity and the avoidance of contrast in artificial lighting have on the amount of light required. He came to the conclusion that in a room with black walls an illumination of 35 to 40 candle-metres is required, whereas in a place with white ceilings and light walls the amount of light can be reduced to 30 candle-metres. For perfect uniformity in such places, as obtained with inverted lamps, 20 candle-metres give, in the opinion of the author, complete satisfaction. The effects of various lamp-shades on the uniformity of illumination were also shown.

CALCUTTA.

Asiatic Society of Bengal, September 7.—T. H. D. **La Touche**: The Lonar Lake.—B. L. **Chaudhuri**: *Triacanthus weberi*, sp. nov. It is one of the new fishes found widely distributed in the Bay of Bengal by the trawling operation of the *Golden Crown*. In the collection of the Indian Museum there are five species of this interesting genus besides this new one.—J. Coggin **Brown**: A description of a Lisu Jew's harp. The paper describes a Jew's harp which is the favourite musical instrument of the Lisu's, a tribe living in western China. It differs from those described from Assam, and approximates to those found in the Malay Peninsula. It consists of three delicate harps cut out of bamboo, and held upright between the thumb and first finger or between the first and second fingers of the left hand, while the tongues are made to vibrate with the right hand. The mouth acts as the sounding-board. The instrument is used by the young men in their serenades, and forms a part of the orchestra at all their festivals.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), parts ii. and iii. for 1910, contain the following memoirs communicated to the society:—

May 28.—R. **Courant**: The establishment of the Dirichlet-principle.—M. **Born**: Kinematics of a rigid body in relation to the principle of relativity.—P. **Koebe**: The uniformisation of algebraic curves by means of automorphous functions with imaginary substitution-groups (concluded).—R. **Gans**: The electron-theory of ferromagnetism.—J. K. **Whittemore**: Convex curves.—H. **Bohr** and E. **Landau**: The behaviour of the functions $\zeta(s)$ and $\zeta_{\lambda}(s)$ in the neighbourhood of the straight line $\sigma=1$.

June 11.—F. **Riesz**: Quadratic forms with an infinite number of variables.

The *Business Communications* of the society, part i. for 1910, contains reports on the Samoa Observatory (1909–10), on the progress of the complete edition of Gauss's works, and on subjects for prize dissertations. The obituary notices of F. Kohlrausch, by **Riecke**, and of T. W. Engelmann, by **Verworn**, are included.

THURSDAY, OCTOBER 6, 1910.

THE MAMMALS OF MANITOBA.

Life-histories of Northern Animals: an Account of the Mammals of Manitoba. By Ernest Thompson Seton. Vol. i., Grass-Eaters. Pp. xxx+673. Vol. ii., Flesh-Eaters. Pp. xii+674–1267. (London: Constable and Co., Ltd., 1910.) Price £3 13*s*. 6*d*. net.

SO far as this country is concerned, it is a great pity that Mr. Seton did not include in his admirable life-histories the whole mammalian fauna of North America, as the restriction of the species to those inhabiting a particular area can scarcely fail to be faulty in the eyes of English readers, who will miss such well-known animals as the big-horn sheep, white goat, Columbian black-tailed deer, and the brown bears and caribou of Alaska. It is likewise a matter for regret that the whole of the table of contents is included in the first volume, instead of the portion relating to the Carnivora being reserved for the second. Except this very small modicum of fault-finding, I have nothing but commendation to bestow on these handsome volumes, which, it may be presumed, are an English edition of the work issued last year in America under the same title.

The mammals of Manitoba are fifty-nine in number, and of these the author describes the life-history in his own inimitable manner, and with a wealth of detail that leaves little, if anything, for future field naturalists to record. The great feature of the work is, of course, that it is the result of personal observation and first-hand knowledge, acquired during wanderings extending over a long series of years, and embracing a very large portion of the North American continent. The map of his travels shows, in fact, that Mr. Seton has explored the whole of the United States, from ocean to ocean, so that the red lines which mark his route form a perfect network. Southward he has touched the Mexican border, while northward he has visited Labrador on the east, and on the west has made a single traverse to the heart of the Mackenzie district. And it is these extensive journeys, with the knowledge thereby acquired, that intensifies our regret that he did not see fit to make his work cover the whole North American mammal fauna. In spite of the almost omniscient character of his personal knowledge of the habits and distribution of the animals of which he writes, the author has been at the pains to quote the names of observers by whom special traits were first recorded.

In addition to his well-known power of conveying important scientific information in most attractive and popular language, Mr. Seton enjoys the great advantage of being a skilled artist, so that he is able to present to his readers portraits of the animals in the particular pose which he considers most characteristic and interesting. The amount of labour he has expended on artistic work may be inferred from the fact that the whole of the 560 illustrations were drawn with his own pencil. Such sketches are, in my opinion, infinitely superior to photographs, which too frequently do not bring out the characteristic features which the describer desires to emphasise. That many of these illustrations, if I mistake not, have appeared in other publications, testifies to public appreciation of their artistic merit.

In the space at my disposal it is quite impossible to attempt anything in the way of a critical review of these two bulky quarto volumes, and I shall therefore content myself with noticing some of the author's observations relating to the larger species which appear of special interest.

By far the most characteristic American type of big game is undoubtedly the prongbuck, a species the distributional area of which has been reduced by about one-half, and the numbers of which were estimated by the author in 1900 not to exceed, at most, 100,000, of which half must be in Mexico. And yet from the accounts of travellers of no earlier date than 1868 it seems probable that these graceful antelopes, as they are locally called, actually outnumbered the bison in the days of its prime. Taking the number observed in one particular district as a basis, the author calculates that, on a low estimate, there must have been over 40 millions on the great plains. Since 1900 these antelopes, in spite of reported local increases, have probably suffered a further serious decrease, the number in Wyoming in 1905 being estimated at not more than one-fourth of what it was five years previously.

As regards the extermination of the bison, Mr. Seton, although as a naturalist regretting the event, takes what may be called the practical view of the subject, and declares it to have been absolutely inevitable. The plains were required by the advance of civilisation, and the supporting of vast herds of stupid bison, ready to stampede in an overwhelming mass on the slightest alarm, was not the best use to which they could be put. On the testimony of two independent observers, he asserts that blizzards, especially those of 1871–2 and 1880–1, had a share in the extermination of the bison, one of the two witnesses stating that the Dakota blizzard was more destructive to the herds than the Indians. Since, however, blizzards are only occasional events, Mr. Seton doubts if their destructiveness was equal to that of agencies working with greater regularity.

In concluding this brief notice of a first-class work, it may be noted that the author is a firm believer in the evolution of the mind of man from that of animals below him in the zoological scale.

R. L.

THE CARE OF TREES.

The Care of Trees in Lawn, Street, and Park. By Bernard E. Fernow. Pp. x+392. (New York: Henry Holt and Co., 1910.)

ALTHOUGH there is scarcely a garden or park of any pretensions in this country which does not contain within its boundaries one or more trees particularly valued for their interest, beauty, or associations, how rarely do their owners ever take any steps to keep them in health, and thus prolong their term of years. The care of trees, indeed, more especially those parts in it which may be described as surgical and antiseptic, is an art strangely recent in origin. Some of the practices of still living "tree-doctors" (one may instance the leaving of a stump "to draw the sap" when a branch or limb is sawn off) betray a simple faith curiously reminiscent of the methods of sixteenth-century practitioners on the human frame.

But owners of trees are, on the whole, content to let them run their ordinary course, although nothing is more certain than that by judicious treatment the span of years of many trees may be extended by tens, perhaps hundreds, of years. The value, of course, of many such trees is a purely sentimental one. Yet among individual living things trees seem to link the centuries together more effectually than anything else. What heart is not moved by the sight, and still more by the possession, of a tree under which it is known some famous man of old, or even one's own forbears, sat and mused.

The author of this work is well known to those in his own walk in life, as one of the most eminent and trustworthy authorities on the subject in the United States and Canada. And we may say at once that this book fully bears out his reputation. It is a pleasant change, after wading through much of the ignorant twaddle that is nowadays so plentifully offered to the tree-loving public, to come across a book the author of which has (what, indeed, the unsophisticated might regard as essential) an adequate knowledge of his subject.

Mr. Fernow's object is, briefly, to interest his readers in their trees, to give them some idea of how they grow and do their work, and to give directions for their cultivation and preservation. Much of what he writes is more particularly applicable to the north-eastern United States and the adjacent parts of Canada, where the climatic conditions, especially in relation to tree and shrub growth, are sufficiently dissimilar to our own as to render some modification of his recommendations necessary before they can be adopted here. But his treatise, on the whole, is very well worth study by those interested in the trees and shrubs of English parks and gardens.

We regret that the author thought it necessary to give a sort of recommendation—although certainly a half-hearted one—to the book on pruning written by A. des Cars, nearly fifty years ago. Des Cars' system of pruning is hopelessly discredited by now. As applied to trees grown solely for timber it was out of the question for reasons of cost, and as applied to the purely ornamental trees of gardens, the rigid formality he advocated was absolutely at variance with the tastes of ninety-nine people out of a hundred.

The latter part of this book is taken up with the description of trees and with the consideration of their respective value and treatment. It is somewhat cursorily done, and is the least satisfactory part, in that it is far from free of errors. The horse chestnut, for instance, is not Chinese (p. 250), nor is *Prunus pissardii* Japanese (p. 304). The author has sadly confused the *Pyrus sinensis* of Lindley, a true pear, with the common *Cydonia japonica*, which is, of course, a quince (p. 297). It is a remarkable lapse to recommend rhododendrons for calcareous soils, which, with the exception of one or two species, they abhor (p. 372). The list of "shrubs fit for rock gardens" is strangely inadequate (p. 373). About a dozen plants are mentioned, half of which are absolutely unfitted for any ordinary rock garden, whilst the scores of dainty shrubs, mainly alpine, the neatness of habit and slow growth of which render them peculiarly fitted for such a position, are quite ignored. Errors in spelling, too, are numerous.

In view of the thoughtless and ignorant outcry which is usually set up in the daily Press whenever the removal or thinning, or even lopping, of trees in public places is done, it was a happy thought to quote a letter written by J. R. Lowell to the president of Harvard University in 1863. The following words will bear repeating:—

"Something ought to be done about the trees in the college yard. They remind me always of a young author's first volume of poems; there are too many of 'em and too many of one kind. If they were not planted in such formal rows, they would typify very well John Bull's notion of 'our democracy,' where every tree is its neighbour's enemy, and all turn out scrubs in the end, because none can develop fairly. . . . We want to learn that one fine tree is worth more than any mob of second-rate ones. Do pray take this matter into your own hands—for you know how to love a tree—and give us a modern instance of a wise saw."

THE MAKING OF BEET-SUGAR.

Beet Sugar Making and its Chemical Control. By Y. Nikaido. Pp. xii+354. (Easton, Pa.: The Chemical Publishing Co.; London: Williams and Norgate, Ltd., 1909.) Price 12*s*. 6*d*. net.

THE aim of this work, the author remarks, is to aid those who are starting on a career of beet-sugar manufacture, but who lack systematic training in the technique thereof.

In principle, the production of sugar from beetroots is a simple matter. The sugar and other soluble bodies are extracted from the sliced roots by diffusion in water; the juice thus obtained is purified from acids and other objectionable matter by "defecation" with lime, and after the excess of lime has been removed by treatment with carbonic acid, the liquor is concentrated by evaporation until the sugar crystallises out. Whilst, however, there is nothing complicated about the principle, successful and profitable production depends upon close attention to a number of points in respect of which the chemist's help is needed.

These points Mr. Nikaido describes and explains at length. The essential part of the book is contained in one chapter—the eighth. This is devoted to expounding the "practical operation," *i.e.* management, "of a beet-sugar house." It sets forth the various steps involved, from harvesting the beets to packing the sugar, and gives details of the chemical examinations necessary for the proper control of the processes. The descriptions bear the stamp of practicality, and the value of the book in actual work is enhanced by a series of useful tables. In the last chapter a number of "special analyses" are considered; they relate to methods of testing beetroot seed, to the examination of various materials used in sugar manufacture, and to particular cases of sugar analysis—*e.g.* the determination of raffinose.

The chief criticism suggested, on looking through the volume, is that a disproportionate amount of space is allotted to preliminary and incidental matters. Apart from an appendix of tabular material and the index, the book contains 294 pages. Of these only 120 are devoted to the real object of the work—beet-sugar making and its chemical control. The rest is taken up with accessory description, much of which is merely general elementary chemistry. This would be much better learned from an ordinary textbook. A "theory of the origin of limestone" (p. 40); a description of the metallurgy of iron (p 48), or the chemistry of lead (p. 54); a dissertation on the molecular structure of the hydrocarbons (pp. 61–2): all these are rather out of place in a book devoted to sugar; or, at least, such things should not get the lion's share of the space. Whilst it is legitimate enough to discuss the general chemistry of the sugars, and even perhaps the theory of the polariscope, the rest of the matter in question gives one the impression of being largely "padding."

This apart, the book deals lucidly with the everyday problems of beet-sugar production, and should prove very useful to those for whom it is written.

C. S.

METHODS OF ROCK-ANALYSIS.

Analyse der Silikat- und Karbonatgesteine. By W. F. Hillebrand; translated by E. Wilke-Dörfurt. Zweite Auflage. Pp. xvi + 258. (Leipzig: W. Engelmann, 1910.) Price 6 marks.

The Analysis of Silicate and Carbonate Rocks. A revision of Bulletin 305. By W. F. Hillebrand. Bull. 422, U.S. Geol. Survey. Pp. 239. (Washington: 1910.)

AS a consequence of the modern developments of petrology, accurate chemical analyses of rocks, and of the component minerals of rocks, have become more than ever an urgent desideratum; and it is a fortunate coincidence that there has been at the same time a decided revival of mineral chemistry, so long overshadowed by that of the carbon compounds. Not only is the discovery of new rock-types continually providing fresh material, but also it has to be recognised that the older rock-analyses, admirable in their own time, no longer suffice for the requirements of the present day. The best modern analyses have the advantage of greatly improved methods of separation; and, further, they aim at a much greater thoroughness of treatment, often including estimations of twenty or more constituents, instead of the eight or nine which satisfied Bunsen and Delesse.

In this work a leading part has been taken by the American chemists, and particularly those of the United States Geological Survey. In the last thirteen years four bulletins have been issued giving complete analyses of many American rocks, conducted in the laboratory at Washington. In the first of these, some forty pages were devoted to a discussion of methods of analysis by Dr. Hillebrand. This part, considerably enlarged, was issued as a separate bulletin in 1900, a new edition appearing in 1907; and it is this last which has now been translated into German, with some revision and additions by the author. It has been closely followed by a revised edition of the original, so that the latest advances in this branch of practical chemistry are now accessible equally to German and English readers.

The methods which are here fully and clearly set forth are, in the main, those which the experience of the author and his colleagues has led him to prefer; but alternative methods are often given, especially when the first one requires complicated and costly apparatus. Many of the analytical methods described are, of course, familiar to the working chemist, but the author's matured judgment on their relative merits cannot fail to be of use; and, even apart from this critical discussion, it is a great convenience to have the scattered literature of the subject brought together and presented in systematic shape.

As an illustration of the author's treatment, we may select the estimation of ferrous iron, always a crux in rock-analyses (pp 154–71). First comes a section, added in the present edition, pointing out the important error introduced by oxidation of the material during the process of grinding, and the devices by which this error may at least be minimised. This is followed by a comparison between Mitscherlich's sealed tube method of estimation and the hydrofluoric acid methods; the former is in general to be avoided, on account of the reducing action of sulphides present in the rock. Since, however, Mitscherlich's method is probably the best in those cases where it can safely be used, it is described, with important modifications suggested by experience. The general principle of the hydrofluoric acid method is then set forth, with a discussion of the chief sources of error and of the influence of sulphides, vanadium, and carbonaceous matter on the determination of the ferrous iron. Finally, the author describes the method itself in its various modifications, as advocated by Cooke, Pratt, and Treadwell, respectively.

Twenty years ago the petrologist who did not perform his own chemical analyses felt that he was delegating part of his legitimate task to another. A more exacting standard has made a division of labour, as regards complete rock-analyses, almost inevitable, and Dr. Hillebrand's manual is accordingly addressed to the chemist rather than the petrologist. On the other hand, few of us are in the advantageous position of the United States Geological Survey, which can command the services of six or eight skilled specialists; and it is also to be remembered that one complete analysis demands as much time and labour as, perhaps, three of a less ambitious kind. Some petrologists will be of opinion that there is still a place for rock-analyses, conducted according to the best methods, but including estimations of only a moderate number of constituents.

If the petrologist cannot make his own analyses, he should, none the less, be competent to interpret them with judgment, and we should have been grateful to the author for some guidance in this matter. Everybody knows, for instance, that the silica is likely to be more correctly determined than the alumina, and so in a general way for other constituents; but a summary discussion by a skilled mineral analyst of the probable errors attaching to the several chief constituents of igneous rocks would be very welcome.

(3) *A Physiographical Introduction to Geography.* By Prof. A. J. Herbertson. The Oxford Geographies. Pp. 120. (Oxford: The Clarendon Press, 1910.) Price 1s. 6d.

(4) *Geology.* By Prof. J. W. Gregory. Dent's Scientific Primers. Pp. 140. (London: J. M. Dent and Sons, Ltd., n.d.) Price 1s. net.

(5) *An Economic Atlas.* By J. G. Bartholomew, with an introduction by Prof. L. W. Lyde. Pp. xii+64. (Oxford: The Clarendon Press, 1910.) Price 3s. 6d. net.

(6) *Devonshire.* By F. A. Knight and Louie M. (Knight) Dutton. Cambridge County Geographies. Pp. xii+245. (Cambridge: University Press, 1910.) Price 1s. 6d.

(7) *Dorset.* By A. L. Salmon. Cambridge County Geographies. Pp. ix+154. (Cambridge: University Press, 1910.) Price 1s. 6d.

(8) *Derbyshire.* By H. H. Arnold-Bemrose. Cambridge County Geographies. Pp. x+174. (Cambridge: University Press, 1910.) Price 1s. 6d.

(9) *A Systematic Geography of Asia.* By G. W. Webb. Pp. vi+100. (London: Methuen and Co., Ltd., 1910.) Price 1s.

MR. MACKINDER has now brought his studies in the teaching of geography by means of its correlation with history to a penultimate stage. Approximately half this book (1) deals with history in some form, either with the world-movements of peoples, such as the Magyars or Turks, or with the history of discovery connected with the names of Marco Polo or Cook. There is, as yet, little political geography, all of which is promised in the final volume of the series, and the treatment tends to ignore the possibilities of correlation with other subjects in the school curriculum. Most pupils learn something of the value of coordinates in relation to the fixing of the position of points in space, and provided the problems of latitude and longitude be postponed, their adequate treatment follows as a special case of this method of recording the positions of points; Mr. Mackinder approaches these problems by way of an account of the work of Eratosthenes and of the eclipse of the sun at the battle of Arbela. The book makes an interesting reader, and is profusely illustrated with maps and diagrams, some of which imply a geographical knowledge which the text does not call upon the pupils to utilise.

The beginner in any study should know the technical language in which the phenomena of that subject are described: hence the utility of the three books which represent the physiographic aspect of geography. Mr. Carey (2) brings to his explanation of the terms of physical geography, and of the "principles which underlie and control the development of the physical conditions" of any region, the methods of the successful teacher. He gives a series of practical exercises which familiarise the pupil with the matter to be considered; he then presents the facts in their usual setting, and elucidates the technical terms and the principles, and, finally, asks questions which force the pupil to realise the meaning of the matter studied. The references are usually to parts of the British Isles.

Prof. Herbertson (3) attempts a succinct summary of world geography. The text and the illustrations require the active cooperation of the teacher with the pupil at every step, and thus the work is much more difficult for the pupil than either of the two previously mentioned. For example, Mr. Carey makes the pupil draw an isotherm, and then discusses the interpretation of typical isotherms for the British Isles; Prof. Herbertson deals with world isotherms at once, assuming that the pupil knows how they are made and what they mean. Prof. Herbertson gives a useful concluding chapter on map nets, while there is an appendix containing many revision questions contributed by Miss Kirk.

Prof. Gregory (4) contributes an explanation of the technical terms employed in geology, which should serve as an excellent introductory primer, but there is lacking the apparatus of exercise and question for school use. Probably, of all subjects, geology requires the assistance of an expert who can suggest and advise as to the particular ways in which practical work in the field should be performed, and the beginner, whether school pupil or private student, would be greatly helped were this primer provided with guidance in this direction.

The "Economic Atlas" (5) is a re-issue of the "School Economic Atlas," with slight modifications. Prof. Lyde, in an introduction, limits economic geography to a study of the earth in relation to man, and provides a series of valuable hints as to the study of the maps which follow. In this introduction Prof. Lyde claims that the water-parting between the Atlantic and the Indo-Pacific Oceans divides the world into two fairly equal parts, and in an inset map the water-parting is shown by a black line on a map of the world, having the Pacific Ocean in the middle. There is no suggestion of the internal drainage systems of the continents, nor of the drainage into the Arctic Ocean. A consideration of the map and text, apart from a consideration of these other facts, would probably lead to erroneous conclusions. The introduction and the maps are distinctly valuable, but there are certain difficulties with regard to this method of presenting the facts of geography. In the first place, the statistics given should be averages for a series of years, and diagrams should show the proportions of their various parts; the diagrams relating to the production of cereals, &c., give no statement of the proportions in which the different areas contribute to the total production. Further, maps without some other form of data are apt to be misleading; for example, the traditional English idea of Canada is that it is a producer of wheat. The fact that Canada produces more oats than wheat does not appear from the maps in the atlas. Oats are, curiously enough, omitted from the economic map of the United States and Canada. Similarly, in regard to the maps of minerals, such as iron and coal, it would be distinctly useful if some indication were added as to the areas in which the mineral deposits are being worked; for example, coal and iron are shown in India, but there is no indication that practically the only mining carried on in India is for coal.

The three additions to the Cambridge County Geographies, "Devonshire" (6), "Dorset" (7), and "Derbyshire" (8), are of the already familiar type of descriptive geography which this series illustrates. In "Derbyshire," Mr. Arnold-Bemrose exemplifies one of the best features of the series. He tells the story of the rocks, and shows the relation between these and the surface features, the climate, and the occupations of the people. His facts range from the Derwent Valley water scheme to the life of early man in these islands as inferred from the deposits in the caverns. In the other volumes, the authors deal with the coastal features of the counties and with the changes in the outline of the coast due to sea encroachments. These books are storehouses of facts of many kinds, and will be useful as reference books in school and other libraries. It may be urged that both in the text and in the appendix the statistics should be average values for a series of recent years.

Mr. Webb's "Asia" (8) is systematic but not regional; for example, the existence of the Thar desert is explained out of all connection with the desert belt immediately to the west; again, in the case of Japan, the large proportion of the country which is forested is ignored, and emphasis is laid upon the growth of rice, "for which the climate is specially suitable," and tea. B. C. W.

OUR BOOK SHELF.

Catálogo Sistemático y Descriptivo de las Aves de la República Argentina. By Roberto Dabbene. Tomo Primero. *Anales Museo Nacional de Buenos Aires,* serie 3, vol xi., pp xiv+513+map. (Buenos Aires: 1910.)

In this work, of which the present portion occupies the whole of the serial volume in which it appears, the author proposes to do for the birds of Argentina that which Mr. Ridgway is accomplishing for those of North and Central America. To a great extent the two works will, when completed, cover the whole of the South American avifauna, for, owing to the imperfect information with regard to the zoology of the outlying provinces of the Argentine Republic, Dr. Dabbene has felt himself compelled to include in his catalogue the birds of the south of Brazil, Bolivia, and Paraguay, and of the frontier districts of Chile and Uruguay.

The author has in the main followed the classification adopted in the British Museum "Hand-list of Birds," although for the Passerines he had to rely on the Museum "Catalogue," as the last part of the former work did not reach him in time to be used. This is a pity, as Dr. Sharpe made certain amendments in the arrangement of the orders which might have been advantageously followed. The present volume commences with a general account of the structure of birds, illustrated with text-figures, which, although somewhat crude, serve their purpose well, the whole account being well up to date. Ending with a bibliography, this section is followed by one on the distribution of Argentine birds, which is perhaps the most important part of the whole volume; the geographical ranges of the various species being shown in tabular form. The volume concludes with a somewhat heavy list of addenda and corrigenda (in addition to an extensive list of errata in the preliminary portion), followed by several copious indexes. The systematic part of the work will, it may be presumed, commence in the next volume, and will afford a better criterion for testing the value of the undertaking than is afforded by the one in hand. R. L.

Land and Fresh-water Mollusca of India, &c. By Lieut.-Col. H. H. Godwin-Austen. Vol. ii., part xi. Pp. 239–310; cxviii–cxxxii. plates. (London: Taylor and Francis, 1910.)

Malacologists will gladly welcome a further instalment of this valuable work from the pen of that nestor of Indian conchology, Col. Godwin-Austen. Like the previous part (Nature, vol. lxxvi., 1907, p. 244), this contains further descriptions of forms, some of them new, belonging to the families Zonitidæ and Endodontidæ.

In 1907, as we pointed out, the author transferred the genera Austenia, Girasia, and Cryptosoma from the Heliocarioninæ to the Macrochlamyinæ. Next year, in the "Fauna of India: Mollusca," and now again in the part under notice, these genera reappear in their old position. These changing views are not so much to be wondered at when the extreme difficulty of reducing this complex and puzzling group to order is taken into consideration. Their classification depends on anatomical differences which are by no means so well defined by nature as one could desire. The apparent introduction, however, of one genus into two subfamilies is due to an unfortunate misprint on p. 272, where *Austenia* appears for *Euaustenia.*

All the Endodontidæ described belong to the genus Pupisoma, comprising forms included by the early writers in the genus Pupa.

A reference to the Mauritian species of Macrochlamys (Proc. Malac. Soc., vol. vi., 1905, p. 320), which the author now refers to *M. renitens,* Morelet, concludes the number.

The plates, which are faithful reproductions of the author's vigorous and effective drawings, call as such for commendation.

Jack's Insects. By Edward Selous. With forty-four illustrations by J. A. Shepherd. Pp. xiii+379. (London: Methuen and Co., Ltd., 1910.) Price 6s.

All we need say about this book is that Jack and his sister fall asleep over a book of natural history, and dream that they are talking to the insects, &c., to which it relates.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Fur Trade.

It is recorded in the "Life of Professor Owen" that on one occasion Lord John Russell sent him a bone, requesting that it might be identified. Owen replied that it was an ordinary ham-bone, pertaining to the genus Sus, and was informed that Lord John had received from President Grant what purported to be a bear's ham, concerning which he had his doubts, hence the inquiry.

It is not improbable that naturalists are occasionally appealed to in a similar manner for judgments on the identity of furs. In these circumstances, they may well be excused if they lack Prof. Owen's assurance, or are found entirely wrong. The mysteries of the fur trade are surely beyond the understanding of even a skilled zoologist; but there is an American publication in which they are revealed to the astonished reader. This is the retail catalogue of Albrecht and Son, of Minnesota. This firm does a very large business, and has no wish to deceive its customers as to the nature of their purchases, and yet cannot get away from the current trade names. Consequently, it publishes a detailed synonymy, some of which has not yet found its way into zoological works. I venture to extract a few items for the instruction and entertainment of those who have not access to the catalogue.

Alaska Bear.—"The best Minnesota Raccoon, coloured a dark brown."

Adelaide Chinchilla.—Australian Opossum.

French Ermine.—"Made from selected skins of the French Coney."

Baltic (*White*) *Fox.*—"The fur of the large Hare of northern Europe."

Iceland White Fox.—"White Thibet Lamb, combed until the hair is straight."

Kamtschatka Fox.—"Trade name of the northern Timber Wolf."

Baltic Lynx.—"This fur is secured from the large Belgian Hare of northern Europe, dyed a jet black."

Finland Lynx.—Australian Wallaby.

Natural Black Marten.—"From the black Marten (commonly known as skunk)."

Russian Marten.—American Opossum.

Russian Mink.—Mongolian Marmot.

Siberian Pony.—Russian Calf.

Inland Seal.—French Coney.

Coast Seal.—"Albrecht coast seal is made from the skins of the French Coney."

But the catalogue itself should be in every zoological library. It contains other items of interest; thus it appears that one may spend the trifling sum of 625 dollars on a muff made of Russian sable. Single skins of this animal are valued as high as 500 dollars when of the best quality.

An Attempt to Determine the Supposed Change in Weight Accompanying the Radio-active Disintegration of Radium.

Some time ago Mr. Grant and I designed and constructed a micro-balance (Proc. Royal Society, A, vol. lxxxii., p. 580) for the purpose of demonstrating, if possible, the occurrence of a change in weight accompanying the radio-active disintegration of radium.

We have recently been attempting to do this, using 7·5 milligrams of pure radium bromide. It was necessary to have two balances of great sensitiveness in order to carry out our proposed experiment, and the two balances which we have used have each a sensitiveness of $2\cdot5\times10^{-9}$ grams, and for both of them the resting point has not varied by more than 5×10^{-9} gram during several periods of observation varying in length from a week to a month.

The plan of our proposed experiment was as follows. The two balances were mounted side by side in the same balance case in such a way that the images of a fine illuminated slit could be reflected on to the same scale from the mirrors on the two balances.

One of the balances was to serve as a check on the second, which was to be used to determine the weight of the active deposit from the radium. This second balance was of the type B figured in our paper (*loc. cit.*), and was provided with a fine fibre attachment and quartz hook from which could be suspended a piece of fine platinum wire.

A piece of stout platinum wire was passed through the wall of the balance case, and well insulated from it, and by a mechanical contrivance this insulated wire could be brought, when desired, into contact with the wire suspended from one end of the balance beam. By means of this second wire the suspended wire could be raised to a negative potential of five hundred volts.

Through the wall of the balance case were also passed two glass tubes leading to an air-circulating apparatus and to a bubbler containing the solution of radium bromide.

By means of this circulating apparatus the air contained in the balance case could be bubbled continuously through the radium bromide solution, thus keeping it charged with the radium emanation. As this decayed into radium A, the latter in the electric field should be driven to the charged and counterpoised platinum wire and accumulated there, and so its weight determined.

The behaviour of the balance was investigated with the greatest care, and after many disturbing effects had been discovered and eliminated one at a time, it was finally shown that the resting point of both balances was constant for at least a month, when every condition was the same as for the actual experiment with the single exception that the bubbler contained water instead of the radium bromide solution. Thus the following changes in conditions did not affect the resting point by more than $5\cdot0\times10^{-9}$ gram:—(*a*) Releasing and arresting the balance beam; (*b*) touching and jerking the suspended platinum wire; (*c*) starting and stopping the circulation of the air; (*d*) charging and discharging the platinum wire.

The experiment was then started by replacing the water in the bubbler by the solution of radium bromide and the behaviour of the balance again tested, when it was found that the resting point was still unaffected by the operations (*a*), (*b*), and (*c*).

The wire was then charged, and it was expected that this would cause an increase in weight of the order of 10×10^{-9} gram per day, but instead of this an increase of weight of about 30×10^{-7} gram has been found to occur.

Whilst it is not impossible that this increase in weight is due to radio-active changes, it is so much greater than that calculated on the basis of the electrical evidence that the conditions of the experiment require to be re-examined with the greatest care. An explanation that suggests itself to us is the following. With the balance case used by us and described in our paper (*loc. cit.*) the ground joints and flange are necessarily made vacuum tight by some form of lubricant. We have used the so-called rubber grease, which probably distributes vapour of heavy molecular weight throughout the balance case, although its vapour pressure is far too small to be detected by ordinary methods.

It is possible that the ions produced by the emanation and its radio-active products form nuclei for the condensation of this vapour, and that these condensed aggregates are driven with the charged nuclei to the charged and counterpoised platinum wire, there accumulated, and weighed.

The balance case and other apparatus employed is being modified so as to exclude all possibility of condensation of vapour, and it is hoped, when the necessary preliminary study of the behaviour of the instruments has been carried out, to determine whether the large change in weight that has been observed is an accompaniment of the radio-active process or an adventitious effect.

The Habits and Distribution of Scutigera in India.

Beyond the bare fact of its occurrence, but little else seems to have been recorded concerning either the habits or distribution of this remarkable myriapod in India. During the last three years I have come across it on many occasions, and it proves to be very widely distributed in the United Provinces. It occurs from a few hundred feet above sea-level in the plains, at Allahabad, up to nearly 11,000 feet in the Himalayas, having thus a considerable vertical range. I have found it plentiful at Bhowali, among the Himalayan foot-hills of Kumaon, at 5700 feet, and at many other localities in the same district. It occurs at Dhakuri and Dhwali at an elevation of 9000 feet, and also at Phurkia at about 10,300 feet—about five miles below the Pindari glacier. In the neighbouring district of Garhwal I have met with it this year under stones between Badrinath and the village of Mana, situated at the entrance of the pass of the same name into Tibet. The elevation was approximately 10,800 feet, or possibly a little more. How many species are included within this area of distribution I am unable to say, as the Indian forms are at present being worked out by Prof. Silvestri.

Scutigera exhibits a strong dislike to expose itself to daylight and sunshine, and lurks during the daytime in dark places. The commonest situation for finding it is under matting covering the floors of bungalows, or on walls in dark corners, or under stones, &c., out of doors. Sinclair, in vol. v. of the "Cambridge Natural History," states that in Malta Scutigera darts about in the hot sunshine after its prey. In India, so far as my experience goes, it is a nocturnal animal. It is difficult to secure perfect examples, for Scutigera never seems loth to part with one or more of its extremely long and fragile limbs, which are dismembered with extreme readiness. After separation from the body the legs exhibit active muscular contractions for about twenty or thirty seconds. One of its chief enemies in the plains seem to be scorpions, which inhabit very much the same situations. On one occasion a large Buthus was observed to seize a Scutigera by several of its legs with one of its pedipalps. The Scutigera departed in great haste, and made good its escape, leaving several legs behind in the possession of the scorpion. From this occurrence one is led to suggest that the extreme length of the legs of Scutigera may perhaps be an adaptive modification for defensive purposes. When an animal is encompassed by such an armature of appendages it makes it difficult for an enemy to seize it by a more vital part of the body.

From watching the living animal, there seems no doubt that the extremely long and antenna-like hind pair of legs function as sense-organs. Individuals in captivity kept these appendages frequently uplifted and on the move after the same manner as antennæ. A large spider was placed in a vessel along with a Scutigera, and the latter manifested great alarm. The long posterior appendages were kept in constant agitation, apparently to guard against a rear attack, while the antennæ were behaving in the same manner at the opposite end of the body.

Fire Tests with Textiles.

I shall be glad if you will insert the following letter in reference to fire test with textiles, as the conclusions at which I have arrived, after repeated experiments, are so different from those reached by the British Fire Prevention Committee that I feel I cannot allow the assertions of that committee to pass unchallenged. I have over and over again shown publicly and privately, including a demonstration to the members of the Home Office Committee referred to below, that "Non-flam" flannelette is only non-inflammable if it is washed in a certain way. If washed in the manner usually employed by the ordinary housewife, *i.e.* washed with soap and water, and finally wrung out of clear water until all trace of soap has gone, it burns as readily as ordinary cheap flannelette. This fact was testified to by many witnesses besides myself before the Home Office Committee. The manufacturers of "Non-flam" acknowledge this in a letter to me (a letter which was added as a footnote to my evidence before the Departmental Committee on Coroner's Law, second report, p. 42), from which the following are extracts:—"If a piece of Non-flam is washed . . . with plenty of soap to form a good lather, and then rinsed in water, but not beyond the point at which the water on wringing runs a little milky, showing that a little soapy water still remains in the cloth, it will be found to have lost scarcely any of its fire-proof qualities even after repeated washings. . . . You may perhaps ask why we have not issued instructions as to the method of washing to be adopted with Non-flam. . . . It has never been done for two reasons. One is that to issue such instructions would create suspicion. . . . The other reason is that, upon inquiry, we are satisfied that ninety-nine times out of a hundred the method which is followed in the domestic wash could hardly be improved upon. . . . The clothes, after washing, are seldom, if ever, rinsed until no soap is left in them." My contention is that this method of washing is *not* the one employed by the ordinary woman who washes at home. My school nurse made inquiries for me of a dozen mothers as to their method of washing their children's flannelette garments, and, without exception, they all said they finally wrung out of fresh water to get rid of all traces of soap. (The reason for this is, I believe, that if any soap is left in it makes the clothes nasty and sticky.)

I am confident that the 1400 lives annually lost by burning and scalding in this country will only be substantially diminished when fire-guards are compulsory. Eighty-five per cent. of these deaths were proved to be due to the want of a guard. Section 15 of the Children Act, excellent as it is, needs strengthening. It only renders it a penal offence if a child is burnt to death or seriously injured owing to the want of a fire-guard. It does not compel a parent to take reasonable precautions, by the provision of a guard, to prevent this burning.

I shall be most interested to see what conclusions are arrived at by Mr. Gladstone's committee after having heard the evidence of the various witnesses. The final report may be expected shortly.

Customs at Holy Wells.

It has been suggested that the following information is of sufficient interest to justify insertion in Nature.

Some of your readers doubtless know the Well of St. Cubert, near Crantock, Newquay, and have read the guide-book description of the miraculous cures of infants which used to take place there in old times.

The book on ancient and holy wells in Cornwall, by Mr. Quiller-Couch, gives a full account of the ceremonies which must be observed, and Sir Norman Lockyer quotes them in the chapter on holy wells in "Stonehenge and other Stone Circles."

These authorities seem, however, to be unaware that the help of St. Cubert was sought as late as the latter half of the nineteenth century. When we were at Newquay in 1886, my parents' man-servant, a native of Mawgan, near Newquay, told the other servants that he as a delicate infant had been passed through the hole in the rock of St. Cubert's Well "for luck."

Whether all the proper ceremonies had been observed I cannot say. The servant must have been about eighteen years old in 1886, and he was alive and well in 1898, since which time we have lost sight of him.

A Meteorological Phenomenon.

On Monday, September 26, travelling between Etaples and Breteuil, Chemins de Fer du Nord, *en route* to Paris, my family and myself and a friend (five in all) observed the following meteorological phenomenon.

The sun was hidden, but traceable, behind a white mist from 3.30 p.m. until 4.55 p.m. (French time), and on the north and south at a considerable distance through the mist there appeared two arcs of a circular halo, showing on the north colours from red to green, and on the south colours from red to yellow, only the other spectrum colours were absent.

About 4.30 p.m. a dark grey cloud hid the whole phenomenon, but about 4.45 p.m. until the end of the display the grey cloud passed, and the sight was both beautiful and brilliant.

The colour-bands were very wide; the green was the widest and palest, and I only observed it on the northern arc. R. ASHINGTON BULLEN.

Bordeaux, September 28.

RADIUM STANDARDS AND NOMENCLATURE.

THE International Congress of Radiology and Electricity, held at Brussels, September 12th to 15th, afforded an excellent opportunity of discussing several important questions of general interest to workers in radio-activity. The need of a definite radium standard, in which all results should be expressed, has been growing more acute with the increase of accuracy of radio-active measurements. At the present time, scientific results are expressed in many cases in terms of arbitrary radium standards kept in each laboratory, and it has been difficult to be certain of the accuracy or relative value of such standards. Mr. C. E. S. Phillips several years ago pointed out to the Röntgen Society the desirability of adopting a fixed radium standard, and arranged for the preparation of several small radium standards which were compared with the working standard adopted by Rutherford and Boltwood. Duplicates of the latter standard have been used for several years by a number of English, American, and Continental workers.

At the opening meeting, Prof. Rutherford read a report on the desirability of establishing an international radium standard. He pointed out that he had compared by the γ ray method the radium standards used by several important European laboratories, and had found that there was a considerable difference amongst them, amounting in some cases to 20 per cent. It is now possible to measure with considerable precision a number of magnitudes connected with radium; for example, the volume of the emanation, the heating effect, the rate of production of helium, and the rate of emission of α and β particles. The values of each of these quantities is dependent on the accuracy of the radium standard in which the results are expressed. For the comparison of results obtained by workers in different laboratories, it is necessary that they should all be expressed in terms of the same standard. For example, at the present time it is not possible to compare the results obtained on the heat emission of radium by various observers until the radium standards employed have been accurately compared. When once a standard has been adopted, it is relatively a simple matter to determine the radium contents of substandards by the γ ray method or modification of it, without opening the tube containing the radium.

A special international committee was appointed to report to the congress on the best means to be adopted to fix an international radium standard. This committee comprises the following workers in radio-activity representative of a number of countries: Mme. Curie, Debierne, Rutherford, Soddy, Hahn, Geitel, Meyer, Schweidler, Eve, and Boltwood. No doubt representatives of other countries who are prepared to assist in the work will be added later. This committee reported to the congress at its final meeting and their suggestions were adopted by the congress. As a member of the committee, Mme. Curie agreed to prepare a radium standard containing about 20 milligrammes of radium enclosed in a suitable sealed tube. This standard is somewhat large, but the amount was considered necessary on account of the difficulty of weighing small quantities of radium salt with the requisite accuracy. The thanks of all workers in this subject are due to Mme. Curie in undertaking the full responsibility of preparation of a standard, and for the large expenditure of time and labour its preparation will involve. The committee agreed to reimburse Mme. Curie for the cost of the radium and its preparation, after which the standard becomes the property, and is under the control, of the international committee. It was suggested that the standard should be suitably preserved in Paris. The initial cost of preparation of this standard will be somewhat heavy (about 500*l.*), but it is hoped that scientific societies and Governments of various countries will assist in defraying the expenses.

As soon as the primary standard has been prepared, it is proposed to approach through the committee the various national laboratories to ask them to acquire a radium standard accurately determined in terms of the primary standard. In this way it was thought that any Government interested in the question could acquire an accurate radium standard to be used as a basis for standardisation of quantities of radium in use in scientific laboratories, or to be sold commercially. As the primary standard is somewhat large for use in ordinary laboratories, the committee propose to investigate the question of the best method of comparing accurately in terms of the primary standard smaller substandards containing one or two milligrams of radium.

The committee also has under consideration the question of the preparation of very small substandards to be used for the determination of minute quantities of radium and of radium emanation. It is proposed that special investigations be made by the committee to determine the most suitable method of preparation and preservation of such standards. There is at present some uncertainty of how far radium solutions are affected by time in consequence of the tendency of radium to be precipitated out of the solution. No doubt before long it should be possible to secure accurate standard solutions to distribute amongst scientific workers.

In the course of the congress it was suggested that the name Curie, in honour of the late Prof. Curie, should, if possible, be employed for a quantity of radium or of the emanation. This matter was left for the consideration of the standards committee; the latter suggested that the name Curie should be used as a new unit to express the quantity or mass of radium emanation in equilibrium with one gram of radium (element). For example, the amount of emanation in equilibrium with one milligram of radium would be called 1/1000 Curie or one millicurie. The adoption of this unit will avoid much circumlocution, and will prove useful since the radium emanation is now so widely used in all kinds of experiments.

The committee has under consideration the question whether special names should be given to a very small quantity of radium, and also to the emanation in equilibrium with it. For example, the quantity 10^{-12} gram radium seems a natural unit for expression of the radium content of rocks and soils. At the same time, the large amount of investigation on the emanation content of springs and waters may make it desirable to adopt a convenient unit for expression of such quantities.

The committee pointed out that its recommendations were tentative, as all the members of the standards committee were not present at the congress, and had no opportunity of expressing their opinions. It is intended that the preparation of the radium standard should be proceeded with as soon as possible, and it is hoped that the standardisation of sub-standards will be possible before a year has elapsed. Prof. Stefan Meyer, of the University of Vienna, was appointed secretary of the international committee, and all communications relative to standards should be addressed to him.

The question of the nomenclature of radio-active products was informally discussed at the congress. There was a general consensus of opinion that it was not desirable to alter materially the present system of nomenclature, although it was recognised that it is far from perfect. It was felt that the gain to be obtained by a possibly more systematic nomenclature was more than counterbalanced by the confusion that would arise in consequence of a change of names. It was pointed out that the present system of nomenclature was capable of extension to include possible new products. For example, if future investigation should disclose that the product radium C consists of several products these could be named radium C_1, radium C_2, radium C_3, &c., but the term radium C would be used generally to represent the group of products as they normally always occur together. Reference was made to the undesirability of individual workers assuming the right to give new and fancy names to well-known substances.

A number of suggestions in regard to general nomenclature in radio-activity and ionisation were also made to the congress. For example, it is proposed that the term "half-value period" should be used in all cases to represent the term required for a substance to be transformed to half its original value. It is suggested that the terms "induced" and "excited" activity should be abandoned and the term "active deposit" employed in its stead, as reference is usually made to the radio-active matter itself and not to its radiations. There was a good deal of informal discussion amongst members as to the exact use of a number of scientific terms arising in radio-activity and allied subjects. Such discussions are of great importance in preventing unnecessary confusion in nomenclature due to the development of a rapidly growing subject.

A more general account of the meetings and deliberations of the congress, prepared by Dr. Makower, will appear in another issue of Nature.

E. Rutherford.

HEREDITY AT THE CHURCH CONGRESS.

THE discussion on heredity and social responsibility at the meeting of the Church Congress at Cambridge showed clearly the growing appreciation of the importance of biological principles in the study of social phenomena. The debate was opened by a paper by Dr. G. E. Shuttleworth, who dealt with the subject of the feeble-minded, chiefly from the medical point of view. After tracing the history of the different methods of treatment, he pointed out that in the case of most of the feeble-minded "there existed morbid heredity of a strongly transmissive character," and that the only sound process of attacking the problem was to be found in segregating the rising generation of the feeble-minded in industrial colonies, apart from the general community, for in that way alone could the propagation of the evil be prevented by means in harmony with our feelings of humanity.

Mrs. Pinsent, of Birmingham, a member of the Royal Commission on the Feeble-Minded, gave a brilliant address, which was clearly the chief feature of the meeting. She produced the histories of several mentally defective families, in which disease, mental defect, and crime appeared generation after generation. She pointed out the cost of such families to the community, and the appalling waste of social effort involved in their supervision and maintenance. Good and useful families, themselves often with narrow means, were being taxed to support these degenerate folk, until the more efficient restricted their families under the growing economic pressure, and reduced expenditure on maintenance and education. Thus the unfit replaced the fit within our own civilisation and under our own eyes.

The crowded audience was clearly in sympathy with Mrs. Pinsent's view of the situation, and realised the dangers of ignoring any longer the increased chances of reproduction and survival which our modern humanitarian legislation and social action had given to the degenerate classes.

The Bishop of Ripon spoke on the declining birth-rate, and said that, had it appeared in the less worthy elements of society it would have been welcome, but that, as it chiefly affected the better stocks of our race, it was deeply to be deplored. Especially was it disastrous from the point of view of the Empire, which could not hope to stand against other peoples, and especially against the increasing birth-rate, the growing numbers, and the improving organisation of the Eastern nations, unless our empty spaces in the Colonies were filled with men of British race. Marriage ought to be discouraged among the unfit, while the growth of the fit should be encouraged by a higher sense of duty in the homes and an imperial ideal of national life.

Mr. W. C. D. Whetham traced the part played by religion in the sociological development of society, and pointed out that it alone could give a motive strong enough to lead the mass of mankind to prefer the ultimate good of humanity to the immediate advantage of the individual. Hence religion possessed a real biological survival value, as Kidd showed in his book on "Social Evolution." It followed that the National Church had a very great responsibility towards the race. To play its proper part, it must maintain its hold on the efficient families of the nation, and preach the duty of encouraging the rapid reproduction of the good stocks, while limiting the output of those defective in mind or body. The future belongs to those nations whose religious teachers realise this responsibility.

In the general discussion which followed, there was an almost unbroken agreement with the main point of view of the readers of papers. While one speaker thought that only 50 per cent. of mental defect could be traced to heredity, and another emphasised the importance of alcoholism, there was a general consensus of opinion that the country must be awakened to the need of encouraging the growth of good stocks, and that the reproduction of the feeble-minded must be prevented by legislative action.

The general effect of the meeting on the mind of the listener was to produce the belief that the Church Congress, at all events, was ready, in matters of social action, to "think biologically"—surely an encouraging sign.

COCOS-KEELING ATOLL.[1]

THE author, who was for fifteen months medical officer to the cable station at Cocos-Keeling, presents us with an interesting book on that atoll made classical by the researches of Darwin during the voyage of the *Beagle*. The account of the formation and history of the colony is a romance vividly portrayed, but the main interest of the book lies in the author's observations on coral-life and on the processes in operation which can shape an atoll.

The true coral animal (Madreporaria) is a colonial sea-anemone, which continually deposits under itself carbonate of lime, thus raising its seat higher and higher above the bottom. It sits on the surface of the dried coral, such as it is commonly known to us, and in no way presents the features of an Alcyonacean, such as is represented in Fig. 6 of the book. It is peculiarly unfortunate that this figure should have been inserted, since the skeleton of reef corals, with which the author is dealing, consists entirely of dead material. It exposes the writer to the suspicion that he is unacquainted with the real nature of the coral skeleton, and hence largely throws doubt on his really admirable observations on the growth of corals in relation to their environment. These are in no way scientific, but consist of the notes of a painstaking naturalist.

The extraordinary variability in coral skeletons is well known to zoologists, and may aptly be compared to the growth shown by our forest trees in different environments. Reef corals, too, resemble trees in that they are largely dependent for their food on chlorophyll, which is present in minute algæ, living in their digestive cavities. The coloration of most reef corals is largely due to these algæ, and their mode of growth is sympathetic to them in that the coral skeleton is deposited so as to expose the polyps to the maximum amount of light. Such appear to us the ordinary views of zoologists, but our author regards sediment as the main factor to account for the variability of corals; that it is an important subsidiary factor cannot, of course, be denied. Some corals, such as Cœnopsammia, have no algæ, but pigments in granules in their cells; they, of course, are unaffected by light. Yet others probably have similar pigment together with algæ, but our author does not follow out what should be a most profitable line of research.

The statement that corals know "no natural death," does not rest on observation, and is contrary to the few facts we have. No zoologist would consider the rate of growth of corals slow. The observations on the forms of growth of corals are not convincing, since our author does not appear to have examined the zooids to see whether he is really dealing in any genus with one or more species. He is hence not justified in stating that the distribution of atoll corals "is a distribution of types and *not of species*." The observations on the effect of silt suggest research, such as has for some years been undertaken by Wayland Vaughan at the Tortugas; they are not definitive enough to be of much value. Vaughan, by the way, found no great difficulty in transplanting corals.

FIG. 1.—The Lagoon Shore of Pulu Tikus, to show the Sand-piling by a westerly wind. From "Coral and Atolls."

The third part of the book deals with the Cocos-Keeling atoll and its problems, concluding with chapters on the formation of atolls in general. We agree with the author that "it is almost impossible to judge of the method of formation of any atoll not actually visited and examined." The lagoon of Cocos-Keeling is filling up, we are told, both by organic

[1] "Coral and Atolls." By F. Wood-Jones. Pp. xxiii + 392. (London: Lovell, Reeve and Co., Ltd., 1910.) Price 24s. net.

growth within it and by material washed into it over the barrier. It may be so, but it does not justify the statement that "atoll lagoons tend, as a rule, to become smaller and shallower," and there is no attempt by reference to other atolls to justify it. Solution and material swept out by the tides are said to have nothing to do with the formation of the lagoons of atolls. The picture of a high island crumbling to pieces within the calm of an encircling barrier reef appears to our author to be contrary to all natural laws. On what view does he explain Agassiz's wonderful series of photographs of Fijian islands within barrier reefs? "In this (his own) description," he states, "it is assumed throughout that the lagoon is a slightly submerged reef"; why this assumption without evidence? The encircling reef is said to be "a mosaic inlay of coral fragments, cemented together into a solid platform," but there is no evidence that it was ever really examined. It is supposed to have grown up as a platform, and many of its constituent organisms must surely have remained in their growth-positions. A similar platform is found at 13 feet above mean tide level; it is stated that such a platform can only be formed below this level, and its existence is explained as due to elevation.

FIG. 2.—Photograph of a Boulder of Alga-covered Dead Coral Rock, to show the bites of a fish of the genus Scarus. The black line marks the edge of the alga covering not bitten away by the fish. From "Coral and Atolls."

Our author does good service in directing attention to the important effects of sedimentation. Sedimentation banks largely form the foundations of reefs, but "it matters not what the base may be so long as its platform comes within the wind-stirred area." "Any elevation which rises to this plane (the *limiting line of sedimentation*) will furnish the corals with a suitable basis." The depth of this *line* varies. It is entirely a supposititious *line*, and, so far as we can understand, may lie at any depth. Direct investigation on the processes of sedimentation in the ocean is certainly needed.

In conclusion, it cannot be said that Dr. Wood-Jones has much new to tell us. His volume is, however, a very readable one, and most suggestive of lines of research on corals, which might profitably be pursued by more precise methods. His range of investigation and reading were obviously too restricted to enable him to draw conclusions as to the formation of coral reefs in general. The account of the fauna and flora is very good, and the note on Scarus as a coral-feeder interesting. The illustrations of corals and other organisms are good, but a specialist should have been consulted, so that the names of the coral genera might have been inserted. An obvious Actinian (p. 161) would not then have been labelled as an Alcyonarian.

RESEARCHES IN STELLAR PARALLAX.[1]

THE Observatory of Yale College has acquired a deservedly high reputation for the zeal with which the staff has prosecuted the inquiry into stellar parallax and the standard of accuracy consistently maintained. This latest contribution to the subject cannot but enhance that reputation for accuracy, for the results sought do not aim so much at applying the method to fresh instances, as to the re-examination of previous investigations with the view of improving their trustworthiness. Of the stars, the distances of which are here discussed, two-thirds have already been the subject of inquiry at Yale or elsewhere, but on various grounds the results have been regarded with a degree of suspicion that made the repetition of the measures desirable.

The new material falls into two classes, one containing stars having a larger annual proper motion than about $0{\cdot}4''$; the other, selected stars in the Pleiades the observation of which might afford evidence as to the distance of the group as a whole. As the results derived from these Pleiades stars are not regarded as conclusive, and do not enter into the final catalogue, they may be dismissed here. One star gave the value zero, indicating that the Pleiades group is at the same distance as the star; the measures of another assigned the small negative parallax of $-0{\cdot}3''$, "a value that would give a possible limit of systematic error"; while the third series, resulting in the value $+0{\cdot}6''$, suggests that the star does not belong to the group at all, but is nearer to our system, "and this result would seem to be fairly assured." The approximate distance of the Pleiades group still remains a matter of conjecture.

Naturally in a work so long and laborious, difficulties arose in connection with the instrumental and optical equipment, necessitating interruptions in the continuance of the sequences. The most formidable of these was a tendency for the field lens of the eyepiece to work loose, to which inconvenience it is not necessary to refer further, than to express our assurance that the skill and experience of the observers would succeed in effectually removing any traces of systematic error arising from this untoward accident. To show that this confidence is warranted, we may give the final results obtained by the three observers in the case of the Arcturus determination, a star the measures of which have been most scrupulously examined, since for a star of such brilliancy and large proper motion the earlier values of parallax were so suspiciously small, as to suggest that some inherent quality in the star itself, such as colour, or some peculiarity in the observers' method of measuring, had influenced the result. With regard to the detection of

[1] Transactions of the Astronomical Observatory of Yale University Vol. ii., part ii. Parallax Investigations on thirty-five selected stars by Frederic L. Chase, Mason F. Smith, and William L. Elkin (Director). (New Haven: Published by the University, 1910.)

a colour effect in the observations, to which a reference is made in Nature (vol. lxxv., p. 234), further examination has failed to disclose any systematic error attributable to that cause, while the arrangement and discussion of the several series of measures—Dr. Elkin himself made no fewer than seven—exclude the possibility of any personal peculiarity or habit escaping detection. The adopted parallax values for each of the three observers are as follows :—

Observer.	Parallax.	Probable Error.	Probable Error of Single Obn.	No. of Observation.
Elkin ...	+0"·051 ...	±0"·013 ...	±0"·240 ...	126
Chase ...	+0·085 ...	±0·007 ...	±0·127 ...	154
Smith ...	+0·050 ...	±0·011 ...	±0·126 ...	123

After an elaborate system of "weighting," for details of which we must refer to the original paper, the finally adopted value of the parallax of Arcturus is 0·066"±0·006".

The interesting stars 61 Cygni and Groombridge 1830, notwithstanding the repeated attempts that have been made to determine the parallax, are among those stars of which it has been thought desirable to repeat the measures. Without entering into further particulars, it may be said that the results are equally consistent as those obtained in the case of Arcturus, and command equal confidence.

The grand result of the work at Yale, which has occupied the three observers for some years, is to assign a parallax to 200 stars, with an accuracy that we believe has not been attained elsewhere. The three stars in the Pleiades not being included, we have here a catalogue of 197 stars, which Dr. Elkin forms into groups depending on magnitude and proper motion. This table is so small that it can be conveniently given here. It may seem but a modest outcome for so many years of careful and anxious work, but those who appreciate it most will be warmest in their congratulations to Dr. Elkin and his able colleagues on the satisfactory completion of a task of no common difficulty. The table into which so much work is compressed is as follows :—

Proper Motion	0"·00–0"·34	0"·41–0"·54	0"·55–0"·65	0"·66–0"·96	1"·01–7"·07
Mag. 0·0–2·5	+0"·031 (13)	+0"·100 (2)	+0"·113 (3)	... ... (0)	+0"·200 (2)
,, 3·0–5·0	+0·026 (9)	+0·024 (7)	+0·114 (5)	+0·091 (8)	+0·162 (6)
,, 5·1–7·0	−0·010 (7)	+0·034 (14)	+0·064 (16)	+0·036 (20)	+0·111 (8)
,, 7·1–9·0	... ... (0)	+0·040 (23)	+0·032 (23)	+0·018 (19)	+0·128 (12)

The number in brackets after the parallax signifies the number of stars in each group. As Dr. Elkin remarks, "There is, with slight exception, manifest a very decided sequence of values, both with respect to magnitude and size of proper motion, such as one might expect." W. E. P.

THE PERFILOGRAPH.

The perfilograph is an ingenious instrument for recording graphically the undulations of the bottom of a channel in depths up to about six or seven fathoms. It is the invention of Augustus Mercau, an Argentine engineer, by whom a paper was read at Buenos Aires before the Naval Section at the recent meeting of the International American Scientific Congress, in the course of which the instrument was fully described. The principles on which its construction depends and the practical results obtained from its use appear to present some points of interest.

A heavy weight of from 150 to 200 lb. being slowly dragged along the bottom by a wire rope attached to the stern of a steam launch, it is obvious that as the depth changes the inclination of the wire will vary. By an ingenious mechanism, the sine of the angle made by the wire with the horizontal plane is registered graphically in parallel ordinates on a roll of paper, which is slowly unwound by means of clockwork at a rate proportionate to that of the vessel. The lengths of the ordinates, being proportional to the sines of the varying angles, represent the undulations of the bottom referred to the horizontal plane, and are registered on a convenient scale on the paper by means of a system of levers.

The instrument, mounted in the stern of the launch, is placed accurately at a height of 5 feet above the water-line, and the depths are measured from a zero line drawn by a pencil pressing against the roll of paper as it is unwound. The system of levers by which the sines of the angles are registered is connected to a length of tubing of small diameter, through which a thin guiding wire passes. One end of this wire, which is about 50 feet in length, is secured to a spiral spring attached to the weight on the bottom; the other end is led underneath the base of the instrument and secured. The spiral spring yielding to a strain of about 150 lb., the tension on the guiding wire is automatically relieved by throwing the excess of strain on to the towing cable, the length of which is adjusted accordingly. The guiding wire, being thus kept taut by a strain not exceeding 150 lb., the length of tubing through which the wire passes takes up an inclination to the horizontal dependent on the depth of water, and in so doing it actuates the system of levers with which it is connected.

The speed at which the weight can be towed should not exceed three or four knots. There is an arrangement for marking on the paper the instant at which the position of the vessel may be fixed by means of sextant angles. The horizontal scale of the diagram may thus be determined between successive "fixes" by actual observation, independently of the rate at which the paper is being unrolled or the speed at which the vessel may be moving. Unless these two factors remain constant throughout the run, the horizontal scale will be subject to variation. It is desirable therefore to reconstruct the diagram, so far as its horizontal components are concerned, from the data afforded by the "fixes."

The horizontal scale of the diagram is roughly about 1/1000 or about 70 inches to the nautical mile; the vertical scale is about $\frac{1}{4}$ inch to a foot. The instrument has been adopted by the Argentine Hydrographic Service, and has been in constant use for some time past. It is understood that the results are considered quite satisfactory.

An opportunity of witnessing a practical trial was courteously afforded to the present writer by the Argentine naval authorities. The instrument was readily set up and adjusted, and several sectional lines were run across the dredged channel leading to the docks at Buenos Aires. The resulting diagrams over the same section run in opposite directions agreed accurately, and no difficulty whatever was experienced during the trials.

The following advantages have been claimed for the instrument :—(1) Continuity of the section traced; (2) accuracy of results; (3) rapidity as compared with ordinary methods; (4) economy of skilled labour; (5) facility of manipulation; (6) capability of use in circumstances of sea and weather when accurate soundings by the lead could not be obtained.

The trials were carried out in open water with its surface considerably disturbed by a fresh breeze, and afforded a very fair test of the capabilities of the instrument. There is certainly a source of error owing to the motion of the vessel. The section as shown on the diagram is necessarily a combination of effects due to the pitching of the vessel and the actual form of the bottom.

In several of the diagrams the rapid scending of the vessel was noticeable in oscillations to the extent of 2 or even 3 feet; but it was not difficult to draw a mean line which would eliminate the motion with a fair degree of accuracy. Practically the speed of the launch scarcely exceeded that at which she might have proceeded with two leadsmen sounding in the ordinary manner, and the same number of hands are required, although they need not necessarily be skilled leadsmen. Two officers are necessary for fixing the vessel, as they would be in ordinary circumstances.

On a rocky bottom, where dredging has been carried out, the weight would be constantly liable to catch in the inequalities of the bottom, and bring up the boat, thus causing delays and possibly breakage of gear. In such cases, moreover, the usual method of sweeping with an iron bar could not safely be dispensed with, however accurately each separate section might be obtained.

On the whole, it may be said that the advantages to be derived from the invention do not at present seem so clearly pronounced as to make it likely that it would be adopted for use under the conditions usually prevailing in the examination of dredged channels. There might, however, be special circumstances in which it could be used advantageously.

A. M. F.

NOTES.

A monument to Gregor Mendel, the naturalist, who was born at Amsterdam in 1822 and died at Brünn in 1884, was unveiled at the latter place on October 2.

The summer season, comprised by the six months from April to September, can in no sense be considered ideal, although from a meteorological point of view it has not differed very widely from the average. At Greenwich the mean temperature for the six months was 57·0°, which is 0·9° below the average of the past sixty years, but is 0·9° higher than for the corresponding six months in 1909. The warmest month was August, with a mean temperature of 62·2°, and this was followed by a mean of 61·5° in June. May and June were the only two months with the mean temperature in excess of the average. The highest shade temperature during the summer was 82·3°, in June, and there was no other month with a temperature of 80°. The only years since 1841 with a slightly lower absolute maximum summer temperature are 1853, 1862, 1879, and 1882. There were in all only fifty-one days with a temperature of 70° or above, and the only summers with so few warm days are 1860, 1879, and 1888. The most conspicuous month for the absence of warm days was July, when there were only six days with a temperature of 70° or above; this is the smallest number of such warm days in July since the establishment of trustworthy records in 1841. August had twenty days with a temperature of 70° or above, and June follows with seventeen; in September there were only two. The only instances of frost in the shade in the six summer months are two in April and one in May. The aggregate rainfall at Greenwich was 13·60 inches, which is 1·22 inches more than the average of the past sixty years, but is 0·44 inch less than for the corresponding period in 1909. The rainfall was in excess of the average in each month, with the exception of September, when there was a deficiency of 1·47 inches. The wettest summer month was July, with a total measurement of 3·55 inches, which is 1·15 inches more than the normal. In all, rain fell on ninety-two days, but only on three days in September, when the aggregate measurement was 0·72 inch, and on one day the fall was 0·66 inch. The duration of bright sunshine was 966 hours, which is 165 hours fewer than the average, and May is the only month with an excess of sunshine. The sunniest month was May, with a total duration of 219 hours, and the least sunny month was July, with 112 hours' duration, which is 124 hours fewer than the normal. The finest month of the six was undoubtedly September.

Mr. Marconi has informed the Marconi Wireless Telegraph Company that wireless telegraphic messages have been successfully transmitted between Clifden (Galway) and Buenos Aires, a distance of about six thousand miles, without the employment of an intervening relay station. We learn from a note in the *Engineer* for September 30 that the tramp steamer *Nonsuch*, whilst on her voyage from Bombay to Hull and Middlesbrough, was heard at the wireless station at the North Foreland calling her name when she was fifteen miles south of Cape de Gaa, at the south-east corner of Spain, a position distant 940 nautical miles from the North Foreland. This distance, across the obstacle of the whole of France and Spain, and the Pyrenees, is a remarkable range for wireless signals from a ship. The owners received a message through the station at Ushant, sent from the ship off Cape Roca, near Lisbon, no less than 610 nautical miles from Ushant. The *Nonsuch* is the first tramp steamer to be fitted with wireless telegraph.

The council of the Institution of Civil Engineers has made the following awards in respect of papers published in Section ii. of the Proceedings for the session 1909–10:—A Telford gold medal to Major W. W. Harts, U.S. Army (Nashville, Tenn.); a Watt gold medal to Mr. A. Trewby (London); a Crampton prize to Prof. A. H. Gibson and Mr. A. Ryan (Manchester); and Telford premiums to Messrs. W. R. Baldwin-Wiseman (Southampton), O. W. Griffith (London), Dr. W. E. Lilley (Dublin), W. Corin (Sydney), J. A. Saner (Northwich), and F. O. Blackwell (New York). The council has awarded the Indian premium for 1910 to Mr. C. W. Lloyd-Jones (Secunderabad).

The Paris correspondent of the *Times* has reported the death, in his sixty-ninth year, of Prof. Fulgence Raymond, clinical professor of diseases of the nervous system in the University of Paris, and superintendent of the Salpêtrière. Prof. Raymond became known first by a special study on "L'Hémichorée, L'Hémianasthésie, et Les Tremblements Symptomatiques." On the death of his friend and teacher Charcot, in 1894, Raymond was appointed to succeed to the chair of clinical professor of nervous diseases. He was the author of many works on nervous and kindred diseases, and was celebrated for the laboratories of pathological anatomy and physiological psychology which he instituted and superintended at the Salpêtrière. Prof. Raymond was a member of many of the scientific societies of Europe.

The ordinary meetings of the Royal Geographical Society for the winter session will begin on November 7, when Major P. Molesworth Sykes will lecture on his further journeys in Persia. Subsequent meetings have been provisionally arranged as follows:—November 21: some results of the Duke of the Abruzzi's Karakoram expedition, Dr. Filippo de Filippi; December 5: the new geography and its aims, Mr. H. J. Mackinder, M.P.; December 19: the French Antarctic Expedition, 1909–10, Dr. J. B. Charcot; January 16, 1911: the *Michael Sars* North Atlantic deep sea expedition, Sir John Murray and Dr. Hjort. A selection from the following papers may be expected during the session:—Recent explorations in Dutch New Guinea, Dr. H. A. Lorentz; the development of British Central Africa, Sir Alfred Sharpe; recent boundary work in Bolivia, Major P. H. Fawcett; the peoples of the Sudan, Dr. C. G. Seligmann; the geographical conditions affecting the development of Canada, Prof. W. L. Grant; economic geography of the Tyne, Mr. A. J. Sargent; distribution of cotton culture within the British Empire, Mr. J. Howard Reed; researches in the Himalayas, Dr. Arthur Neve; explorations in western and northern Australia, Mr. A. W. Canning.

Mr. C. G. Thorp, 182 St. George's Terrace, Perth, Western Australia, writes:—"I am endeavouring to prove the origin of obsidianites; it has been stated that Mr. Dunn's bubble hypothesis is impossible on account of the occurrence of dumb-bells. I wish to endeavour to make a dumb-bell by the union of the drops of two bubbles. Perhaps one of your readers would help me to the formation of a very viscid fluid that would dry." The inquiry was submitted to Prof. C. V. Boys, who has kindly sent the following reply: "The best mixture for blowing bubbles that will solidify, not exactly dry, is resin containing one-tenth, more or less, of beeswax, melted and blown when fluid. Possibly the addition of Canada balsam would make the mixture more adhesive. No soap and glycerine mixture will make a bubble that will dry."

In a letter entitled "An Undescribed Feather-element," which appeared in Nature of September 15, Mr. F. J. Stubbs described a remarkable feature of the structure of the primary feathers of certain birds, which he said "seems to be hitherto undescribed." Two correspondents have written to point out that the peculiarity in question has been described before. Mr. W. P. Pycraft states that he published an account of the structure seventeen years ago in the pages of *Natural Science* (vol. iii., 1893, p. 197). Prof. R. v. Lendenfeld, of Prague, informs us that "these structures have been studied in my laboratory and carefully described and figured by one of my students, Dr. E. Mascha, in his paper 'Ueber die Schwungfedern' (*Zeitschrift fur wissenschaftliche Zoologie*, vol. lxxvii., 1904, pp. 606–51, nine text figures, Plates 29–31), on p. 614 ff, an English version of which appeared in the Smithsonian Miscellaneous Collections (vol. xlviii., 1905, 30 pp., 15 plates) under the title 'The Structure of Wing Feathers.'"

In *Man* for September Mr. W. E. Hardenburg, in an account of the Indian tribes of the Putumayo River, one of the principal tributaries of the Upper Amazon, describes what he terms a system of "wireless telegraphy" in use among this race. It consists of two logs of hard wood pierced by narrow holes of longitudinal section, burnt out by heated stones. One log is always thicker than the other, producing two grave notes, while the smaller trunk gives out two which are acute. They are hung from the roof timbers, and are beaten with a club tipped with rubber. A code is arranged based upon the differences of tone and the length and number of the blows, so that messages can be exchanged, on a clear day the sound reaching a distance of from 12 to 15 kilometres.

A series of experiments by Messrs. R. M. Yerkes and D. Bloomfield is described in the *Psychological Bulletin* for August, planned to answer the question, Do kittens kill mice instinctively? The experiments decide in the affirmative. They show that "the instinct to kill may manifest itself in the kitten before the end of the first month of life, while the animal is yet feeble and barely able to eat a young mouse." The instinctive reaction, though somewhat variable with individual kittens, is fairly definite in character. It appears quite suddenly, and is aroused by the movement of the mouse, and, after the first reaction, by the smell of the mouse. Usually it develops during the second month of the kitten's life, and does not completely wane during the following two or three months, but "it apparently becomes increasingly difficult to evoke. The practical inference is: allow a kitten to exercise its killing instinct when young if a good mouser is desired." The authors admit the great value of imitation and experience for the killing reactions of kittens, and for the modification and development of these reactions. But the prime object of their experiments is to show that kittens, reared in solitude, seize the mouse, even in the first kill, so that they cannot be bitten by it, and that the visual experience of movement is the primary condition for the initiation of the instinct.

In the Bulletin of the Johns Hopkins Hospital for September Dr. C. L. Minor, of Asheville, N.C., has a paper on the use of the X-ray in the diagnosis of pulmonary tuberculosis. This subject was discussed at the recent annual meeting of the British Medical Association in London (see Nature, August 4). Dr. Minor gives full directions as to the most suitable arrangement of the apparatus and of the dark-room, and as to the positions in which patients should be examined. His paper is chiefly interesting as representing the point of view of a physician in general practice in contrast to that of the X-ray specialist. In his opinion the general practitioner should confine himself to the use of the fluorescent screen, and leave the taking and the interpretation of photographic plates, with the great amount of detail they contain, to the X-ray specialist. He enters fully into the controversy regarding the comparative value of the clinical and the radioscopic methods of diagnosis of phthisis in its earliest stages. Many X-ray specialists, he says, insist that signs of early phthisis are shown by the Röntgen rays before the physician is able to demonstrate them by the ordinary methods of physical diagnosis. In Dr. Minor's opinion this is due to the fact that many clinical physicians are not really expert in the method of physical diagnosis, and that they frequently overlook signs which a more trustworthy diagnostician would have discovered. Dr. Minor's own experience goes to show that there are few cases in which, although distinct shadows are shown by the X-rays, no physical signs can be elicited in the chest. The present writer, however, has frequently had patients sent for examination by thoroughly competent physicians with the statement that no physical signs of lung disease were present. He has then demonstrated to the physician the exact position and extent of the pulmonary lesion, and the physician has thereupon been able, by a careful examination, to detect definite signs at this spot. Dr. Minor directs special attention to the frequency of the discovery of enlarged lymphatic glands in the chest, and he describes the positions in which they are to be found. His conclusions lend further confirmation to the view, now generally accepted as true, that the X-ray examination of the lungs is a very valuable aid to the early diagnosis of pulmonary phthisis.

Dr. P. L. Sclater has contributed to the "Handbook of Jamaica for 1910" a revised list of the birds of Jamaica, based on the one by Messrs. A. and E. Newton in the same publication for 1881. The new list, which is printed separately in pamphlet form, and can be obtained in London of Messrs. H. Sotheran and Co., contains notes on the distribution of the various groups.

THE European hedgehog has been hitherto considered to differ from other species of its genus in the peculiar form and single root of the third upper incisor and upper canine, while it has also been supposed to be characterised by the constant presence and relatively large size of the second upper premolar. From an examination of a large number of specimens, Mr. E. Hollis (*Zoologist* for September) finds, however, that two of these characters are by no means constant. Thus, out of eleven British examples, in only one case was the upper canine single-rooted, while in six instances it was double-rooted, and in the remaining four in a kind of intermediate condition. In the same series the second upper premolar was absent in three instances, rudimentary in one case, and normal in the remainder. From this it is inferred that *Erinaceus europaeus* is in a state of unstable equilibrium in regard to the latter tooth, thereby resembling the Asiatic *E. micropus* and *E. pictus*. Somewhat similar variations were observed in the collection of skulls of the European species in the British Museum, but in no instance was the third upper incisor observed to be double-rooted. A single root to this incisor may therefore still be characteristic of *E. europaeus*.

THE fourth part of the Flora of Glamorgan, dealing with the division Incompletæ of the Dicotyledons, has been recently published. The flora is being prepared under the editorship of Prof. A. H. Trow by a committee, for whom Dr. and Miss Vachell act as secretaries. It is noted that several critical and polymorphic species require more detailed observation and study.

A SECOND report on the Hymeniales of Connecticut, constituting Bulletin No. 15 of the State of Connecticut Geological and Natural History Survey, requires to be taken in conjunction with the preliminary report published as Bulletin No. 3, in which the keys to the genera were given. Analytical keys for the species are supplied in the present bulletin, and are accompanied by excellent illustrations of selected types. Prof. A. E. White, who is responsible for both reports, also provides a good account of some edible species of Agaricaceæ; most of the species are similar to those recommended by British fungologists, but the author is bolder than some authorities in recommending *Lactarius piperatus* and *Cantharellus aurantiacus*.

THE plant formations of East Bolivia, which were briefly outlined and illustrated by Dr. Th. Herzog in a number of the *Vegetationsbilder*, are described at greater length in Engler's *Botanische Jahrbucher* (vol. xliv., part iii.). A well-defined formation is that of the Pantanales, developed near Carumba, in the extreme south-east, which is a fertile virgin forest, consisting largely of deciduous trees with a wealth of lianes. *Piptadenia macrocarpa* is a dominant tree, valued for its timber and astringent bark; *Tecoma Ipe* is another magnificent tree, yielding a durable timber, and *Calcophyllum multiflorum* is also characteristic of the formation. The lianes include *Urvillea laevis*, *Bignonia unguis cati*, and species of Serjania. The author presents a graphic description of the magnificent palm, *Orbignya phalerata*, *Physocalymma scaberrima* (Lythraceæ), and various species of Tecoma, that inhabit the highlands of Velasco, and extols the beauty of the flowering shrubs found on the Cordilleras.

DR. FELIX OSWALD, so well known for his geological map and description of Armenia, has published an account of the tectonic development of the Armenian highlands in *Petermann's Mitteilungen* for 1910 (pp. 8, 70, and 126). The movements that affected the pre-Devonian rocks are obscured by the potency of the Hercynian and Alpine movements. The Alpine uplift was foreshadowed in Armenia by considerable folding in Upper Eocene times, but the resulting land-surface was reduced almost to a peneplain before the great transgression of the Miocene sea. This sea even spread over land that had remained unsubmerged since the opening of the Mesozoic era. Its invasion, however, was soon checked, since in the Upper Miocene epoch the Alpine folding set in, accompanied by great intrusions of ultrabasic rocks. This folding continued long enough to involve the Sarmatian deposits on the south flank of the Caucasian chain. Dr. Oswald, with the aid of a map, explains the grouping of the main lines of folding, and discusses the breaking up of the highlands into elevated plateaus and regions of depression. He regards the volcanic phenomena as manifested along planes of fracture. When these, in Upper Miocene times, reached down to the ultrabasic regions, peridotites rose among the folded rocks. Regions of decreasing basicity have since been drawn on, and only the higher zones are now penetrated, as is evidenced by the recent rhyolitic lavas of the crater of Nimrud.

AN interesting lecture on "Vegetation and Rainfall," recently delivered at Perth, Western Australia, by Dr. A. Morrison, is reported in the *West Australian* of August 4. The author does not deal specially with the distribution of rainfall in the colony, but with the importance of a plentiful water supply and the warmth of the sun on vegetation generally, and on the influence of the latter in preserving the moisture of the soil. On hill-sides, without the protection of vegetation, the natural streams become choked with débris, causing floods and devastation in the country below, but vegetation gives time for water to percolate the soil without displacing it. The cosmic causes of rainfall must be carefully distinguished from local causes, which only modify the precipitation brought from distant parts. Irrigation during the dry season would do much in maintaining the desired moist condition of air and soil, and the plantation of trees would help to make it permanent; but when the settler has cleared the bush for cultivation he sometimes finds that a heavy fall of rain will run off the surface without having time to sink into the ground. The author considers that a large proportion of the country in Western Australia should be left in its original state, clothed with forests.

WE have received a separate copy of Prof. L. Palazzo's paper on his magnetic survey of Sardinia, which appeared last year in *Terrestrial Magnetism and Atmospheric Electricity*. While the eastern side of the island appears to be normal, the western shows great abnormalities which are not due to surface rocks. While the equal vertical force lines run nearly east and west across the island, the equal horizontal force lines, which have the general direction north-east to south-west, are disturbed at points near the middle and north end of the west coast. The isogonic and isoclinic lines show irregularities near the same points. The annual secular changes are:—in west declination, $-4 \cdot 6'$; in inclination, $-1 \cdot 5'$; in horizontal force, $+0 \cdot 00020$ dyne per unit pole.

THE *South African Journal of Science* for June contains an important paper by Dr. D. M. Tomory on modern methods of water purification. The Modder River water, from which Bloemfontein draws its supplies, refuses to settle clear, and cannot be effectively purified by sand filters, which, however, are very soon choked by the suspended clay. A remarkable improvement was effected by precipitating with lime and permanganate, and filtering rapidly through a mechanical filter, the deaths from enteric fever falling from 83 per 10,000 in 1896 and 20 per 10,000 in 1904 to 2·75 per 10,000 in 1908. In view of the necessity of increasing the plant, a tour was made to inspect the chief purification plants both in Europe and in America. England and the northern part of the States do not show many examples of river-waters of the Modder type, and appear to be admirably served by the "fool-proof" method of sand-filtration. But in Egypt and in the southern States the author found many analogous cases in which extraordinary results were achieved by chemical precipitation followed by rapid mechanical filtration. He concludes that the extraordinary rapidity of the mechanical filtration is accompanied by no special risks of pollution when it is used intelligently in conjunction with a chemical precipitation process, and that in the case of non-settling waters, which can only be purified by such a precipitation, the rapid mechanical filtration is decidedly to be preferred on the ground of efficiency combined with economy. The paper will be read with interest by many who have been compelled to limit their observations of water purification to the somewhat uniform conditions which prevail in the water supplies of Great Britain.

The *American Journal of Science* for September contains an account of an important series of researches upon the complexity of tellurium, by Mr. W. R. Flint, of Yale University. The material used amounted to 500 grams of the redistilled metal; a series of five conversions of the basic nitrate $2TeO_2.HNO_3$ into the dioxide gave an atomic weight 127·45, with a maximum error 0·04. The material was fractionated by repeatedly precipitating the dioxide from solutions of the chloride by the addition of a large excess of water. Four precipitations reduced the atomic weight to 126·59, whilst ten precipitations gave the value 124·32 for a fraction amounting to 23 grams. This figure does not necessarily represent the lowest possible value for the atomic weight, but it agrees well with Mendeléeff's prediction that the true value would be 123 to 126, and "is apparently the nearest approach which has yet been made to the true atomic weight of the element tellurium." The fractions less easily hydrolysed by water were also worked up, and yellow to green substances were isolated; these gave negative results when tested for the commoner elements, but gave nearly all the reactions of tellurium, and many perhaps contain an unknown homologue.

The trials of H.M. second-class cruiser *Bristol*, completed on September 27, form the subject of an illustrated article in *Engineering* for September 30. The *Bristol* is the first British ship tried with other than the Parsons type of turbine, her propelling machinery consisting of Curtis turbines of a special character designed by the builders, Messrs. John Brown and Co., of Clydebank. This firm has taken up the Curtis turbine on account of the following reasons:—(1) the potential advantages of acquiring experience with a type of marine turbine capable of using superheated steam, as in land installations; (2) the attainment of economy at low powers, without the disadvantage of very close-fitting parts, and the extremely fine adjustments entailed thereby; and (3) the simplification of the connections and general engine-room arrangement, and also the expectation of attaining higher efficiency by an increase in size of the individual propellers. With characteristic thoroughness, the firm first constructed experimental plant and conducted a lengthy research on several modifications of the Curtis turbine, the results of which are now embodied in the machinery of the *Bristol*. It is a pleasure to record that the result of this policy is that the *Bristol* on her official trials has secured the same mileage per unit of water consumption as has been obtained in the four ships of her class which preceded her, these having Parsons turbines, embodying the inventor's latest improvements at the date of their construction. As this is the first Brown-Curtis installation, even better results may be looked for as the experience of the makers extends.

The syndics of the University Press, Cambridge, have entered into an agreement with the directors of the Chicago University Press to undertake the publication and sale in England and in the British colonies of books issued by the Chicago University Press. This will apply to all future publications and, subject to certain existing arrangements, also to books already published.

The October issue of the quarterly list of second-hand instruments which he has for sale or hire has been published by Mr. C. Baker, of 244 High Holborn, London. The catalogue contains details of 1635 pieces of apparatus, and is concerned with microscopes, surveying and drawing instruments, telescopes, spectroscopic apparatus, as well as instruments for use in the study of most other branches of physics. Messrs. H. F. Angus and Co., 83 Wigmore Street, London, have also sent a copy of their first catalogue of second-hand scientific apparatus and accessories. This department has been added to the business but recently, but the list shows that workers in science will find already a good selection of instruments likely to provide the apparatus of which they may be in search.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in October:—

October 7. 5h. 6m. to 6h. 23m. Moon occults δ Scorpii (mag. 2·5).
,, 10. 11h. 7m. Minimum of Algol (β Persei).
,, 11. Mercury at greatest elongation west and visible as a morning star.
,, 13. 7h. 56m. Minimum of Algol (β Persei).
,, 18–22. Epoch of the October shooting stars (*Orionids*, radiant at $92° + 15°$).
,, 26. 14h. 44m. to 15h. 51m. Moon occults η Leonis (mag. 3·6).
,, 27. 22h. 52m. Venus and Jupiter in conjunction, Venus 0° 11′ N.
,, 29. 13h. 16m. Mercury and Jupiter in conjunction, Mercury 0° 21′ N.

A Bright Meteor.—From a correspondent we have received the following particulars of a bright meteor seen at South Kensington during Monday night, October 3:—Time, 12h. 50m.; approximate path, from 310°, +35°, to 294°, +35°; size, about one-third diameter of moon; duration of flight, about three seconds; no trail; colour, whitish-yellow.

Rediscovery of Brooks's Periodical Comet (1889 V.), 1910*d*.—A telegram from the Kiel Centralstelle announces that Brooks's periodical comet was rediscovered by Messrs. Aitken and Wilson, at the Lick Observatory, on September 28. Its position at 9h. 17·3m. (Lick M.T.) was R.A. = 19h. 47m. 51s., dec. = 28° 8′ 39″ S., which agrees closely with the ephemeris by Prof. Bauschinger mentioned in these columns on September 8. This position lies in Sagittarius about $1\frac{1}{2}°$ south-west of the fifth-magnitude star ω, and is on the meridian about 7.30 p.m.

As the magnitude of the comet is given as 13·0, it is unlikely that observations in these latitudes will be possible for some time, but the southern declination is decreasing, and perihelion passage is not due until January 8, 1911. According to the ephemeris, the comet was at its nearest point to the earth early in August, and its present distance is about 155 million miles.

The Luminosity of Comets.—As a reprint from *Science*, N.S., vol. xxxii., No. 817, we have received a paper in which Mr. W. L. Dudley discusses the causes which produce luminosity in cometary bodies. According to the author's reasoning, luminous comets are simply masses of gaseous matter illuminated by the heavy electric discharges constantly flowing from the sun to each of the planets. The "ionic breeze" thus produced renders the comet luminous, and at the same time brushes matter along with it to form the tail. Should the comet get into such a position as to be under the influence of two planets (kathodes) at the same time, more than one tail is produced by the streams of ions from the sun (anode). The author also offers explanations on this hypothesis for the production of multiple heads, the change of direction which sometimes takes place in the tail, and the polarisation of cometary light.

Coloured Stars between the Pole and 60° N. Declination.—In continuation of previous lists, Herr Krüger now publishes, in No. 4441 of the *Astronomische Nachrichten*, a list of coloured stars which lie between the North Pole and 60° N. declination. The list includes 191 stars, and for each object gives the catalogue numbers, the colour on the Potsdam scale, Herr Krüger's observed colour, on a scale where 0° = white, 10° = red, the magnitude and the spectral type. Ninety-three of the stars lie within the colour-limits WG–G–, and are of the second and third types.

Observations of the Companion of Sirius.—The observations of the companion of Sirius, made with the 40-inch refractor by Prof. Barnard during November 30, 1909, to March 15, are recorded in No. 617 of the *Astronomical Journal*. The values for position-angle and distance, for the mean epoch (1910·106), are 89·09° and 9·07″ respectively.

The Perseid Shower, 1910.—In a note appearing in No. 617 of the *Astronomical Journal* Mr. E. F. Sawyer describes the meteor observations made by him at North Weymouth, Mass., on August 9, 11, 12, and 13. The hourly rates for one observer, covering one-sixth of the visible sky with the centre in Perseus, were 15, 15, 8, and 6 on these respective dates. The meteors generally were bright, and left streaks for one or two seconds; the radiant was found to be at 38·5°, +55·5°.

A Modified Method for Nadir Observations.—In making the ordinary nadir observations, where a bright thread is made to coincide with its reflected image, there is always some little doubt as to when exact coincidence occurs. To obviate this difficulty, Mr. R. M. Stewart suggests a method where the reflected bright image is obliterated by a dark thread. Experiments made with the Ottawa meridian circle show that this method is simple, and gives greater accuracy than the older one. In making the observation, the bright reflected image and the illuminated thread are brought nearly to coincidence as usual, but the eye-piece, or attached plane mirror, is then slightly rotated so that the field becomes dark and the thread invisible, although the reflected image remains bright. A slight motion then causes the dark thread to occult the bright image, and it is stated that this operation can be performed with much greater certainty than can the bringing into exact coincidence two bright lines (Journal R.A.S. Canada, vol. iv., No. 4).

A New Micrometer.—Dr. Doberck describes a new micrometer in No. 4432 of the *Astronomische Nachrichten* made to his specifications by Messrs. Cooke and Son. In this instrument the frame carrying the wires is the only readily movable part, so that there is practically no fear of dragging, and the whole is built very rigidly and strongly, thus obviating any likelihood of derangement.

The errors of the screw, as shown by an investigation involving 4000 settings, are extremely small, the corrections being considerably below the probable errors of setting on stars. The instrument is called the Elizabeth Thompson micrometer.

The Mean Parallax of Tenth-magnitude Stars.—From a number of measures, made during 1907–9, of the Engelhardt companions of Bradley stars, Dr. H. E. Lau finds that the mean parallax of tenth-magnitude stars, taking Campbell's value for the sun's velocity, is 0·0010″; this is smaller than the value found by Comstock. The value derived by Kapteyn's method should be 0·0011″, so that it would appear that these faint stars are not abnormal in constitution, nor is there indicated any marked absorption in space (*Astronomische Nachrichten*, No. 4430).

HALLEY METEORS.

In a communication to Dr. W. J. S. Lockyer, Prof. David Todd, of the Amherst College Observatory, writes as follows:—

"So well established is the Schiaparelli-Newton theory of the connection between comets and meteors, that it is highly important to obtain observations from every possible radiant, in order to ascertain whether there may be any that do not conform to the general law.

"Particularly is it desirable to observe the meteors of the Halley stream. Prof. W. H. Pickering directed attention to the possibility of observing such meteors early last May, when the earth was at its nearest, not to the comet, but to the comet's orbit. Many astronomers kept an outlook for these meteors; and on the night of May 5–6 I made a balloon ascension for this purpose, with a certainty of clear skies, as the spring season had been especially cloudy. However, hardly more meteors than usual on a May night were seen, and none of them appeared traceable to the Halley radiant. Indeed, I had very little expectation of seeing Halley meteors on that occasion, as the region of the cometary orbit then nearest to us was that through which the comet had passed seventy-five years ago.

"Quite different will be the conditions next month. On October 18 the earth is closest to that region of Halley's orbit where the comet passed on March 13–15, 1910, and from which, therefore, it may be expected that many meteors will enter the earth's atmosphere, as the comet has visited that region so recently. Very unfortunately, the moon fulls at just that time, so that all the faintest shooting stars would be lost.

"Probably it will be well to begin the watch as early as October 15, as evidently the meteoric matter in this case is widely scattered along the comet's path."

According to the *Daily Mail* of October 4, a very brilliant meteor is recorded to have been observed at Johannesburg on October 3. Perhaps this may be a forerunner of the swarm referred to by Prof. Todd. The account of this large meteor is as follows:—

"Johannesburg, *Monday*.

"Johannesburg was startled at 8.50 this evening by the largest shooting star or meteor ever seen in the district.

"Its light was equal to that of a naval searchlight at fifty yards' range. The sky was illumined for three minutes, and the streets were as light as if it were day. Natives were terrified, believing that the end of the world was at hand.

"The astronomical observers at the local observatory were nearly blinded. The director of the observatory estimated that the meteor was only 150 miles from the earth. The head of the meteor, he says, was pear-shaped and half the size of the moon in diameter. The tail was straight at first, but afterwards turned towards the south."

THE AUTUMN MEETING OF THE IRON AND STEEL INSTITUTE.

When Buxton was selected as the locality for the autumn meeting of the Iron and Steel Institute doubts were freely expressed as to the suitability of the choice. These doubts proved to be groundless, for the attendance of members was larger than usual, and visits to the Midland Railway works at Derby, the London and North-Western works at Crewe, and to the Staveley Iron Works afforded opportunities for instruction, while the beautiful weather conditions caused the Duke of Devonshire's garden-party at Chatsworth, and other excursions in Derbyshire, to be very successful and enjoyable functions.

From a scientific point of view, the paper which attracted the most attention was that on the theory of hardening carbon steels, by C. A. Edwards, of Manchester. As is well known, metallurgists have long been divided into two camps, the "carbonists" and the "allotropists," and at times much heat has been introduced into the discussions which have taken place. The position advocated by Mr. Edwards is to an extent an intermediate one, as it is based on the assumption of the existence of three allotropic forms of iron, known as α, β, and γ respectively. At the same time, the absolute necessity of carbon for true hardening is maintained. After a clear explanation of the elementary facts connected with the phase rule in its application to alloys in general, and particularly to the iron carbon series, the author concludes that the hardness of carbon steel is due to the retention, by quenching, of the solid solution of carbon, or carbide of iron, in γ iron, and that the β-iron theory, as applied to the explanation of the increased hardness of steel, is untenable. The solid solution of carbon or carbide in γ iron decomposes with slow rates of cooling, and some force must be applied to prevent inversion taking place. The force is mechanical, and is caused by the contraction of the outer shell. There is no constitutional difference between austenite and martensite, the apparent difference being due to the twinning of the γ solid solution as a result of the mechanical pressure.

In the discussion which followed the reading of this paper, Prof. Arnold warmly congratulated the author on his contribution, but contended that more facts were required before generalisations were accepted, and pointed out that the cooling curves as given by himself, and confirmed at Charlottenburg, did not agree with those published by Dr. Carpenter. The latter stated that the difference was not one of observation, but of methods of recording and of interpretation. Prof. Turner asked for evidence of twinning, and suggested that twinning in crystalline rocks or in the brasses was the result of annealing after pressure, but that in the hardening of steels there was no such annealing.

Two papers which also led to an interesting discussion were taken together, and dealt, *inter alia*, with the changes on the length of cast-iron bars when cooling in a sand mould. These papers were entitled "The Influence of Silicon on the Properties of Pure Cast Iron," by A. Hague and Prof. T. Turner, and "Manganese in Cast Iron, and the Volume Changes during Cooling," by H. I. Coe. It was pointed out that in Prof. Turner's original papers on silicon in cast iron, published in 1885, the materials used were relatively impure, and though the results have been confirmed by very extended practical application, it was thought well to start with the purest available materials and to observe the temperature and contraction changes and the microstructure, which had not been examined in the earlier tests. White iron, when free from elements other than carbon, shows only two slight arrests in the rate of contraction, and these correspond with the eutectic and the pearlite points respectively. On adding silicon or manganese, the iron, though still white, expands during and immediately after solidification. With more silicon the carbon is thrown out of solution, and a marked additional expansion occurs. Though much manganese tends to make iron white, about 0·5 per cent. of manganese, in presence of silicon, produces more secondary graphite, and thus lowers the combined carbon. In the manganese series of white iron the expansions form a regular curve with the percentages of manganese, and minima are found corresponding with the existence of four definite carbides. In the grey-iron series the expansions were relatively large, and the pearlite point disappeared suddenly with about 3·5 per cent. of manganese.

In the discussion references were made to the great detail involved in such an inquiry, and to the need of further work and generalisation. In a paper by S. Hilpert and E. Colver-Glauert, sulphurous acid was recommended as an etching agent for metallographic work. The acid is used as a saturated solution of sulphurous acid in water. It should be free from sulphuric acid, and should be diluted with water to about 3 or 4 per cent. of such acid. The time taken is said to vary from seven seconds to one minute. S. Hilpert, of Berlin, submitted a useful note on the preparation of magnetic oxides of iron from aqueous solutions, and stated that the production of Fe_3O_4 from aqueous solution is only possible through the precipitated FeO dissolving in the ammoniacal residue. The true magnetic oxide is Fe_2O_3 in the form of ferric ferrate, and the magnetic properties of Fe_3O_4 have their source in the acid properties of Fe_2O_3.

The remaining papers of a varied programme dealt with briquetting iron ores, electric power and electric steel refining, the Hanyang iron works in China, the production of rolled **H** beams, and experiments on fatigue in metals.

THE GEOLOGICAL CONGRESS AT STOCKHOLM.

The eleventh International Geological Congress in Stockholm from August 17–25 has been generally pronounced by the members to have been one of the most successful yet held. There was an attendance of about 900, including representatives of all European countries except Portugal, of Australia, China, and Japan, and a distinguished contingent from America. The excursions at this congress have been unusually various and instructive, and they were heartily enjoyed, thanks to their skilful organisation and management. Before the meeting there were excursions to Spitsbergen, Lapland, and central Sweden; during it to the Archæan areas and glacial deposits around Stockholm and Upsala, and to the classical Silurian sections at Gothland; and after it to the chief iron fields and areas of geological interest in southern Sweden. The library of guide-books issued for the excursions forms an invaluable summary of the field geology of Sweden. The Swedes as a people are characterised by the thoroughness of their work and the charm of their manners; the foreign visitors return impressed by the excellence of Swedish contributions to geology and with pleasant memories of the hospitable reception from all classes, from the gracious courtesy with which the King and Queen received us in the palace to the smiling welcome of the peasants in the field.

So much work was done at the congress that no adequate account of it can be given in a short notice. Five sections and various commissions and committees met simultaneously.[1] The discussions were sometimes not influential, for they often followed the reading of several disconnected papers, and many of the speeches were rather further contributions to the subject-matter than discussions of the papers that had been submitted.

The first formal meeting of the congress was held on August 18, when the honorary president, H.R.H. Prince Gustave Adolphe, welcomed the congress in a graceful speech, referring to the dependence of mining on geology and the increasing importance of science now that it is devoting more attention to practical questions. The King of Sweden then declared the congress open. Prof. de Geer was installed as president, and gave a lecture on "The Geochronology of the last 12,000 Years." He remarked the complete failure of previous attempts to measure geological time in years, and described his determination of the length of post-glacial time in the Stockholm district. He noticed there that the marine post-glacial clays

[1] For notes on some of the meetings the writer is indebted to Prof. Hobbs, Prof. Cole, and Dr. J. W. Evans.

had been deposited in regular layers, which differ in colour and composition; the same succession is repeated time after time, with layers of varying thickness. He early suspected that each cycle in this series might represent one year's deposition, the layers laid down in the summer being thicker, as the floods then carried most mineral matter to the sea, and being brown owing to oxidisation, the autumnal layers being thinner and also blacker, owing to the higher percentage of organic matter. Near Stockholm there are many small linear moraines, each line of which he thought might be the terminal moraine deposited in one year. After thirty years' work he has discovered, by the correlation of the evidence of the seasonally banded clays, of the northward advance of their successive layers as they followed the receding ice front, of the annual moraines, and of the annual delta deposits laid down at the mouths of glacial rivers, that the retreat of the ice from Scandinavia was more rapid and less ancient than had been thought. The ice covered the site of Stockholm only a few thousand years ago, and withdrew at the rate of 200 metres a year. The latter part of the lecture was abridged, but Prof. de Geer announced that at Ragunda he had found a section which showed the full sequence of clays, from a layer formed in 1796, through a succession of lake clays and a fjord clay, to the seasonally banded clays deposited along the front of the receding ice-sheet; and, according to his determination, the ice receded from Ragunda only 7000 years ago. Prof. de Geer concluded his lecture with expressions of hope that the application of his method would allow of positive proof whether the glaciations of Scandinavia, the British Isles, and North America were synchronous.

Prof. Van Hise then delivered a lecture on "The Influence of Applied Geology and the Mining Industry upon the Economic Development of the World." He confined his lecture to the conservation of natural resources, and considered mainly the cases of iron and coal, as the failure of other metals would involve only minor readjustments. The working of coal and iron on a large scale introduced the industrial revolution of the nineteenth century, and gave commercial supremacy to countries endowed with both minerals. A civilisation can exist without iron; but a man with a wooden plough could till only one-tenth as much as with an iron plough, and hence the exhaustion of iron would mean that countries would support much smaller populations. The supply of high-grade iron ores will not last long in the chief iron-producing countries, but the quantities of low-grade ores are so immense that the total failure of iron ores is practically out of the question. Moreover, much of the iron extracted is available for all time. The coal question is more serious, as fuel when burnt is gone for ever, and the supply is so limited that it cannot last indefinitely. At the present rates of consumption, the coal in Britain and Germany may last from 500 to 1000 years, and the United States has sufficient for 6000 years; but if the consumption continues to increase at its recent rate all the coal in seams that can be worked under existing conditions will be used in 150 years; within 100 years rising prices will force men to turn to other sources of power—natural gas, petroleum, tides, and the sea; these, though all possible sources of power, are too expensive. The only perennial source of cheap power is water. The industrial future lies with countries rich in iron ores and water-power. Scandinavia has both, and it is especially favoured, as its recent glaciation has left so many lake basins, which provide easy water storage and the uniform discharge most suitable for the production of power.

Prof. van Hise made an earnest appeal to men of science to ask how long our natural resources can last, and to protest against needless waste. Primitive man and any philosopher at the beginning of the nineteenth century would have felt confident that natural resources would last indefinitely. But it is now manifest that new principles must apply to the conservation of our mineral supplies, and it is our manifest duty to leave our descendants a fair share, so that they may enjoy the comfort and leisure necessary for the intellectual development by which they can attain the godlike destiny of man.

Iron Ore Supplies.

The question of the iron ore supplies of the world was subsequently considered in a conference opened by the Prime Minister of Sweden, M. Lindman, who declared the conservation of iron ores to be more necessary than of coal, as water supply offers a permanent source of power and heat. He stated the measures adopted by Sweden to limit the export of its high-grade ores; they appear to amount to the future nationalisation of the chief iron mines.

Prof. Sjögren regarded the iron ore reserves as practically inexhaustible, and he added some fresh data to those announced in the report on the iron ore reserves of the world. Estimates received from Mr. Inouye, of Japan, show that the reports as to the unlimited iron ores in China are without adequate foundation. According to Prof. Sjögren, the best idea as to the amount of ore available in the less known regions of the world can be learnt by multiplying the area by a factor obtained by dividing the ore reserves, actual and potential, of Europe, the United States, and Japan, by their total area. On that assumption the ore supply available is 425,000 million tons.

Prof. Beyschlag defended the estimates of German ore supplies prepared for the congress from some recent criticisms, and proposed a commission to secure official evidence as to the ore reserves of the United States and the chief iron-producing countries.

M. de Launay, on the other hand, issued a warning against a serious possible source of loss, which is often disregarded by the advocates of conservation. There are in Europe vast quantities of low-grade ores, distant from supplies of fuel or power, that could not be worked in competition with the high-grade ores of many countries not yet iron-producing. If the European low-grade ores are not used now, in fifty years' time they will probably be useless. M. de Launay claimed, therefore, that under such conditions the sound policy is to accelerate by all means the production of these ores.

Prof. J. F. Kemp also repudiated the fears of an iron famine. He predicted a diminished demand on iron ores, as we are now passing from the age of steel to the age of cement, and also further discoveries of ores, such as that in Cuba, which will probably lead to the establishment of large iron works on the Atlantic coast of America. He insisted that the critical point with iron is not the supply of ore, but the exhaustion of the coking coals. Even if all the heat be supplied by electricity, half a ton of coking coal will still be required for the reduction of a ton of ore.

The only speaker in the discussinn, Prof. J. W. Richards, of Lehigh, also agreed that the danger is with the coking coal, and he suggested a commission on the supplies of this material.

Glacial Erosion.

The first sectional discussion was on glacial erosion, under the chairmanship of M. de Margerie. Papers were contributed by Profs. Högbom, Penck, Davis and Reusch, and Dr. Nordenskjold, and in the discussion speeches were made by Profs. Wahnschaffe, Baltzer, Heim and Salomon, Dr. G. F. Becker, and Dr. Sederholm. Prof. Penck, in an eloquent summary of his paper, explained the evidence which has led him to attribute the main work in the formation of Alpine valleys to the action of ice. Prof. Davis insisted on the importance of the physiographic study of the question, and the comparison of never glaciated mountains, taken as the "norm" of mountain form, with those that have been glaciated: he advocated the formation of cirques by the "plucking" away of the rocks at the head of a valley, until the whole mountain ridge at the head of the valley may be torn away. Prof. Högbom, while advocating the erosive power of ice, remarked the difficulty of explaining some Swedish valleys that had been filled with ice, which had not removed their soft, pre-glacial deposits. Prof. Wahnschaffe referred to cases where ice had covered soft deposits, and had not even shifted boulders lying on them.

Prof. Reusch described the glaciated valleys near Christiania, which he thought were pre-glacial, and contrasted the effect of low-level ice in deepening and moulding valleys with the planing effect of high-level ice.' The powerful influence of pre-glacial structures in determining the course and character of ice-worn valleys was also maintained by Dr. Becker, who attributed the Yosemite and other valleys in the Sierra Nevada to the existence of a vast system of joints, the decomposed rocks along which have been removed by ice. Dr. Nordenskjold insisted that long straight valleys like fjords can only be due to ice erosion.

The adjourned discussion, with Prof. Wahnschaffe in the chair, was opened by Prof. Salomon, of Heidelberg, who remarked that erosion must take place where a glacier presses firmly on the ground; but we must wait for the ice to withdraw before we can study its effects, just as we have to wait for the dissection of a volcano before we can see what has been going on in the depths. He had seen cause to change his mind, and to accept the potency of glaciers as eroding agents, especially where the rock-structures lend themselves to "plucking." Joints in igneous rocks are not always evenly distributed, and thus one part of the same mass may show erosion while another resists. The suggestion of the action of freezing water in the rock-joints under a glacier deserves full consideration. Dr. von Dechy, from his studies in the Caucasus, urged that much seeming erosion was due to the clearing out of previously filled valley floors and of lake basins by glaciers, and by catastrophic glacier-slides. Prof. Wahnschaffe remarked that the Caucasian area was not comparable with that north of the Alps, since no great Piedmont glacier had formed north of the Caucasus. Prof. Heim, in a vigorous speech, said the rock-surfaces were palimpsests of river action and glacier action, and the work of each was thus obscured. While stream action concentrates itself in a portion of the valley floor, a glacier spreads too widely to compare with it in erosive power. So-called "plucked" masses had often merely fallen from above on to the ice, and had come out below. Glaciers have overriden Alpine landslides, but even then without carrying many blocks away. The broad, rounded form of glacier valley floors may even be due to the wandering of a previous stream from side to side within its valley walls. Then comes a glacier, and gives a final touch to the form, overriding the taluses of a previous age at either side.

Prof. Högbom, of Upsala, regarded the great chalk masses, said to have been moved in northern Germany and elsewhere by glacial erosion, as having been prepared by fractures. He compared a great glacier to the overthrust mass in mountain-building, and the ground moraine to the breccia along the thrust plane. Erosion must be greatest under the vertical nose of an advancing glacier, and not much under the glacier as a whole. Prof. E. Stolley, of Brunswick, said the German chalk masses represented genuine plucking and pushing forward. Lakes due to glacial erosion occur even in the North German plain. Prof. Reusch confessed, like Salomon, to having changed his mind. He answered an objection in Heim's speech by showing how a glacier must leave some upstanding masses in its floor, and cannot be expected to plane all equally away. Prof. Penck, on closing the discussion, accepted excavating action of subglacial streams, especially along valley sides, and urged that the only differences between Prof. Heim and himself were now really quantitative.

The Pre-Cambrian Fauna.

The discussion on the sudden appearance of the varied Cambrian fauna showed the firm belief in the evidence of pre-Cambrian life as contended by Prof. Barrois from the graphite of Brittany, by Dr. Sederholm from traces of pre-Cambrian fossils in Finland, and by Prof. Rothpletz from the oolitic pebbles and organic traces in the pre-Cambrian conglomerates of Sweden. The discussion showed a general agreement as to the influence of the absence of carnivorous organisms from the pre-Cambrian seas. Thus, according to Dr. J. W. Evans, creatures then had no need of defensive structures, and according to Dr. R. A. Daly there was, for the same reason, an accumulation of decomposing organic matter in the early seas, and the resultant ammonium carbonate led to the precipitation of the pre-Cambrian limestones; Profs. Sollas and Steinmann both thought that the early organisms had no hard parts, which developed as the organisms became more complex. Prof. Walther suggested that the pre-Cambrian sea consisted of isolated basins, the waters of which differed in chemical composition, and that organisms living in water rich in silica secreted siliceous skeletons, those in water rich in carbonate of lime formed calcareous shells; the phosphatic skeletons of trilobites and some brachiopods were due to life in a sea rich in phosphate, and chitinous shells were developed in fresh-water basins.

In the section on general and regional geology, Dr. Evans exhibited an elaborate and ingenious model to illustrate the movements along the line of the San Andreas fault during the recent Californian earthquake. It is constructed of two sets of flexible wooden strips held together by strings at their common edge; the one part was subjected to slow lateral stresses, and suddenly released from the strain by cutting the strings. Vibrations were thus set up, the amplitudes of which were greatest at the adjacent edges, and a musical note was produced through the friction of metal attachments. Dr. Evans believed the earthquake stresses to be of slow accumulation, the larger vibratory movements after release causing the sensible shocks, the frictional small tremors the sounds.

Prof. Hobbs gave a lecture on "The Fracture Systems of the Earth's Crust," and urged their international investigation, owing to their importance in relation to land sculpture, the course of rivers, the discovery of obscure faults, and earthquake disturbances. Prof. H. F. Reid discussed the results of a recent paper on the California earthquake, and exhibited a model similar in principle, but not in construction, to that of Dr. Evans. Dissent from his views as to the cause of the earthquake was expressed by Prof. Rothpletz, Dr. Oldham, and the chairman (Prof. Hobbs).

An important paper by Prof. Tarr on the advance of glaciers in Alaska as a result of earthquake shaking indicated how the sudden advance and equally sudden subsequent stagnation of many Alaskan glaciers might be accounted for by masses of snow being shaken from the névé regions during the heavy earthquake of 1899. In discussing this paper, Prof. Frech showed how the explanation offered would account for the hitherto inexplicable sudden advances of the glaciers of the Alps.

Dr. H. Stille described the earth movements in the later rocks of north-western Germany, and showed the influence of the Palæozoic areas of the Rhine and the Harz.

Pre-Cambrian Geology.

The petrographic section met on Saturday, in the morning under President van Hise, to consider the principles of pre-Cambrian geology and the cause of regional metamorphism, and in the afternoon under M. Barrois, to discuss pre-Cambrian stratigraphic classification. There were fourteen papers and many speeches. The general result of the morning's discussion was summarised at the close by Prof. Cole as showing the great advance in recent years of the views of Michel-Levy and Barrois as to the formation of crystalline schists by intense granitic injections, which in recent years had been supported by Sederholm in Finland and his own work in Donegal. These views were clearly expressed by a statement of the evidence from Brittany by Prof. Barrois. Prof. Adams opened the discussion by an account of the constant association with the crystalline schists of vast granitic batholites, to which he attributed the metamorphosis. Dr. Sederholm exhibited a map of a Finnish islet on the scale of one-twentieth of natural size, and he described the granitisation of the pre-Cambrian sediments by injection with granite when the adjacent rocks were half melted and plastic. On the other hand, attention was directed to intrusive gneisses elsewhere which had a less metamorphic effect. Thus Prof. U. Grubenmann, of Zurich, contrasted the actions of the gneisses of Scandinavia and Finland with those of the Alps, which had done less in melting the adjacent rocks, but had a greater pneumatolitic effect.

Prof. Coleman described the alteration of conglomerates at Sudbury, Ontario, into rocks that had been mapped as

Laurentian gneisses, and contrasted the slight metamorphism of the Lower Huronian conglomerates of Cobalt with their alteration into gneiss at Michipicoten by infolding with Keewatin batholites.

Dr. Lane stated the three possible sources of the gneissic rocks known as the Laurentian, and from a comparison of the size of their constituents with those of the adjacent rocks concluded that the Laurentians must be due to the ascent of deep-seated fluid material.

In the afternoon meeting various subdivisions of the pre-Cambrian rocks were advocated. Mr. W. G. Miller explained the classification used by the Geological Survey of Ontario, which adopts three main divisions: the Keweenawan for the upper sandstones, the Huronian for the underlying schists, quartzites, &c., and the Laurentian-Keewatin for the basal complex. Prof. Coleman objected to the retention of Laurentian except as a temporary convenience, since the Laurentian are intrusive rocks of various ages. Dr. Sederholm explained the classification he had adopted for Finland and Scandinavia, where the pre-Cambrian system is broken up by great unconformities into divisions, each of which he thought from its thickness must correspond to the groups, and not to the systems, of the post-Cambrian rocks. He objected to the terms previously used, and proposed to call the pre-Cambrian rocks the Progonozoic, and to divide them into three divisions, the Archeo-, Meso-, and Næo-progonozoic.

Another case of supposed Palæozoic schists proving to be pre-Cambrian was described by Prof. J. F. Kemp from evidence displayed during recent work for the New York water supply.

President van Hise supported the threefold division of the pre-Cambrians, and Mr. Fermor the twofold division found more convenient in India, and referred to Sir Thomas Holland's term Purana for the non-foliated pre-Cambrian sediments. Miss Raisin directed attention to the analogous case in the English Midlands, and to Lapworth's term Uriconian for the comparatively unaltered pre-Cambrian volcanic series.

The petrographic section, under the presidency of Dr. Teall, devoted a morning to discussion of the principles of rock classification. Prof. Adams exhibited photographs of the structures he had produced in rocks, including the formation of flaser gabbro or augen gneiss by pressure at temperatures of 450° F. No fresh minerals were produced, but by mechanical movements the material of a massive diabase was rearranged as a gneiss.

Prof. Vogt urged the claim of eutectics as a factor in rock classification. Dr. A. L. Day explained the aims and methods of the researches on mineral formation and stability conducted in the Carnegie Institute, and expressed confidence that their methods could in time be applied to even such complex mixtures as ordinary rocks.

Dr. Whitman Cross defended the quantitative system of rock classification from recent criticisms, and said that the other systems were only less arbitrary in the degree that they were less definite. He referred to Becke's petrographic types—the Atlantic and Pacific—as based on distinctions that could not be sharply defined. Dr. Evans repeated his criticisms on the quantitative system, and the general discussion was continued by Dr. Benett, Prof. Kœnigsberger, and Prof. Tschirwinsky.

Meetings of the other sections were devoted to tectonic geology, especially of Switzerland, to the causes of the Ice age, to polar geology, applied geology, stratigraphy, and palæontology.

At the final meeting it was decided that the next meeting, in 1913, should be in Canada, and the hope expressed that the meeting in 1916 should be in Belgium.

THE THOMAS YOUNG ORATION.

PROF. R. W. WOOD, in delivering the Thomas Young Oration at the Optical Society on Thursday, September 29, described some apparatus with which he has been experimenting recently. The first of these, which he calls the echelette grating, is an instrument occupying a position between the echelon and the ordinary diffraction grating. It is a grating ruled with a crystal of carborundum on gold deposited on copper; the carborundum has the advantage over a diamond point of having perfectly straight sides meeting at an angle of 120°. The spacing is about ten times as coarse as usual. No metal is removed in ruling, but the gold is compressed so as to form ridges and hollows. The sides of these ridges are highly polished and almost optically flat. Such a grating may have various faults, such as having a flat or irregular top to the ridges, or the sides of one groove may be deformed in ruling the next; tests to determine whether the grating is free from faults were described.

A variety of gratings is obtained by altering the position of the crystal in ruling; thus some gratings have their two sides equally inclined to the surface of the plate, and in others there are inequalities in the inclinations of various magnitudes. The gratings thus obtained, with a known form of groove, have been used to determine the causes which throw the greater part of the light of a definite wave-length into one particular spectrum. These gratings bear the same relation to heat waves that the ordinary diffraction grating bears to light waves; thus they are specially suitable for use in investigations into radiant energy, being many times more efficient than prisms of rock salt. Diagrams were shown which demonstrated the greater resolving power of the grating compared with the rock-salt prism. A number of gratings were exhibited, and some of the tests for detecting faults were shown. A demonstration was also given of the ability of these gratings to concentrate the light of a definite colour into a particular spectrum.

Prof. Wood next described his mercury telescope, in which the mirror is a vessel containing mercury, the surface of which is made to assume a steady parabolic form by rotation under gravity. The practical difficulties to be overcome in preventing ripples on the mercury surface due to vibration or to a very slight obliquity in the axis of rotation were described. The mercury vessel is mounted on an axis with two conical bearings, and the whole mount is placed on a stand with levelling screws. To avoid the excessive friction due to conical bearings, the greater part of the weight is taken by a steel ball under the centre of the objective. A magnetic drive was first attempted, but was abandoned in favour of a mechanical connection consisting of half a dozen fine threads of pure elastic, thus any vibrations in the motor are absorbed by the elastic threads. Some star trails taken with the instrument in and out of adjustment were described.

Finally, some photographs of landscapes taken with infra-red light were shown.

THE POLAR ESKIMOS.[1]

ANTHROPOLOGISTS are now beginning to realise the necessity of supplementing the methods of a general ethnographic survey by a more intensive study of smaller groups within limited areas. A good example of this class of investigation is provided by the account of the Polar Eskimos by Dr. H. P. Steensby, who was a member of the expedition commissioned by the Danish Missionary Society in 1909 to establish a station in Greenland.

The tribe known as the Polar Eskimos occupies the west side of the Hayes Peninsula, extending from north-west Greenland towards the west between the Kane Basin in the north and the Melville Sound in the south. At present they number about two hundred souls. Compared with the people of the more southerly west Greenland, they appear to be a different race, the Mongolian type prominent in the latter region being here replaced by that called by Dr. Steensby the Indian. The so-called Mongolian racial characters, the low nose, oblique eyes, flat face, broad and large cheek-bones, are more prominent in the women than in the men. The skull is of the dolichocephalic class. The skin has always a yellowish ground-colour, and the so-called "Mongolian spot" is present in the sacro-lumbar region of children.

Much of the existing culture of the tribe seems to be due to the emigration of a body of their kinsmen from the coasts of North Devon and Ellesmere Land in the early 'sixties, and they present the almost unique condi-

[1] "Contributions to the Ethnology and Anthropogeography of the Polar Eskimos." By Dr. H. P. Steensby. Pp. 253—406. (Copenhagen: Bianco Luno, 1910.)

tion that during the comparatively short period since they came under European observation they have risen from practically the lowest to a comparatively high stage of culture. Kane, who in the early 'fifties first described them, found that they possessed little iron or wood, using sledge-runners of bone and pieces of barrel-hoops as knives. They did not hunt the reindeer, and were ignorant of the use of the bow and arrow; they could not catch salmon, and did not use the kayak. These cultural deficiencies were certainly survivals of their primitive social condition. During the 'sixties, however, they learned from emigrants from the American side of Smith's Sound the art of reindeer hunting, the use of the bow and arrow, skill in salmon catching, and the mode of building kayaks and hunting from them. The leader of this party of foreigners, Kridlarssuark, has now become the legendary culture hero. Finally, in 1891, Peary began his intercourse with them, which enabled them to obtain in exchange for their fox and bear skins the finest American weapons, with the result that the rapid destruction of game will probably soon destroy their main source of livelihood. Even up to the time of Peary's first visit stone knives and axes were in use, and they used to make rude implements with cutting edges of meteoric iron, the source of which was discovered by Peary during a later expedition in 1894. Even now they make their harpoon points of iron with a head-piece of bone, and they work iron with much skill with the files they used for the older material.

A similar course of evolution may be traced in the construction of their houses. In their original home they must have used whale-ribs for the support of the roof. Wood of sufficient span being now not procurable, they have, while retaining the primitive plan, adopted a new device for supporting the roof, planned on the model of the cantilever.

With this modern and fairly advanced culture the Polar Eskimo combines many savage characteristics. He is, says Dr. Steensby, "a confirmed egoist, who knows nothing of disinterestedness. Towards his enemies he is crafty and deceitful; he does not attack them openly, but indulges in back-biting; he will not meet his deadly enemy face to face, but will shoot or harpoon him from behind." They practise a rude form of justice. One man, because he was a notorious liar, was summarily killed by two chiefs, one of whom annexed the wife of the deceased.

We have said enough to show the interest and value of this account of a little known tribe. It is illustrated by characteristic sketches, the work of an Eskimo woman, which in style closely resemble the Bushman drawings recently published under the editorship of Mr. H. Balfour.

THE BRITISH ASSOCIATION AT SHEFFIELD.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY PROF. A. B. MACALLUM, M.A., M.B., PH.D., SC.D., LL.D., F.R.S., PRESIDENT OF THE SECTION.

THE record of investigation of the phenomena of the life of animal and vegetable cells for the last eighty years constitutes a body of knowledge which is of imposing magnitude and of surpassing interest to all who are concerned in the studies that bear on the organic world. The results won during that period will always constitute, as they do now, a worthy memorial of the intense enthusiasm of the scientific spirit which has been a distinguishing feature of the last six decades of the nineteenth century. We are to-day, in consequence of that activity, at a point of view the attainment of which could not have been predicted half a century ago.

This body of knowledge, this lore which we call cytology, is still with all this achievement in one respect an undeveloped science. It is chiefly—nay, almost wholly—concerned with the structural or morphological side of the cell, while of the functional phenomena our knowledge is only of the most general kind, and the reason is not far to seek. What little we know of the physiological side of the cell—as, for example, of cellular secretion, absorption, and nutrition—has only to a very limited extent been the outcome of observations directed to that end. It is in very great part the result of all the inferences and generalisations drawn from the data of morphological research. This knowledge is not the less valuable or the less certain because it has been so won, but simply because of its source and of the method by which we have gained it; it is of a fragmentary character, and therefore less satisfactory in our estimation.

This state of our knowledge has affected—or, to express it more explicitly, has fashioned—our concept of living matter. When we think of the cell it is idealised as a morphological element only. The functional aspect is not ignored; but we know very little about it, and we veil our ignorance by classing its manifestations as vital phenomena.

It is true that in the last twenty years, and more particularly in the last ten, we have gathered something from biochemical research. We know much concerning ferment or catalytic action, of the physical characters of colloids, of the constitution of proteins, and their synthesis in the laboratory promises to be an achievement of the near future. We are also in a position to understand a little more clearly what happens in proteins when, on decomposition in the cell, they yield the waste products, urea, and other metabolites, with carbon dioxide and water. Further, fats can be formed in the laboratory from glycerine and fatty acids, a large number of which have also been synthesised, and a very large majority of the sugars of the aldohexose type have been built up from simpler compounds. These facts indicate that some of the results of the activity of animal and vegetable cells may be paralleled in the laboratory, but that is as far as the resemblance extends. The methods of the laboratory are not as yet those of nature. In the formation of carbohydrates, for example, the chlorophyll-holding cell makes use of processes of the most speedy and effective character, but nothing of these is known to us except that they are quite unlike the processes the laboratory employs in the artificial synthesis of carbohydrates. Nature works unerringly, unfalteringly, with an amazing economy of material and energy, while "our laboratory syntheses are but roundabout ways to the waste sink."

In consequence, it is customary to regard living matter as unique—*sui generis*, as it were, without an analogue or parallel in the inorganic world—and the secrets involved in its actions and activities as insoluble enigmas. Impelled by this view, there are those, also, who postulate as an explanation for all these manifestations the intervention in so-called living matter of a force otherwise and elsewhere unknown, biotic or vital, the action of which is directed, according to the character of the structure through which it operates, to the production of the phenomena in question. Living protoplasm is, in this view, but a mask and a medium for action of the unknown force.

This is an old doctrine, but it has again made headway in recent years owing to the reaction from the enthusiasm which came from the belief that the application of the known laws of physics and chemistry in the study of living matter would explain all its mysteries. A quarter of a century ago hopes were high that the solution of these problems would soon be found in a more profound comprehension of the laws of the physical world. Since then there has been an extraordinary increase in our knowledge of the structure and of the products of the activity of living matter without a corresponding increase in knowledge of the processes involved. The obscurity still involving the latter appears all the greater because of the high lights thrown on the former. Despair, in consequence, has taken the place of hope with some, and the action of a mysterious force is invoked to explain a mystery.

It may be admitted that our methods of investigation are very inadequate, and that our knowledge of the laws of matter, seemingly comprehensive, is not at present profound enough to enable us to solve all the problems involved in the vital phenomena. The greatest factor in the difficulty of their solution, however, has been the fact that there has been a great lack of investigators specially trained, not only in biology, but also in physics and chemistry, for the very purpose of attacking intelligently such problems. The biologists, for want of such a wide training, have emphasised the morphological aspect and the readily observable phenomena of living matter; while the physicist and chemist, knowing little of the morphology of the cell and of its vital manifestations, have been unable to apply satisfactorily the principles of their sciences to an understanding of its processes. The high degree of specialism which certain departments of biology has in recent years developed has made that difficulty greater than it was.

It must also be said that in some instances in which the physicist and chemist attempted to aid in the solution of biological problems the result, on the whole, has not been quite satisfactory. In, for example, the phenomena of osmosis, the application of Arrhenius's theory of ionisation and van 't Hoff's gas theory of solutions promised at first to explain all the processes and the results of diffusion through animal membranes. These theories were supported by such an array of facts from the side of physics and physical chemistry that there appeared to be no question whatever regarding their universal validity, and their application in the study of biological phenomena was urged with acclaim by physical chemists and eagerly welcomed by physiologists. The result in all cases was not what was expected. Diffusion of solutes, according to the theories, should, if the membrane is permeable to them, always be from the fluid where their concentration is high to that in which it is low. This appears to happen in a number of instances in the case of living membranes—or, at least, we may assume that it occurs—but in one signal instance, at least, the very reverse normally obtains. In the kidney, membranes formed of cells constituting the lining of the glomeruli and the renal tubules separate the urine, as it is being formed, from the blood plasma and the lymph circulating through the kidney. Though the excreted fluid is derived from the plasma and lymph, it is usually of much greater osmotic concentration than the latter.

It may be urged that this and other discrepancies are explained by the distribution (or partition) coefficient of the solutes responsible for the greater concentration of the product of excretion, these solutes being more soluble in the excreted medium than in the blood plasma, and distributing or diffusing themselves accordingly. If such a principle is applicable here as an explanation, it may be quite as much so in other physiological cases in which the results are supposedly due only to the forces postulated in the theories of van 't Hoff and Arrhenius. Whether this be so or not, the central fact remains that the enthusiastic hopes with which the theories were applied by physiologists and biologists in the explanation of certain vital phenomena have not been wholly realised.

The result has been a reaction amongst physiologists and biologists which has not been the least contributory of all the causes that have led to the present revival of vitalism.

Another difficulty in accounting for the vital phenomena has been due, until recently, to a lack of knowledge of the physical and chemical properties of colloids and colloidal "solutions." The importance of this knowledge consists in the fact that protoplasm, "the physical basis" of life, consists mainly of colloids and water. Until eleven years ago, what was known regarding colloids was derived chiefly from the researches of Graham (1851–62), Ljubavin (1889), Barus and Schneider (1891), and Linder and Picton (1892–7), who were the pioneers in this line. In 1899 were published the observations of Hardy, through whose investigations very great progress in our knowledge of colloids was made. In 1903 came the invention of the ultramicroscope by Siedentopf and Zsigmondy, by which the suspension character of colloid material in its so-called "solutions" was visually demonstrated. During the last seven years a host of workers have by their investigations greatly extended our knowledge of the physical and chemical properties of colloids, and now the science of Collochemistry bids fair, the more it develops, to play a very important part in all studies bearing on the constitution and properties of living matter.

Then, also, there are the phenomena of surface tension. This force, the nature of which was first indicated by Segner in 1751, and described with more detail by Young in 1804 and Laplace in 1806 in the expositions of their theories of capillarity, was first in 1869 only casually suggested as a factor in vital processes by Engelmann. Since the latter date and until 1892, when Bütschli published his observations on protoplasmic movement, no serious effort was made to utilise the principle of this force in the explanation of vital phenomena. Even to-day, when we know more of the laws of surface tension, it is only introduced as an incidental factor in speculations regarding the origin of protoplasmic movement and muscular contraction, and yet it is, as I shall maintain later on in this address, the most powerful, the most important of all the forces concerned in the life of animal and vegetable cells.

It may be gathered from all that I have advanced here that the chief defect in biological research has been, and is, the failure to apply thoroughly the laws of the physical world in the explanation of vital phenomena. Because of this too much emphasis is placed on the division that is made between the biological and the physical sciences. This division is very largely an artificial one, and it will in all probability be maintained eventually only as a convenience in the classification of the sciences. The biologist and physiologist have to deal with problems in which a wide range of knowledge is necessary for their adequate treatment; and, if the individual investigator has not a very extensive training in the physical sciences, it is impossible for him to have at his command all the facts bearing on the subject of his research, unless the problem involved be a very narrow one. The lack of this wide knowledge of the physical sciences tends to specialism, and, as the specialism is ever growing, it will produce a serious situation eventually, for it will develop a condition in the scientific world in which coordination of effort and a broad outlook will be much more difficult than is the case now.

This growing defect in the biological sciences can only be lessened by the insistence of those in charge of advanced courses in biological and physiological laboratories that only those whose training is of a very wide character should be allowed to take up research. It is, perhaps, futile to expect that such a rule will ever be enforced, for in the keen competition between universities for young teachers who have made some reputation for original investigation there may not be too close a scrutiny of the qualifications of those who offer themselves for post-graduate courses. There is, further, the difficulty that the heads of scientific departments are not desirous of limiting the output of new knowledge from their laboratories by insisting on the wider training for the men of science who are in the process of developing as students of research.

It is perhaps true, also, that there still remains a great deal unobserved or unrecorded in the fields of biology, physiology, and biochemistry, in the investigation of all of which a broad training is not specially required to give good service; and that, further, this condition will obtain for one or two decades still. It is quite as certain, however, that the returns from such service will tend to diminish in number and value, and, if the coming generation of workers is not recruited from a systematically and broadly trained class of students, a period of comparative sterility may supervene.

As it is to-day, there are few who devote themselves to the direct study of the chemical and physical properties of the cell, the fundamental unit of living matter. There are, of course, many who are concerned with the morphology of the cell, and who employ in their studies the methods of hardening and staining which have been of very great service in revealing the structural as well as the superficial chemical properties of the cell. On the facts so gained views are based which deal with the chemistry of the cell, and which are more or less widely accepted, but the results and generalisations drawn from them give us but little insight into the chemical constitution of the cell. We recognise in the morphologists' chromatin a substance which has only in a most general way an individuality, while the inclusions in the nucleus and the cytoplasm, on the distinction by staining of which great emphasis is laid, can only in a most superficial way be classified chemically.

The results of digestion experiments on the cell structures are also open to objection. The action of pepsin and hydrochloric acid must depend very largely on the accessibility of the material the character of which is to be determined. If there are membranes protecting cellular elements, pepsin, which is a colloid, if it diffuses at all, must in some cases, at least, penetrate them with difficulty. In Spirogyra, for example, the external membrane, formed of a thick layer of cellulose, is impermeable to pepsin, but not to the acid, and, in consequence, the changes which occur in it during peptic digestion are due to the acid alone. Even in the cell the periphery of which is not protected by a membrane, the insoluble colloid material at the surface serves as a barrier to the free entrance of the pepsin. It is, however, more particularly in the action on the nucleus and its contents that peptic digestion fails to give results which can be regarded as free from objection. Here is a membrane which during life serves to keep out of the nucleus, not only all inorganic salts, but also all organic compounds, except chiefly those of the class of nucleo-proteins. That such a membrane may, when the organism is dead, be permeable to pepsin is at least open to question, and in consequence what we see in the nucleus after the cell has been acted on by pepsin and hydrochloric acid cannot be adduced as evidence of its chemical or even of its morphological character.

The results of digestive experiments on cells are, therefore, misleading. What may from them appear as nucleo-protein may be anything but that, while, if the pepsin penetrates as readily as the acid, there should be left, not nucleo-protein, but pure nucleic acid, which should not stain at all.

The objections which I now urge against the conclusions drawn from the results of digestion experiments have developed out of my own observations on yeast cells, diatoms, Spirogyra, and especially the blue-green algæ. The latter are, as is Spirogyra, encased in a membrane which is an effective barrier to all colloids. When, therefore, threads of Oscillaria are subjected to the action of artificial gastric juice, a certain diminution in volume is observed owing to the dissolving power of the hydrochloric acid, and an alteration of the staining power of certain structures is found to obtain; but the pepsin has nothing to do with these, as may be determined by examination of control preparations treated with a solution of hydrochloric acid alone.

It is thus seen how slender is our knowledge of the chemistry of cells derived from staining methods and from digestion experiments. That, however, has not been the worst result of our confidence in our methods. It has led cytologists to rely on these methods alone, to leave undeveloped others which might have thrown great light on the chemical constitution of the cell, and which might have enabled us to understand a little more clearly the causation of some of the vital phenomena.

It was the futility of some of the old methods that led me, twenty years ago, to attack the chemistry of the cell from what appeared to me a correctly chemical point of view. It seemed to me then, and it appears as true now, that a diligent search for decisive chemical reactions would yield results of the very greatest importance. In the interval I have been able to accomplish only a small fraction of what I hoped to do, but I think the results have justified the view that, if there had been many investigators in this line instead of only a very few, the science of Cytochemistry would play a larger part in the solution of the problems of cell physiology than it does now.

The methods and the results are, as I have said, meagre, but they show distinctly indeed that the inorganic salts are not diffused uniformly throughout the cell, that in vegetable cells they are rigidly localised, while in animal cells, except those devoted to absorption and excretion, they are confined to specified areas in the cell. Their localisation, except in the case of inorganic salts of iron, is not due to the formation of precipitates, but rather to a condition which is the result of the action of surface tension. This seems to me to be the only explanation for the remarkable distribution, for example, of potash salts in vegetable cells. We know that, except in the chloroplatinate of potassium and in the hexanitrite of potassium, sodium and cobalt, potassium salts form no precipitates; and yet, in the cytoplasm of vegetable cells, the potassium is so localised at a few points as to appear at first as if it were in the form of a precipitate. In normal active cells of Spirogyra it is massed along the edge of the chromotophor, while in the mesophylic cells of leaves it is condensed in masses of the cytoplasm, which are by no means conspicuous in ordinary preparations of these cells.

This effect of surface tension in localising the distribution of inorganic salts at points in the cytoplasm would explain the distribution of potassium in motor structures. In striated muscle the element is abundant in amount, and is confined to the dim bands in the normal conditions. In Vorticella, apart from a minute quantity present at a point in the cytoplasm, it is found in very noticeable amounts in the contractile stalk, while in the holotrichate infusoria (Paramæcium) it is in very intimate association with the basal elements of the cilia in the ectosarc. This, indeed, would seem to indicate that the distribution of the potassium is closely associated with contraction, and, therefore, with the production of energy in contractile tissues. The condensation of potassium at a point may, of course, be a result of a combination with portions of the cytoplasm, but we have no knowledge of the occurrence of such compounds; and, further, the presence of such does not explain anything or account for the liberation of energy in motor contraction. On the other hand, the action of surface tension would explain, not only the localisation of the potassium, but also the liberation of the energy.

In vessels holding fluids, the latter, in relation to surface tension, have two surfaces, one free, in contact with the air, and known as the air-water surface, the other that in contact with the wall of the containing vessel (glass). In the latter the tension is lower than in the former. When an inorganic compound—a salt, for example—is dissolved in the fluid it increases the tension at the air-water surface, but its dilution is much greater here than in any other part of the fluid, while at the other surface its concentration is greatest. In the latter case the condition is of the nature of adsorption. The condensation on that portion of the surface where the tension is least is responsible for what we find when a solution of a coloured salt, as, *e.g.*, potassium permanganate, is driven through a layer of dry sand. If the latter is of some considerable thickness, the fluid as it passes out is colourless. The air-solution surface tension is higher than the tension of each of the solution-sand surfaces, on which, therefore, the permanganate condenses or is adsorbed. The same phenomenon is observed when a long strip of filter paper is allowed to hang with its lower end in contact with a moderately dilute solution of a copper salt. The solution is imbibed by the filter paper, and it ascends a certain distance in a couple of minutes, when it may be found that the uppermost portion of the moist area is free from even a trace of copper salt.

If, on the other hand, an organic compound—as, for instance, one of the bile salts—instead of an inorganic compound is dissolved in the fluid, the surface tension of the air-water surface is reduced, and in consequence the bile salt is concentrated at that surface, while in the remainder of the fluid, and particularly in that portion of it in contact with the wall of the vessel, the concentration is reduced.

The distribution of a salt in such a fluid, whether it lowers surface tension or increases it, is due to the action of a law which may be expressed in words to the effect that the concentration in a system is so adjusted as to reduce the energy at any point to a minimum.

Our knowledge of this action of inorganic and organic substances on the surface tension in a fluid, and of the differences in their concentrations throughout the latter, was contained in the results of the observations on gas mixtures by J. Willard Gibbs, published in 1878. The principle as applied to solutions was independently discovered by J. J. Thomson in 1887. It is known as the Gibbs' principle, although the current enunciations of it contain the more extended observations of Thomson. As formulated usually it is more briefly given, and its essential points may be rendered in the statement *that when a substance on solution in a fluid lowers the surface tension of the latter, the concentration of the solute is greater in the surface layer than elsewhere in the solution; but when the substance dissolved raises the surface tension of the fluid, the concentration of the solute is least in the surface layers of the solution.*

It is thus seen how in a system like that of a drop of water with different contact surfaces the surface tension is affected, and how this alters the distribution of solutes. It is further to be noted that for most organic solutes the action in this respect is the very reverse of that of inorganic salts. Consequently, in a living cell which contains both inorganic and organic solutes, and in which there are portions of different composition and density, the equilibrium may be subject to disturbance constantly through an alteration of the surface tension at any point. Such a disturbance may be found in a drop of an emulsion of olive oil and potassium carbonate in the well-known experiments of Bütschli. When the emulsion is appropriately prepared, a minute drop of it, after it is surrounded with water, will creep under the cover-glass in an amœboid fashion for hours, and the movement will be more marked and rapid when the temperature is raised to 40° to 50° C. All the phenomena manifested are due to a lowering of the surface tension at a point on the surface, as a result of which there is protrusion there of the contents of the drop, accompanied, Bütschli holds, by streaming cyclic currents in the remainder of the mass.

Surface tension also, according to J. Traube, is all-important in osmosis, and he holds that it is the solution pressure (*Haftdruck*) of a substance which determines the velocity of the osmotic movement and the direction and force of the osmotic pressure. The solution pressure of a substance is measured by the effect that substance exercises when dissolved on the surface tension of its solution, or, to put it in Traube's own way, the more a substance lowers or raises the surface tension of a solvent (water), the less or greater is the solution pressure (*Haftdruck*) of that substance. This solution pressure, Traube further holds, is the only force controlling osmosis through a membrane, and he rejects completely the bombardment effect on the septum postulated in the van 't Hoff theory of osmosis.

The question as to the nature of the factors concerned in osmosis must remain undecided until the facts have been more fully studied from the physiological point of view, but enough is now known to indicate that surface tension plays at least a part in it, and the omission of all consideration of it as a factor is not by any means a negligible defect in the van 't Hoff theory of osmosis.

The occurrence of variations in surface tension in the individual cells of an organ or tissue is difficult to demonstrate directly. We have no methods for that purpose, and, in consequence, one must depend on indirect ways to reveal whether such variations exist. The most effective of these is to determine the distribution of organic solutes and of inorganic salts in the cell. The demonstration of the former is at present difficult, or even in some cases impossible. The occurrence of soaps, which are amongst the most effective agents in lowering surface tension, may be revealed without difficulty microchemically, as may also neutral fats, but we have as yet no delicate microchemical tests for sugars, urea, and other nitrogenous metabolites, and in consequence the part they play, if any, in altering the surface tension in different kinds of cells, is unknown. Further research may, however, result in discovering methods of revealing their occurrence microchemically in the cell. We are in a like difficulty with regard to sodium, the distribution of which we can determine microchemically in its chief compounds, the chloride and phosphate, only after the exclusion of potassium, calcium, and magnesium. We have, on the other hand, very sensitive reactions for potassium, iron, calcium, haloid chlorine, and phosphoric acid, and with methods based on these reactions it is possible to localise the majority of the inorganic elements which occur in the living cell.

By the use of these methods we can indirectly determine the occurrence of differences in surface tension in a cell. This determination is based on the deduction from the Gibbs-Thomson principle that, where in a cell an inorganic element or compound is concentrated, the surface tension at the point is lower than it is elsewhere in the cell. If, for example, it is concentrated on one wall of a cell, the surface tension there is less than on the remaining surfaces or walls of the cell. The thickness of this layer must vary with the osmotic concentration in the cell, with the specific composition of the colloid material of the cytoplasm and with the activity of the cell, but it should not exceed a few hundredths of a milimetre (0·02–0·04 mm.), while it might be very much less in an animal cell the greatest diameter of which does not exceed 20 μ.

Numerous examples of such localisation may be observed in the confervoid protophyta. In Ulothrix, ordinarily, there is usually a remarkable condensation of the potassium at the ends of the cell on each transverse wall. The surface tension, on the basis of the deduction from the Gibbs-Thomson principle, should be, in all these cases, high on the lateral walls and low on those surfaces adjoining the transverse septa.

The use of this deduction may be extended. There are in cells various inclusions the composition of which gives them a different surface tension from that prevailing in the external limiting area of the cell. Further, the limiting portion of the cytoplasm in contact with these inclusions must have surface tension also. When, therefore, we find by microchemical means that a condensation of an inorganic element or compound obtains immediately within or without an inclusion, we may conclude that there, as compared with the external surface of the cell, the surface tension is low. It may be urged that the condensation is due to adsorption only; but this objection cannot hold, for in the Gibbs-Thomson phenomena the localisation of the solute at a part of the surface as the result of high tension elsewhere of the solution is, in all probability, due to adsorption, and is indeed so regarded.[1]

It is in this way that we can explain the remarkable localisation of potassium in the cytoplasm at the margins of the chromatophor in Spirogyra, and also the extraordinary quantities of potassium held in or on the inclusions in the mesophyllic cells of leaves. In infusoria (Vorticella, Paramœcium) the potassium present, apart from that in the stalk or ectosarc, is confined to one or more small granules or masses in the cytoplasm.

How important a factor this is in clearing the active portion of the cytoplasm of compounds which might hamper its action, a little consideration will show. In plants, very large quantities of salts are carried to the leaves by the sap from the roots, and among these salts those of potassium are the most abundant as a rule. Reaching the leaves, these salts do not return, and in consequence during the functional life of the leaves they accumulate in the mesophyllic cells in very large quantities, which, if they were not localised as described in the cell, would affect the whole cytoplasm and alter its action.

Enough has been advanced here to indicate that surface tension is not a minor feature in cell life. I would go even farther than this, and venture to say that the energy evolved in muscular contraction, that also involved in secretion and excretion, the force concerned in the phenomena of nuclear and cell division, and that force also engaged by the nerve cell in the production of a nerve impulse, are but manifestations of surface tension. On this view the living cell is but a machine, an engine, for transforming potential into kinetic and other forms of energy through or by changes in its surface energy.

To present an ample defence of all the parts of the thesis just advanced is more than I propose to do in this address. That would take more time than is customarily allowed on such an occasion, and I have, in consequence, decided to confine my observations to outlines of the points as specified.

It is not a new view that surface tension is the source of the muscular contraction. As already stated, the first to apply the explanation of this force as a factor in cellular movement was Engelmann in 1869, who advanced the view that those changes in shape of cells which are classed as contractile are all due to that force which is concerned in the rounding of a drop of fluid. The same view was expressed by Rindfleisch in 1880, and by Berthold

[1] See Freundlich, "Kapillarchemie," p. 50, 1909.

in 1886, who explained the protoplasmic streaming in cells as arising in local changes of surface tension between the fluid plasma and the cell sap, but he held that the movement and streaming of Amœbæ and Plasmodiæ are not to be referred to the same causes as operate in the protoplasmic streaming in plant cells. Quincke in 1888 applied the principle of surface tension in explaining all protoplasmic movement. In his view the force operates, as in the distribution of a drop of oil on water, in spreading protoplasm, which contains oils and soaps, over surfaces in which the tension is greater, and as soap is constantly being formed, the layer containing it, having a low tension on the surface in contact with water, will as constantly keep moving, and as a result pull the protoplasm with it. The movement of the latter thus generated will be continuous, and constitute protoplasmic streaming. In a similar way Bütschli explains the movement of a drop of soap emulsion, the layer of soap at a point on the surface of the spherule dissolving in the water and causing there a low tension and a streaming of the water from that point over the surface of the drop. This produces a corresponding movement in the drop at its periphery and a return central or axial stream directed to the point on the surface where the solution of the soap occurred and where now a protrusion of the mass takes place resembling a pseudopodium. In this manner, Bütschli holds, the contractile movements of Amœbæ are brought about. In these the chylema or fluid of the foam-like structure in the protoplasm is alkaline, it contains fatty acids, and, in consequence, soaps are present which, through rupture of the superficial vesicles of the foam-like structure at a point, are discharged on the free surface and produce there the diminution of surface tension that calls forth currents, internal and external, like those which occur in the case of the drop of oil emulsion.

The first to suggest that surface tension is a factor in muscular contraction was D'Arsonval, but it was Imbert who, in 1897, directly applied the principle in explanation of the contractility of smooth and striated muscle fibre. In his view the primary conditions are different in the former from what obtain in the latter. In smooth muscle fibre the extension is determined, not by any force inside it, but by external force such as may distend the organ (intestine, bladder, and arteries) in the wall of which it is found. The "stimulus" which causes the contraction increases the surface tension between the surface of the fibre and the surrounding fluid, and this of itself has the effect of making the fibre tend to become more spherical or shorter and thicker, which change in shape does occur during contraction. He did not, however, explain how the excitation altered the surface tension, except to say that its effect on surface tension is like that of electricity, with which the nerve impulse presents some analogy. In striated fibre, on the other hand, the discs constituting the light and dim bands have each a longitudinal diameter which is an effect of its surface tension, and this causes extension of the fibre during rest. When a nerve impulse reaches the fibre the surface tension of the discs is altered, and there results a deformation of each involving a shortening of its longitudinal axis, and thus a shortening of the whole fibre.

According to Bernstein, in both smooth and striated muscle fibre there is, in addition to surface tension, an elastic force residing in the material composing the fibre which, according to the conditions, sometimes opposes and sometimes assists the surface tension. The result is that in the muscle fibre at rest the surface must exceed somewhat that of the fibre in contraction. In both conditions the sum of the two forces, surface tension and elasticity, must be zero. In contraction the surface tension increases, and with it the elasticity also. Taken as a whole, this would not explain the large force generated in contraction, for the energy liberated would be the product of the surface tension and the amount representing the diminution of the surface due to the contraction. As the latter is very small the product is much below the amount of energy in the form of work done actually manifested. To get over this difficulty, Bernstein postulates that in muscle fibres, whether smooth or striated, there are fibrils surrounded by sarcoplasma, and that each fibril is formed of a number of cylinders or biaxial ellipsoids singly disposed in the course of the fibril, but separated from each other by elastic material and surrounded by sarcoplasma. Between the ellipsoids and the sarcoplasma there is considerable surface tension which prevents mixture of the substances constituting both. The excitation through the nerve impulse causes an increase of surface tension in these ellipsoids, and they become more spherical. In consequence, the decrease in surface of all the ellipsoids constituting a fibril is much greater than if the fibril were to be affected as an individual unit only by an increase of surface tension, and thus the surface energy developed would be correspondingly greater. The ellipsoids, Bernstein explains, are not to be confused with the discs, singly and doubly refractive in striated fibre; for these, he holds, are not concerned in the generation of the contraction, but with the processes that make for rapidity of contraction. The extension of a muscle after contraction is due to the elastic reaction of the substance between the ellipsoids in the fibrils. Bernstein further holds that fibrils of this character occur in the protoplasm of Amœbæ, in the stalk of Vorticella, and in the ectoplasma of Stentor, and this explains their contractility.

It may be said in criticism of Bernstein's view that his ellipsoids are from their very nature non-demonstrable structures, and, therefore, must always remain as postulated elements only. Further, it may be pointed out that he attributes too small a part to surface tension in the lengthening of the fibre after contraction, and that the elasticity which muscle appears to possess is, in the last analysis, but a result of its surface tension.

As regards Quincke's explanation of protoplasmic movement and streaming, as well as of muscular contraction, Bütschli has shown that it is based on a mistaken view of the structure of the cell in Chara and other plant forms in which protoplasmic streaming occurs. Bütschli's own hypothesis, however, is defective in that it postulates a current in the fluid medium just outside the Amœba and backward over its surface, the existence of which Berthold denies, and Bütschli himself has been unable to demonstrate, even with the aid of fine carmine powder in the fluid. He did, indeed, observe a streaming in the water about a creeping Pelomyxa, but the current was in the opposite direction to that demanded by his hypothesis. Further, his failure to demonstrate the occurrence of the postulated backflow in the water about the contracting or moving mass of an Amœba or a Pelomyxa makes it difficult to accept the hypothesis he advanced to explain that backflow, namely, that rupture of peripheral vesicles (*Waben*) of the protoplasm occurs with a consequent discharge of their contents (proteins, oils, and soaps) into the surrounding fluid. Surface tension, further, on this hypothesis, would be an uncertain and wasteful factor in the life of the cell. On *a priori* grounds, also, it would seem improbable that this force should be generated outside instead of inside the cell.

One common defect of all these views is that they made only a limited application of the principle of surface tension. This was because some of its phenomena were unknown, and especially those illustrating the Gibbs-Thomson principle. With its aid and with the knowledge of the distribution of inorganic constituents in animal and vegetable cells that microchemistry gives us we can make a more extended application of surface tension as a factor in cellular life than was possible ten years ago.

In regard to muscle fibre this is particularly true, and microchemistry has been of considerable service here. From the analyses of the inorganic constituents of striated muscle in vertebrates made by J. Katz and others we know that potassium is extraordinarily abundant therein, ranging from three and a half in the dog to more than fourteen times in the pike the amount of sodium present. How the potassium salt is distributed in the fibre was unknown before 1904, in which year, by the use of a method, which I had discovered, of demonstrating the potassium microchemically, the element was found localised in the dim bands. Later and more extended observations suggested that in the dim band itself, when the muscle fibre is at rest, the potassium is not uniformly distributed, and it was found to be the case in the wing muscles of certain of the Insecta—as, for example, the scavenger beetles—in which the bands are broad and conspicuous enough to permit ready observation on this score. In these the potassium salt was found to be localised in the zones of each dim band adjacent to each light band. Subsequently Miss M. L. Menten, working in my laboratory and using the same microchemical method, found the potassium similarly limited in its distribution in the muscle fibres of a number of other insects. She determined, also, that the chlorides and phosphates have a like distribution in these structures, and it is consequently probable that sodium, calcium, and magnesium have the same localisation.

Macdonald has also made investigations on the distribution of potassium in the muscle fibre of the frog, crab, and lobster, using for this purpose the hexanitrite reagent. He holds, as a result of his observations, that the element in the uncontracted fibril is limited to the sarcoplasm in the immediate neighbourhood of the singly refractive substance, while it is abundantly present in the central portion of each sarcomere of the contracted fibril—that is, in the doubly refractive material. I am not inclined to question the former point, as I have not investigated the microchemistry of the muscle in the crab and lobster, and my only criticism would be directed against placing too great reliance on the results obtained in the case of frog's muscle. The latter is only very slowly penetrated by the hexanitrite reagent, and, apparently because of this, alterations in the distribution of the salts occur; and, as I have observed, the potassium may be limited to the dim bands of one part of the contracted fibre and may be found in the light bands of another part of the same. In the wing muscles of insects in the uncontracted condition such disconcerting results are not so readily obtained, owing, it would seem, to the readiness with which the fibrils may be isolated and the almost immediate penetration of them by the reagent. Here there is no doubt about the occurrence of the element in the zones of the dim band immediately adjacent to the light bands.

Whether the potassium in the resting fibre is in the sarcoplasm or in the sarcostyle I would hesitate to say. It may be as Macdonald claims; but I find it difficult to apply in microchemical studies of muscle fibre the concepts of its more minute structure gained from merely stained preparations. Because of this difficulty I have refrained from using here, as localising designations, other expressions than "light bands" and "dim bands." The latter undoubtedly include some sarcoplasm, but in the case of the resting fibre I am certain only of the presence of potassium, as described, in the dim band regarded as an individual part, and not as a composite structure.

Now, on applying the Gibbs-Thomson principle enunciated above, this distribution would seem to indicate that in the dim band of a fibril the surface tension is greatest on its lateral walls, in consequence of which the potassium salts are concentrated in the vicinity of the remaining surfaces, *i.e.* those limiting the light bands. This explanation would seem to be confirmed by the observations I made on the contracted fibrils of the wing muscles of a scavenger beetle. In these the potassium was found uniformly distributed throughout each dim band, which, instead of being cylindrical in shape as in the resting element, is provided with a convexly curved lateral wall, and therefore with a smaller surface than the mass of the dim band has when at rest. This contour suggests that the surface tension on the lateral wall is lessened to an amount below that of either terminal surface, followed by a redistribution of the potassium salt to restore the equilibrium thus disturbed. The consequent shortening of the dim bands of the fibrils would account for the contraction of the muscle.

How the surface tension of the lateral wall of the dim band is lessened in contraction is a question which can only be answered after much more is known of the nature of the nerve impulse as it reaches the muscle fibril, and of the part played by the energy set free in the combustion process in the dim bands. It may be that electrical polarisation, as a result of the arrival of the nerve impulse, develops on the surface of the lateral wall, and as a consequence of which its surface tension is diminished. The energy so lost appears as work, and it is replaced by energy, one may suppose, derived from the combustion of the material in the dim band. In this case the disturbance of surface tension would be primary, while the combustion process would be secondary, in the order of time. In support of this explanation may be cited the fact that the current of action in muscle precedes in time the contraction itself—that is, the electrical response of the stimulus occurs in the latent period and immediately before the contraction begins.

It may, however, be postulated, on the other hand, that the chemical changes occur in those parts of the dim band immediately adjacent to the light bands, and as a result the tension of the terminal surfaces may be increased, this resulting in the shortening of the longitudinal axis of the dim band and the displacement laterally of the contents. This would imply that the energy of muscle contraction comes primarily from that set free in the combustion process, and not indirectly as involved in the former explanation.

Whatever may be the cause of the alteration in surface tension, there would seem to be no question of the latter. The very alteration in shape of the dim band in contraction makes it imperative to believe that surface tension is concerned. The redistribution of the potassium which takes place as described in the contracting fibrils of the wing muscles of the scavenger beetle can be explained in no other way than through the alteration of surface tension.

In the smooth muscle fibre potassium is also present and in close association throughout with the membrane. When a fresh preparation of smooth muscle is treated so as to demonstrate the presence of potassium, the latter is shown in the form of a granular precipitate of hexanitrite of sodium, potassium, and cobalt in the cement substance between the membranes of the fibres. In the smooth muscle fibres in the walls of the arteries in the frog the precipitate in the cement material is abundant, and its disposition suggests that it plays some part in the *rôle* of contraction. Inside of the membrane potassium occurs, but in very minute quantities, which, with the cobalt sulphide method, gives a just perceptible dark shade to the cytoplasm as a whole. Microchemical tests for the chlorides and phosphates indicate that the cytoplasm is almost wholly free from them, and consequently there is very little inorganic material inside of the fibre. Chlorides and phosphates, but more particularly the former, are abundant in the cement material, and their localisation here would seem to indicate that the potassium of the same distribution is combined chiefly as chloride.

In smooth muscle fibre, then, the potassium is distributed very differently from what it is in striated fibre, and on first thought it seemed difficult to postulate that the contraction could be due to alterations of surface tension. This, however, would appear to be the most feasible explanation, for the potassium salts in the cement substance might be supposed to shift their position under the influence of electrical force so as to reach the interior of the membranes of the fibres, in which case the surface tension of the latter would be immediately increased, and the fibre itself would in consequence at once begin to contract. The slowness with which this shifting into, or absorption by, the membrane of the potassium salts would take place would also account for the long latent period of contraction in smooth muscle.

It is of interest here to note that the potassium ions have the highest ionic mobility (transport number) of all the elements of the kationic class, except hydrogen, which are found to occur in connection with living matter. Its value in this respect is half again as great as that of sodium, one-eighth greater than that of calcium, and one-seventh greater than that of magnesium. This high migration velocity of potassium ions would make the element of special service in rapid changes of surface tension.

Loew has pointed out that potassium in the condensation processes of the synthesis of organic compounds has a catalytic value different from that of sodium. For example, ethyl aldehyde is condensed with potassium salts to aldol, with sodium salts to crotonic aldehyde (Kopf and Michael). Potassium is, but sodium is not, effective in the condensation of carbon monoxide. When phenol is fused with potassium salts condensation products like diphenol are produced, but when sodium salts are used the products are dioxybenzol and phloroglucin (Barth). It is, therefore, not improbable that potassium, along with those properties which come from its ionic mobility, has a special value in the metabolism of the dim bands of striated muscle fibre and in the condensation synthesis which characterise the chromatophors of protophyta (Spirogyra, Zygnema).

With the use of this method of determining differences in surface tension in cells it is possible, in some cases at least, to ascertain whether this force plays a part in both secretion and excretion, and evidence in favour of this view can be found in the pancreatic cells of the rabbit, guinea-pig, and in the renal cells of the frog. In the pancreatic cells there is an extraordinary condensation of potassium salts in the cytoplasm of each cell adjacent to the lumen of the tubule, and during all the phases of activity—except, it would appear, that of the co-called "resting stage"—potassium salts occur in, and are wholly confined to, this part of each cell. It is difficult to say whether they pass into the lumen with the secretion and their place taken by more from the blood-stream and lymph, but the important point is that the condensation of potassium salts immediately adjacent to the lumen seems to indicate a lessened surface tension on the lumen surface of the cell.

According to Stoklasa,[1] the pancreas of the pig is much richer in potassium than in sodium, the dried material containing 2·09 per cent. of potassium and 0·28 per cent. of sodium, while the values for the dried material of ox muscle are, as he determined them, 1·82 and 0·26 per cent. respectively. It is significant that in the pancreas this large amount of potassium should be localised as described.

In the renal cells of vertebrates there is usually a considerable amount of potassium salts distributed throughout the cytoplasm. These cells are always active in the elimination of the element from the blood, and it is in consequence not possible to determine whether there are differences in surface tension in them. Under certain conditions, however, these can be demonstrated. In the frogs which have been kept in the laboratory tanks throughout the winter, and in the blood of which the inorganic salts have been, because of the long period of inanition, reduced to almost hypotonic proportions, the renal cells are very largely free from potassium. When it is present it is usually diffused throughout the cytoplasm. If now a few cubic centimetres of a decinormal solution of potassium chloride be injected into the dorsal lymph sacs of one of these frogs, and after twenty minutes the animal is killed, appropriate treatment, with the cobalt reagent, of a thin section of the fresh kidney made by the carbon dioxide freezing method, reveals in the cells of certain of the tubules a condensation of potassium salts in the cytoplasm immediately adjacent to the wall of the lumen. There is also a very slight diffuse reaction throughout the remainder of the cytoplasm, except in that part immediately adjacent to the external boundary of the tubule. In these cells the potassium injected into the lymph circulation is being excreted, and the condensation of the element at or near the surface of the lumen is evidence that there the tension is less than at the other extremity of the cell.

These facts are in their significance in line with some observations that I have made on the absorption of soluble salts by the intestinal mucosa in the guinea-pig. When the "peptonate" of iron was administered in the food of the animal it was not unusual to find that in the epithelial cells of the villi the iron salt was distributed through the cytoplasm, but its concentration, as a rule, was greatest in the cytoplasm adjacent to the inner surface of the cell, from which it diffused into the underlying tissue. Here also, inferentially, surface tension is lower than elsewhere in the cell.

It would perhaps be unwise to form final conclusions at this stage in the progress of the investigation of the subject, but the results so far gained tempt one to adopt as a working hypothesis *that in the secreting or the excreting cell lower surface tension exists at its secreting or excreting surface than at any other point on the cell surface.* How this low surface tension is caused or maintained it is impossible to say, but, whatever the solution of the question may be, it is important to note that we must postulate the participation of this force in renal excretion in order to explain the formation of urines of high concentration. These have a high osmotic pressure, as measured by the depression of the freezing point, while the osmotic pressure of the blood plasma determined in the same way is low. On the principle of osmosis alone, as it is currently understood, this result is inexplicable, for the kinetic energy, as required in the gas theory of solutions, should not be greater, though it might be less, in the urine than in the blood. It is manifest that in the formation of concentrated urines energy is expended. We know also from the investigations of Barcroft and Brodie that the kidney during diuresis absorbs much more oxygen per gram weight than the body generally, and that, assuming it is used in the combustion of a proteid, a very large amount of energy is set free, very much more, indeed, than is necessary. It has also been observed that a portion of the energy set free is found in a higher temperature in the excretion than obtains in the blood itself circulating through the kidney. This large expenditure of energy is, probably, a result of the physiological adaptation of the principle of the "factor of safety," which, as Meltzer has pointed out, occurs in other organs of the body.

In cell and nuclear division surface tension operates as a force, the action of which cannot be completely understood until we know more of the part played by the centrosomes and centrosphere. That this force takes part in cell reproduction has already been suggested by Brailsford Robertson. He has devised an ingenious experiment to illustrate its action. If a thread moistened with a solution of a base is laid across a drop of oil in which is dissolved some free fatty acid, the drop divides along the line of the thread. When the latter is moistened with soap the drop divides in the same way and in the same plane. The soap formed in one case and present in the other, it is explained, lowers the surface tension in the equatorial plane of the drop, and this diminution results in streaming movement away from that plane which bring about the division. He suggests that in cell division there is a liberation of soaps in the plane of division which set up streaming movements from that plane towards the poles, and terminating in the division of the cytoplasm of the cell.

I have observed in the cells of Zygnema about to divide a remarkable condensation of potassium in the plane of division. In the "resting" cell of this Alga the potassium is, as a rule, more abundant in the cytoplasm near the transverse walls of the thread, and only traces of the element are to be found along the line of future division of the cell. But immediately after division has taken place the potassium is concentrated in the plane of division. This would seem to indicate that surface tension in the plane of division is, as postulated by the deduction from the Gibbs-Thomson principle, lower than it is on the longitudinal surface, and lower, especially, than it is on the previously formed transverse septa of the thread.

One must not, however, draw from this the conclusion that in all dividing cells surface tension is lower in the plane of division than it is elsewhere on the surface of the dividing structure. All that it means is that in the dividing cell of Zygnema the condition already exists along the plane of division, which subsequently makes for low surface tension in the cell membrane immediately adjacent to each transverse septum in the confervoid thread. If the evidence of low surface tension vanished immediately after division was complete, then it might be held that it determined the division. As it is, the low surface tension in this case is the result, and not the cause, of the division.

This conclusion is corroborated by the results of observations on the cells of the ovules of Lilium and Tulipa. The potassium salts in these are found condensed in minute masses throughout the cytoplasm. When division is about to begin the salts are shifted to the peripheral zone of the cytoplasm, and when the nuclear membrane disappears not a trace of potassium is now

[1] Stoklasa gave the values in K_2O and Na_2O.

found in the neighbourhood of the free chromosomes, a condition which continues until after nuclear division is complete. The absence of potassium, the most abundant basic element in the cytoplasm, would indicate that soaps are not present, and appropriate treatment of such cells, hardened in formaline only, with scarlet red demonstrates that fats, including lecithins, are absent also. This would seem to show that high instead of low surface tension prevails about the nucleus during division. During the "resting" condition of the nucleus this high tension is maintained, for, except in very rare cases, and these of doubtful character, there is no condensation of inorganic salts in the neighbourhood or on the surface of the nuclear membrane. It is also to be noted that the nucleus, with exceptions, the majority of which are found in the Protozoa, is of spherical shape, which also postulates that high surface tension obtains either in the cytoplasmic layer about the nucleus or in the nuclear membrane itself. It may also be suggested that high surface tension, and not the physical impermeability of the nuclear membrane, is the reason why the nucleus is, as I have often stated, wholly free from inorganic constituents.

It does not follow from all this that surface tension has nothing to do with cell division. If, as Brailsford Robertson holds, surface tension is lowered in the plane of division, then the internal streaming movement of the cytoplasm of each half of the cell should be towards that plane, and, in consequence, not separation, but fusion of the two halves would result. The lipoids and soaps would, indeed, spread superficially on the two parts from the equatorial plane towards the two poles, and, according to the Gibbs-Thomson principle, they would not distribute themselves through the cytoplasm in the plane of division, except as a result of the formation of a septum in that plane. In other words, the septum has first to exist in order to allow the soaps and lipoids to distribute themselves in a streaming movement over its two faces. In Brailsford Robertson's experiment this septum is provided in the thread. If, on the other hand, surface tension is higher about the nucleus in and immediately adjacent to the future plane of division, then constriction of the nucleus in that plane will take place accompanied or preceded by an internal streaming movement in each half towards its pole, and a consequent traction effect on the chromosomes which are thus removed from the equatorial plane. When nuclear division is complete, then a higher surface tension on the cell itself limited to the plane of division would bring about there a separation of the two halves, a consequent condensation on each side of that plane of the substances producing the low tension elsewhere, and thereby also the formation of the two membranes in that plane.

In support of this explanation of the action of surface tension as a factor in division I have endeavoured to ascertain if, as a result of the Gibbs-Thomson principle, there is a condensation of potassium salts in the cytoplasm at the poles of a dividing cell, that is, where surface tension, according to my view, is low. The difficulty one meets here is that, in the higher plant forms, cells preparing to divide appear to be much less rich in potassium than those in the "resting" stage, and under this condition it is not easy to get unambiguous results, while in animal cells potassium may even in the resting cell be very minute in quantity, as, for example, in Vorticella, in which, apart from the contractile stalk, it is limited to one or two minute flecks in the cytoplasm. Instances of potassium-holding cells undergoing division are, however, found in the spermatogonia of higher vertebrates (rabbit, guinea-pig), and in these the potassium is gathered in the form of a minute and thin cap-like layer at each pole of the dividing cell.

This of itself would appear to show that surface tension is less in the neighbourhood of the poles than at the equator of the dividing cell; but I am not inclined to regard the fact as conclusive, and a very large number of observations to that end must be made before certainty can be attained. I am, nevertheless, convinced that it is only in this way that we can finally determine whether differences of surface tension in dividing cells account, as I believe they do, for all the phenomena of cell division. The difficulties to be encountered in such an investigation are, as experience has shown me, much greater than are to be overcome in efforts to study surface tension in cells under other conditions, but I am in hopes that what I am now advancing will influence a number of workers to take up research in microchemistry along this line.

I must now discuss surface tension in nerve cells and nerve fibres. I have stated earlier in this address that I hold that the force concerned in the production of the nerve impulse by the nerve cell is surface tension. The very fact that in the repair of a divided nerve fibre the renewal of the peripheral portion of the axon occurs through a movement—a flowing outward, as it were—of the soft colloid material from the central portion of the divided fibre is, in itself, a strong indication that surface tension is low here and high on the cell body itself. This fact does not stand alone. I pointed out six years ago that potassium salt is abundant along the course of the axon and apparently on its exterior surface, while it is present but in traces in the nerve cell itself. In the latter chlorides also are present only in traces, and therefore sodium, if present, is there in more minute quantities, while haloid chlorine is abundant in the axon. Macdonald has also made observations as to the occurrence of potassium along the course of the axon, and has in the main confirmed mine. We differ only as to mode of the distribution of the element in the axon, and the manner in which it is held in the substance of the latter; but, whichever of the two views may be correct, it does not affect what I am now advancing. Extensive condensation or adsorption of potassium salts in or along the course of the axon, while the nerve cell itself is very largely free from them, can have but one explanation on the basis of the Gibbs-Thomson principle, and that explanation is that surface tension on the nerve cell itself must be high while it is low on or in its axon.

The conclusions that follow from this are not far to seek. We know that an electrical displacement or disturbance of ever so slight a character occurring at a point on the surface of a drop lowers correspondingly the surface tension at that point. What a nerve impulse fundamentally involves we are not certain, but we do know that it is always accompanied by, if not constituted of, a change of electrical potential, which is as rapidly transmitted as is the impulse. When this change of potential is transmitted along an axon through its synaptic terminals to another cell, the surface tension of the latter must be lowered to a degree corresponding to the magnitude of the electrical disturbance produced, and, in consequence, a slight displacement of the potassium ions would occur at each point in succession along the course of its axon. This displacement of the ions as it proceeded would produce a change of electrical potential, and thus account for the current of action. The displacement of the ions in the axon would last as long as the alteration of surface tension which gave rise to it, and this would comprehend not more than a very minute fraction of a second. Consequently, many such variations in the surface tension of the body of the nerve cell would occur in a second; and, as the physical change concerned would involve only the very surface layer of the cell, a minimum of fatigue would result in the cell, while little or none would develop in the axon.

It may be pointed out that in medullated nerve fibres the lipoid-holding sheath, in close contact as it is with the axon, must of necessity maintain on the course of the latter a surface tension low as compared with that on the nerve cell itself, which, as the synaptic relations of other nerve cells with it postulate, is not closely invested with an enveloping membrane. In non-medullated nerve fibres the simple enveloping sheath may function in the same manner, and probably, if it is not rich in lipoid material, in a less marked degree.

What further is involved in all this, what other conclusions follow from these observations, I must leave unexplained. It suffices that I have indicated the main points of the subject, the philosophical significance of which will appear to those who will pursue it beyond the point where I leave it.

In bringing this address to a close, I am well aware of the fact that my treatment of the subjects discussed has not been as adequate as their character would warrant.

The position which I occupy imposes limits, and there enters also the personal factor to account in part for the failure to achieve the result at which I aimed. But there is, besides, the idea that in applying the laws of surface tension in the explanation of vital phenomena I am proceeding along a path into the unknown which has been as yet only in a most general way marked out by pioneer investigators, and in consequence, to avoid mistakes, I have been constrained to exercise caution, and to repress the desire to make larger ventures from the imperfectly beaten main road. Perhaps, after all, I may have fallen into error, and I must therefore be prepared to recall or to revise some of the views which I have advanced here should they ultimately be found wanting. That, however, as I reassure myself, is the true attitude to take. It is a far cry to certainty. As Duclaux has aptly put it, the reason why Science advances is that it is never sure of anything. Thus I justify my effort of to-day.

Notwithstanding this inadequate treatment of the subject of surface tension in relation to cellular processes, I hope I have made it in some measure clear that the same force which shapes the raindrop is an all-important factor in the causation of vital phenomena. Some of the latter may not thereby be explained. We do not as yet know all that is concerned in the physical state of solutions. The fact, ascertained by Rona and Michaelis, that certain sugars, which neither lower nor appreciably raise surface tension in their solutions, condense or are adsorbed on the surface of a solution system, is an indication that there are at least some problems with a bearing on vital phenomena yet to solve. Nevertheless, what we have gained from our knowledge of the laws of surface tension constitutes a distinct step in advance, and a more extended application of the Gibbs-Thomson principle may throw light on the causation of other vital phenomena. To that end a greatly developed science of microchemistry is necessary. This should supply the stimulus to enthusiasm in the search for reactions that will enable us to locate with great precision in the living cell the constituents, inorganic and organic, which affect its physical state and thereby influence its activity.

SECTION K.

BOTANY.

Opening Address by Prof. James W. H. Trail, M.A., M.D., F.R.S., President of the Section.

The honour conferred in the election to be President for the year of the Botanical Section of the British Association imposes the duty of preparing an address. I trust that my selection of a subject will not be attributed by anyone to a want of appreciation of the worth and importance of certain sides of botanical research to which I shall have less occasion to refer. These have been eloquently supported by former Presidents, and I take this opportunity to express the thanks I owe for the benefit received from their contributions to the advancement of the science of botany. They have told us of the advance in departments of which they could speak as leaders in research, and I do not venture to follow in their steps. My subject is from a field in which I have often experienced the hindrances of which I shall have to speak, both in personal work and still more as a teacher of students, familiar with the many difficulties that impede the path of those who would gladly give of their best, but find the difficulties for a time almost insurmountable, and who are too frequently unable to spare the time or labour to allow of their undertaking scientific investigations that they might well accomplish, and in which they would find keen pleasure under other conditions. Those whose tastes lie in the direction of studying plants in the field rather than in the laboratory are apt to find themselves hampered seriously if they seek to become acquainted with the plants of their own vicinity; and, if they wish to undertake investigations in the hope of doing what they can to advance botanical science, they may find it scarcely possible to ascertain what has been already done and recorded by others.

For a time the knowledge of plants was too much confined to the ability to name them according to the system in vogue and to a knowledge of their uses, real or imagined. The undue importance attached to this side of the study, even by so great a leader as Linnæus, naturally led to a reaction as the value of other aspects of botany came to be realised, and as improvements in the instruments and methods of research opened up new fields of study. The science has gained much by the reaction; but there is danger of swinging to the other extreme and of failing to recognise the need to become well acquainted with plants in their natural surroundings. The opportunities for study in the laboratory are so great and so much more under control, and the materials are so abundant and of so much interest, that there is for many botanists a temptation to limit themselves to such work, or at least to regard work in the field as subordinate to it and of little value. It is scarcely necessary to point out that each side is insufficient alone. Yet some find more pleasure in the one side, and do well to make it their chief study; while they should recognise the value of the other also, and learn from it.

It is especially on behalf of the work in the field that I now wish to plead. There are few paths more likely to prove attractive to most students. The study of the plants in their natural environments will lead to an understanding of their nature as living beings, of their relations to one another and to other environments, of the stimuli to which they respond, and of the struggle for existence that results in the survival of certain forms and the disappearance of others. In this way also will be gained a conception of the true meaning and place of classification as an indispensable instrument for accurate determination and record, and not as an end in itself. To one that has once gained a true insight into the pleasure and worth of such studies, collections made for the sake of mere possession or lists of species discovered in a locality will not suffice. Many questions will arise which will prove a constant source of new interest. From such studies a deep and growing love for botany has in not a few cases arisen.

The British flora has interested me for upwards of forty years, and has occupied much of my attention during that time—not only as desirous to aid by my own efforts to extend our knowledge of it, but also, as a teacher, seeking to assist my students to become able to do their parts also, and making use of the materials within reach to enable me to help them. Thus our present knowledge of the plants of our own country has become known to me, and the difficulties of acquiring that knowledge have also become known through both my own experience and those of my students. The nature of the hindrances and difficulties that at present bar the way has also become familiar, as well as the steps to be taken to clear some of them away and to make the path less difficult to those who come after us; and I have also gained a fairly good acquaintance with the means at the command of students of the floras of other countries, so as to have a standard for comparison in the estimate to be formed of the condition of matters in our own country.

In how far is the present provision for the study of the flora of the British Islands sufficient and satisfactory?

I venture to hope that the subject will be regarded as among those for the consideration of which the British Association was formed, and that a favourable view will be taken of the conclusions which I take this opportunity to lay before you. What, then, is the present provision for the study of our plants? Since the days of Morrison and Ray there have been many workers, especially during the past century; and an extensive literature has grown up, in the form both of books and of papers, the latter more or less comprehensive, in the scientific journals and in the transactions of societies. These papers contain much that is of great value; but, owing to the absence of any classified index, most of the information in it is beyond the reach of anyone, except at the expenditure of much time and labour. The constantly increasing accumulation of new publications makes the need for a classified index always more urgent; for the mass of literature is at present one of the greatest obstacles to the undertaking of new investigations, because of the uncertainty whether they may not have been already undertaken and overlooked through want of time or opportunity to search the mass exhaustively.

While the early writers of descriptive floras sought to include every species of plant known to occur in Britain, this has not been attempted during the past seventy or eighty years, and instead of one great work we now have monographs of the greater groups, such as Babington's "Manual" and Hooker's "Student's Flora" of the vascular plants, Braithwaite's "Mossflora," &c. Local floras still, in a good many cases, aim at including all plants known to grow apparently wild in the districts to which they refer; but they are often little more than lists of species and varieties and of localities in which these have been found. In some, however, there are descriptions of new forms and notes of general value, which are apt to be overlooked because of the place in which they appear.

The early works were necessarily not critical in their treatment of closely allied species and varieties, but they are valuable as giving evidence of what plants were supposed to be native in England when they were published. Even the works that were issued after Linnæus had established the binominal nomenclature for a time related almost wholly to England. Sibbald in "Scotia Illustrata" (1684) enumerated the plants believed by him to be native in Scotland, and of those then cultivated. Between his book and Lightfoot's "Flora Scotia," published in 1777, very little relating to the flora of Scotland appeared. Irish plants were still later in being carefully studied.

The floras of Hudson, Withering, Lightfoot, and Smith, all of which include all species of known British plants, follow the Linnæan classification and nomenclature in so far as the authors were able to identify the Linnæan species in the British flora. "English Botany," begun in 1795, with plates by Sowerby and text by Smith, was a work of the first rank in its aim of figuring all British plants and in the excellence of the plates; but it shared the defect of certain other great floras in the plates being prepared and issued as the plants could be procured, and thus being without order. Its cost also necessarily put it beyond the reach of most botanists, except those that had the advantage of access to it in some large library. A second edition, issued at a lower price, and with the plants arranged on the Linnæan system, was inferior to the first, in the plates being only partially coloured and in having the text much curtailed. The so-called third edition of the "English Botany," issued 1868–86, is a new work so far as the text is concerned, that being the work of Dr. Boswell Syme, who made it worthily representative of its subject; but the plates, with few exceptions, are reissues of those of the first edition, less perfect as impressions and far less carefully coloured; and this applies with still greater force to a reissue of the third edition a few years ago. This edition, moreover, included only the vascular plants and Characeæ. As this is the only large and fully illustrated British flora that has been attempted, it is almost needless to add that in this respect provision for the study of the flora of our islands is far behind that of certain other countries, and very notably behind that made in the "Flora danica."

Turning next to the provision of less costly aids to the study of British plants, we have manuals of most of the larger groups. The vascular plants are treated of in numerous works, including a considerable number of illustrated books in recent years, inexpensive but insufficient for any but the most elementary students. Fitch's outline illustrations to Bentham's "Handbook to the British Flora," supplemented by W. G. Smith, were issued in a separate volume in 1887, which is still the best for use in the inexpensive works of this kind. Babington's "Manual," on its first appearance in 1843, was gladly welcomed as embodying the result of careful and continued researches by its author into the relations of British plants to their nearest relatives on the Continent of Europe; and each successive issue up to the eighth in 1881 received the careful revision of the author, and contained additions and modifications. In 1904 a ninth edition was edited, after the author's death, by H. and J. Groves; but, though the editors included notes left by Prof. Babington prepared for a new edition, they were "unable to make alterations in the treatment of some of the critical genera which might perhaps have been desirable." The "Student's Flora of the British Islands," by Sir J. D. Hooker, issued in 1870, took the place of the well-known "British Flora" (1830, and in subsequent editions until the eighth in 1860, the last three being issued in collaboration by Sir W. J. Hooker and Prof. Walker-Arnott). The third edition of the "Student's Flora" appeared in 1884, and there has been none since. Mr. F. N. Williams's "Prodromus Floræ Britannicæ," begun in 1901, of which less than one-half has yet appeared, though a work of much value and authority, is scarcely calculated for the assistance of the ordinary student; and Mr. Druce's new edition of Hayward's "Botanist's Pocket Book" "is intended merely to enable the botanist in the field to name his specimens approximately, and to refresh the memory of the more advanced worker." In all the books that are intended for the use of British botanists, apart from one or two recently issued local floras, the classification is still that in use in the middle of last century, even to the extent in the most of them of retaining Coniferæ as a division of Dicotyledones. Apart from this, the critical study of British plants has led to the detection of numerous previously unobserved and unnamed forms, which find no place in the "Student's Flora," and are only in part noticed in the recent edition of the "Manual."

The "Lists" of vascular plants of the British flora that have recently been issued by Messrs. Rendle and Britten, by Mr. Druce, and as the tenth edition of the "London Catalogue of British Plants," are all important documents for the study of the British flora; but they illustrate very forcibly certain of the difficulties that beset the path of the student eager to gain a knowledge of the plants of his native land. In these lists he finds it scarcely possible to gain a clear idea of how far the species and varieties of the one correspond with those of the other, owing to the diversities of the names employed. It would be a great boon to others, as well as to students, were a full synonymic list prepared to show clearly the equivalence of the names where those for the same species or variety differ in the different lists and manuals. Probably in time an agreement will be generally arrived at regarding the names to be accepted, but that desirable consummation seems hardly yet in sight. Meantime, the most useful step seems to be to show in how far there is agreement in fact under the different names.

Among the Cryptogams certain groups have fared better than the higher plants as regards both their later treatment and their more adequate illustration by modern methods and standards. Several works of great value have dealt with the mosses, the latest being Braithwaite's "British Moss-flora," completed in 1899. The Sphagna were also treated by Braithwaite in 1880, and are to be the subject of a monograph in the Ray Society's series. The liverworts have been the subject also of several monographs, of which Pearson's is the fullest.

Among the Thallophyta, certain groups have been more satisfactorily treated than others—*e.g.* the Discomycetes, the Uredineæ and Ustilagineæ, the Myxomycetes, and certain others among the fungi, and the Desmidiaceæ among the algæ; but the Thallophyta as a whole are much in need of thorough revision to place them on a footing either satisfactory or comparable to their treatment in other countries.

Of the Thallophyta, many more of the smaller species will probably be discovered within our islands when close search is made, if we may judge by the much more numerous forms already recorded in certain groups abroad, and which almost certainly exist here also; but among the higher plants it is not likely that many additional species will be discovered as native, yet even among these some will probably be found. It is, however, rather in the direction of fuller investigation of the distribution and tendencies to variation within our islands that results of interest are likely to be obtained.

The labours of H. C. Watson gave a very great stimulus to the study of the distribution of the flora in England and Scotland, and the work he set on foot has been taken up and much extended by numerous botanists in all parts of the British Islands. It is largely owing to such work and to the critical study of the flora necessary for its prosecution that so many additions have been made to the forms previously known as British. Many local works have been issued in recent years, often of a very high standard of excellence. Besides these larger works, scientific periodicals and transactions of field clubs and other societies teem with records, some of them very brief, while others are of such size and compass that they might have been issued as separate books. A few of both the books and papers are little more than mere lists of names of species and varieties observed in a locality during a brief visit; but usually there is an attempt at least to distinguish the native or well-established aliens from the mere casuals, if these are mentioned at all. In respect of aliens or plants that owe their presence in a district to man's aid, intentional or involuntary, their treatment is on no settled basis. Every flora admits without question species that are certainly of alien origin, even such weeds of cultivated ground as disappear when cultivation is given up, as may be verified in too many localities in some parts of our country. Yet other species are not admitted, though they may be met with here and there well established, and at least as likely to perpetuate their species in the new home as are some native species.

Comparatively few writers seek to analyse the floras of the districts treated of with a view to determine whence each species came and how, its relation to man, whether assisted by him in its arrival directly or indirectly, whether favoured or harmfully affected by him, its relations to its environment—especially to other species of plants and to animals, and other questions that suggest themselves when such inquiries are entered on. It is very desirable that a careful and exhaustive revision of the British flora should be made on these and similar lines. In such a revision it is not less desirable that each species should be represented by a good series of specimens, and that these should be compared with similar series from other localities within our islands, and from those countries from which it is believed that the species originally was sprung. Such careful comparison would probably supply important evidence of forms being evolved in the new environments, differing to a recognisable degree from the ancestral types, and tending to become more marked in the more distant and longer isolated localities. An excellent example of this is afforded by the productive results of the very careful investigation of the Shetland flora by the late Mr. W. H. Beeby.

Within recent years excellent work has been done in the study of plant associations, but the reports on these studies are dispersed in various journals (often not botanical), and are apt to be overlooked by, or to remain unknown to, many to whom they would be helpful. The same is true in large measure of the very valuable reports of work done on plant-remains from peat-mosses, from lake deposits, and from other recent geological formations, researches that have cast such light on the past history of many species as British plants, and have proved their long abode in this country. Mr. Clement Reid's "Origin of the British Flora," though published in 1899, has already (by the work of himself and others) been largely added to, and the rate of progress is likely to become still more rapid. Among the fruits and seeds recorded from inter-glacial and even from pre-glacial deposits are some the presence of which could scarcely have been anticipated, *e.g.* *Hypecoum procumbens*, in Suffolk. Some of the colonists, or aliens now almost confined to ground under cultivation, have been recorded from deposits that suggest an early immigration into the British Islands. While much remains to be discovered, it is desirable that what is already established should find a place in the manuals of British botany.

Apart from the descriptive and topographical works and papers on our flora, there is a serious lack of information gained from the study of our British plants. Although a few types have received fuller study, we have little to compare with the work done in other countries on the structure and histology of our plants, on the effects of environment, on their relations to other species and to animals, and on other aspects of the science to which attention should be directed. On these matters, as on a good many others, we gain most of what information can be had, not from British sources, but from the literature of other countries, though it is not wise to assume that what is true elsewhere is equally true here. It is as well, perhaps, that for the present such subjects should find scanty reference in the manuals in ordinary use; but, when trustworthy information has been gained within the British Islands, under the conditions prevailing here, these topics should certainly not be passed over in silence. Students of the British flora have as yet no such works of reference as Raunkjaer's book on the Monocotyledons of Denmark or the admirable "Lebensgeschichte der Blütenpflanzen Mitteleuropas," at present being issued by Drs. Kirchner, Loew, and Schröter.

In a complete survey of the British botany there must be included the successive floras of the earlier geological formations, though they cannot as yet be brought into correlation with the recent or existing floras. In the brilliant progress made recently in this field of study our country and the British Association are worthily represented.

The present provision for the study of the British flora and the means that should be made use of for its extension appear to be these:—

Much excellent work has already been accomplished and put on record towards the investigation of the flora, but much of that store of information is in danger of being overlooked and forgotten or lost, owing to the absence of means to direct attention to where it may be found. A careful revision of what has been done and a systematic subject-index to its stores are urgently required.

The systematic works treating of the flora are in great part not fully representative of the knowledge already possessed, and require to be brought up to date or to be replaced by others.

Great difficulty is caused by the absence of an authoritative synonymic list that would show so far as possible the equivalence of the names employed in the various manuals and lists. There is much reason to wish that uniformity in the use of names of species and varieties should be arrived at, and a representative committee might assist to that end; but, in the meantime, a good synonymic list would be a most helpful step towards relieving a very pressing obstacle to progress.

There is need for a careful analysis of the flora with the view of determining those species that owe their presence here to man's aid, intentional or unconscious; and the inquiry should be directed to ascertain the periods and methods of introduction, any tendencies to become modified in their new homes, their subsequent relations with man, and their influence on the native flora, whether direct or by modifying habitats, as shown by *Lupinus nootkatensis* in the valleys of rivers in Scotland.

Those species that there is reason to regard as not having been introduced by man should be investigated as regards their probable origins and the periods and methods of immigration, evidence from fossil deposits of the period during which they have existed in this country, their constancy or liability to show change during this period, their resemblance to or differences from the types in the countries from which they are believed to have been derived, or the likelihood of their having originated by mutation or by slow change within the British Islands, and their relation to man's influence on them (usually harmful, but occasionally helpful) as affecting their distribution and permanence.

The topographical distribution, though so much has been done in this field during the past sixty or seventy years, still requires careful investigation to determine, not merely that species have been observed in certain districts, but their relative frequency, their relations to man (natives of one part of our country are often aliens in other parts), whether increasing or diminishing, altitudes, habitats, &c. From such a careful topographical survey much should be learned of the conditions that favour or hinder the success of species, of the evolution of new forms and their relation to parent types in distribution, especially in the more isolated districts and islands, and of other biological problems of great interest. A most useful aid towards the preparation of topographical records would be afforded by the issue at a small price of outline maps, so as to allow of a separate map being employed for recording the distribution of each form.

A careful study of the flora is also required from the point of view of structure and development, with comparison of the results obtained here with those of workers in other countries where the same or closely allied species and varieties occur. It is also needed in respect of the relations between the plants and animals of our islands, both as observed here and in comparison with the already extensive records of a similar kind in other countries. On such topics as pollination, distribution of seeds, and injuries inflicted by animals and galls produced by animals or plants we have still to make use very largely of the information gained abroad; and the same holds good with regard to the diseases of plants.

While "English Botany" in its first edition was deservedly regarded as a work of the first rank among floras, it has long been defective as representing our present knowledge of British plants, and it has not been succeeded by any work of nearly equal rank, while other countries now have their great floras of a type in advance of it. There is need for a great work worthy of our country, amply illustrated so as to show, not only the habit of the species and varieties, but also the distinctive characters and the more important biological features of each. Such a flora would probably require to be in the form of monographs by specialists, issued as each could be prepared, but as part of a well-planned whole. It should give for each plant far more than is contained in even the best of our existing British floras. Means of identification must be provided in the description, with emphasised diagnostic characters; but there should also be the necessary synonymy, a summary of topographical distribution, notes on man's influence upon distribution, abundance, &c., on any biological or other point of interest in structure or relations to habitat, environment, associated animals or plants, diseases, &c. Local names, uses, and folklore should also be included; and for this the need is all the greater, because much of such old lore is rapidly being forgotten and tends to be lost. In a national flora there should be included an account of the successive floras of former periods, and, so far as possible, the changes that can be traced in the existing flora from its earliest records to the time of issue should be recorded.

A flora of this kind would not only afford the fullest possible information with regard to the plant world of the British Islands at the date of issue, but would form a standard with which it could be compared at later periods, so as to permit of changes in it being recognised and measured. In the meanwhile, the production of such a flora can be regarded only as an aim towards which to press on, but which cannot be attained until much has been done. But while the fulfilment must be left to others, we can do something to help it on by trying to remove difficulties from the way, and to bring together materials that may be used in its construction.

I have sought to direct attention to the difficulties that I have experienced and to directions in which progress could be made at once, and to provision which should be made for the advancement of the study of the British flora with as little delay as possible. There is, I feel assured, the means of making far more rapid and satisfactory progress towards the goal than has yet been accomplished. Many persons are interested in the subject, and would gladly give their aid if they knew in what way to employ it to the best purpose. As a nation we are apt to trust to individual rather than to combined efforts, and to waste much time and labour in consequence, with discouragement of many who would gladly share the labour in a scheme in which definite parts of the work could be undertaken by them.

I believe that a well-organised botanical survey of the British Islands would give results of great scientific value, and that there is need for it. I believe, also, that means exist to permit of its being carried through. There is no ground to expect that it will be undertaken on the same terms as the Geological Survey. A biological survey must be accomplished by voluntary effort, with possibly some help towards meeting necessary expenses of equipment from funds which are available for assistance in scientific research. Is such a survey not an object fully in accord with the objects for which the British Association exists? In the belief that it is so, I ask you to consider whether such a survey should not be undertaken; and, if you approve the proposal, I further ask that a committee be appointed to report on what steps should be taken towards organising such a survey, and preparing materials for a national flora of the British Islands.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—On Saturday last, October 1, Dr. Mason, the outgoing Vice-Chancellor, announced in his valedictory address to the Senate two munificent benefactions which have recently been offered to the University. The Drapers' Company, which has already done so much for the Agricultural School, has offered a sum of 22,000*l.* towards the cost of erecting a new physiological laboratory on the Downing site, and a further sum of 1000*l.* for fittings. The proposed new laboratory for psychophysics, the cost of which has been collected by Dr. C. S. Myers, will, it is hoped, be erected in the close neighbourhood of the proposed building for physiology.

Since the foundation of the Schröder chair for German, the Cambridge Association has been turning its attention to the further endowment of the teaching of English. Through the instrumentality of Lord Esher, one of their members, Sir Harold Harmsworth became interested in the project, and he has very generously offered to endow a chair of English language and literature by presenting the University with 20,000*l.* The professor is to be called the King Edward VII. professor, and will be elected by the Crown.

The next combined examination for sixty-seven entrance scholarships and a large number of exhibitions at Pembroke, Gonville and Caius, King's, Jesus, Christ's, St. John's, and Emmanuel Colleges will be held on Tuesday, December 6, and following days. Mathematics, classics, and natural sciences will be the subjects of examination at all the above-mentioned colleges. Forms of application for admission to the examination may be obtained at the respective colleges.

THE Child Study Society has arranged a number of lectures and discussions on the recreational activities of children, to be delivered at the Royal Sanitary Institute between now and Christmas. The programme includes the following subjects:—October 13: Some first results of an investigation into the play interests of English elementary-school children, Miss Alice Ravenhill; October 27: games and toys for children under eight, Miss Clara E. Grant; November 3: story of some children's games, Mrs. Lawrence Gomme; November 17: the origin of certain games and toys, Dr. A. C. Haddon, F.R.S.; November 24: philosophy of boys' games, Mr. Felix Clay; December 1: the child's inheritance, Dr. C. W. Saleeby.

The sixty-second session of the Bedford College for Women begins to-day. The college was founded in 1849 by Mrs. Elizabeth Jesser Reid, with the intention of offering to women the opportunity of a liberal education in the higher branches of knowledge. The number of students has increased steadily. We notice from the current calendar of the college that in 1889 the number of students was 145, in 1899 226, and in 1909 357. It will be remembered that the institution is now one of the constituent colleges of the University of London, and prepares its students for degrees in arts, science, and medicine. It is hoped that the new buildings of the college at York Gate, Regent's Park—which will provide accommodation for from 400 to 500 students, with residence for about a quarter of the number—will be ready for occupation in 1912.

The new chemical and physiological laboratories for the University of Bristol are now complete, and were opened for students this week. The formal opening will take place on November 15 by Lord Winterstoke, Chancellor of the University. The new chemical department consists of thirty rooms and laboratories, and contains working places for two hundred students. The main laboratory is capable of accommodating eighty students working at one time. The laboratories have been wired for electrical experiments and so on, and heavy currents from the city supply are available for electro-metallurgical and physico-chemical investigations. Smaller laboratories, specially designed and equipped for physical, organic, biological, and photographic chemistry, have been provided. The department of physiology is arranged to accommodate fifty students. The main lecture theatre has seats for about 120, and is served by a preparation room, store, and museum, all on the same floor. Chemical physiology is taught in a special laboratory. Optical work, photography, and gas analysis are allotted a fine room, to which is attached a well-ventilated dark-room of ample size. Experimental physiology has its own laboratory, and histology is housed in one of the finest rooms in the building, with north light, weaving-shed roof, and a gallery over. There is also a demonstration theatre, built on the model of the operating theatre of a hospital. Research is amply provided for: there is a room for the preparation of electrometer and other records by photography, and a fine suite of rooms apart from the teaching laboratories. Incubator room, constant temperature room, and cold store are also provided. Altogether, between twenty and thirty rooms are comprised in the department, and they are thoroughly convenient and up-to-date. It is noteworthy that nearly 50,000*l*. has been expended on these additions.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 26.—M. Bouchard in the chair.—The president announced the death of Mme. Pasteur.—M. **Darboux** presented vol. xiv. of the *Travaux et Mémoires du Bureau international*, containing a full account of the measurements of the exact volume of the kilogram of water. Three different methods have been employed, and the mean of the closely concordant results gives 1·000027 cubic decimetres as the volume of the kilogram of water at 4° C. and under normal atmospheric pressure.—A. **Laveran**: The treatment of different trypanosomiases by arsenic and antimony emetic. The compound used was obtained in large crystals by crystallising together under certain conditions aniline-arsenyl-tartrate and aniline-antimonyl-tartrate. Details of the methods and dosage are given. Fifteen guinea-pigs infected with *T. evansi*, *T. gambiense*, *T. dimorphon*, or by *T. congolense* were cured. In four of these cases there was a relapse, which was cured by a second treatment. The possibilities of application to the human subject are discussed.—R. **Bourgeois**: The comparison of two astronomical pendulums with the aid of electrical signals transmitted by a submarine cable of great length. A Thomson siphon recorder was modified in a manner to suit this work. The method will be used to determine the difference of time between Brest and Dakar, a distance of about 4500 kilometres.—A. **Demoulin**: The families of Lamé composed of surfaces possessing singular points.—Gaston **Darboux**: Remarks on the preceding communication.—Carl **Störmer**: The canonical forms of the general equations of motion of a particle in a magnetic field and an electric field superposed.—H. **Truc** and C. **Fleig**: Experimental ocular action of the dust on tarred roads. Dust from tarred roads is shown experimentally to be capable of provoking much more serious eye troubles than dust from untreated roads, and the smaller the lapse of time since the road has been tarred the more serious are the lesions produced.—H. **Guillemard** and G. **Regnier**: Observations on animal calorimetry made on Mt. Blanc. Increase of altitude has no sensible effect on the body temperature, but there is a marked increase in the amount of heat evolved by the body as the altitude increases, amounting to more than 30 per cent. between Chamonix and the summit of Mt. Blanc. A discussion of the results leads to the conclusion that protection against the cold is the best way of combating mountain sickness.—Charles **Nicolle** and E. **Conseil**: Properties of the serum of convalescents and animals cured of exanthematic typhus. Serum collected from the ninth to the fourteenth day of convalescence has well-marked preventive and curative properties against the disease. The curative effects disappear if the serum is collected later.—Joseph **Roussel**: The mode of formation of tricalcium phosphate in Algeria and Tunis.

THURSDAY, OCTOBER 13, 1910.

THE HISTORY OF PHYSICS.

Geschichtstafeln der Physik. By Prof. Felix Auerbach. Pp. v + 150. (Leipzig: J. Ambr. Barth, 1910.) 4 mk.

PROF. AUERBACH has embodied in this little book of 150 pages upon the chief discoveries in physics the result of notes made during many years for his personal use, in preparation for lectures. It consists of three parts: part i. (110 pages) is a chronological list of the main steps in the development of physics, with the year and the name of the discoverer, but without citing either the authority or the reference by which the discovery is fixed, and extending down to the year 1900. Part ii. (17 pages), a list of selected works, monographs, treatises, and text-books, with their authors, also to the year 1900. Part iii. (5 pages) is a selected list of leading physicists, except those still living, with their years of birth and death. There is also an alphabetical index of names.

Doubtless such a list will be found convenient for reference—much more convenient, for example, than Darmstaedter's recent "Handbuch zur Geschichte der Naturwissenschaften und der Technik," which is a more ambitious work It also covers the ground much more fully than Prof. Lehfeldt's list published in 1894 by the Physical Society.

A good idea of its nature and scope will be gathered by the following selection of the entries about the successive steps in photography.

1311, Camera obscura; Levi ben Gerson.
1505, Improved camera obscura; Lionardo da Vinci.
1556, Blackening of silver chloride by sunlight; Fabricius.
1558, Improved camera obscura; Porta.
1728, Action of light on silver compounds; J. H. Schulze.
1757, Copying of silhouettes on silver chloride paper; Beccaria.
1777, Photochemical reduction of silver; Scheele.
1777, Violet rays are photographically most active; Scheele.
1782, Colour sensitiveness of the silver compounds; Senebier.
1801, The strongest chemical action lies in the ultra-violet; Ritter.
1802, Production of light-images on silver chloride paper in the camera obscura; Davy.
1802, Photographic silver nitrate silhouettes; Wedgewood.
1810, Photochemical production of colours by coloured illumination; Seebeck.
1816, First permanent and printable photographic plates; Niepce.
1826, Discovery of silver bromide and its sensitiveness to light; Balard.
1833, Invention of the actinometer; Herschel.
1837, Production of the first plates with silver iodide, and developed by mercury vapour; Daguerre.
1838, Achromatic landscape-lens; Chevalier.
1839, Production of the first negatives copyable upon paper; Talbot.
1840, Foundation of microphotography; Donné.
1840, Portrait-objective for photography; Petzval.
1842, First useful photographs of the solar spectrum; E. Becquerel and Draper.
1842, Printing-out process with iron salts; Herschel.
1843, Discovery of gold-toning of photograms; Fizeau.
1847, First photographs on albuminised plates; Niepce de St. Victor.
1850, Introduction of gelatine into photography; Poitevin.
1851, Wet collodion process for photography; Archer.
1852, Chrome-gelatine process for photography; Talbot.
&c., &c., &c.

The subsequent steps are narrated in similar detail; but, strangely enough, the name of Sir Joseph Swan is entirely omitted from the list. Similar lists might be adduced in every branch of physics. As might be expected from Prof. Auerbach, the list in acoustics is particularly complete, while those in optics and in magnetism are scarcely less so.

The omission of all references to authorities renders criticism difficult; because the critic, even where he is fairly certain that some error exists, has no means of learning what the compiler of the list relies upon for his statement. Thus the author credits Wilcke, in 1757, with the introduction of the conception of electric resistance; he attributes to Scoresby, in 1827, the discovery of the destruction of magnetism by glowing heat; he credits to Hankel, in 1848, the suggestion of the hot-wire galvanometer. One would wish to know the authorities for these statements. There are several inexplicable omissions: Du Bois Reymond's discovery of non-polarisable electrodes is not mentioned; Shelford Bidwell and George F. FitzGerald are unknown to the author as having achieved anything in physics; Barrett's discovery of recalescence is ignored, as is Osmond's work in the same field. Earnshaw's discovery of the dependence of the velocity of sound on its intensity is unnoticed. Lord Kelvin's publication in 1855 of the doctrine of available energy is not referred to. Osborne Reynolds's work on dilatancy is not mentioned. The foundation of crystallometry is attributed to Weiss in 1813; all reference to the work in that direction of Wollaston, of Haüy, and even of Steno being omitted! In several cases the dates need revision. Thus, Maxwell's electromagnetic theory of light is given as 1871, several years too late. A reference to Dr. Gilbert, who died in 1603, is given as 1630. The first research to register the curves of alternating electric currents is attributed to Colley in 1885; Joubert has dropped out, even from the index. Aitken's classical observations on dust nuclei are not recorded. Lord Kelvin's mariner's compass is dated back to 1868, though only patented in 1876. Foucault's use of gas retort carbon for electric light pencils certainly dates back before 1850; but here it is given as 1866. These blemishes can easily be removed when a second edition is called for—as it ought to be before long.

PSYCHIATRY AND PSYCHOTHERAPY.

(1) *A Text-book of Mental Diseases.* By Prof. Eugenio Tanzi. Authorised translation from the Italian by Dr. W. Ford Robertson and Dr. T. C. MacKenzie. Pp. xvi+803. (London: Rebman, Ltd., 1909.) Price 24*s.* net.

(2) *Psychotherapy.* By Prof. Hugo Münsterberg. Pp. xi+401. (London: T. Fisher Unwin, 1909.) Price 8*s.* 6*d.* net.

THESE two books appeared towards the end of last year, the one being a thoroughly up-to-date work on psychology, normal and morbid, and the other dealing with the psychical treatment of disease, especially of mental disorder.

(1) Prof. Tanzi's book has already been published in Italy for nearly five years and from the first has been recognised as a standard work on mental diseases. It begins with a study of the seat of the psychical processes and considers seriatim the data of physiology and experimental anatomy, embryology, pathology and normal anatomy. Then follows a discourse on the causation of mental diseases, and there is a chapter on the morbid anatomy of the brain, microscopical and macroscopical, in respect of mental diseases. About 150 pages are devoted to psychology of a practical kind, under the headings of sensibility ("sensation" would have been a better translation), ideation, sentiment, movements and other external reactions. This last chapter is really a disquisition on the conduct of the insane and deals with anomalies of the will, of the instincts, of emotional expression and of speech and writing. The classification adopted is mainly that of Kraepelin, but the author does not follow that authority with any slavish rigidity.

It will seem curious to English physicians to find the study of mental diseases beginning with that of pellagra, but it will not be forgotten that this disease plays almost as large a *rôle* in some parts of Italy as general paralysis does in this country.

Many will object to the use of the term "amentia" in the sense of acute confusional insanity or acute hallucinatory insanity; but this is the sense in which the word has been used on the Continent ever since the days of Meynert, whereas in this country "amentia" means idiocy or imbecility. The term maniacal-depressive insanity does not appear; but melancholia, periodic melancholia, periodic mania, and circular insanity are discussed under the heading of "the affective psychoses."

Paranoia is more clearly defined and receives fuller consideration than we have seen in any other text-book. The author divides paranoiacs into those with abstract delusions (mattoids) and those with an ego-centric delusion (the querulants, the persecuted, the erotic and the ambitious). Under these various headings there are interesting references to the history of the Middle Ages and to the peculiarities of certain primitive races. There are also some very full accounts of individual cases of paranoia.

The chapter on constitutional immorality is well worth reading. Prof. Tanzi takes a broad view of the subject, and criticises the penal law on the one hand and the narrow views of some of his own countrymen on the other. He rightly condemns stigmatising a person as a criminal merely because he possesses a certain number of the physical stigmata of degeneration, such as a Darwinian ear, plagiocephaly, hexadactylism, &c.

There is a full and excellent index. The book is well illustrated and got up, and there are 132 figures which materially assist the reader in understanding the text.

(2) Prof. Münsterberg divides his book into three parts, the first being on the "Psychological Basis of Psychotherapy," the second on the "Practical Work of Psychotherapy," and the third on the "'Place' of Psychotherapy."

Part i. seems rather unnecessary to anybody who has studied psychology before and, to the practical physician, part iii. will appear rather redundant, as it deals with the relation of psychotherapy to the church, &c. The essential section of the book is part ii., and this will be found exceedingly interesting. It treats of the conditions in which psychotherapy is likely to be of use, general and special methods, and of mental and bodily symptoms. The special methods discussed are suggestion, hypnotism, side-tracking and psycho-analysis.

The methods of psycho-analysis are beginning to be well understood in this country, although they have not yet reached the popularity they have in Austria, where the name of Freud, the propounder of its principles, has become a household word. Freud and his followers hold that by the psycho-analytic method they are able to discover in a patient some long-forgotten memory, and that in their discovery they bring to the surface a source of mental irritation, thus removing from the mind a foreign body in the same way as a surgeon picks a thorn from the finger. English physicians are disinclined to regard the method in this light; they consider that the proceeding is rather one of suggestion to the patient. The patient lies on a sofa whilst the operator sits at his head and reels off a series of words to which the patient is required to fit associated ideas; and the operator subsequently, from the study of the patient's associations, evolves some incident in his past history. This he relates to the patient, and hey, presto! recovery. The same result, however, may be quite well attained by taking a careful history of the patient's past life. Psycho-analysis is most suited for hysterical patients, but Münsterberg recommends it for cases of psychasthenia.

Side-tracking is a somewhat different principle which, however, may be used in conjunction with psycho-analysis. Patients suffering from psychasthenia are obsessed with some thought which they are unable to dispel. By psycho-analytic methods the physician searches for an origin of the obsession and then, by devices of various kinds (side-tracking), he diverts the patient's thoughts from the original incident into different channels. To take an example, a man found that he had developed a tendency to hesitate when walking in the street, and was unable to cure himself. Münsterberg was consulted, and found that on a certain occasion when the patient was running to catch a tram he suddenly saw almost immediately before him a big hole dug out for laying gas pipes. He was able to stop himself quickly enough to avoid falling into the hole, but he had a strong emotional shock from the experience. Münsterberg persuaded him under slight hypnosis to think himself once more in the situation of his run for the car, but, as soon as he reached the hole, to jump over it. He went through this motor feature on ten successive days with increasing energy, and from that time the trouble disappeared.

Both books make a very useful addition to the libraries of people interested in the subjects with which they deal.

COMMERCIAL GEOGRAPHY.

Physical and Commercial Geography. By Profs. H. E. Gregory, A. G. Keller, and A. L. Bishop. Pp. viii+469. (London: Ginn and Co., n.d.) Price 12s. 6d.

THE aim of this work is stated to be "to infuse orderliness and sequence into the chaotic data and statistics of trade," and this the authors regard as constituting "a new departure."

The question whether their work constitutes a new departure or not is, however, one of comparatively small importance. We may at least admit that the attempt to carry out this aim in their "own chosen way" is new, and we may add that that way is a good way, and, on the whole, admirably followed. We feel sure that no student or teacher of commercial geography could fail to profit greatly by the perusal of this work, and, above all, of its more general sections.

The work is divided into three parts, each of which, we are told, belongs essentially to one of the three authors, though they have a joint responsibility for the outline and general character of treatment. The first part is entitled "The Natural Environment," the second "The Relation of Man to Natural Conditions," and the third "The Geography of Trade." It is in the first two sections that the aim of the work as above indicated, the tracing of the influence in the moulding of trade of what "might be called the environmental (or geographical) factors," is kept most consistently in view, and with the most satisfactory results.

The third part of the work is the most disappointing. Here the geographical point of view is much less prominent. In it, the authors say, their treatment is "Topical, a short monograph upon each preeminent article of commerce occurring under the general politico-geographical section which leads in the production or use of the article in question."

But in some of the most important cases little or no attempt is made to show what, if any, geographical influences have been at work to help in creating that importance. Emphasis is laid on the remarkable lead which Great Britain takes in the cotton industry and in transmarine carriage; but the question whether geographical circumstances have had anything to do with this in either case is not even raised. There is very little comment on the seats of manufacturing industry in the United States. There is a reference to water-power in certain cases, and coal, iron, and limestone, as determining the localisation of the iron industries of Pittsburg and the Birmingham districts, but little else. The reason for this apparently is the attaching an exaggerated degree of importance to sources of power as localising manufacturing industries, and overlooking the importance of the relation to labour supply and the market. When the latter relations are kept in view it may be shown that the fact that so few important manufacturing towns in the United States are situated on the coalfields is as much due to geographical causes as the fact that in England and Germany so many are.

RESTORATIONS OF EXTINCT ANIMALS.

Extinct Monsters and Creatures of Other Days; a Popular Account of Some of the Larger Forms of Ancient Animal Life. By the Rev. H. N. Hutchinson. New and enlarged edition. Pp. xxxiii+329. (London: Chapman and Hall, Ltd., 1910.) Price 10s. 6d. net.

SINCE the author of this volume was the first to recognise that the larger extinct animals of former ages presented a promising field for a popular work showing what these creatures probably looked like in life, he thoroughly deserved success in his attempt to fill a gap in literature, and we have therefore great pleasure in congratulating him on the appearance of a second edition. In the volume now before us, Mr. Hutchinson has combined his original two works in one, with some condensation of the old matter, and with the addition of a large quantity of new material, both in the shape of text and illustrations, in order to bring it abreast of modern palæontology. Since 1892 and 1894, the respective dates of publication of "Extinct Monsters" and "Creatures of Other Days," vertebrate palæontology has indeed made vast strides, as is especially noticeable in the case of the anomodont reptiles and the proboscideans, and the author appears to have discharged the difficult task of bringing the work up-to-date in a satisfactory and interesting manner. From first to last the volume is thoroughly readable, and it is to be hoped that it may aid in dissipating the ignorance still so prevalent with regard to the relative ages of the mammoth and the iguanodon.

In referring to the iguanodon as a smooth-skinned reptile, and then giving a plate of it clad in crocodile-like armour, the author appears to display inconsistency; and in the plate of Ceratosaurus the individuals in the background are depicted with relatively larger fore-limbs than the one in front. Reference might also have been made to the evidence in favour of an elephant-like pose of the bones afforded by the figure of an undisturbed limb of Diplodocus; and recent researches indicate that the restoration of Stegosaurus with a double row of plates is incorrect. A few improvements might also be suggested in the text, as, for instance, on p. 169, where it is stated that the teeth of Claosaurus resemble those of Hadrosaurus, without any clue being given as to the nature of the latter. Misprints and typographical inaccuracies are singularly few, although we notice Jakutsh on plate xliii., and Yakutsk in the first note on p. 276. The book is thoroughly deserving of a large sale. R. L.

HINTS FOR THE GARDEN.

(1) *The Carnation Year Book*, 1910. Edited by J. S. Brunton. The official organ of the Perpetual Flowering Carnation Society. Pp. 53. Price 1*s.*

(2) *Gardening Difficulties Solved. Expert Answers to Amateurs' Questions.* Edited by H. H. Thomas. Pp. 160. (London: Cassell and Co., Ltd., 1910.) Price 1*s.* net.

(3) *Leitfaden für gärtnerische Pflanzenzuchtung.* By M. Löbner. Pp. vii+160. (Jena: Gustav Fischer, 1909.) Price 1.50 marks.

(4) *Wild Flowers and How to Identify Them.* By H. Friend. Pp. 64. (London: Robert Culley, 1910.) Price 1*s.* net.

THE popularity of the carnation as a florist's flower has already been enhanced by the spread of the American or perpetual flowering carnation, and will become more so as the qualities of this type are more generally recognised. Originally raised in France where they were known as "remontants," their value was not realised until American growers took up their cultivation with excellent results. Only within the last decade have British horticulturists entered the field, but sufficient growers were found in 1906 to form the society which offers the "Carnation Year Book" (1) as its official organ. One important object of the society is to undertake the registration of new varieties; about a dozen have so far been registered, including the already famous Britannia and Mrs. H. Burnett, as compared with about 800 recognised by the corresponding American society. The volume contains several short articles, of which the most interesting deal with cultivation and hybridisation.

(2) Amateur gardeners do not lack opportunities for obtaining assistance in their difficulties, as all the gardening papers are prepared to supply expert advice. The brochure edited by Mr. Thomas has been collated from replies to correspondents inserted in the columns of the *Gardener*. The questions cover a wide field, so that, although they are grouped in sections, it is a small chance that any specific matter for which the book is consulted will be mentioned therein. So far as it goes, the information is sound and practical, and some practical hints are conveyed in the illustrations.

(3) The perusal of Herr Löbner's book has afforded much pleasure and instruction, as it provides a successful combination of scientific teaching and practical experience. The book consists of a general part dealing with the acquisition of new plants by selection, hybridisation, importation, grafting, and sports—here limited to vegetative anomalies—and a special part in which the origin of specific novelties is treated. It is only possible in the limited space to note that the author discusses seed-fixation, the means of getting seed from double flowers, fertile and infertile hybrids, and the keeping qualities of pollen. In the latter part no section is more interesting than that on roses which includes some account of the author's experience.

(4) The arrangement for identifying British plants offered by Mr. Friend is, to all intents and purposes, the Linnean system, with the omission of many genera; species are only cited for eight genera, and then partially. The notes on season, habitat, and structure provide but little help towards identification, especially as no clear definition is given for some of the technical terms, *e.g.* fruit, bract, and stipule; further, there is a singular confusion on p. 32 of bulb and root, corm and tuber.

OUR BOOK SHELF.

The Telegraphic Transmission of Photographs. By T. Thorne Baker. Pp. xi+146. (London: Constable and Co., Ltd., 1910.) Price 2*s.* 6*d.* net.

THOSE who look at the illustrated papers, and especially readers of *The Daily Mirror*, are aware that the telegraphic transmission of photographs has already entered the commercial stage, and if the results are not yet all that can be desired it will generally be admitted that they reach a high standard of merit considering the very numerous difficulties that have had to be surmounted. This little book from the pen of Mr. Thorne Baker, who has been carrying out the work for *The Daily Mirror* during the last two-and-a-half years, is consequently very welcome.

A brief historical survey of the earlier work is given, and a more detailed account of the later work of Prof. Korn, M. Belin, and the author, which has resulted in the development of systems of actual commercial value. One is impressed throughout by the number of small difficulties which have had to be overcome by persevering experiment, and it is evident that the present state of the art owes its perfection considerably to the development of the kindred arts of photography and reproduction without which the advances on the purely electrical side would have been of slight avail. Problems such as this, though theoretically simple of solution, present great difficulties on account of the amount of technical skill and knowledge of a number of different subjects that is required.

The book is well written and illustrated. A good deal will only be understood by the technical reader fairly well equipped with electrical knowledge, but there is sufficient simple description to enable the non-technical reader to acquire a very fair idea of the whole subject. Some of the phototelegrams which are reproduced are excellent, especially when looked at from a sufficient distance to render the "grain" indistinct, and the two sketches transmitted by wireless telegraphy, though poor in themselves, afford evidence of still further possibilities of development.

M. S.

Liste des Observatoires Magnétiques et des Observatoires Séismologiques. By E. Merlin and O. Somville. Pp. x+192. (Brussels: Havez, Rue de Louvain, 112, 1910.)

To those who seek to establish definite relationships between solar and terrestrial phenomena, the multiplication of well-distributed stations equipped for the observation of terrestrial magnetism and earth movements is a hopeful sign. Hitherto, one of the grave difficulties encountered in such researches has been the paucity of trustworthy and continuous data for sufficiently long periods.

The list now published leads us to hope that a future generation may be more fortunate, for here we find some 220 observatories, of which at least eighty are devoted to the study of terrestrial magnetism and electricity.

The usefulness of such a list has been proved, in principle, by the publication of a similar list of astronomical observatories in 1907, and the Royal Observatory of Belgium, under the auspices of which both were prepared and published, is to be congratulated upon having performed an exceedingly useful, if tedious, duty.

As any attempt to separate magnetism and seismology would have led to needless duplication and confusion, the arrangement is purely alphabetical. For each station are given the geographical position, the altitude, the nature of the ground on which the observatory stands, the publications wherein the results appear, the names of the staff, a brief history of the observatory, and the nature and distance of any disturbing elements, such as tramways, &c., and, finally, a description of the instruments and the special researches to which they are dedicated. Other lists show the continental and national distribution of the two kinds of observatories, and, alphabetically, the names of the observers.

Such a list was to have been prepared by the International Commission for Terrestrial Magnetism, but the project failed; the data then collected, however, have been placed at the service of the compilers of the present work, and have proved very useful.

W. E. R.

An Inconsistent Preliminary Objection against Positivism. By Prof. Robert Ardigo. Translated by Emilio Gavirati. Pp. 52. (Cambridge: W. Heffer and Sons, Ltd., 1910.) Price 1s. net.

THIS pamphlet, by the veteran leader of Italian positivism, is issued in translation by a devoted admirer and disciple who wishes to find an English helper in the translation and publication of other works by the "great master." Its argument is directed against those opponents who, on behalf of modern idealism, contend that in positivism there is to be found this fundamental fault—namely, that, according to the method which the positivist has prescribed to himself, the subject ought, in his system, to become an object which cannot have, therefore, any of the characteristics belonging to subjectiveness. Prof. Ardigo, as St. George to the dragon of metaphysics, develops a subtle and closely reasoned argument for a positivist treatment of psychology, criticising the positions associated with the names of Bergson and Boutroux. He is also careful to show that positivism differs widely from materialism, with which there is—very naturally—a tendency to confound it. The substance of this pamphlet is contained in the second part of volume x. of Ardigo's "Philosophical Works."

Analytical Chemistry. By Prof. F. P. Treadwell. Authorised translation from the German by William T. Hall. Vol. ii. Quantitative Analysis. Second edition. Pp. x+787. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1910.) Price 17s. net.

A REVIEW of the first edition of Mr. Hall's translation of Prof. Treadwell's work on quantitative analysis was published in NATURE of August 11, 1904 (vol. lxx., p. 341). In the present issue certain additions have been made which are not found in the German text, and the main part of the work has been compared with the fourth German edition.

Students' Life and Work in the University of Cambridge. Two lectures by Prof. Karl Breul. Revised edition. Pp. 60. (Cambridge: Bowes and Bowes, 1910.) Price 1s. net.

THE two lectures delivered by Prof. Karl Breul to the students attending the University Extension summer meeting in 1908 give an interesting and informative account of the life and work of Cambridge undergraduates. In the revised edition a few corrections and additions have been made.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Early Burial Customs in Egypt.

ALL who are interested in the serious attempts that are being made to reconstruct the real history of ancient Egypt and to sift established truth from wild conjecture must deplore Prof. Flinders Petrie's attempt (see NATURE of September 29, p. 401) to revivify the corpse of a belief in the supposition that the archaic Egyptians were in the habit of cutting up their dead, a view which has been so effectually hanged, drawn, and quartered during the last ten years.

When Prof. Petrie states (*op. cit.*, p. 401, quoted from *Man*, September) that "it has long been known that in prehistoric burials the corpse was stripped of its flesh, the bones even being broken to extract the marrow," he should have written that he and M. de Morgan had *stated* that the prehistoric Egyptians dissected the bodies of their dead. But, even though Profs. Maspero, Sayce, Wiedemann, and Lortet repeated these or similar statements (Sayce and Lortet invoking the aid of birds of prey to do the bone-cleaning!), the experience gained by other excavators has totally shattered and destroyed every scrap of evidence that could lend any support to the belief in the reality of such practices.

In 1896 Prof. Petrie ("Naqada and Ballas," p. 32) attempted to explain the disturbed condition of the skeletons found in many archaic Egyptian graves by saying "*that bodies were sometimes—with all respect—cut up and partly eaten*"!

Four years later Dr. George A. Reisner proved that such disturbances of the bones as Prof. Petrie mentioned were the result of the operations of grave-plunderers (see the Egyptian Exploration Fund's Archæological Report for 1900–1, p. 25); and every year since then this explanation has been proved to be true in every case where disturbances have been found amongst many thousands of burials of all ages and in every part of Egypt and Nubia, which have been submitted to the most thorough and critical examination, not only by Dr. Reisner himself, but also of many independent witnesses. The evidence referring to Nubia is set forth *in extenso* in the First Annual Report of the Archæological Survey of Nubia, which is being published in Cairo this month. During my ten years' association with Dr. Reisner, my collaborators in the anatomical branch of the work and I have examined and made notes on the remains of more than 15,000 human beings buried in the Nile Valley, and we have not seen a single case which afforded any evidence whatsoever of the practices postulated by Prof. Petrie.

Secondary burials, of course, occurred in ancient Egypt: but they were exceedingly rare, probably more so than in modern England. Perhaps some archæologist of the next millennium will find infinitely more evidence in English graveyards of the twentieth century in support of speculations on our "customs of mutilation of corpses and cannibalism" than Prof. Petrie has been able to gather in Egypt.

It would, indeed, be a matter for astonishment if such a people as the ancient Egyptians, whose respect for their dead is proverbial, did not attempt to restore to order the graves of relatives that had been desecrated by grave-plunderers. The surprising thing is not that we find instances of reburial, but that they are so exceedingly rare.

During the Græco-Roman period in Egypt and Nubia, when the decadence of the art of mummification had definitely begun, it often happened that bodies handed over to the embalmers were treated in such a careless manner that they fell to pieces in an early stage of the process, and had to be rebuilt—sometimes with limb-bones reversed, leg-bones as skeletons for arms, portions of other skeletons introduced, and often foreign materials added. This "faking" of mummies is described in detail in the forthcoming Report of the Archæological Survey of Nubia.

Would it be unreasonable to suppose that in the early experimental stages of the art of embalming—corresponding to the epoch with which Prof. Petrie is dealing—similar failures may have occurred, and that such a condition, for example, as Prof. Petrie has described from Deshasheh, where the fibula was upside down (see "Deshasheh," 1898, Pl. xxxvii.), would receive a natural explanation? Such cases are so exceedingly rare that it is idle to quote them as representing the "custom" of the country.

Apart from these rare exceptional cases of secondary burial and embalmers' "faking," all the disturbances of the bones of unplundered graves result from (1) the operation of the force of gravity on bodies falling into decomposition, and (2) the occasional action of rodents moving small bones. That this is so has been conclusively demonstrated by Dr. Reisner in the minute and critical examination of many thousands of burials in Egypt and Nubia. Thus there are very precise and definite reasons for discarding Prof. Petrie's fantastic speculations, and for accepting in their stead the simple and perfectly obvious explanation of the disturbed state of the skeleton in many graves, which he who runs may read.

The phrase "the bones even being broken to extract the marrow" (*op. cit.*, Nature, p. 401) calls for some further comment. Does it mean that Prof. Petrie is reaffirming his former statement of a belief in the practice of cannibalism (already quoted)? Can he point to one single case where the bones of a prehistoric Egyptian have been broken *post-mortem*, except by grave-plunderers, excavators, or the natural forces of the denudation of the soil and the disintegration of organic matter?

In "Naqada and Ballas," p. 32, Prof. Petrie referred to the forcible scooping out of the marrow as an evidence of cannibalism; but that statement was clearly inspired by his lack of familiarity with the normal medullary cavity of a human long bone and its relation to the cancellous tissue at the ends. But he added, further, that "there were grooves left by gnawing on the bones"—a sure sign of anthropophagy! Dr. Fouquet, who examined M. de Morgan's material of a similar nature, also saw these grooves, but called them "syphilitic ulcers."

Two years ago (*Lancet*, August 22, 1908, p. 521) I was able to demonstrate that the bones of many pre-dynastic Egyptians were certainly gnawed, but neither by man nor the spirochæte: the damage was inflicted by small necrophilous beetles. Although Prof. Petrie no longer refers to these signs of gnawing, he still speaks of the prehistoric Egyptian breaking human bones "to extract the marrow," *i.e.* presumably to eat it. The whole evidence afforded by excavations in Egypt goes to prove that this statement is pure fiction.

British Marine Zoology.

"The proof of the pudding is in the eating," and surely Prof. MacBride will admit that whether a biological station is or is not suitable for research must be decided, not by the expensiveness of the equipment, but by observing whether research is being carried on there.

That one station is ten times as large and expensive as another is no advantage and no credit to it unless it is also ten times as efficient. That it is only in such an establishment that Prof. MacBride can "bring research to a successful issue" is, of course, an important personal record, but it might be unsafe to generalise from one such observation.

I am sorry not to be able to agree with Prof. MacBride in the distinctions he draws between the stations equipped for research and others; and I cannot avoid a doubt as to whether he has personal knowledge of the smaller stations of this country.

W. A. Herdman.

October 1.

I shall gratify Prof. Herdman's curiosity so far as to say that I have worked at more than one small station in this country.

I fully agree that "the proof of the pudding is in the eating," and I am content to leave it to the judgment of my fellow-zoologists whether in reviewing the work done at the various zoological stations in this country Plymouth has not justified its superior equipment by the superiority of the original work, both as to quantity and quality, which has been accomplished there.

E. W. MacBride.

Hormones in Relation to Inheritance.

With reference to my presidential address to Section D of the British Association, of which a full report appeared in Nature of September 22, I must rectify an omission by pointing out that the theory of the possible influence of hormones in inheritance was first enunciated by Mr. J. T. Cunningham in a paper in the *Archiv für Entwicklungsmechanik*, vol. xxvi., 1908, entitled "The Heredity of Secondary Sexual Characters in Relation to Hormones, a Theory of the Heredity of Somatogenic Characters." It was through inadvertence that the reference to Mr. Cunningham's paper was not printed in the copies of the address distributed at the meeting at Sheffield.

Gilbert C. Bourne.

Savile House, Oxford, October 4.

Pwdre Ser.

My friend Mr. Frank Darwin has sent me the following additional information respecting the *Pwdre Ser.*

"The 'Treasury of Botany' says that Nostoc is called 'Falling Stars,' and quotes Dryden (no reference)—

'And lest our leap from the sky prove too far,
We slide on the back of a new falling star,
And drop from above
In a jelly of love.'

"The note is signed M. J. B. = Berkeley, so it may be trusted so far as that it really refers to Nostoc."

T. McKenny Hughes.

Ravensworth, Brooklands Avenue, Cambridge, September 30.

Unemployed Laboratory Assistants.

A number of lads who have been employed as laboratory monitors in secondary schools, and whom the London County Council are unable to retain in their service beyond the age of sixteen years, have been referred to us by the London County Council with the view of our placing them. Some of them we have already been able to place in suitable employment, but there are still one or two on our books for whom we seek situations.

They all have an elementary knowledge of physics and chemistry. Some have learned glass-blowing and bending, and a few of the applicants have already passed the Board of Education examination in Chemistry (Stage I.). If any readers of Nature would like to have further particulars of these boys, I should be glad to supply them with information.

THE INTERNATIONAL UNION FOR COOPERATION IN SOLAR RESEARCH.

THIS union held a very successful meeting—the fourth since its foundation—on Mount Wilson Observatory, California, during the last week of September, when there was an assembly of nearly forty European astronomers and physicists, who had crossed the Atlantic for the meeting, and many more American men of science. England was represented, among others, by Sir Joseph Larmor, Profs. Newall, Turner, Fowler, and Mr. Dyson. The gathering, representative as it was of all nations actively engaged in solar work, would have been even more so if a number of those who had signified their intention of being present had not at the last moment been prevented by illness or other causes from attending. Among them were Sir David Gill, Dr. Lockyer, Profs. Righi and Violle. To the great regret of everyone present, Prof. Hale was prevented by bad health, brought on through overwork, from taking part in the discussions. Together with Mrs. Hale, he received his guests at a garden-party at their home in Pasadena, and was able to come up to the observatory on the first day of the meeting, but on the advice of his doctor he returned to Pasadena, after delivering a short address on the general work of the conference.

As regards the results of the meeting, the first place must be given to the extremely satisfactory report of the committee on the determination of standard wave-lengths. The requirements of modern spectroscopic research having rendered all previous measurements obsolete, even for purposes which only require relative values, the Solar Union set itself the task of preparing new tables. The direct comparison between the wave-lengths of the red cadmium line with the standard metre carried out by Fabry and Pérot gave a result practically identical with that of Michelson, so that already three years ago its numerical value could be definitely adopted. Taking this line to be the primary standard, a sufficient number of iron lines had next to be compared with it, so that they might serve in subsequent work as secondary standards, with an accuracy hardly, if at all, inferior to that of the primary. This work was undertaken independently in three different laboratories by Fabry and Buisson, at Marseilles, by Eversheim under Kayser at Bonn, and by Pfungst under Ames at Baltimore. The numbers obtained agree so well that we are now already in possession of a large number of lines with accurately known wave-lengths. How accurately? Using the Angström (10^{-8} cms.) as unit, the average differences of the three independent determinations only amount to about three or four in the third decimal place, which means less than one part in a million. The few cases where the differences are somewhat greater are easily explained by a deficiency in the homogeneity of the lines, except in a small region in the orange.

The secondary standards are now sufficiently close together to serve as fixed points for interpolations, when gratings are used, and it is intended to proceed immediately with the further determination of tertiary standards so near to each other, that even with a prismatic dispersion every observer will have at his command a system of lines on which he can depend entirely for comparison or interpolation. In the orange region referred to, some barium lines will have to be added, and the total length of spectrum dealt with, which extends from λ 4282 to λ 6494, will before long be substantially increased on the red side. In order to avoid confusion between the new and old determinations, the now adopted unit will be known as the "international Angström" (I.A.). If the Solar Union had done nothing else than this work on wave-lengths, it would have justified its existence.

We next note the report of the committee on the investigation of sun-spot spectra, which was presented by Prof. Fowler. Its work is sufficiently indicated by the following recommendations, which were adopted by the meeting:—

(1) That, notwithstanding the progress of photographic work, visual observations of spot spectra should be continued, and that the committee should be re-appointed to continue the organisation of this work.

(2) That in view of our increased knowledge of spot spectra, the committee should be authorised to prepare and circulate a revised and extended scheme of visual observations.

(3) That it is desirable that, for the use of visual observers, the separate sections of the new photographic map of the sun-spot spectrum should not exceed 60 centimetres in length, and should be on a scale of 5 mm. to the Ångström.

Another committee dealt with spectroheliograph work, and here also we may confine ourselves to quoting the more important resolutions:—

(1) That daily photographs of the calcium flocculi be continued by the co-operating observatories.

(2) That provision be made, if possible, for the measurement of the photographs.

(3) That the desirability of utilising large spectroheliographs of high dispersion for the study of the upper layers of the solar atmosphere is recognised by the committee.

A report on the spectroheliograph work carried on at South Kensington was sent in by Sir Norman Lockyer, and will be printed in the transactions of the union, as also a discussion of solar phenomena as revealed by the spectroheliograph, which was presented by M. Deslandres.

An important, but from the nature of things somewhat slowly progressing, committee deals with the study of solar radiation. Its work has been seriously retarded by the lamented death of Knut Angström, whose pyrheliometer had been adopted by the union as standard instrument, and who had undertaken personally to standardise all pyrheliometers sent out from Upsala. Latterly serious defects in the constancy of the indications of the instrument have shown themselves, and unless a ready means is found to keep an accurate log of their changes by frequent comparison with some standard radiator, the union will be forced to modify its previous decision. Mr. Abbott presented the report of the committee, and gave an account of his own important work on solar radiations, which has revealed some fluctuations in the amount of heat and light which enters our atmosphere. These fluctuations, which frequently amount to 5 or 6 per cent., may still be due to uncorrected influences of atmospheric absorption, and Mr. Abbott laid stress on the importance of establishing an independent station in a locality where the atmospheric conditions are favourable, so that simultaneous observations can be carried out, at least in two places, and atmospheric inequalities still further eliminated.

It remains to record an important alteration in the constitution of the union, which has decided to extend its scope, and include astrophysics in the range of its activity. In voting for the change, the members of the union were fully aware of the importance of their decision. It was pointed out by several speakers that the union exposed itself to the danger of undertaking more than could be managed, and that before long the primary object of the union might be swamped by the additional problems now introduced. But, on the other hand, everybody recognised that the distinction between the sun and a star was an artificial and accidental one, and that the study of one was a necessary complement to the study of the other. The danger of being overwhelmed by the additional subjects is not great, because only a few well-defined portions of astrophysics are adapted for investigation by international cooperation. At the conclusion of an interesting discussion, the vote went unanimously in favour of the change. A beginning of the new order of things was made at once, and a committee was appointed, with Prof. E. Pickering as chairman, to discuss the possibility of coming to an agreement on the classification of stellar spectra.

The next meeting of the union will be held at Bonn in the year 1913.

Arthur Schuster.

POPULAR BOOKS ON BIOLOGICAL SUBJECTS.[1]

(1) THE first of these books forms vol. iv. of the handsomely got-up and well-illustrated "Science in Modern Life." The first eighty-eight pages are a continuation of the account of botany begun in the previous volume, and deal with geographical distribution as influenced by climate, &c., followed by a general systematic survey of the vegetable kingdom. So much of the space is filled by illustrations (usually very good) that the letterpress is exceedingly condensed, and makes the style rather that of an encyclopædia than of a book to be read, but the substance is good.

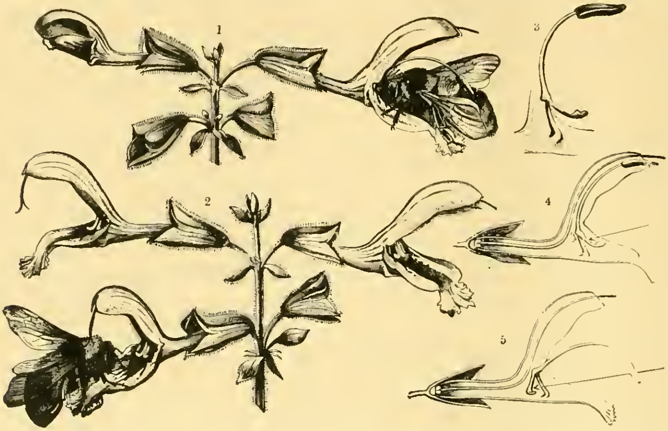

FIG. 1.—Transference of pollen to the bodies of insects by means of mechanism of the percussive type. (1) Part of an inflorescence of *Salvia glutinosa*; the right-hand flower is being visited by a humble-bee, and the pollen-covered anther is in the act of striking the insect's back. (2) Another part of the same inflorescence with three open flowers in different stages of development: the lower flower on the left-hand side is being visited by a humble-bee which carries on its back pollen from a younger flower and is rubbing it off on to the deflexed stigma. (3) A stamen of *Salvia glutinosa* with rocking connective. (4) Longitudinal section through a flower of the same plant. The arrow indicates the direction in which humble-bees advance towards the interior of the flower. (5) Same section; the lower arm of the connective lever is pushed backward, and in consequence the pollen-covered anther at the end of the other arm of the lever is deflexed.—From "Science in Modern Life."

The section on zoology (114 pages) includes six pages on the history of the science, and ten on a general survey of the animal kingdom, and these are so much condensed as to be almost meaningless without further reading. The remainder is devoted to an account of the evolution of animals as revealed by their fossil remains. In this way descriptions are given of all the chief orders of animals, but short diagnostic descriptions of groups, sometimes with no illustration, convey little definite impression to the reader, and the general effect is distinctly disappointing. The physiological side of zoology, in which its relation with "modern life" is perhaps closest, is not dealt with.

The pages devoted to fisheries are the most readable in the volume. The style is necessarily very concise, but the author succeeds in picking out the salient features and in making the subject interesting. The volume is provided with a full list of contents, but no index.

(2) "A Bush Calendar" consists of a series of articles on nature in the neighbourhood of Sydney, reprinted from the *Sydney Morning Herald*. They are pleasantly written descriptions of the birds, flowers, &c., seen, with observations on their habits and haunts; and although to most English readers the names will not convey any clear idea, to those living in that part of Australia it should be a useful little book. It is illustrated with pretty photographs, and for each month a list is given of the flowers, migrant birds, and nests which may be found. An Englishman is at once struck with the fact that there is no month in which some bird does not breed. One small blemish is that generic names should be written with initial capitals.

(3) "Nature Studies by Night and Day" does not claim originality, and consists of a series of disconnected chapters on well-worn subjects—the opening and closing of flowers, protective coloration, the sundew, &c. The photographs are not very well repro-

FIG. 2.—Tadpole before the emergence of the fourth limb.—From "Nature Studies by Night and Day."

Ainsworth Davis; Botany (continued), by J. M. F. Drummond; Zoology, by Prof. J. R. Ainsworth Davis; and Science and the Sea Fisheries, by Dr. J. Travis Jenkins. Pp. x+236. (London: Gresham Publishing Co., n.d.)
(2) "A Bush Calendar." By Amy E. Mack (Mrs. L. Harrison). Pp. vi+109. (Sydney: Angus and Robinson, Ltd.; London: Australian Book Company, 1909.) Price 3s. 6d. net.
(3) "Nature Studies by Night and Day." By F. C. Snell. Pp. 319. (London: T. Fisher Unwin, n.d.) Price 2s.
(4) "Insect Wonderland." By Constance M. Foot. Pp. xi+196. (London: Methuen and Co., 1910.) Price 3s. 6d. net.
(5) "The Landscape Beautiful." A Study of the Utility of the Natural Landscape; Its Relation to Human Life and Happiness, with the Application of these Principles in Landscape Gardening, and in Art in General. By F. A. Waugh. Pp. 336. (New York: Orange Judd Co., 1910.)
(6) "Bees for Profit and Pleasure." By H. Geary. Farm and Garden Handbooks. Edited by T. W. Sanders. Pp. 114. (London: W. H. and L. Collingridge, n.d.) Price 1s. net.

duced; perhaps the most interesting is that of a tadpole with three legs, the right front limb not yet having emerged from the opercular fold. A book which might interest a novice in "nature-study."

(4) In "Insect Wonderland" the author endeavours to interest little children in the natural history of insects by conversations between insects and flowers, birds, &c., to which the insects describe their life and habits. It may be doubted whether this method is really more attractive to children than straightforward accounts, if written simply and easily, but in any case, it is unfortunate to write of *Mr.* Bee when the individual speaking is a worker, or of the orange-tip butterfly as "she," when the orange colour is confined to the male. The flowers and insects described as talking together also are not all to be found at the same season. Otherwise the descriptions are clear and good; the illustrations are pretty, but not always easy to understand.

(5) "The Landscape Beautiful" is written by an American "landscape architect," to encourage the appreciation of beauty in nature and in gardens. The first five chapters ("Essays") are in praise of natural beauty in its broader aspects, followed by a chapter to prove that landscape gardening is entitled to a place among the fine arts, since it combines all the objects and technical difficulties of painting and sculpture. This subject is amplified in the succeeding chapters, which deal especially with American landscape gardening, and the need for a greater appreciation of beauty and care for its preservation by the American people. The concluding chapter on "Some Practical Applications," describing the methods used or suggested by the author for encouraging the study of natural beauty in schools is particularly interesting, and might well be read by teachers of "nature-study." The book is pleasantly written and illustrated by very pretty photographs by members of "The Postal Photographic Club."

(6) "Bees for Profit and Pleasure" is a practical handbook to bee-keeping, written by an expert on the subject. It points out the advantages of keeping bees either for pleasure or as a supplementary source of income, gives a clear, concise account of their natural history and habits, and a good account of the various kinds of hives and other apparatus, with prices, but in some places the mention of apparatus not described until later in the book might cause some difficulty to the beginner. The instructions for successful management are straightforward and interesting, and the book is provided with an index.

THE GEOLOGY AND ARCHÆOLOGY OF ORANGIA.[1]

THIS work is the fourth of a series containing the author's personal observations and conclusions on the economic geology and archæology of South Africa. The present volume is devoted to Orangia, where the author has resided in practice as a mining engineer; his work gave him excellent opportunities for observation and research, and he has used his chances with admirable industry and judgment.

The first chapters are devoted mainly to the geology of Orangia, which is of less interest, owing to its monotonous uniformity, than that of any other South African State. Most of the country is occupied by rocks belonging to the Karoo system. The granitic mass of Vredeport outcrops near the northern frontier, and is surrounded by a belt of rocks corresponding to those of the Rand goldfield, which is situated further to the north. The extension of the Rand series under the Karoo has been proved by the bores recently made under the superintendence of Mr. A. R. Sawyer, and some of the results revealed by those boring operations are stated in the work. Mr. Johnson gives a short account of the diamond-bearing pipes of northern Orangia; he describes especially the Roberts-Victor Mine, of which he was for some time the mining engineer. This mine, among other points of interest, has yielded an eclogite boulder containing diamonds, which has been described by Dr. Corstorphine. The first such occurrence was found in the Newlands Mine at Kimberley, and is well known from the classical paper by Prof. Bonney. Mr. Johnson rejects the view that the eclogite was the original matrix of the diamond, and his conclusion is supported by the results of Mr. Gardner Williams's elaborate test, which proved by testing a large number that these boulders at Kimberley are barren of diamonds. He adopts the conclusions that the kimberlite, the igneous rock that fills the diamond-bearing pipes, is due to the intrusion of a magma at a comparatively low temperature.

Representation of Zebra, Hippotragus, and Quagga pecked and engraved on rock, Biesjesfontein. (Scale ⅛.) Reduced from "Geological and Archæological Notes on Orangia."

Mr. Johnson's archæological contributions include figures and descriptions of many rock paintings, of which one is here reproduced; the figures show no new general results, but they are interesting additions to those previously recorded. They are cruder than many of those found in South Africa, as shown by the exaggerated steatopygy in one of the figures. Mr. Johnson has diligently collected stone implements at many localities in Orangia, and investigated the sites of many ancient settlements. At one site he collected 700 stone implements from a small area in a short time. Mr. Johnson's most original archæological contribution is the claim that the stone implements belong to two separate periods, which he compares with the Acheulian and Solutrian of Europe. In some localities he found his Acheulic type—a common form of which he calls amygdaliths—below the alluvium and the Solutrian above it. The author candidly remarks at the end of his discussion of this question that his observations may merely prove that some of his Acheulic are older than some of his Solutric implements. This caution appears justified, as the results stated are not quite convincing, and more details as to the depths at which the implements were found would be useful.

In his agricultural notes the author directs attention to the great progress that has been made in Orangia by the adoption of the methods often known as "dry farming," which have long been used by farmers on our chalk downs. They have only recently been adopted in South Africa, where they have already

[1] "Geological and Archæological Notes on Orangia." By J. P. Johnson. Pp. vi+102. (London: Longmans and Co., 1910.) Price 10s.

proved remarkably successful; Mr. Johnson reports that the rainfall for the ten years' records at Kimberley, Kronstad, and Bloemfontein are respectively 20·4, 27·1, and 25·2 inches; so the climate would not be regarded as arid in Australia, where wheat cultivation has long been undertaken in areas with a rainfall of as low as fourteen inches. Most of the rain in South Africa falls in the six summer months, and its amount is sufficient to justify Mr. Johnson's confidence as to the future agricultural prosperity of the State.

J. W. G.

SPORT ON THE MOORS AND BROADS.[1]

SO far as I am aware, Messrs. Malcolm and Maxwell are the first to present the public with a concise, authentic, and at the same time highly interesting account of the rise and expansion of modern grouse-shooting in the North—a sport which they rightly declare to have been rendered accessible to English sportsmen as a whole by the development of railways. In our own days the steadily increasing demand for well-stocked moors produced by these means has given rise to great improvements in the care and cult of the moors, themselves coupled with a large extension of the area devoted to grouse; and this, in turn, has added very considerably to the financial prosperity of many parts of North Britain. How enormous is the value of Scottish and Yorkshire moors is told in the second chapter of the volume by Mr. Malcolm, who also discourses, with the confidence of an authority, on the management of moors, the connection between grouse and heather, and grouse disease. At one time it was hoped that the number of grouse on a moor might be largely augmented by suitable treatment, but it is now ascertained that there is a limit to this. In view of the prospect of a second edition, Mr. Malcolm's attention may be directed to a couple of obvious grammatical errors on the latter part of the second page.

The last six chapters are from the pen of Captain Maxwell, who discourses pleasantly on ancient and modern grouse-shooting, with a couple of chapters devoted to blackcock and ptarmigan. In urging the need for an extension of the close season in the case of blackcock, the author ought to enlist the support and sympathy of true sportsmen, since it is a crying shame that half-fledged "cheapers" should, as is so often the case, be shot in August. It is also satisfactory to find Captain Maxwell remarking that grouse-driving has resulted in a more or less indifference to natural history and wood-craft on the part of the modern sportsman, who thereby falls far behind his grandfather, to whom such knowledge was essential.

Coot and Great Crested Grebe on their Nests. From "Life and Sport on the Norfolk Broads.

In commending the united efforts of the two authors, I must not omit a word of praise for the 16 coloured reproductions of sketches of Scottish game-birds and scenery, by Mr. C. Whymper, which add so greatly to the attraction of the volume.

Mr. Ready, the author of the second volume mentioned above, is a born "Broadsman," having been brought up in a rectory in the heart of the broad-country, where forty years ago no railway had penetrated, while a visit to Norwich entailed an eighteen-mile journey by coach. Those early days of the author's life can be recalled only in memory, for the penetration of the district by the railway has altered its primitive character in many ways, although the charm of the more secluded portions of the Broads cannot, fortunately, be destroyed.

1 "Grouse and Grouse Moors." By George Malcolm and Aymer Maxwell. Illustrated by Charles Whymper. Pp. viii+286. (London: A. and C. Black, 1910). Price 7s. 6d. net.
"Life and Sport on the Norfolk Broads in the Golden Days." By Oliver G. Ready. Pp. xvi.+249. (London: T. Werner Laurie, n.d.) Price 7s. 6d. net.

That one who knows and loves his subject so thoroughly as does the author of this volume should furnish a mine of information about the Broads, is only what might be expected; but Mr. Ready is also possessed of a pleasant and readable style, although it may be noted that on the very first page he writes "Peninsular" when he means "Peninsula." Perhaps the three most interesting chapters out of the twelve which form the volume are those on birds' nests and fishing; and attention may be specially dir cted to the account of the nests of the great grebe—locally known as loon—and the buzzard, the former being illustrated by an excellent reproduction from a photograph. In the chapters on fishing much space is devoted to eels and eel-spearing; and it may be noted that in the author's opinion the old-fashioned spear on which eels were impaled is less cruel than the modern weapon in which they merely become entangled between the prongs. For while the former meant death, the latter allows a number of mangled fish to escape.

The illustrations, in addition to the one of the grebe, depict broadland scenery, Wrexham Hall and Church, various implements connected with eel-fishing, and other local subjects.

R. L.

DR. JOHN PEILE.

The death of the Master of Christ's College, Cambridge, has removed from the University a striking figure, and from the college over which for twenty-three years he presided so successfully a great master. Dr. Peile came of a well-known Cumberland family. His father was Mr. Williamson Peile, of Whitehaven, a geologist of repute. The late master was born in 1838, and was educated at Repton, whence he proceeded to Christ's College in 1856.

Dr. Peile had a distinguished university career, being bracketed Senior Classic in 1860, and winning the Craven Scholarship the year before, and being bracketed Chancellor's Classical Medallist in 1860. Soon after taking his degree, he became a fellow and lecturer of his college, and in 1870 he began his most successful career as a college tutor. This lasted until 1884, in which year he was elected reader in comparative philology in the University. In 1887 he succeeded Dr. Swainson as master of the college, and four years later, becoming vice-chancellor, he resigned his readership.

Dr. Peile took a large part in university matters. He was always on the side of progress, and, together with Henry Jackson and Henry Sidgwick, led many of the movements which have done much to advance learning in all its aspects at Cambridge during the last forty years. He was for an unprecedented time a member of the council of the Senate, and he took a foremost part in the movement for granting degrees to women, for the abolition of compulsory Greek, for the further provision of university buildings for science and other subjects, in the work of University Extension, and in the rearrangement of triposes and other examinations. He was in university affairs and politics a Liberal in the best sense of the word. His lifelong work in the cause of the higher education of women was recognised in the early "nineties," when he succeeded the late Prof. Adams as chairman of the council of Newnham College; and it was a great pleasure to him and to his wife to learn that the new building, opened only this term, was to be called the Peile building.

Dr. Peile's services to philology were those of the teacher rather than the discoverer. He was one of the first to introduce the study into England, and his manual of comparative philology and the little primer long held the ground practically unchallenged. These books showed a touch of taste and literary charm which are not often found in comparative philologists, perhaps rarely in any branch of science. When Brugmann's "Grundriss" summed up the results of twenty years' brilliant discoveries, Peile's books ceased to be useful, though they could not cease to be interesting. He never revised them. All through the period of transition, however, he was keeping abreast of the new discoveries, and acting on them. He brought a critical mind to bear on these; he took nothing on authority, and very often suggested a way of his own to meet the case. What struck the hearer was his humorous common sense. He had a sense of the fitness of things that kept him from pedantry. And the dullest details were illuminated by some chance remark, as when he lectured on the moods, he said one day, "Now you have Delbrück's view and my view; but I confess that I feel some misgiving when I see that we prove two contrary theories by the same examples." The lectures on comparative syntax probably contained his most original work. These were never published. Peile's infectious enthusiasm never failed to influence his hearers, and the impression is still quite strong after a quarter of a century.

In his own college, Dr. Peile was singularly successful in promoting the study of science in its widest sense. Christ's, which was the first college to award open scholarships in the natural sciences, has ever since maintained a high standard in science. Amongst Dr. Peile's pupils were the late Prof. Marshall Ward and the late Prof. H. Newell Martin, Prof. S. H. Vines, Prof. E. W. Hobson, Dr. W. J. Sell, Dr. H. J. H. Fenton, Prof. Liversidge, Prof. Percy Gardner the president of Queen's College, Dr. Rouse, Prof. J. G. Adami, Dr. A. C. Haddon, Prof. E. W. Brown, of Yale University, Prof. Graham Kerr, Dr. E. A. T. W. Budge, Dr. C. A. Barber, Dr. A. W. Rogers, of the South African Geological Survey, Prof. I. Gollancz, Mr. A. Hutchinson, Mr. R. H. Rastall, Mr. A. W. Clayden, Dr. F. H. A. Marshall, Prof. Gwynne-Vaughan, Mr. C. Warburton, and many others who are holding up the lamp of science in all its forms in many parts of the world.

The master was an untiring worker, and devoted his energies, which were great, whole-heartedly to the services of the University and of his college. During his mastership, Christ's College has been greatly enlarged, and to a great extent rebuilt. The chapel and the hall have been decorated by the late Mr. Bodley, and the same architect rebuilt and rearranged the library. A third court has been opened up, and contains a handsome building, with sets of students' rooms, and a more recently constructed pile of lecture-rooms erected at the time of the quatercentenary of the college. John Peile was a wise counsellor, a loyal colleague, absolutely unselfish and unself-seeking. He has left an impress on his University and on his college which can never be effaced.

NOTES.

By the bequest of the late Mr. F. Tendron, for many years chairman of the St. John Del Rey Mining Company, the trustees of the British Museum have recently acquired a few choice mineral specimens. Conspicuous among them is a magnificent, and probably unique, crystal of pyrrhotite, measuring as much as fourteen centimetres across. The suite also includes smaller specimens of pyrrhotite, two specimens of the rare mineral chalmersite, some well-crystallised gold, &c.

The States of the South African Union have decided to present to His Majesty the King a representative collection of living specimens of the wild animals of the country, and arrangements are already in progress for bringing together the collection and transporting it to England. The latter part of the task will be under the superintendence of the Zoological Society of London, in whose menagerie it is hoped that the whole collection will be ready for exhibition next summer, under the title of the King's African Collection.

It is announced in *Science* that the original laboratory of Liebig in Giessen is to be purchased and preserved as a memorial to the eminent chemist. An anonymous donor has guaranteed 3000*l*. for this purpose.

We notice with deep regret the announcement that Mr. J. W. Clark, who until quite recently held the post of Registrary of the University of Cambridge, died on Monday, October 10, at seventy-seven years of age.

The death is announced of Prof. W. H. Niles, Meredith professor of geology at the Massachusetts Institute of Technology. Prof. Niles was appointed to the chair in 1871, and was known for his contributions to geology.

The death is announced, at fifty-five years of age, of Dr. F. W. D. Fraser, formerly professor of anatomy and physiology at the Imperial University of Osaka, Japan; and also of Mr. A. H. Stokes, until recently Chief Inspector of Mines in the Midland district, at sixty-eight years of age.

We record with regret the death, on October 5 at Eastbourne, of Mr. Cecil H. Leaf, known for his studies of cancer. Mr. Leaf was in 1900 appointed to the staff of the Cancer Hospital, and at the time of his death was one of the senior surgeons of this institution. He was the author of numerous important surgical works on cancer of the breast, diseases of the rectum, experiments with chloroform, and other subjects.

Prof. A. Vambéry, the well-known Orientalist, completed on Sunday his fiftieth year of membership of the Hungarian Academy of Sciences. In honour of the occasion the society presented him with a jubilee diploma on Monday, October 10. The *Times* correspondent at Vienna states that in the course of the day Prof. Vambéry received congratulatory visits from a large number of Hungarian men of science and others, as well as telegrams of congratulation from learned bodies and friends in England and America. A subscription has been opened for the purpose of founding a Vambéry scholarship in philology.

We notice with regret the death of M. Maurice Lévy, who became a member of the Paris Academy of Sciences in 1883, when he took the place vacated by Bresse. M. Lévy was born at Ribeauvillé in Alsace in 1838. After studying at the École Polytechnique he entered the corps des Ponts et Chaussées, becoming eventually inspector-general. In 1885 he succeeded Serret as professor of mechanics in the Collège de France. His work was chiefly connected with mechanics and mathematical physics. His best known mathematical researches were on elasticity, hydrodynamics, action at a distance, and conservation of energy.

The Berlin correspondent of the *Times* has announced the death, on October 5 at Charlottenburg, of Prof. Ernst von Leyden in his seventy-eighth year. In 1865 Leyden was appointed professor at the University and director of the Klinik at Königsberg. In 1872 he was sent in the same capacity to the newly founded university at Strassburg. Four years later he succeeded Traube at Berlin, where he continued to work until 1907, when he retired. Leyden was the author of a work on the diseases of the spinal cord and of other medical books. He was a corresponding member of various foreign medical societies, and amongst other distinctions he received a patent of hereditary nobility.

The death is announced of Mr. John Roche Dakyns, who for thirty-four years was attached to the Geological Survey. He was born in St. Vincent, West Indies, on January 31, 1836, and died at Beddgelert on September 27. After joining the Geological Survey in 1862 he was actively engaged for twenty-two years in Yorkshire and the bordering counties of Derbyshire, Lancashire, and Westmorland; for ten years he was occupied in mapping the central Highland rocks in the counties of Perth, Stirling, and Dumbarton, and he was engaged during two years in the neighbourhood of Abergavenny before he retired from the public service in 1896. He was part author of numerous memoirs of the Geological Survey, and he contributed papers, mainly on Carboniferous and igneous rocks, and on Pleistocene deposits, to the Geological Society, the *Geological Magazine*, and the Yorkshire Geological and Polytechnic Society.

The lecture list of the London Institution for the session 1910–11 includes the following subjects:—Secrets in a pebble-beach, Cecil Carus-Wilson; malaria, Major Ronald Ross, F.R.S.; smoke and its prevention, Prof. Vivian B. Lewis; autumn and winter, the web of life, F. Martin-Duncan; Cretan discoveries, David G. Hogarth; the art of aviation, R. W. A. Brewer; life and work of Lord Kelvin, Prof. S. P. Thompson, F.R.S.; and the art of Palaeolithic man, Dr. A. C. Haddon, F.R.S.

In connection with the London County Council's work of indicating the houses in London which have been the residences of distinguished persons, a tablet has been affixed to No. 4 Marlborough Place, St. John's Wood, N.W., where at one time Huxley lived. Huxley moved into the house in 1872, and lived there nearly twenty years. Most of his letters in London were written at Marlborough Place, and a picture of the house appears in his "Life and Letters."

A copy of the list of the zoological gardens of the world in September, compiled by Capt. S. S. Flower, of the Zoological Gardens, Giza, Egypt, has been received. The list includes the names of 104 such gardens in existence at the date specified, as well as references to many others now closed or in process of formation. The oldest of the gardens appears to be the Schönbrunn in Vienna, founded in 1752; the zoological garden in Madrid was opened in 1774, and that in the Jardin des Plantes in Paris was inaugurated in 1793. The gardens in Regent's Park date back to 1828. Two collections have been opened this year, one in Munich and the other in the Edgbaston Gardens, Birmingham.

Prof. Raymond McFarland, of Middlebury College, Vermont, has just returned from a two months' tour of exploration, during which he penetrated into parts of western Labrador never previously visited by a white man. During the first part of his journey, from Lake St. John to the Mistassini post of the Hudson Bay Company, he was accompanied by two colleagues, Profs. T. C. Brown and P. N. Swett. His companions then left him in order to make magnetic observations and to study geological formations along the Fiel Axe and Chief Rivers. Prof. McFarland, with a single Indian guide, then travelled a hundred miles further north, visiting hitherto unexplored regions to the east and north of Grand Lake, Mistassini, and climbing the Porcupine range of mountains. The three explorers are well satisfied with the results of their expedition, having brought back many valuable geographical and geological data.

Prof. E. Fugger, of Salzburg, one of the explorers of the newly discovered ice-cave near Obertraun, in the Hallstadt region of Upper Austria, has favoured us with the following particulars relating to it. The opening is visible from Obertraun, and lies 1600 metres above the sea in the back wall of a cirque between the Mittagkogel and the Hirschberg. A low, narrow passage leads into a hall 10 metres high, the floor of which is covered with ice, bright and clean as a mirror. A cone of ice rises nearly to the roof. After a steep descent of 25 metres an ice-lined cathedral is entered, measuring 40 metres from floor to roof. The floor is strewn with blocks of ice 4 to 7 m. high, the walls are thickly coated with ice, and an ice-pyramid rises here also almost to the roof. A ridge of ice, running in the direction of the length of this cave, leads upwards from it into a gigantic ice-grotto, containing superb needle-like groups of ice-crystals. From a conspicuous group, styled "Monte Cristallo," a stream of clear ice stretches eastward for more than 100 m., leading up to a cross-passage. The right-hand passage is free from ice, and a tooth of *Ursus spelaeus* was found in it. It can be followed into another large hall 100 m. long, 50 m. wide, and 25 m. high, with a castle-like mass of ice rising from its floor. An ice-chasm has now to be scrambled down to an imposing doorway of ice, from which a very narrow passage, 20 m. long, leads into a hall 200 m. long and at least 30 m. high. This hall is free from ice, and breaks up into a series of tunnels, in some of which water-worn pebbles indicate the course of an ancient stream. The total length of the series of caves is 2000 metres. Where ice prevails, the temperature is from 0° to 1° C., while it rises to 5° C. in the portions free from ice.

Under the title of "Byways in the Caucasus," in *Travel and Exploration* for September, Colonel C. E. de la Poer Beresford gives a graphic account of a tour through a region which was the scene of some of the hardest fighting in the great struggle between the Russians and the tribesmen. He describes Gergebil, which was attacked by Vorontzoff in June, 1847, when held by the Murids under Shamil; Gunib, the famous fortress into which Shamil retired in 1857 after waging war against the Russians for twenty-five years; Akhoulgo, like "Edinburgh Castle with another higher rock covering Scott's and Wallace's monuments, rivers rushing round their bases, and a connecting ridge between the rock and Arthur's Seat." He commends the system by which the Russians have reduced these stubborn mountaineers to subjection to the notice of British officers now engaged in the task of subduing the frontier tribes like the Afridis and Waziris.

In the twentieth Bulletin of the Sleeping Sickness Bureau the records of fifty cases of sleeping sickness in Europeans are tabulated and discussed. Of these cases, forty-five were men, five women; nineteen came from the Belgian Congo, fourteen from the French Congo, and four from Uganda. "Of the fifty patients, thirty are known to be dead, eleven survive, and the fate of the remaining nine is uncertain. Of the thirty, fourteen lived a year or more after trypanosomes were discovered, and four two years or more. Of these, one lived three and a quarter years and one six years." One of the survivors, infected probably in 1900, but possibly earlier, is considered to have made a real recovery, and there are grounds for hope that at least four other cases have done the like. Full clinical details of the cases and their treatment are given. The case that is regarded as cured was treated with Fowler's solution.

The *Journal of Hygiene* (vol. x., No. 2) contains a memoir by Miss Harriette Chick on "The Process of Disinfection by Chemical Agencies and Hot Water," giving the results of experiments with phenol on *Bacillus typhosus*, *B. coli communis*, and *Staphylococcus pyogenes aureus*, and with hot water on the same three species and on *Bacillus pestis* and *B. paratyphosus*. It is concluded that "disinfection is an orderly time-process, which may be considered analogous with a chemical reaction." "The fact that the individuals [in a culture of bacteria] do not die all at once, but at a rate proportional to the concentration of the survivors at a given moment, is to be attributed to temporary and rhythmical changes in resistance which, by analogy with chemical processes, may be supposed to be due to temporary energy changes of the constituent proteins."

In the Launceston *Examiner* of August 23 Mr. H. H. Scott records the discovery of a skeleton of Diprotodon in the Smithton district, this being the first record of the occurrence of the genus in Tasmania. The species is presumed to be identical with the Australian *D. australis*.

According to their reports for 1909, all the five museums of the Cape of Good Hope have suffered from shortness of funds, largely owing to the policy of economy rendered necessary by the present state of the colonial finances. In the case of the South African Museum, lack of space for exhibition purposes and the numerical inadequacy of the staff have likewise hindered progress. The director of this institution states that, in his opinion, the time has come for prohibiting the export from South Africa of ethnological and anthropological relics. The plea for the prohibition is based on the systematic manner in which such objects have of late years been exploited, and the high prices paid for them.

The August number of the Journal of the South African Ornithologists' Union contains the report of the migration committee for 1908–9. Eight records of the arrival of storks, either singly or in parties, are chronicled, from which it appears that December is the month when most of these birds reach Cape Colony, although the period of immigration lasts from September to January. In a separate communication Mr. Haagner states that four storks marked by the Vogelwarte Rositten and five by the Royal Hungarian Central Ornithological Bureau have been taken in South Africa, but adds that many more records must be secured before full knowledge of the migration of these can be obtained. Mr. Seebohm, for instance, was of opinion that the birds which travelled farthest north of the equator likewise flew farthest south, but another observer has suggested the reverse of this. Only one record of the movements of the cuckoo is mentioned, this being a departure in the middle of March. No reference is made to a query which recently appeared in the *Field* as to whether cuckoos ever utter their characteristic note in South Africa.

A noteworthy paper by Dr. M. Nowikoff appears in the August number of the *Zeitschrift für wissenschaftliche Zoologie* (Bd. 96, Heft 1) on the structure, development, and significance of the parietal eye of saurians. The author's investigations were conducted chiefly upon species of Lacerta and Anguis. The parietal or pineal eye in these genera agrees closely in histological structure with that of Sphenodon, but the author finds that it is innervated from the right habenular ganglion, and not from the left as Dendy has shown to be the case in the Tuatara. He now adopts the view that the pineal eye and epiphysis are dislocated members of one and the same pair of sense-organs, serially homologous with the lateral eyes, as Dendy has also maintained in the cases of Sphenodon and Geotria. He suggests that, inasmuch as the pineal eye is well developed in small and unprotected lizards, it is, though incapable of image-formation, probably still of service in giving notice of the approach of an enemy flying in the air when the lizards are sleeping in the sun with their paired eyes closed.

WE have recently had an opportunity of seeing at work the large new microtome brought out by the Cambridge Scientific Instrument Company. It is designed to cut flat sections up to 150×120 mm., the thickness of which can be varied by 0·002 mm., the maximum thickness of the section being 0·06 mm. The sliding carriage, in which the object, embedded in paraffin or celloidin, is held, is moved backwards and forwards on plane guides by a handle working through levers. The object is fed upwards by a ratchet turning a toothed wheel, and an arrangement similar to that found in the well-known rocking microtome of this company is adopted to lower the object-holder on the return stroke, so as to prevent the object fouling the knife. The knife can be very securely clamped either at right angles to the direction of movement of the object, when the latter is embedded in paraffin, or at an oblique angle when cutting celloidin. Arrangements are provided for changing the inclination of the cutting edge of the knife, and there is a small angular scale on the knife-holders, so that the angle found most suitable when cutting a particular object can be easily noted and repeated. The strength and rigidity of the instrument are striking features, but the care and attention devoted to the details of construction are no less evident, the device just mentioned, for reading off the angle of the knife, being an example of the useful details which will be greatly appreciated by the operator. We have seen a number of sections, cut by this microtome, of various tissues which can be cut only with some difficulty, which demonstrate the capabilities of the instrument, and we can recommend it to those whose work necessitates the preparation of large flat sections of material containing cartilage, decalcified bone, and other resistant tissues.

A SMALL pamphlet on the cultivation of mushrooms, of which Mr. R. L. Castle is the author, has been published in the series of "One and All" garden books. It can be recommended as a practical and authoritative guide.

A LIST of varieties of sweet peas classified according to colour has been prepared by the National Sweet Pea Society, and is published in the *Gardener's Chronicle* (October 8). It is described as an up-to-date selection of varieties in commerce, and comprises sixty-three varieties grouped in twenty-five classes; the first item in each class is that which produced flowers most true to colour in the society's trials. The society has also issued a list of varieties "too-much-alike" with the intention of allowing only one out of each colour group to be shown on a competition stand. Further, the society is taking steps to arrange for the registration of new varieties.

A COLLECTION of plants obtained by Mr. G. Nakhara in the southern half of the island of Saghalien is described by Mr. G. Koidzumi in the Journal of the College of Science, University of Tokyo (vol. xxvii., art. 13). It provides a supplement to the list of plants collected and determined by Dr. Fr. Schmidt in 1868, to which it adds about fifty species—one, *Cirsium Mamiyanum*, being new to science—and raises the total number of ferns and flowering plants to three hundred. A dozen species are limited to the Ochotsk region, including an Abies and a Picea. The special features of the flora are a predominance of the families Compositæ and Rosaceæ, and the small proportion (3 : 2) of species to genera.

ON the subject of tree plantations in Inverness-shire Mr. W. Dallimore places on record in the *Kew Bulletin* (No. 7) some useful data regarding cost and the species that have given good results on different estates. The area planted on the Ardverikie Estate since 1873 exceeds 10,000 acres, for which 34,000,000 plants have been required. Scots pine, larch, and spruce have been most extensively planted; the pine and larch have grown well on dry ground at altitudes exceeding 900 feet, while the spruce has succeeded better on wet ground, but *Abies nobilis* has, on the whole, proved more vigorous than any of the three. The cost of planting, including fencing, is given at 3*l.* 12*s.* per acre. Interest attaches to a note regarding a larch forest on the Invergarry Estate that at an early stage was condemned on account of the larch disease, but was spared at the urgent request of the forester in charge, and has now developed perfectly clean, straight trees.

THE issue of the *Geographical Journal* for October includes the paper on the land of the Incas, read before the society by Sir Clements R. Markham, K.C.B., F.R.S.; the paper provides a graphic account of southern Peru and part of the north of Bolivia, with their variety of climates, geographical features, and products. The land of the Incas extends from the water-parting of the maritime Cordillera to that of the eastern Andes, and from the gorges through which the rivers force their way into the Amazonian plain to the Knot of Vilcañonota, where the two Andean chains unite. The paper gives interesting glimpses at the Tiahuanacu ruins of unknown history, and shows how intimate is the author's knowledge of this part of South America. In the same issue appears Major G. F. A. Whitlock's paper on the Yola-Cross River Boundary Commission, Southern Nigeria, from which some idea can be obtained of the difficulties of accurate surveying in little known countries. Mr. Edward A. Martin gives an exhaustive account of further experiments he has made on dew-ponds. He has come to the conclusion that very rarely does dew ever form on the surface of ponds, and rarely on the puddled margins. He holds that if we continue to use the term dew-pond we must remember that the word must be used in the widest sense as including any form of condensation out of the atmosphere. Rain appears to be the all-important replenisher of these as of all other ponds which are not fed by springs.

THE application of the method of correlation to investigations of the connection between meteorological elements at different places promises to be a fruitful, though somewhat laborious, method of approaching the problem of seasonal forecasts. In a note in Bulletin 4, 1910, of the Central Meteorological Observatory of Japan, Dr. T. Okada has correlated the mean monthly pressures and temperatures for some places in the Far East. He finds that at Zikawei (Shanghai) the coefficient of correlation between pressure and temperature in December is $-0{\cdot}764 \pm 0{\cdot}050$. Taking pressure at Zikawei and temperature at Nagasaki, 500 miles distant, he finds for the value of the coefficient -0.044 ± 0.076. Thus high pressure at Zikawei is accompanied by low temperature, not only there, but also at Nagasaki. Again, taking pressure at Zikawei and rainfall at Keelung, in northern Formosa, 450 miles distant, he finds for the value of the coefficient 0.925 ± 0.037. Thus when pressure is high at Zikawei in winter rainy weather in northern Formosa may be confidently predicted. The paper includes diagrams, in which the relationships can be distinguished, but the definite numerical index furnished by the correlation supplies the meteorologist with much more satisfactory means of comparing the similarity with that for other places and of using the results in more extended researches.

INTEREST in the diurnal variations of the meteorological elements has been stimulated of late years by the addition to our knowledge of the analysed results of wind velocity for certain representative places, and by the difficulty of bringing into dynamical relation with each other the results for pressure, temperature, and wind. In Bulletin 4, 1910, of the Central Meteorological Observatory of Japan, Y. Tsuiji discusses the daily variation of wind and the displacement of the air at Nagasaki. After analysing the variation into its harmonic components, he attempts to connect it with the variation of pressure gradient deduced from the mean hourly values of pressure at the three stations Nagasaki, Fukuoka, and Kumamoto. He concludes that the phases of the variation of the components of wind are almost identical with those of the variation of the corresponding components of pressure gradient. Apart from any effect due to the earth's rotation, it would be expected that these phases would differ by 90°, and although the nearness of Nagasaki to latitude 30° might account for the identity in the phases for the diurnal wave, it is unlikely that the effect in the semi-diurnal wave can be attributed to such a cause. The author does not attempt to explain the anomaly. An examination and recalculation of some of the results shows that time is to be measured from 1 a.m. in the expressions given for the harmonic components, although it is stated that it is measured from midnight. Thus the diagram (Fig. 5) showing the diurnal and semi-diurnal waves is seen to be wrong by a comparison of the sum of the deviations at noon taken from the diagram with the actual values given in Table I. The fact that the phases of the diurnal term in the south and east components of velocity are almost exactly equal, while those for the semi-diurnal wave differ by 40° only, shows that convection is the predominating factor in determining the diurnal variation, and exercises a considerable influence on the semi-diurnal wave.

IN a paper which appeared in vol. xxxii. of the *Annalen der Physik* Dr. M. Knudsen, of the University of Copenhagen, describes an absolute manometer for the measurement of gas pressures not greater than a few thousandths of a millimetre of mercury. It depends on the measurement of the force of repulsion between two plates at different temperatures immersed in the gas, when their distance apart is extremely small compared with the mean free path of the molecules of the gas. This repulsion the author shows is equal in dynes per square centimetre to half the product of the pressure of the gas by the excess of the square root of the ratio of the two absolute temperatures of the plates over unity. The instrument consists of a polished copper plate, which is supported with its surfaces vertical by a thin platinum wire. Opposite part of one surface is the polished end of a fixed copper cylinder, the temperature of which can be raised above that of the suspended plate and the case of the instrument by sending an electric current through a platinum wire wound on it. The rotation of the moving plate about its suspension is determined by means of a mirror attached to the plate, and thermometers give the temperatures of plate and cylinder.

PROF. PATERNO, of the University of Rome, has given an account in the *Revue scientifique* of August 20 of some recent work on colloidal solutions, arising out of an early observation that tannic acid, which behaves as a colloid and produces no osmotic or cryoscopic effects in water, behaves in the normal way as a crystalloid when dissolved in acetic acid. The aqueous solution is a deep brown, although the tannic acid separating from it is white, and the solution in acetic acid is only yellowish. Observations by the ebullioscopic method indicated that the Grignard reagent, magnesium ethiodide, probably exists as a colloid in its ethereal solutions. Several alkaloids were found to dissolve in ether without raising its boiling point, whilst the alcoholic solutions showed a normal elevation.

IN an article in the *American Architect* for September 28 Prof. William H. Goodyear analyses the report of the Pisa Commission on the Leaning Tower, and brings forward evidence to show that the figures of the commission are in error. Prof. Goodyear maintains that the tower has moved 30 centimetres more than the commission has supposed, and that this movement had taken place before the date of De Fleury's "Monuments de Pise" in 1859. The actual movement, he says, has been one of 50 cm., not of 20; but this movement, which was probably caused by the earthquake of 1846, certainly occurred before 1859. Prof. Goodyear also challenges other results published by the commission. Thus the commission's supposed rate of inclination per metre in 1829 is $86\frac{1}{2}$ mm.; the article gives the real average rate as 84 mm. The supposed present rate of inclination per metre is announced by the commission as 92 mm.; here it is said to be really $94\frac{1}{2}$ mm. in 1859. The commission announces 20 cm. additional inclination between 1829 and 1910. There was really, it is said, 50 cm. additional inclination before 1859. The commission announces the rate of increase per metre between 1829 and 1910 as being $5\frac{1}{2}$ mm. Therefore, says Prof. Goodyear, if the supposed increase of 20 cm. be divided by the rate of increase per metre, we ought to obtain the axial height on which the increase was figured, viz. the axial height of the tower. "But when this division is made, the resulting axial height is only 36·36 m., which is the axial height, according to Cresy and Taylor, of the six stories above the first, thus leaving the entire lower story, which is nearly one-fourth of the axial height, out of the computation."

AN illustrated article on the Portsmouth water works appears in *Engineering* for October 7. The borough of Portsmouth has recently put into commission a new system of filter-beds and covered service reservoirs. The new works are situated at Farlington, on the side of Portsdown Hill, distant five miles from Portsmouth. The water supply comes from chalk springs at Havant and Bedhampton, where pumping-stations are situated. The water is delivered through three rising mains to the filter-beds, from which, after passing through the service reservoirs, it gravitates to the town. Previous to the construction of the new works, the water was delivered from the pumping-stations to two open service reservoirs on Portsdown Hill; these are now covered, and form part of the reconstructed scheme. It was the practice under the old conditions to deliver the water in an unfiltered state from the open service reservoirs to the town. The raw water is normally excellent, owing doubtless to the underground chalk through which it passes, but discoloration occasionally occurs during wet weather following a period of drought. Ferro-concrete on the Hennebique system has been employed largely on the new constructional work.

In this month's *Aeronautics* appears an announcement to the effect that, recognising the importance of flying from a military point of view, that journal offers to present a complete aëroplane to the first suitable officer of the army who applies for it and is willing to try his best to become proficient with it.

In the article on "Mathematics in Austria," in NATURE of September 29, mention was made of arithmetic papers set by the Civil Service Commissioners and other examining bodies. The writer asks us to say that his allusion to the Civil Service Commissioners was due to his belief that they regulated the Army Qualifying as well as the Army Competitive examination. He has since found that the former is conducted by the "Army Qualifying Board." His reference, therefore, to the Civil Service Commissioners was incorrect.

A TRANSLATION into German by Prof. Julius Ruska of Prof. W. H. Hobbs's book on "Earthquakes" has been published by Messrs. Quelle and Meyer, of Leipzig. A review of the original volume was published in the issue of NATURE for March 26, 1908 (vol. lxxvii., p. 481). The price of the German work is 6.60 marks.

OUR ASTRONOMICAL COLUMN.

ANNOUNCEMENT OF A NOVA.—A circular received from the Kiel Centralstelle states that in a telegram from Cambridge, Mass., received on October 5, it is announced that a new star in Sagittarius has been discovered by Mrs. Fleming on a plate taken on May 31·831 (G.M.T.). This object, Nova Sagittarii No. 2, was then bright enough to be visible in a small telescope, and its position is $\alpha=17$h. 52m. 15s., $\delta=27^\circ$ 32·2′ south, about 7m. west and 3° north of the third-magnitude star γ Sagittarii; like most other objects of its class, this nova lies in, or very near to, the Milky Way.

It is interesting to recall that Nova Sagittarii No. 1 was also discovered by Mrs. Fleming on a photograph taken at Arequipa on March 8, 1898, but was not detected until March, 1899.

TIME OF THE SOLAR TRANSIT OF HALLEY'S COMET.—The examination of various solar photographs for traces of Halley's comet during its transit of the solar disc on May 18 has hitherto been somewhat indefinite, because the exact times of ingress and egress were not certainly known. Figures which should permit of more definitive examinations are now given in No. 616 of the *Astronomical Journal*; they are as follows:—

	G.M.T. h. m.		
Ingress	15 40	...	Angle 279°
Least distance between centres .	16 9	...	Comet 3′ 15″ N.
Egress	16 39	...	Angle 76°

OBSERVATIONS OF COMET 1910*a*.—In a Bulletin of the Catania Academy of Natural Science, just received, Prof. Riccò discusses the observations of comet 1910*a*, visual, photographic, and spectroscopic, made at the Catania Observatory during January and February. After describing the visual and spectroscopic results, Prof. Riccò directs special attention to the greater similarity of the visual and photographic images in this comet than in several which immediately preceded it, due to the greater proportion of yellow radiations. He also suggests that the appearance of the three "hydrocarbon" and one yellow band, when the comet was near perihelion, is in accordance with Hasselberg's experiment with a Geissler tube containing hydrocarbon and sodium vapours. With the tube cool, only the hydrocarbon bands showed in the spectrum, but when it was heated the sodium band was seen to be relatively strong.

It is stated in the *Observatory* (No. 427) that whilst the object observed by M. Sykora (NATURE, September 8, p. 322) was in the right position-angle, it was considerably too far from the centre of the disc.

ARABIAN ASTRONOMICAL INSTRUMENTS.—Vol. xli. (1909) of the *Sitzungsberichte der Physikalisch-Medizinischen Sozietät in Erlangen* contains No. 18 of Prof. E. Wiedemann's contributions to the history of science, which deals with some of the astronomical instruments of the Arabs (53 pp.). Chapter i. gives descriptions of the astrolabe and the quadrant, founded on two writings by Al Birûni in the Royal Library of Berlin. Chapter ii. gives a review of the trigonometry of the Arabs and its application to problems arising from the use of the gnomon ("determination of the shadow"). Chapter iii. contains an account (chiefly from Al Birûni) of the use of the astrolabe in surveying. The paper is of special interest on account of the many extracts it gives from unpublished manuscripts, and makes us hope that some further details may yet be brought to light about the instruments used in the great observatories at Cairo, Merâgha and elsewhere, as to which our knowledge is very imperfect.

NEW EPHEMERIDES FOR SATURN, URANUS, AND NEPTUNE.—For some time it has been a known fact that the observed positions of the three outermost planets showed considerable discordance with Leverrier's tables. In No. 427 of the *Observatory* Dr. Downing directs attention to the advance made by the compilers of the *Connaissance des Temps* in publishing, for 1912, ephemerides based on Gaillot's "Tables Rectifiées" instead of Leverrier's tables. A comparison of the respective corrections shows that an important step in advance, in the calculation of accurate ephemerides of the major planets, has been made.

IRREGULARITIES IN THE MOTION OF ALGOL'S SATELLITE.—In the October number of the *Bulletin de la Société astronomique de France* M. Enzo Mora shows that, according to observations made in 1908, 1909, and 1910, the relative motion of the satellite of Algol has been subject to an extraordinary perturbation. Comparisons made between the brightness of Algol and that of ϵ Persei, within about 40 minutes of the minimum of the former, indicate departures from the normal of the time of minimum ranging from 0 to 26 minutes. The latter figure is somewhat uncertain and unique, but the difference cannot be traced to observational error; prior to 1909 the departure from normal had never exceeded 6 minutes. The perturbative action of other satellites is suggested as a possible cause of these irregularities.

THE CAMBRIDGE OBSERVATORY.—The annual report of the work done at the Cambridge Observatory during the year ended May 18 is divided into two sections, in the former of which Sir Robert Ball gives an account of the general observations. From this we learn that the results of the investigations into the constant of aberration and the variation of latitude, made by Mr. Cookson during 1905–7, are being prepared for press by Mr. Stratton, while the manuscript photographic catalogue of 6000 stars, observed at eleven observatories during the Eros campaign, has now been completed by Mr. Hinks.

In the second part Prof. Newall describes the work done in the astrophysical department. The radial velocities of certain red stars, of which many show fluctuations of brightness with long periods of variation, are being investigated by Mr. Stratton. It is with regret that we note that some difficulty is being experienced in obtaining a perfect 12-inch objective, of 60 feet focal length, for use in the solar observations.

OBSERVATIONS OF NEPTUNE'S SATELLITE.—The observations of Neptune's satellite, made by Prof. Barnard with the 40-inch refractor during 1900–10, are published in No. 617 of the *Astronomical Journal*. A magnifying power of 700 was usually employed, but the satellite was frequently found to be an extremely difficult object; the recorded magnitudes range from 13·0 to 14·5.

SOME RECENT STUDIES OF FOSSIL PLANTS.

WHEN, many years hence, a history of the study of fossil plants during the first decade of the twentieth century is being elaborated, it will be found that two discoveries, announced in 1903 and 1906 respectively, will stand out as particularly far-reaching in their "after effects." These contributions will be found to rank in importance with any that may be cited in the whole range of the previous history of the study of palæobotany.

In 1903, Oliver and Scott showed that Lyginodendron, a well-known fern-like plant of the Carboniferous period, was in reality a seed plant. Within the next two years a number of similar discoveries were made in the case of several other genera, though since 1905 no further contributions of a like nature have been published. The identification, however, in that year of the male organs of Lyginodendron, which we owe to Dr. Kidston, completed our knowledge of that genus.

In 1906, Dr. Wieland, in his handsome volume on the "American Fossil Cycads," brought home to us, with a vividness which left little to be desired, the amphisporangiate nature of the cone of the Mesozoic genus Bennettites, or Cycadeoidea, as the Americans prefer to call it.

As Wieland himself foresaw, this discovery has thrown light on the phylogeny of the Angiosperms and Gnetales,[1] two groups hitherto of obscure affinities. These contributions have been already reviewed in NATURE[2] at some length, and it is therefore not proposed to discuss them further here.

A very extensive series, amounting to several hundreds, of memoirs, both large and small, have also been published on various palæobotanical subjects within the last ten years. The results there contained all contribute to our knowledge in one direction or another, but these directions are so varied, and often so disconnected, that it will only be possible to notice a few of them very briefly in a concise review such as the present. Further, the selection here made will be chiefly confined to those which have appeared during the last four years, and especially to those dealing with petrified material.

The true Ferns of the past have recently received considerable attention. It is now recognised that the ancient Ferns of the Palæozoic period, for which the name Primofilices has been suggested, differed in certain important respects from the Mesozoic, Tertiary, and recent Leptosporangiatæ. The latter appear to have sprung from the Primofilices, during the latter portion of the Permian period, and it would seem that, very soon after the initiation of the group, it differentiated in a fan-like manner into a number of families, many of which are still represented to-day. The Osmundaceæ, for instance, which of all the Leptosporangiate ferns stand nearest to the archaic stock, the Primofilices, were in existence in Upper Permian times.

This fact is emphasised by the recent studies of Kidston and Gwynne-Vaughan,[3] on the anatomy of a number of Osmundaceous stems from the Permian, Mesozoic, and Tertiary rocks. Three of these memoirs have appeared, and a fourth has been added since this review was written. This work is especially interesting, for not only is our knowledge of petrified plant remains from the rocks of these periods extremely scanty, but the study of the structure of these ancient representatives of the family has thrown light on the ancestral history of certain structural peculiarities met with in living ferns, especially the origin of the adaxially curved leaf trace.[4] The primitively solid, protostelic nature of the stem cylinder of the ancient Osmundaceæ is emphasised, and the evolution of the stele in this group is no longer a matter of theory, but of fact.

Our knowledge of the Primofilices has also recently advanced rapidly. A full account of this group will be found in the new edition of Scott's "Studies in Fossil Botany" (chapter ix.). Dr. Paul Bertrand, in his "Études sur la Fronde des Zygoptéridées," a handsomely illustrated volume published last year, has traced the course of evolution of the petiolar stele of members of this group. In this connection Mr. Gordon's paper on the structure of the stem and petiole of *Diplolabis roemeri* (Solms) from the Calciferous Sandstone of Scotland, which is shortly to appear in the Transactions of the Royal Society of Edinburgh, will be found of interest as carrying further broad conclusions of a similar, if not identical, character.

So far as the other Palæozoic groups are concerned, attention has recently been devoted almost entirely to the Lycopods. The Sigillarias, which until a short time ago remained the one important genus of the anatomy of which we knew very little, especially as regards the numerous species which possessed ribbed stems (Eu-Sigillariæ), have now been studied in detail. The structure of the stele closely resembles that of other Palæozoic Lycopods, especially Lepidophloios, the chief distinguishing features being found in the cortical tissues and leaf-bases. The anatomy of the cone scars is now known.[1] It has been found that, in certain species of ribbed Sigillariæ, the leaf-trace, when traversing the leaf-base and the lower part of the leaf, possesses a double xylem strand[2] (Fig. 2). The ribbing of the stem appears to be quite independent of the leaf-bases. The external features of three species of ribbed Sigillarias have now been correlated with their internal structure.

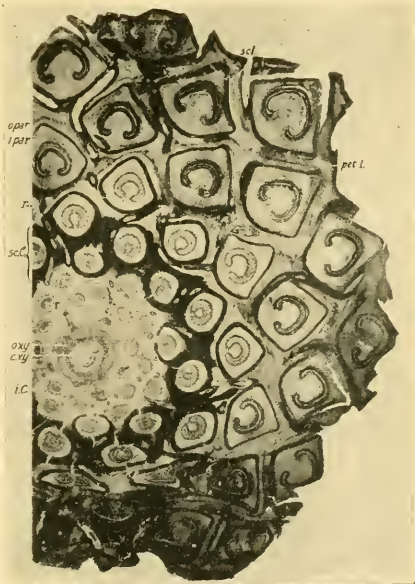

FIG. 1.—*Thamnopteris Schlechtendallii*, an Osmundaceous stem from the Upper Permian of Russia. A transverse section showing *o.xy*, outer xylem ring; *c.xy*, central xylem; *i.C*, inner cortex; *sc C.* sclerotic outer cortex; *i.par*, inner parenchyma of petiole; *o.par*, outer parenchyma of petiole; *scl.* sclerotic ring of petiole; *r.*, root. Reduced after Kidston and Gwynne-Vaughan.

The Sigillarias, like the Lepidodendrons, were large forest trees, often 100 feet or more in height. Herbaceous members of the group appear to have been comparatively rare, and until recently have been little known. Halle[3]

has, however, figured several impressions of herbaceous Lycopods from the Palæozoic and Mesozoic rocks, some of which appear to be similar in habit to the recent Lycopodium, and others to Seloginella. The latter have dimorphic leaves, and in some cases the sporangia are aggregated into stroboli, while, in at least one species, they are borne in the axils of foliage leaves, a very interesting feature in comparison with the modern Selaginellas. Zeiller, in his fine memoir, "Bassin houiller et permien de Blanzy et du Creusot" (1906), has figured, among other very interesting impressions, a Selaginellites, in which the leaves are arranged in the same manner as in the recent tetrastichous Selaginellas. The heterosporous cones contain a large number of megaspores in the megasporangia, another interesting feature unknown in the modern representatives of the group.

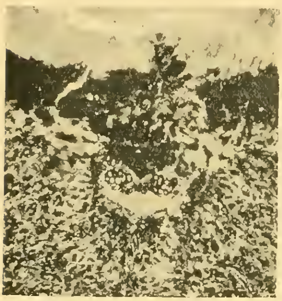

FIG. 2.—Tangential section through the leaf-base of *Sigillaria scutellata*, Brongn., showing the two xylem groups. After Arber and Thomas.

These specimens, however, are mere impressions. Fortunately, however, Miss Benson [1] has recently extended our knowledge of these plants by describing the anatomy and fructification of *Miadesmia membranacea*, Bertr., the first instance in which we have any information as to the structure of a *herbaceous* Palæozoic Lycopod. The fructification of this plant proves to be a primitive seed-like organ, recalling Lepidocarpon among fossils, and Isoetes among living plants.

Numerous other memoirs on Palæozoic Lycopods have also appeared, which it is impossible to discuss here. Among these may be mentioned Prof. Weiss's [2] description of a Stigmaria with centripetal wood, Mr. Watson's [3] discovery of the cone of *Bothrodendron mundum* (Will.), and Mr. David White's [4] *Archaeosigillaria primaeva*, an interesting impression from the Devonian rocks of New York State.

Although, as has been stated, no further attributions of seeds to the Palæozoic fern-like plants or Pteridospermeæ have been made during the last few years,[5] our knowledge of this group has been extended in other directions. Scott [6] has described a new stem, *Sutcliffia insignis*, Scott, a member of the Medulloseæ, characterised by concentric petiolar bundles, and a stem of very simple structure with a single main stele; a unique case of dialystely without siphonostely.

The structure of isolated seeds of pteridospermous affinity has also received attention, Scott and Maslen's [7] studies of Trigonocarpus, of which the first part has appeared, and Oliver's [8] memoir on *Physostoma elegans*, Will., being notable contributions in this direction.

Turning next to the studies of Mesozoic plants, Wieland's elucidation of the cone of Bennettites, to which we have already alluded, has been followed by the very important discoveries by Nathorst [9] of the male organs of Williamsonia, Anomozamites (now called Wielandiella), and several other genera of Triassic or

Jurassic age, also belonging to the Bennettitales. Nathorst's specimens were impressions and not petrifactions, but by means of his new methods for studying carbonised impressions [1] he has been extremely successful in obtaining, from mere impressions, information which, until a few years ago, would have been regarded as quite impossible.

Nathorst finds that the flowers of Williamsonia, unlike those of Bennettites, are unisexual, a very important point. The male sporophylls (Fig. 3) were arranged in a whorl, and were fourteen or fifteen in number. They were united laterally for nearly half their length. The microsporangia were borne on the inner side of the sporophyll on segments which were somewhat divided. The male organs may be of a similar nature to the extraordinary "male-fronds" of Bennettites, but in Williamsonia they are very greatly reduced.

In Wielandiella, however, the cones are amphisporangiate, and the male sporophylls are still more reduced, and form a palisade-like ring near the base of the cone. The cone was markedly protogynous (Fig. 4).

The fact that the male sporophylls of some members of the Bennettitales have now been found, which are very much reduced as compared with those of Bennettites itself—an event which was confidently expected to occur—has an important bearing on the question of the origin of the Angiospermous stamen.[2]

Wieland [3] has also recently described a male flower of a Williamsonia, which does not, apparently, agree exactly with that discovered by Nathorst in Yorkshire last summer. On this specimen Wieland has founded a theory of the phylogeny of the Gamopetalæ, which, however, will probably not meet with general acceptance.

Mesozoic plants are now attracting a more considerable share of attention than they have in the past. The great drawback to studies of this nature has always been the absence of petrified material. Impressions alone are available, though there has been no lack of large, isolated stems or trunks of Gymnospermous or Angiospermous affinity in certain deposits belonging to this period. Such petrifactions, however, do not tell us very much, and we have hitherto failed to find plant-bearing concretions, similar to

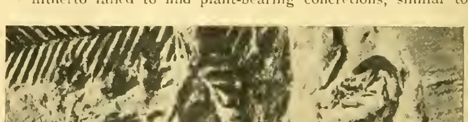

FIG. 3.—The Male Flower of *Williamsonia spectabilis*, Nathorst, from the Lower Oolite of Whitby, Yorkshire. After Nathorst.

the coal-balls of the English Carboniferous rocks, with their wealth of fragments of leaves, cones, or other organs, from which so much can be ascertained, both from an anatomical and a phylogenetic standpoint. Stopes and Fujii [4] have now, however, discovered such concretions in the Upper

Cretaceous of Japan, which in several respects appear to be quite analogous to our English coal-balls. In their paper published a few months ago, they describe a varied series of fossil plants from these nodules, such as the sporangia of a fern of Schizæaceous affinities, a leaf, Niponophyllum, with parallel nerves, several stems and cones of Gymnosperms, especially Yezonia, a trunk in which the wood consists of thick- and thin-walled tracheids arranged on the same radii, and which is regarded as a representative of a new family of Coniferæ. Among the Angiospermous remains are woods allied to the Saururaceæ, to the Juglandaceæ, the Sabiaceæ, and Cupuliferæ. But perhaps the most interesting specimen is that discussed as being a flower of Liliaceous affinity, and termed *Cretovarium japonicum* (Fig. 5). This is regarded by the authors as the first fossil flower known in the petrified state. It is described as a trilocular ovary with axile placentation, though the ovules are absent.

FIG. 4.—The amphisporangoic cone of *Wielandiella angustifolia*, Nathorst, from the Rhætic of Sweden. (1) The axis with the "palisade-ring" of male sporophylls below. (2) The ring of male sporophylls enlarged. After Nathorst.

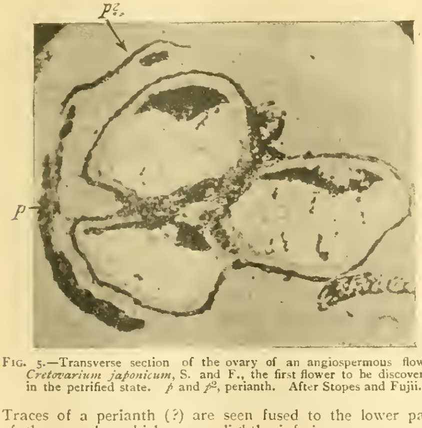

FIG. 5.—Transverse section of the ovary of an angiospermous flower *Cretovarium japonicum*, S. and F., the first flower to be discovered in the petrified state. p and p^2, perianth. After Stopes and Fujii.

Traces of a perianth (?) are seen fused to the lower part of the carpels, which were slightly inferior.

Baldwin (Ethical Library). *Williams and Norgate.*—A popular edition of Herbert Spencer's First Principles, 2 vols.

THE INTERNATIONAL CONGRESS ON RADIOLOGY AND ELECTRICITY.

THE second congress on radiology and electricity was held at Brussels on September 13–15. That two congresses have already been held to consider questions relating to radio-activity and allied subjects affords evidence of the rapid progress in this branch of science of recent years; but that some five hundred workers in physics and medicine should have assembled to discuss the bearing of modern electrical theory and radio-activity upon the various investigations on which they are engaged is a striking proof of the influence which these new ideas have exercised on the progress of science. It is now universally felt to be desirable, if not necessary, that those engaged on investigations in radio-activity in different parts of the world should have occasional opportunities of meeting each other, and perhaps one of the most important results of the recent congress has been the formation of an influential international committee to arrange the time and place of subsequent congresses. The continuation at regular intervals of meetings such as the one which has just taken place is therefore now assured, and thanks are due to the Belgian men of science and to the Belgian Government, under the patronage of which the congress was held, for organising the two successful meetings, the first at Liége in 1905 and the second at Brussels this year. It may be added that the meeting was rendered the more successful and pleasant by the hospitality offered to members by the town of Brussels. In this connection may be mentioned the reception at the Bourse and at the Town Hall by the Municipality, and also the admirable performance at the Théâtre Royal de la Monnaie, at which members were invited to be present.

The work of the congress began on Tuesday, September 13, with a meeting at the Palais des Fêtes in the exhibition grounds, when members assembled to hear an address by the president, Prof. de Heen, on æther and matter. The large gathering included eminent men of science from all parts of the world. The opening meeting finished, members dispersed to spend the remainder of the morning in the exhibition, after which they reassembled in the buildings of the Free University for a meeting which proved of exceptional interest. The proceedings began with a discussion, opened by Prof. Rutherford, on the question of fixing a suitable nomenclature in radio-activity and of establishing radio-active standards adapted to the requirements of quantitative measurements to be made for physical and medical purposes. After a short discussion it was decided that the matter could best be settled by a small committee acquainted with the needs of the different branches of the subject, and that this committee should meet and report to the congress the results of their deliberations at a subsequent meeting. The report of the committee is of such special interest that it is not possible to deal adequately with it within the limits of this article, but a full account of the recommendations was given by Prof. Rutherford in NATURE of October 6. While the necessary arrangements were being made for the formation of this committee the president called upon Madame Curie to give an account of the recent experiments made in Paris to isolate metallic radium. It will be remembered that this metal has hitherto not been separated from its salts, although a radium amalgam was obtained some years ago by Coehn. The beautiful experiments described by Madame Curie, resulting in the isolation of metallic radium, must be regarded as a triumph in chemical manipulation when it is remembered that, in addition to the fact that on account of its chemical properties radium is difficult to isolate, the operations had to be carried out with minute quantities of material in such a way as to avoid loss of the precious substance during the process. These experiments should remove all possible doubt that radium is, in fact, an element belonging to the same group of metals as barium.

After some other communications the meeting adjourned until the following day, when the congress met in three sections to deal with the large number of papers on the physical and medical aspect of radiology. The work of the physical section was of great interest. It began with a lecture, remarkable for the clear and vivid style of its delivery, by M. Perrin, who described his experiments on Brownian movement and their bearing on the determination of atomic magnitudes, followed by a review of the present position of our knowledge of these matters. Dr. Hahn next gave an account of the method of preparation of some highly active samples of radiothorium and mesothorium, of which specimens were shown. The phosphorescent effects produced by them on a zinc-sulphide screen could be clearly seen from all parts of the lecture-room, and there can be no doubt that these products, which are now to be had from Messrs. Knöffler and Co., of Berlin, will prove of great use for many purposes as an alternative to radium. Mr. Soddy followed with a description of the results of his work on the rate of production of helium from a Portuguese specimen of autunite. From his experiments it is possible to assign limits between which must lie the "life" of ionium, that stable product discovered by Boltwood, and known to be the parent of radium.

The papers which remained to be read on the last day were so numerous that it was found necessary at the last moment to subdivide the meeting further, and a separate section was quickly formed under the presidency of Prof. Rutherford for the discussion of purely radio-active questions. A number of important papers on various subjects were read. The proceedings were opened by Prof. Bragg with a discussion of the nature of the γ rays, in which he showed how it is possible to assign a "range" to the path of β rays in different metals on the assumption that the γ rays are material particles, and that the ionisation produced by them is due to β rays produced in their path. The paper was immediately succeeded by one by Prof. Barkla, who explained how each element submitted to a stream of homogeneous X-rays emits several beams of homogeneous X-rays characteristic of the element. Each homogeneous radiation was excited by a primary radiation of greater penetrating power according to Stokes's law for fluorescence, so that it was possible to draw a close comparison between light and X-rays in this respect. Dr. Hahn then gave an account of his experiments with Dr. Baeyer on the magnetic deflection of β rays. Photographs were shown indicating that the deflected rays from a single radio-active product gave rise to definite lines on the photographic plate, showing that during the decay of radio-active substances, just as for the α particle, the β particles leave the atom with a velocity characteristic of the particular product. The question of the recoil of radio-active matter during the expulsion of an α particle was next discussed by Dr. Makower. Experiments made by Dr. Russ, Mr. Evans, and himself on the electric and magnetic deflection of radium B when it recoils made it possible to determine the charge carried by the atoms of radium B, and to determine its atomic weight. The results showed that the atomic weight had approximately the value to be expected on the disintegration theory of radio-active changes. M. Wertenstein followed with a description of his work on the absorption by air of radium B when it recoils. Dr. Kovarik then gave a short account of his investigations on the absorption and scattering of β rays. It was shown how entirely erroneous results might be obtained in determining the absorption of β rays by matter unless certain precautions were taken in making the measurements. Dr. Kleeman next brought before the meeting some theoretical considerations regarding the absorption of α, β, and γ rays in passing through matter, after which M. Moulin described his interesting experiments on the saturation currents obtained in air ionised by α rays when the electric field is inclined at different angles to the trajectories of the rays.

It has only been possible to deal even shortly in this article with the papers on radio-activity, which formed perhaps the most important part of the work of the congress; but communications were presented on almost all branches of modern physics, amongst which some of the most interesting may be mentioned. Dr. Conway gave a paper on the theory of electronic conduction; Prof. Becquerel described his experiments on magneto-optic phenomena in crystals; Prof. Wien discussed the existence of positive and negative ions in canal rays; Prof. Arrhenius dealt with the solubility of the active deposit of actinium; Prof. Weiss spoke of molecular magnetic fields; and Prof. Exner gave a description of the new Radium Institute at Vienna.

The papers read before the biological section of the congress were so decidedly medical in character that an account of them would scarcely be of interest to readers of Nature. W. M.

THE OPENING OF THE MEDICAL SESSION.

THE custom of opening the winter session, the commencement of the medical year, at the medical schools with addresses has much to commend it. The attention of the public is directed to the work, scientific and charitable, of the great hospitals; if the address is delivered by a layman, the lay views on medical education and things medical are expressed, often with advantage; if by a medical man, the students hear words of wisdom culled from a ripe experience.

In the absence of the chairman, Prince Francis of Teck, the gathering at the Middlesex Hospital was presided over by Lord Grenfell, and the address was delivered by Lord Kitchener, who naturally dealt with the relation of medicine to the army and with army medical organisation. He directed attention to the improved sanitary condition of the army and to the vast field still remaining for research. As regards India, he said:—"That scourge of the army—enteric fever—is now at last definitely yielding to improved sanitary methods and to the system of inoculation which has recently become almost universal. Enteric will before long, I feel sure, join the formerly dreaded cholera in total banishment from our barracks. To bring home to you the measure of success which has attended their work in India, I need only point out that during the last ten years the ratio of 'constantly sick, invalided, and deaths' has been reduced by no less than 50 per cent. But there still remains in that country a vast field for your energies and painstaking research."

As regards army medical organisation, Lord Kitchener pointed out that the training which turns out competent medical men for civil work is quite inadequate in equipping medical officers for the special needs of the army in war time.

At St. Mary's Hospital Sir Arthur Conan Doyle gave an address to the students on "The Romance of Medicine." After relating some of his medical experiences in his early days, he pointed out that "there were, perhaps, some dangers which came from a medical training, but there was a great post-graduate course called life, and in that course one learnt to correct these weaknesses. One was an undue materialism. He was educated in a materialistic age, before psychical research, scientific hypnotism, telepathy, and other such agencies emphasised the possibilities which lie outside the things that we can see, handle, and explain. They looked upon mind and spirit as secretions from the brain in the same way as bile was a secretion of the liver. Brain centres explained everything, and if you could find and stimulate the centre of holiness you would produce a saint—but if your electrode slipped and you got on to the centre of brutality, you would evolve a Bill Sikes. That was, roughly, the point of view of the more advanced spirits among them."

In the concluding portion of his address Sir Conan Doyle dealt with medicine and history and some of the modern developments of medicine, particularly the *rôle* of opsonins. The starting point of the opsonin investigation was when it was shown that a white corpuscle taken out of the blood plasma would not digest microbes, and would only renew its activities when it was moistened with that fluid. This experiment showed that in that fluid there was suspended some invisible stuff which increased the activity of the white corpuscle, and made it devour microbes—some sort of sauce, in fact, which made the microbes more attractive to it. This substance was named opsonin. It had been found that, normally, opsonins are present in fixed quantity, but that in microbial infections the opsonins are generally diminished in amount. By the injection of dead microbes the activity of the white blood corpuscles is stimulated, more opsonin is formed, and the disease process tends to be cured.

At Charing Cross Hospital the Huxley memorial lecture constituted the opening address, and was delivered by Dr. Mott, F.R.S., the subject being "The Hereditary Aspects of Nervous and Mental Diseases." He remarked that in certain nervous diseases it is generally recognised that heredity plays a part, but these are due to characteristic morphological defects. As regards insanity, there are few alienist physicians who do not hold a strong belief in hereditary causation. The matter is now being investigated statistically, and a report will shortly be published. Consanguinity does not appear to produce insanity or nervous disease provided both stocks are free from taint. Chronic alcoholism figures largely in the pedigrees of patients admitted to asylums, but the idea that a desire for alcohol is transmitted from parent to offspring is erroneous—what is transmitted is lack of will power and moral sense.

The Dean of Salisbury delivered the address at University College Hospital. He emphasised the importance of complete development in a sound education. An address on "Woman's Sphere in Medicine" was given by Mr. E. W. Roughton at the London School of Medicine for Women. Mr. Roughton said that there were cogent reasons why there should be a female section of the profession. So far as he was able to judge, in suitability, adaptability and other characters, and in intellectual capacity, women would compare equally with men in the profession. There were, of course, some divergences between the sexes; women, for instance, did not, as a rule, seem to be so handy as men in looking after pieces of mechanism.

At the London Hospital Dr. Robert Hutchison gave the annual "Schorstein" lecture to the students of the medical school, the subject being "Congenital Pyloric Stenosis." Prof. Marett Tims delivered the address at the Royal Veterinary College. He pointed out the growing importance of biology with regard to the problems of medical and veterinary science, and suggested the establishment of a bureau at the Royal Veterinary College for the collection of statistics, the working out of all questions of inheritance in animals, not only the inheritance of disease, but also of data desirable from the point of view of the breeder, especially in the question of horse-breeding.

Prof. Howard Marsh, master of Downing College, Cambridge, distributed the prizes in the University of Leeds. In his address he dealt with the problems of medical education. He said that as medicine had now become a department of biology, its pursuit necessarily demanded a sound acquaintance with the broad principles of those departments of biological science with which it was intimately connected, the foundations on which it rested, chemistry, anatomy, physiology, and pathology. The difficulty which the student experienced was to keep pace with his subjects. With the average man the whole business had, from the first, been hopeless. He thought that a conference of those interested in medical education might be useful.

THE BERLIN UNIVERSITY CENTENARY.

The celebration of the hundredth anniversary of the foundation of the University of Berlin began on Monday with a reception of the representatives of universities and other bodies and a torchlight procession of students. The principal ceremony was held on Tuesday in the new Great Hall of the University. The Emperor and Empress, with the Prussian Princes and a brilliant retinue, attended, and his Majesty delivered an address. The festivities will be continued until Thursday night. A Reuter message from Berlin states that all the German and the principal foreign universities of the world are represented by special delegates. The representatives appointed by British universities are (in alphabetical order):—Aberdeen, Principal G. A. Smith; Cambridge, Sir J. J. Thomson; Cape Town, Prof. Marais; Dublin, Prof. Mahaffy; Durham, Vice-Chancellor Dr. Jevons; Edinburgh, Prof. H. J. Eggeling and Sir W. Turner; Glasgow, Principal Macalister; London, Sir H. E. Roscoe and Sir W. Ramsay; Melbourne, Prof. Masson; Montreal, Lord Strathcona; Oxford, Mr. R. W. Macan, the Master of University; Toronto, Prof. McCurdy. The British Academy is represented by Lord Reay; the Royal Society by Sir Joseph Larmor; and the University of Paris by M. Henri Poincaré.

Reuter's correspondent remarked on Monday:—"The patriotic aspect of the fêtes will be more strongly marked than is usual in the case of academic celebrations. The decision to found a university in Berlin was taken while the capital was still in the occupation of French troops, when Prussia's national fortunes were at their lowest ebb. It is now a matter of justifiable pride to the Germans that in those disastrous days there was still courage and energy enough in Prussia to set coolly about the task of rebuilding the intellectual and educational life of the country and giving it a national centre. Since then Berlin University has grown with the growth of Prussia and Germany, and a glance at its records from the handful of professors and the few scores of students who attended the opening winter term of 1810 to the 500 professors and lecturers and the 12,000 students who now throng the University buildings, provides no bad barometer by which to gauge the marvellous progress of Prussia and Germany during the past century."

We hope to give in a later issue an account of the celebration, by one of the delegates attending it. The issues of the *Morning Post* for October 11 and 12 contain particulars of the opening functions, and two valuable leading articles in which German thoroughness and system in educational and scientific work are described. From the latter issue we reprint some interesting extracts from the German Emperor's address.

The German Emperor on Knowledge and Research.

Since the day of its foundation, the destiny of the Friedrich Wilhelm University has been most intimately bound up with that of the Prussian and German Fatherland. When my forefather King Frederick William the Third summoned it into existence, now a hundred years ago, his object was to restore to the State with intellectual what it had lost in physical forces. The University of Berlin was thus born of the same creative spirit from which Prussia's regeneration sprang. This spirit, which raised up Prussia and Germany, and which lived in Fichte, Schleiermacher, Savigny, and their friends, made the University in the course of years the centre of intellectual and scientific life in the Fatherland. The University of Berlin was at first, it is true, far from being a *Universitas Literarum* as conceived by Wilhelm von Humboldt, but it has approached ever nearer to this ideal. A stronghold of the sciences, it has to-day an international importance reaching far beyond the frontiers of Prussia and Germany. This is manifested outwardly in the interchange of teachers and auditors. Working in common with the other universities of the country, it constitutes now the general teaching establishment which it was intended to be by its founders.

Humboldt's great plan demands side by side with the Academy of Sciences and with the University independent research institutions as integral parts of a whole scientific organism. The foundation of such institutions has not kept pace in Prussia with the development of the universities, and this deficiency, especially in our natural scientific equipment, becomes ever more keenly felt in consequence of the mighty advancement of the sciences. We need institutions which, outside the compass of the universities, shall serve solely for research. It appears to me to be the sacred task of the present time to summon such institutions into life at the earliest possible moment, and I consider it my patriotic duty to solicit universal interest in the undertaking. This great aim requires large means, and can be attained only if all circles interested in the progress of science and the welfare of the Fatherland are ready to cooperate in fulfilling this most important task and in making sacrifices for it.

I should like, therefore, to bring before everybody's eyes and lay at everybody's heart this new aim with the fervent exhortation: "Tua res agitur." I hope and firmly trust that the work will succeed, for, although the plan has been made known only in a narrow circle, enthusiastic expressions of concurrence have already reached me from various parts of the country, and the very considerable sum of between nine and ten million marks [between 450,000*l.* and 500,000*l.*] have been placed at the disposal of the enterprise. I feel it a cordial necessity to express my warmest thanks from this place to the self-sacrificing givers. In order to ensure the permanent furtherance of the enterprise, it is my wish to found under my protectorate and name a society which shall make it its task to establish and maintain research institutions. To this society I will gladly transfer the funds offered me. That State help will not be wanting to institutions about to be established my Government will take care.

I have one other wish for the University to take with it into the new century. May it in faithful remembrance of the time of its origin preserve its Prussian-German character. Science, it is true, is the common good of the whole civilised world, and its achievements no longer halt before any boundary line. And yet—as each nation must preserve its own peculiarity if it wishes to maintain an independent existence, and its value for the whole—may the "Alma Mater Berolinensis" always remain conscious of the fact that she is a German university. As heretofore, may it also be in all the future the seat of German manners and customs and of the German nature. . . . May, therefore, the University also henceforward hold the splendid privilege of cultivating the true science which, as Humboldt admirably says, comes from the interior and is planted in the interior which remoulds and creates the character. Let her do this with noble freedom which gives laws to itself and in that intense feeling of being the trustee of a treasure which is bestowed on all mankind. "Communis hominum thesaurus situs est in magnis veritatibus." All truth, however, is from God, and His spirit rests on every work that springs from truth and strives after truth. May this spirit of truth also fill you students; may it penetrate my dear University in its entire efficacy. Then will its old age be as its youth, and it will continue to be the town on a hill to which the nations make pilgrimage, and the ornament and safeguard of the Fatherland.

THE BRITISH ASSOCIATION AT SHEFFIELD.

SECTION L.

EDUCATIONAL SCIENCE.

Opening Address by Principal H. A. Miers, M.A., D.Sc., F.R.S., President of the Section.

To preside over this Section is to incur a responsibility which I confess somewhat alarms me; for the President may, by virtue of his temporary office, be regarded as speaking with authority on the subjects with which he deals.

Now, it is my desire to speak about University education, and for this purpose I must say something of school education; but I would have it understood that I really know little about the actual conduct of modern school teaching. One may read books which describe how it should be conducted, but this is a very different thing from seeing and hearing the teacher in his class; and I fear that personal recollections of what teaching in preparatory and public schools was like from thirty to forty years ago do not qualify one to pose as an intelligent critic of the methods which now prevail.

Human nature, however, has not changed much in the last forty years, and if, in considering the relations between University and school education, I can confine myself to general principles, based upon the difference between boys and men, I trust that I may not go far wrong.

I propose first to consider some general relations between teachers and their pupils, and then explain what, in my opinion, should be the change in the method of teaching, or at any rate in the attitude of teacher to pupil, which should take place when the scene changes from school to University.

First as to general relations between teachers and their pupils.

Educational systems necessarily prescribe the same methods for different teachers, and, being made for the mass, ignore the individual. But happily, in spite of the attempts to formulate methods of instruction and to make precise systems, there are many, and those perhaps some of the most successful, in the army of earnest school teachers who are elaborating their own methods.

Now among all the changes and varieties of system and curriculum there is one factor which remains permanent and which is universally confessed to be of paramount importance—the individuality of the teacher and his personal influence upon the pupil. It is therefore a healthy sign when school teachers who have been trained on one system begin to develop their own methods, for in this they are asserting their individuality and strengthening that personal influence which is the real mainspring of all successful education.

Personal influence is, of course, not only a matter of intellectual attainments; it appears to me, however, that at the present time so much is made of the duty of schools to aim at the formation of character that there is an unfortunate tendency to regard this duty as something distinct from the other functions of a master, and as independent of intellectual qualifications. Among the first qualities now demanded of a master in a public school for boys are manliness, athletic skill, and a hearty and healthy personality, and these are often regarded as compensating for some lack of intellectual equipment. I suspect that there is a similar tendency in schools for girls. And yet I think it will be found that the only permanent personal influence is really wielded by teachers who exercise it through intellectual channels, and that those who acquire intellectual authority will generally succeed in training the characters as well as the minds of their pupils.

On the other hand, the master who is not up to the proper intellectual standard will soon be found out by his cleverer pupils, and will lose influence, whatever may be the personal charm of his character.

The formation of character, so far as it can be distinguished from intellectual training, is largely worked out by the boys themselves in any public school in which healthy tradition and a sound moral atmosphere are maintained, although it is true that these traditions depend upon the character and personality of the teachers.

The educational value of the personal and intimate association with one and the same teacher throughout the school or University career is officially recognised in the tutorial system at Eton, Oxford, and Cambridge. It has generally led to excellent results, provided that the tutor possesses the right qualities and that pupil and tutor do not happen to be two incompatible personalities; but the results may be well-nigh disastrous where there happens to be antagonism between the two, or where the tutor does not realise his opportunities and responsibilities. I have known some tutors who only excited a distaste for learning in their pupils, and others who entirely neglected or abused the high trust which had been committed to them; but far more, I am glad to say, who have not only exercised the most profound influence for good on their better and cleverer pupils, but also inspired intellectual interest in the most unpromising of them. Although such a tutorial system does not enter fully into the scheme of other schools and Universities, and therefore a student does not usually remain long under any one teacher, it must be within the experience of most persons to have come for a time at least under the influence of a teacher who has inspired real enthusiasm for learning and from whose lips the instruction, that might from others have been a trial, has become an intellectual treat.

It is given to comparatively few to exert this powerful and subtle influence in a high degree, for it is a gift confined to a few rare natures. All the more important is it, therefore, to ensure that an effective personal influence may play its part in the intercourse between ordinary teachers and ordinary pupils in the customary routine of school and University life.

How, then, is the proper personal and sympathetic relation to be established between teacher and pupil, so that the individuality of the one may call out the character and the effort of the other? Those who inquire of their earliest school reminiscences will probably recollect that the teachers who obtained a real hold upon them did so by virtue of the power which they possessed of arousing their intellectual interest. I would ask you for a moment to analyse the character of this interest.

In the young child I believe that it will be found to be mainly that of novelty: with him "this way and that dividing the swift mind," sustained thought, or even sustained attention, has not yet become possible; the inquisitive and acquisitive faculties are strong; and every new impression awakens the interest by its novelty quite apart from its purpose. You have only to watch and see how impossible it is for a young child to keep its attention fixed even upon a game such as cricket or football to realise how still more difficult it is to keep his attention fixed upon an intellectual purpose.

To quite young children, except to those who are unfortunately precocious, even an impending examination is not a permanent object of anxiety.

Now contrast the aimless interest which can be aroused in any young child's mind by the pleasure of a new impression, a new activity, or a new idea, with that which appeals, or should appeal, to the more mature intellect of an older student. With him it is not enough that the impression or the idea should be new; if it is to arouse interest it must also direct his mind to a purpose. This is to him the effective interest of his games or sport; in the game the desire to succeed or to win is the animating purpose, just as the expectation of catching a fish is the interest which keeps the angler's attention fixed for hours upon his line. In both the desire is fostered by the imagination, which maintains a definite purpose before the mind.

It is sometimes forgotten that as he grows the pupil is no longer "an infant crying for the light," but has become a man with "splendid purpose in his eyes."

While, therefore, it should be the aim of a teacher of young children to set before them the subjects of their lessons in an attractive manner, so that the novelty is never lost, and not to weary their active and restless minds with too sustained an effort, it should at a later stage be the teacher's aim to keep the object and purpose of the new fact or idea as constantly as possible in view, and not to distract the ardent mind with purposeless and disconnected scraps of learning.

I ask you to bear this distinction in mind, for it is a principle which may guide us in differentiating University methods from school methods of education.

The distinction need not involve us in a discussion of the "Ziel-Angabe" in elementary education, for that is rather a question of keeping the interest alive during each lesson than of maintaining a permanent purpose in view throughout a course.

The much discussed heuristic method as applied to very young children does, no doubt, fulfil this object so far as it provides the inquisitive mind with novelty instead of a set task, but so far as it makes the purpose more prominent than the process it may become a method more suited to the adolescent or the adult mind than to that of the young child.

I can fully realise that a most difficult and anxious time for the teacher must be that of the maturing intellect, in the interval between childhood and the close of the school career, when the method and spirit of the teaching must to some extent gradually change with the changing mental characteristics of the pupil. But, whatever may be the right methods of teaching children of ten and young men and women of twenty, many of our failures are due to one or both of two prevalent mistakes: the first, the mistake of teaching children by methods that are too advanced; the second, that of teaching University students by methods that are better adapted for school children. It is with the latter that I wish to deal in this address; but we may in passing remind ourselves that when young men and young women are sent straight from the University to teach children with nothing but their University experience to guide them, it is not surprising that they often proceed at first on wrong lines, and as though they were dealing with University students.

The difficulty of divesting oneself of the mental attitude and the form of expression familiar in University circles, if one is to become intelligible even to the higher classes in a school, is betrayed by the unsatisfactory nature of many of the papers set by University examiners to school children. The teachers complain, and rightly complain, that there is often an academic style and form about them which just make them entirely unsuitable for the child.

It is, of course, hopeful that a diploma in pedagogy or some evidence that they have received instruction in method is now generally required of those who are to become teachers in schools. It seems to me, however, somewhat curious that, while efforts are now being made to give instruction in educational method to such persons, no similar effort is made to give instruction in more advanced methods to those who are called upon at the close of their undergraduate career to become University teachers, and that in consequence many of them have no method at all.

This may be a matter of comparatively small importance to those who possess, not only the necessary knowledge, but also the natural gift of personal influence and the power of inspiring those whom they teach. But for those who are not blessed with these powers it may be almost as difficult to fall into the ways of successful University instruction after the sudden transformation from student into teacher as it is for those who become teachers in schools.

Granting, then, that there should be a radical difference between the ways of school and University teaching, and that there is at present an unfortunate overlapping between the two, let me next consider how the distinction between the intellectual interest of a child and the intellectual interest of a man may guide us in adjusting our methods of teaching when students pass from school to the University.

A tenable, perhaps even a prevalent, view concerning a liberal school education is that its chief purpose is not so much to impart knowledge as to train the mind; indeed, some teachers, influenced, perhaps, in the first instance by the views of Plato, go so far as to think that no subject which is clearly of direct practical use should be taught as such at school. This view they would carry to the extent of excluding many obviously appropriate subjects from the school curriculum, whereas almost any subject may be made an intellectual training; this being a question not of subject, but of the manner in which it is taught. In any event, if the scheme of intellectual training be adequately fulfilled, the period of mental discipline should come to an end with the close of school life, and the mind should then be able to enter upon new studies and to assimilate fresh knowledge without a prolonged continuation of preparatory courses. Indeed, the professed object of entrance examinations to the University is to exclude those whose minds are not prepared to benefit by a course of University study, and to admit only those who are sufficiently equipped by previous training to do so. An entrance examination, then, should not be merely a test of whether a boy or girl has learnt sufficient of certain subjects to continue those subjects in particular at the University; and yet it has unfortunately come to be regarded more and more as performing this function instead of being regarded as a test whether the student is generally fit to enter upon *any* University course. The result is that an entrance examination tends to become a test of knowledge rather than a test of general intelligence; merely one in an organised series of examinations which endeavour to ascertain the advancing proficiency in a limited number of subjects, and therefore tend really to encourage specialisation. Specialisation is not to be prevented by insisting on a considerable number of subjects, but rather by teaching even one subject in a wide spirit. Another result is that the entrance examination belongs properly neither to the school course nor to the University course; if it is taken at the age of sixteen, the remainder of the school career tends to be devoted to University work, which should not really be done at school; if it is taken after leaving school this means that work is being done at, or in connection with, the University which ought to be done at school. It is certainly true that for various reasons a vast deal of education is now being carried on at the Universities which should belong to school life, and, moreover, is being carried on by methods which are identical with those pursued at school. It is equally true that, owing to the early age at which matriculation examinations or their equivalents may be taken, many schools are now asking that at the age of eighteen or nineteen a school examination may be held which shall be an equivalent, not for matriculation, but for the first degree examination at the University. This would really imply that schools should be recognised as doing University work for two years of their pupils' careers—surely a most illogical procedure, and one which supports my contention that there is now very serious overlapping, for it assumes that the work for the first degree examination can be carried on either at the school or the University, and therefore that there is no difference in the methods of the two.

An increasing number of candidates actually present themselves from secondary schools for the external intermediate examination of the University of London; in 1904 there were about 150; in 1909 there were nearly 500 such candidates. This is, of course, a debatable subject, and there are many who think the overlapping of school and university work a highly desirable thing.

There will always be exceptional boys and girls who reach a University standard, both of attainments and intelligence, long before they arrive at the ordinary school-leaving age. Let them either leave school and begin their University career early, or let them, if they remain at school, widen their knowledge by including subjects which are not supplied by the more rigid school curriculum designed for the average pupils; but let them not cease, save in very exceptional cases, to be taught as school pupils, *i.e.* with mental training as the chief object. It is equally certain that there will also be boys and girls whose development is so slow that they barely reach the University standard when they leave school; yet some among them are the best possible material and achieve the greatest success in the end. For such persons an entrance examination will be required at the age of eighteen or nineteen; but I think it is unfortunate that this should be the same as that which quicker pupils can pass at the age of sixteen or seventeen, for an examination designed for the one age can scarcely be quite satisfactory for the other.

I confess that the whole matter is inextricably involved with the question of University entrance examinations. But to enter upon this here would carry us beyond the limits that I have laid down for myself, and it will be more profitable to decide what should be done at school and the University respectively before discussing how the examinations are to be adapted to our purpose. It will be sufficient for me to say that I have been led to the conclusion that if they are to test the intelligence of those who are ready to enter upon a University course, matriculation examinations should be designed to suit the capacity of average pupils not less than seventeen years of age.

Starting, then, with the principle that the period of mental discipline is closed at the end of the school career, and that those who pass to the University come with fair mental training and sufficient intelligence, let me inquire what should be the relation of University teaching to that which the student has received at school.

Under present conditions the schools which aim at sending students to the Universities endeavour to give a general education which will fit their pupils to enter either upon a University course or upon whatever profession or occupation they may select on leaving school. They do not confine the teaching of any pupil to preparation for a special profession or occupation, and they do not generally encourage special preparation for the University.

Now contrast what happens to the pupils leaving such a school to enter a profession or business with what happens to those who proceed to the University. The former pass into an entirely different atmosphere; they are no longer occupied with exercises and preparatory courses which serve a disciplinary purpose; they are brought face to face with the realities of their business or profession, and, though they have to gain their experience by beginning at the lower or more elementary stages, they do actually and at once take part in it.

The University student, on the other hand, too often continues what he did at school; he may attend lectures instead of the school class, but neither the method nor the material need differ much from what he has already done. Should not the break with school be as complete for him as for his schoolfellow who goes into business? Should he not be brought face to face with the actualities of learning? After his years of preparation and mental drill at school should he not, under the direction of his University teachers, appreciate the purpose of his work and share the responsibility of it?

Let me take, as an illustration, the subject of history. A student who comes to the University and takes up the study of history should learn at once how to use the original sources. It will, of course, be easier for him if he has learnt the rudiments of history and become interested in the subject at school; but, if he is really keen upon his University work, it should not be absolutely necessary for him to have learnt any history whatever. In any case, if he has received a good general education and has reached the standard of intelligence required for University work, he ought to be able to enter at once upon the intelligent study of history at first hand; his teachers will make it their duty to show him how to do this; their lectures and seminars will illustrate the methods of independent study, and will make the need of them clear to him. If, as is probable, some acquaintance with one or more foreign languages be necessary, he will take instruction in them as an essential part of his history course, in order that he may acquire the needful working knowledge, and to learn something of them with a definite purpose will be to him far more interesting and profitable than to study them only for linguistic training, as he would have been compelled to do at school. After all, this is what would be done by his schoolfellow who goes into business and finds it necessary, and probably also interesting, to acquire some knowledge of the particular foreign language required in the correspondence of his firm. It will, of course, be all the better for a University student of history to have acquired some training at school in the rudiments of history both ancient and modern, together with the knowledge of classics which is necessary for the former, and of modern languages which is necessary for the latter. But there is not space in the school curriculum for all the subjects that may be required either for the University or for the business of life; the best that can be done is to give a good all-round training and to foster a marked taste or ability where it exists by allowing the boy or girl to include the subjects which are most congenial to them in the studies of their last two years of school life, as I have already suggested, provided that mere specialisation is not encouraged at school even towards the end of the school career.

The University course might then become a more complete specialisation, but of a broad character—the study of a special subject in its wider aspects, and with the help of all the other knowledge which may be necessary to that purpose.

The University teacher will also differ from the school teacher in his methods, for it will be his business not so much to teach history as to teach his pupil so to learn and study history as though it were his purpose to become an historian; in so doing he will have opportunities to explain his own views and to contrast them with those of other authorities, and so to express his individuality as a University teacher should.

One might choose any other subject as an illustration. In science there should be all the difference between the school exercises, on one hand, which teach the pupil the methods of experiment, illustrate the principles laid down in his text-books, and exercise his mind in scientific reasoning, and, on the other, the University training, which sets him on a course involving the methods of the classical researches of great investigators and a study of the original papers in which they are contained, illuminated by the views of his own teacher. He also should awaken to the necessity of modern languages. A boy who, on leaving school, passes not to the scientific laboratories of a University, but to a scientific assistantship in a business or Government department, will very soon find it necessary to go to the original sources and acquire a working knowledge of foreign languages. It is regrettable that under existing conditions a scientific student sometimes passes through his University without acquiring even this necessary equipment. I believe this to be largely due to the fact that he is compelled to spend so much of his time in preparatory work of a school character during the early stages of his University career.

In the literary subjects, and especially in classics, there is, of course, not the same scope for the spirit of investigation which it is so easy to encourage in experimental science. Here the only new advances and discoveries which can appeal to the imagination in quite the same way are those which are being made every year in the field of archæology, and it is therefore not surprising that this subject attracts many of the most ardent students; the methods of the archæologist are more akin to those of the scientific investigator, and his work is accompanied by the same enthralling excitement of possible discovery. For the more able pupils and those who had a natural taste for language and literature no subjects have been more thoroughly and systematically taught for very many years at school, as well as at the University, than the classics; but for the less intellectual children or those who had no natural taste for such studies no methods could well be more unsuitable than those which used to prevail at schools. The grammatical rules and exceptions, the unintelligent and uncouth translation, the dry comparison of parallel passages, the merely mechanical construction of Greek and Latin verse, produced in many minds nothing but distaste for the finest literature that exists.

With the improved methods now in use Greek and Latin may be, and are, presented to the ordinary boy and girl as living literature and history, and school training in them may be made as interesting as anything else in the curriculum. Upon such a foundation the University should surely be able to build a course devoted to literary, philosophical, historical, or philological learning even for the average student, provided that the University teacher undertakes the task of helping his pupils to learn for themselves, and to pursue their studies with a purpose, not merely as a preparation.

The spirit of inquiry which drives the literary student to find for himself the meaning of an author by study and by comparison of the views of others is really the same spirit of inqury which drives the scientific student to interpret an experiment, or the mathematical student to solve a problem. Only by kindling the spirit of inquiry can teaching of a real University character be carried on. Give it what name you will, and exercise it in whatever manner you desire, there is no subject of study to which it cannot be applied, and there are no intelligent minds in which it cannot be excited.

The first question which a University teacher should ask himself is, "Am I rousing a spirit of inquiry in my pupils?" And if this cannot be answered in the affirmative it is a confession that the University ideal is not being realised.

Some assert that this principle should also guide school education, and that it should be the first aim of the school teacher to stimulate the spirit of inquiry. My own view is that with young children this should be less necessary; they all possess it, and are by nature inquisitive. It should rather be the object of the teacher not to spoil the spirit of inquiry by allowing it to run riot, nor to stifle it by making the work uninteresting; if the lesson interests them, their inquisitive minds will be quick enough to assimilate the teaching. We are, in fact, brought back to what I have already emphasised—that the real difference between the inquisitive mind of the child and the inquiring mind of the adult is that the former is yearning for information quite regardless of what it may lead to, whereas the latter must learn or investigate with an object if the interest is to be excited and maintained.

I have often thought it an interesting parallel that among original investigators and researchers there are two quite distinct types of mind, which have achieved equally valuable results. There is the researcher who pursues an investigation with a constant purpose, and to whom the purpose is the inspiration. But there is also the investigator who has preserved his youthful enthusiasm for novelty, and has in some respects the mind of a child; passionately inquisitive, he will always seek to do something new, and very often, like a child, he will tire of a line of research in which he has made a discovery, and take up with equal enthusiasm a totally different problem in the hope of achieving new conquests. I think that a man well known in Sheffield, the late Henry Clifton Sorby, must have been a man of this character. The latter is, perhaps, the most fertile type of original investigator, but it is not the type that produces the best teacher, except for very exceptional and original-minded students; and such teachers do not often found a school of learning and research endowed with much stability. For ordinary students, the investigator who pursues his researches so far as possible to their conclusion is the safer guide.

It seems to me suggestive that there are to be found, even amongst the famous researchers, these two types of mind, that somewhat correspond to the mental attitude of the school pupil and the University student. It is as though these great men have preserved a juvenile spirit, some from the days of their childhood, others from early manhood.

It will now be clear that the principle which I am advocating is a very simple one, namely, that the business of direct mental training should be finished at school, and that at the University the trained mind should be given material upon which to do responsible work in the spirit of inquiry. Preparatory exercises belong to school life, and should be abandoned at the University.

All this seems so obvious that it might appear to be hardly worth saying were it not that the methods which actually prevail are so far removed from this ideal.

When, for example, a boy who has not learnt Greek or chemistry at school comes to the University and proposes to take up one of these subjects, he is generally put through a course of exercises which differ in no essential respect from those which are set before a boy of twelve. In other words, our University method for the trained mind does not really differ from our school method, which is supposed to be adapted to the mind in course of training. Again, boys who have been learning certain subjects for years at school, but are weak in them, have their education continued at the University in the same subjects by the same school methods until they can be brought up to the requirements of a first University examination, which in its character does not differ much from the examinations held at school. Where in this process is to be found the introduction of that spirit of inquiry and investigation which ought to characterise the University course?

It may be asked, In what manner is this change to be introduced, and how is it possible under present conditions, where so many students are all pursuing ordinary degree courses and have no time or opportunity for special work, to provide teachers who can educate them in this spirit, if it is also their duty to get pass students through their examinations? The answer, I think, is that in a University the professors and higher teachers should be, without exception, men who, whatever may be their teaching duties, are also actively engaged in investigation. Their assistants should be teachers who, even if the whole or part of their time is occupied in routine teaching, have yet had some experience in, and possess real sympathy with, modern advanced work under such professors. This is only to be secured by insisting that teachers in a University should all have had some experience of original work, and, just as one of the necessary qualifications for an elementary teacher is some education in method, so a necessary qualification for a University teacher should be some education in research. Anyone desirous of qualifying for University teaching should be compelled to devote a certain portion of his student career to research, and the funds of a University cannot be better applied than to the retention of the better students at the University for the distinct purpose of enabling them to pursue investigation under the professor for a period of one year after they have completed their degree course, if they have not been able to do so during their undergraduate period. It is not, however, too much to hope that the majority of those who are endeavouring to qualify for the higher educational posts will be assisted to obtain this special experience during their degree course. Under the present system at most Universities, unless the student has been fortunate enough to come in contact with a teacher imbued with the spirit of research who is carrying on his own investigations, it rarely happens that he has the time or the means which would enable him to obtain any insight into the meaning of investigation before he leaves to take up teaching work. The need of post-graduate scholarships for this purpose is very widely felt, and is now frequently expressed. To insist upon such qualifications for all University students is, of course, under present conditions impossible; but there should be no insuperable difficulty in insisting upon them for those who are to be allowed to enter a University as teachers.

Researchers are born, not made, and it is not by any means desirable that all University students should be cast adrift to make new researches and seek discoveries even under the direction of experienced teachers and investigators. This must depend to some extent upon the character of the pupil as well as of the teacher.

The mere publication of papers may mean nothing, and much that is dignified with the name of research is of no account. To turn a lad on to research, unless it be in the right spirit, may be only to set him a new exercise instead of an old one; to leave him to prosecute an investigation for himself may be to condemn him to disappointment and failure. On the other hand, to carry on any piece of work, whether it be new or old, in the zealous spirit of inquiry, with faith in a purpose, is to insure the intellectual interest of the student; and I cannot see why this spirit should not animate all University education, whether it be accompanied by original research or not. The essential condition is that the chief University teachers should themselves create an atmosphere of investigation.

So deep-seated is the belief that nothing must be undertaken without a preparatory course of training that even the best and most brilliant students are frequently discouraged from undertaking a new study until they have been subjected to the mental discipline of an elementary course in it.

I cannot refrain from quoting an example which came within my own experience, although I have already alluded to it in another address delivered last year.

When I was at Oxford a young Frenchman of exceptional ability, whose training had been almost exclusively literary and philosophical, and who was at the time engaged on a theological inquiry, expressed to me his regret that he had never learnt to understand by practical experience the meaning of scientific work. And when I assured him that nothing was easier than to acquire practical experience by taking up a piece of actual investigation under the direction of a scientific worker, he explained to me that when he had applied for admission to scientific laboratories he had been told that it was useless to do so until by preparatory courses he had acquired an adequate knowledge of mathematics, physics, and chemistry. I offered to make the trial with him, and began with a problem that happened to interest me and that required a new method of simple experimental research. I soon found that a well-trained mind, able to grasp the meaning of the problem and eager to investigate it, could begin without delay upon the experiments, and in the desire to interpret them could find a pleasure and a purpose in seeking the necessary chemical and physical knowledge; whereas to have begun by acquiring this in a preparatory course, with no definite object in view, would have been to set back a mature mind to school methods of training, and very possibly to have stifled instead of kindling any real scientific interest.

This is, again, an illustration of my contention that the most special study, if carried on in the true University spirit, is very far removed from ordinary specialisation, and involves very wide extension of interest and learning; whereas, if carried on in a preparatory spirit, it is necessarily limited.

In a very short time this student had published three original papers which seem to me of considerable importance, though perhaps on a somewhat obscure subject, and I see that they are now quoted as marking a substantial advance in knowledge.

Of course, this is the exceptional case of the exceptionally able student; but I think it illustrates two things—first, the prevalence of the conventional attitude that preparation on school lines is necessary even for the post-graduate student; secondly, the fact that what is really necessary to the University student is the purpose, and that with this before his eyes he may safely be introduced to new fields of work.

One result of the conventional attitude is that those who have distinguished themselves at school in some subject are often assumed to have a special aptitude in it, and to be destined by Nature to pursue the same subject at the University, whereas their school success may only prove that they are abler than their fellows, and that this ability will show itself in whatever subject they may take up. Such students would sometimes on coming to the University be all the better for a complete change of subject, without which the continuance of the school studies too often means a perpetuation of the school methods. Those who are wedded to the idea of a systematic progression from secondary to university education run the risk of closing the door to this possibility, or at any rate of seriously prejudicing it.

Another result is that when teachers are always playing a somewhat mechanical part in a systematised course, receiving duly prepared pupils and preparing them again for the next stage, such an atmosphere of preparation is produced that many persons continue to spend the greater part of their lives in preparation without any reasonable prospect of performance.

I am well aware that, on the other hand, there always have been, and are now, many earnest and accomplished University teachers who are pursuing the methods that I advocate, whose teaching is always inspired with a purpose, whose pupils are stimulated to learn in the spirit of inquiry, and who consequently exercise a personal influence that is profound and enduring. I am deeply conscious how much I owe to some such teachers with whom I have studied and to others whom I have known. But still it does remain true that this is not yet the atmosphere of ordinary University education, that it does not yet invigorate the ordinary University student, and that to him the passage from school to the University does not necessarily mean a transition from mental discipline and preparation to mental activity and performance.

The distinction that I have in my mind between University and school reaching may be expressed in this way. At school no subject should be taught to a class as though it were intended to be their life-work; to take an example, it too often happens at present, owing really to excessive zeal on the part of school teachers, that mathematics is taught as though each member of the class were destined to become a mathematician; consequently only the few scholars with a real aptitude for mathematics become interested, and the remainder are left behind. On the other hand, at the University each subject should be studied as though it really were the life-work both of teacher and student. Thus, to take the same subject as an illustration, the mathematical student will attend the full courses of his professors and will follow them with the interest of a mathematician; whereas for the scientific student it will only be in those branches of mathematics which concern him that the interest of his special science will put him on terms of equality with the mathematical student. If I may choose an illustration which is familiar to myself, any student of mineralogy can easily be interested in and benefit by a course in spherical trigonometry, because it is one of the tools of his trade, but to send him to lectures on differential equations would be only to discourage him. On the other hand, the student of chemistry would rather be interested in the latter. To each of them certain branches of mathematics as taught by an ardent teacher afford a real intellectual training, but neither would gain much if compelled to follow a general University course of mathematics designed for mathematicians.

It will be observed that I have endeavoured to confine myself to the subject of University education, and not to say much, except by way of contrast, concerning school teaching.

I must, however, return to it for a moment, if only to emphasise the danger of that specialisation, which, since it takes place at school and not at the University, is bound to be narrow, and which is often encouraged in pupils of special aptitude preparing for University scholarships.

That a boy or girl should for a year or even two years before leaving school be practically confined to one subject and should before entering the University be examined in that alone, appears to me to be contrary to all the best traditions of school teaching, and to the often expressed desire of the Universities to ensure a good general education in those whom they admit. There should, I think, be no scholarship examination which does not include several of the subjects of a normal school curriculum, however much additional weight may be given to any of them. Although it may be necessary that University entrance scholarships in one subject should be given either to encourage its study or to discover those who have a special aptitude, yet, so far as scholarships are intended to be rewards for intellectual pre-eminence, they should, I think, be directed to general capacity, and not be used as an encouragement to limited study. From what I have already said it will be clear that I do not attach much importance to special preparation at school for those who intend to proceed to the University. If a boy has a very special taste or aptitude, it should have abundant opportunity for displaying and exercising itself at the University, provided only that it has not been stifled, but has been given some encouragement in the school curriculum. I understand, for example, that those who teach such a subject as physiology at the University would prefer that their pupils should come to them from school with a general knowledge of chemistry and physics rather than that they should have received training in physiology. With the present modern differentiation into a classical and modern side, or their equivalents, the ordinary school subjects should be sufficient preparation for any University course if they are not mutually strangled in the pressure of an overcrowded curriculum.

To be fair, however, I must state another view. A very experienced college tutor who has had previous valuable experience as a master in a public school tells me that in his opinion the real problem of the public schools is the "arrest of intellectual development that overtakes so many boys at about the age of sixteen." "There are few public schools," he says, "whose fifth forms are not full of boys of seventeen or eighteen, many of them perfectly orderly, well-mannered, and reasonable, in some sense the salt of the place, exercising great influence in the school and exercising it well, with a high standard of public spirit, kindly, and straight-living, in whom, nevertheless, it is difficult to recognise the bright, intelligent, if not very industrious, child of two or three years before."

He thinks that there is a real danger of degeneration at this age, owing, for one thing, to the manner in which the boys are educated *en bloc*; up to a certain age boys can be herded together and taught on the same lines without great harm being done, but after a certain time differentiation begins to set in. The school curriculum, however, does not admit of being adjusted to suit the dawning interests of a couple of hundred boys; and he sees no cure for this difficulty except a considerable increase in the staff and a corresponding reduction in the size of the forms. But he thinks that much may be done by an alteration in the system of matriculation examination, which sets the standard at the public schools. He would make this consist of two parts: an examination coming at about the age of sixteen and well within the reach of a boy of ordinary intelligence and industry, and comprising the ordinary subjects of school curriculum at this age; he would then let the boy leave the subjects from which he is not likely to get much further profit and begin to specialise for the remaining two or three years, say, in two subjects, which would then be the material of the second examination. In this way they would make a wholly fresh start at a critical age, and he thinks that the bulk of the boys would probably find this a great advantage.

I quote this opinion because it shows that an experienced schoolmaster regards it as highly desirable that at a certain period in a schoolboy's career a real change should be made in his curriculum, and I have expressly stated that I find it difficult to express an opinion upon this particular educational period.

What should be the exact nature of the teaching before and after the age of sixteen or seventeen for the mass of ordinary boys I would prefer to leave to the decision of those who are best able to judge. I think it highly probable that there should be a considerable alteration of curriculum at the critical age. But, if a break and change of subject are required at this age, I believe that a yet more complete change is required at the later stage when the boy goes to the University, and that school methods should then be entirely replaced by University methods—not because there is then a natural change in the mental powers of the student, but because it is the obvious stage at which to make the change if we are to abandon preparatory training at all. Should it be proposed that the change ought to be made at sixteen, and that after that age something of the nature of University methods should be gradually introduced, my fear is that this would only lead to the perpetuation of school methods at the University.

An interesting question which deserves to be very seriously considered is the question, What sort of school education affords the best preparatory training for the University? I have often heard it asserted that, if a boy is capable of taking up at the University a course which is entirely different from his school course, he will generally be found to have come from the classical side and not from the modern side. An ordinary modern-side boy is rarely able to pursue profitably a literary career at the University, whereas it often happens that ordinary classical-side boys make excellent scientific students after they have left school. I am bound to say that this is, on the whole, my own experience. It suggests that a literary education at school is at present a better intellectual training for general University work than a scientific education. If this be so what is the reason?

There are no doubt many causes which may contribute. In some schools the brighter boys are still retained on the classical side while those who are more slow are left to find their way to other subjects; and some whose real tastes have been suppressed by the uniformity of the school curriculum turn with relief to new studies at the University and pursue them with zeal. But the facts do also, I think, point to some defect in the present teaching of school science whereby a certain narrowness and rigidity of mind are rendered possible. This may be partly due to the lack of human interest in the teaching of elementary science; the story of discovery has a personal side which is too much neglected, though it is more attractive to the beginner and might with advantage be used to give some insight into the working of the human mind and character. Moreover, it would form an introduction to the philosophy of science which is at present so strangely ignored by most teachers.

But another noteworthy defect is the absence of that mental exercise which is provided by the thoughtful use and analysis of language.

I believe that the practice of expressing thoughts in carefully chosen words, which forms so large a part of a good literary education, constitutes a mental training which can scarcely be surpassed, and it is unfortunately true that in the non-literary subjects too little attention is paid to this practice. In school work and examinations in science a pupil who appears to understand a problem is often allowed full credit, although his spoken or written answer may be far from clear. This is a great mistake. A statement which is not intelligibly expressed indicates some confusion of thought; and, if scientific teaching is to maintain its proper position as a mental training, far more attention must be paid to the cultivation of a lucid style in writing and speaking.

The various Universities seem fairly agreed upon the subjects which they regard as essential to an entrance examination—subjects which may be taken to imply the groundwork of a liberal education. Among these is English: and yet of all the subjects which children are taught at school, there is none in which such poor results are achieved. It may be taught by earnest and zealous teachers; the examination papers are searching, and seem to require a considerable knowledge of English literature and considerable skill in the manipulation of the language, and yet the fact remains that the power of simple intelligible expression is not one that is possessed by the average schoolboy and schoolgirl. It is the most necessary part of what should be an adequate equipment for the affairs of life, whether the pupil passes to the University or not, and yet it is, on the whole, that which is least acquired.

Although it is true that the intelligent reading and study of the great masters should assist in the acquisition of a good style, it is equally true that, if they come to be regarded as a school task, they are not viewed with affection, especially in these days of crowded curricula, when there is little leisure for the enjoyment of a book that requires deliberate reading. If the modern strenuous curriculum of work and games has abolished the loafer, it has also abolished leisure, and has therefore removed one of the opportunities that used to exist for the cultivation of literary and artistic tastes and pursuits by those to whom they are congenial. The art of expressing one's ideas in simple, straightforward language is to be acquired not so much by study as by practice. There is no essential reason why children should write worse than they speak; they do so because they have constant practice in the one and little practice in the other. Our grandparents felt less difficulty in expressing themselves clearly than we do ourselves: of this their letters are evidence. It may have been partly due to the fact that they had more time and encouragement for leisurely reading, though they had not so much to read; but I believe that the letters which they wrote as children were their real education in the art of writing English. Much would be gained if boys and girls were constantly required to express their own meaning in writing. The set essay and the *précis* play a useful part, but do not do all that is needed. Translation does not give quite the necessary exercise. What is required is constant, with certain periods of conscious, practice, and that is only to be obtained by making every piece of school work in which the English language is used an exercise in lucid expression. Very few paragraphs in anything written by the ordinary schoolboy—or, for the matter of that, by the ordinary educated Englishman—are wholly intelligible, and teachers cannot devote too much pains to criticising all written work from this point of view. If we first learnt by practice to express our meaning clearly we should be more likely to acquire the graces of an elegant style later. I must add that I believe the training in the manipulation of words would be improved if all children were required to practise the writing of English verse—not in efforts to write poetry, but narrative verse used to express simple ideas in plain language—and I believe that this would enable them the better to appreciate poetry, the love of which is possibly now to some extent stifled by the pedantic study of beautiful poems treated as school tasks.

In such a subject as English composition, in which reform is so badly needed, something, perhaps, would be gained by an entire break with existing traditions—a break of the sort which would be required if it became suddenly necessary to provide for an entirely new type of student.

Now there is one new and interesting development in which, for the first time, an opportunity offers itself of dealing with a body of students who, although possessed of more than average intelligence and enthusiasm, have not received the conventional training which leads to a University course. The tutorial classes for working people which have now been undertaken by several Universities, and which already number about 1200 students, are attended by persons carefully selected for the purpose and anxious to pursue a continuous course of study of an advanced standard. In these classes the Universities will be compelled to begin new subjects for students of matured minds who have not received the usual preparation, and will therefore necessarily deal with them in a new way. Here, if anywhere, the difference between school methods of teaching and University methods ought to be apparent; and I feel sure that, if University teachers attempt conventional methods with these students, they will be condemned to failure. It is certain that these classes will increase enormously and rapidly, and I have great hope that they will for this reason influence the methods of University teaching in a very healthy manner. In the tutorial classes the teachers will be confronted with the entirely new problem of students who have thought much, and of whom many are experienced speakers, well able to express their thoughts by the spoken word, but who, nevertheless, have received little training, and have had still less experience, in expressing their ideas in writing. Many of the students whom I have met have told me that this difficulty of writing is their real obstacle, and the matter in which they feel the want of experience most acutely. It will be a very valuable exercise for those who conduct these classes to instruct their students in the art of writing simple and intelligible English, and I hope that the necessity of giving this instruction will have a good effect upon the conventional methods of teaching English in schools as well as in Universities.

I am conscious that this address is lamentably incomplete in that it is concerned only with the manner of University teaching, and scarcely at all with its matter, and that, to carry any conviction, I should apply myself to the task of working out in detail the suggestions that I have made. But this would lead me far beyond the limits of an address, and I am content to do little more than touch the fringe of the problem. Reduced to its simplest terms, this, like so many educational problems, involves an attempt to reconcile two different aims.

The acquisition of knowledge and the training of the mind are two inseparable aims of education, and yet it often appears difficult to provide adequately for the one without neglecting the other. If childhood is the time when systematic training is most desirable, it is also the time when knowledge is most easily acquired; if early manhood is the time when special knowledge must be sought, it is also the time when training for the special business of life is necessary. To withdraw from the child the opportunities of absorbing knowledge may be as harmful as it is unnatural; to turn a young man or young woman loose into a profession without proper preparation is cruel, and may be disastrous.

And so we get the battle of syllabus, time-table, scholarships, examinations, professional training, technical instruction, under all of which lies the disturbing distinction between training and knowledge.

But, if we inquire further into these matters, I think we shall find that the fundamental question is to a large extent one of responsibility. Left to himself, a boy or a man will acquire a knowledge of the things which interest him, even though they be only the arts of a pickpocket, and will obtain a training from experience such as no school or college can give. If education is to achieve the great purpose of interesting and instructing him while young in the right objects, and also of training him for the proper business of his life before it is too late, is it not mainly a question of deciding when and how far to take for him, or to leave to him, the responsibility of what he is to learn and how he is to learn it? If the teacher bears the responsibility during the period of school training, should not the student have a large share of responsibility in the quest of knowledge at the University?

Now it is of the essence of responsibility that there should be something sudden and unexpected about it. If, before putting a young man into a position of trust, you lead him through a kindergarten preparation for it, in which he plays with the semblance before being admitted to the reality, if you teach him first all the rules and regulations which should prevent him from making a mistake, you will effectually smother his independence and stifle his initiative. But plunge him into a new experience and make him feel the responsibility of his position, and you will give him the impulse to learn his new duties and the opportunity to show his real powers. It is because I feel that this sudden entrance into an environment of new responsibility is so necessary that I would regard with suspicion any attempt to provide a gradual transition between school and University methods.

In matters of discipline and self-control it is possible and advisable to place responsibility upon school children; in intellectual matters it is not advisable, except for the few who are matured beyond their years. It is, therefore, all the more necessary that this should be done at the moment when they enter the University.

This should be the moment of which Emerson says: "There is a time in every man's education when he arrives at the conviction that he must take himself for better or worse as his portion; that, though the wide universe is full of good, no kernel of nourishing corn can come to him but through his toil bestowed on that plot of ground which is given him to till. The power which resides in him is new in Nature, and none but he knows what that is which he can do, nor does he know until he has tried."

The spirit of independent inquiry, which should dominate all University teaching and learning, is not to be measured, as I have already said, by the number of memoirs published, but it is to be tested by the extent to which University students are engaged upon work for which they feel a responsibility. Visit the Universities at the present moment, and, in spite of all the admirable investigation which is being carried on, you will find the majority of students engaged in exercises in which they feel no responsibility whatever. In my opinion this indicates that for them the spirit of true University education has never been awakened. It is, after all, very largely a question of attitude of mind. Any subject of study, whether it be a scientific experiment or an historical event, or the significance of a text, is a matter of interpretation, and to approach it in the University spirit is to approach it with the question, "Is this the right interpretation?" Upon that question can be hung a whole philosophy of the subject, and from it can proceed a whole series of investigations: it embodies the true spirit of research and it opens the door to true learning.

In discussing University education I have not, of course, forgotten that many persons have taught themselves up to a University standard entirely without the aid of professors; indeed, the University of London long ago provided an avenue to a University degree which has been successfully followed by many such persons with the best possible results. But I have endeavoured to remind you that at the University, as at school, for most students the personal influence of the teacher is the important thing; that at the University, as at school, success in teaching depends mainly on the extent to which the interest of the student is aroused; and that at the University this is only to be done by providing him with a purpose and a responsibility in his work in order that he may understand to what conclusions it is leading him. Until this is done we shall still have University students complaining that they do not see the object of what they are learning or understand what it all means. This complaint, which I have often heard from past and present students of different Universities, suggested to me that I should on the present occasion deal with this defect in our customary methods.

In the hope that the attention of University teachers may be turned more fully to this aspect of their work I have ventured to make it the subject of my address.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—At Emmanuel College research studentships of the value of 150*l.* each have been awarded to G. E. K. Braunholtz and A. Ll. Hughes. Grants of the following amounts have also been made:—S. Mangham, 60*l.*; R. H. Snape, 40*l.*; C. S. Robinson, 20*l.* The exhibition of 50*l.* offered to an advanced student commencing residence this October has been awarded to J. Ivon Graham, London, Royal College of Science for Ireland. Additional exhibitions of 30*l.* have also been awarded to A. J. Grove, Birmingham University, and F. Smith, Manchester University.

The Clerk Maxwell scholarship is vacant by the resignation of Mr. Wellisch. Candidates are requested to send in their applications to Sir J. J. Thomson (the Cavendish Laboratory) on or before November 5.

At Trinity College the following have been elected into fellowships:—G. N. Watson, G. I. Taylor, H. T. J. Norton, and A. V. Hill.

Oxford.—Dr. Arthur Vaughan, well known for his researches on the Carboniferous limestone, has been appointed lecturer in geology.

Mr. A. E. Richey has been appointed demonstrator in geology. Mr. Richey succeeds Mr. J. A. Douglas, who is now engaged on a geological expedition in Peru. The expedition has been sent out by Mr. W. E. Balston to take advantage, for geological research, of the excavations now in progress in the construction of new railways. Mr. Douglas is accompanied by Mr. Thomas, Rhodes scholar, who goes as a volunteer, and the general management of the expedition is undertaken by Prof. Sollas.

Prof. F. M. Sandwith, Gresham professor of physic, will deliver four Gresham lectures on ancient and modern surgery on October 25 to 28. The lectures are free to the public, and will be delivered at the City of London School at 6 p.m. each evening.

The China Emergency Appeal Committee asks for 100,000*l.* to be used as follows:—(1) 40,000*l.* for the establishment of union medical colleges; (2) 40,000*l.* for the establishment of educational schools of training; (3) 20,000*l.* in aid of literature societies and general translation work. A sum of nearly 14,000*l.* had been received or promised up to the end of August; and the following grants have already been made:—Union Medical College, Peking, 2000*l.*; Union Medical College, Hankow, 1000*l.*; Union Medical College, Moukden, 500*l.*; Union Normal Training College, Shantung University, 1500*l.*; Anglo-Chinese College, Tientsin, 1000*l.*; Christian Literature Society for China, 1700*l.*; China Medical Missionary Association for the Translation of Medical Literature, 300*l.* Donations towards the 100,000*l.* required for the China Emergency Fund may be sent to Mr. Robt. L. Barclay, honorary treasurer (Messrs. Barclay and Co.), 54 Lombard Street, London, E.C.; or to the Rev. Edward T. Reed, secretary, China Emergency Appeal Committee, 28 Victoria Street, Westminster, S.W. The committee has arranged for a meeting to be held in the Guildhall on October 18, when addresses will be given on the opportunity of the educational movement in China by Dr. S. L. Hart, and on medical education in China by Mr. D. Main. An address will also be given by Sir Robert Laidlaw.

The inaugural address at the opening of the winter session of the Birkbeck College was this year delivered by Prof. M. E. Sadler. After sketching the development of English education during last century, and showing how much was accomplished by men like Birkbeck, Prof. Sadler went on to say that both in science and in art the passion of modern study has been to see and to represent things as they really are. This at bottom is the basis of scientific thought, and the purpose of the painter's and draughtsman's expression. To keep one's mind clear as a mirror is the intellectual and also the moral condition of real advance both in science and in art. It is impossible, however, to see things as they really are without a long preliminary discipline, in which one learns to see and how to express. Therefore one side of the modern educational movement is to prolong for all students the period of preliminary preparation and discipline, which, having been accomplished, the student may go to that freer, more self-active task which is before those who have received thorough training and preparation. It is in giving that thorough training and preparation that we in England, compared with other leading modern nations, have been until lately grievously in arrear. It is because our system of intermediate or secondary education is meagre, starved, sectional, that the immense efforts bestowed on technical and adult education by such men as Dr. Birkbeck failed for so long to produce the harvest which they confidently expected. The work of strengthening this period of disciplinary preparation for advanced studies—strengthening our whole system of secondary education—is one of the greatest tasks which are before us now as British citizens.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 3.—M. Émile Picard in the chair.—The president gave an account of the life-work of the late M. Maurice Lévy.—Émile **Picard**: A singular functional equation of the Fredholm type of equation.—Charles **Lederer**: The organic compounds of tetravalent tellurium. By the interaction of tellurium tetrachloride and magnesium phenyl bromide in ethereal solution there is obtained chlorobenzene, diphenyl, the compound $Te(C_6H_5)_2$ already described by Kraft and Lyons, and a new derivative, triphenyl-telluronium chloride, the iodide of which, $(C_6H_5)_3TeI$, was prepared by adding potassium iodide. The bromide $(C_6H_5)_2TeBr_2$ is also formed in the reaction.—L. **Gay**: The osmotic equilibrium of two liquid phases.—A. and L. **Lumière** and M. **Seyewetz**: The action of quinones and their sulphonic derivatives on the photographic images formed by silver salts. Aqueous solutions of benzoquinone in presence of sulphuric acid are useful in reducing over-exposed negatives; the replacement of the sulphuric acid by potassium bromide gives a new intensifying solution. The suitable proportions are given in both cases.—Charles **Janet**: The sensitive organs of the mandible of the bee.—Paul **Godin**: Normal asymmetry of the binary organs in man.

RECENT PROGRESS IN PSYCHICAL RESEARCH.

The Newer Spiritualism. By Frank Podmore. Pp. 320. (London: T. Fisher Unwin, 1910.) Price 8*s*. 6*d*. net.

THE recent untimely and tragical death of Mr. Frank Podmore has directed general attention to his writings, especially to the book which, no doubt fully prepared before his death, has been published posthumously.

Mr. Podmore was an early member of the Society for Psychical Research, and he collaborated with Edmund Gurney and F. W. H. Myers in the collection and discussion of that large mass of cases, consisting chiefly of spontaneous apparitions or death-wraiths, which resulted in the publication of the two volumes called "Phantasms of the Living" in the year 1886.

The objectivity of these apparitions of the injured or dying or dead was always doubted or denied by the writers of that book; but inasmuch as the hallucinations were sometimes veridical—that is to say, inasmuch as they corresponded to or represented some actual occurrence, with a precision which, though not complete, was very striking—was found, indeed, on subsequent most careful and conscientious scrutiny, to be immensely beyond any chance coincidence—the writers devised a theory to explain such cases by means of the direct action of one mind on another through some agency not yet recognised in science.

The actual occurrence of such mental interaction, or thought-transference, was investigated by direct experiment, its possibility was considered proved, and a short account of these experimental cases forms part of the standard treatise referred to above. Prof. Barrett, F.R.S., is the leading surviving pioneer in the work of that period. Not only ideas and images could be thus conveyed, but full-blown apparitions of living people could be apparently effected by purposed concentration of mind acting on sufficiently sensitive percipients.

Since that time Mr. Podmore was an enthusiastic supporter of this doctrine of "Telepathy," as the process was conveniently named by Mr. Myers; and subsequent investigation and cumulative experience have gone far to strengthen the belief in it, as a genuine human faculty, among all those who have worked at the subject. So the reality of some unknown mode of communication between mind and mind may now be considered fairly established, notwithstanding that it has not yet received the sanction of high official science.

But it must never be forgotten that the detection of this process as a fact of observation, and the giving it a name for convenience of reference, by no means explains it or reduces it to the level of commonplace. If a fact at all, it must be a fact of exceedingly great importance. For a new or previously unrecognised human faculty is not the kind of thing that may be expected to turn up every century. It has shown signs, indeed, of being but the precursor and most prominent member of a whole group of human faculties, which had been more or less experimented with and more or less believed in, during the course of human history, until the age of science supervened and relegated everything of the so-called magical or occult to the domain of superstition, thereby excluding it from reasonable consideration.

As now contemplated, however, there is nothing superstitious about telepathy. Indeed, it is often employed as the antidote to what may still be called superstition; and Mr. Podmore in particular—so far from regarding it as only the first-discovered member of a series, after the analogy of such a chemical element as Argon—preferred to use it as a master-key wherewith to open a large number of locks, and thereby to let fresh air into chambers which else would be stuffy and obscure. He was apt to forget, I think, that telepathy is itself an obscure and, so to speak, "locked" faculty, inasmuch as no explanation of it has ever been given, or the process explained, either by physicists or psychologists. We do not even know for certain whether it is or is not accompanied by any physical process or stimulus akin to those with which we are familiar in the case of all the ordinary operations of sense-perception. There are some who think it a direct psychical action—that is to say, a direct action of mind on mind; there are others who think that it may be the result of a wider kind of mental interaction than exists among ordinary human beings, and that it points in the direction of the survival of human personality.

Mr. Podmore did not take that view; he does not seem to have pondered deeply on the actual meaning and process of telepathy. He accepted it as a fact, and tried to explain every other occult phenomenon by means of it—showing a tendency, indeed, to accept readily anything that could be thus explained, and to reject, also readily anything that could not. This is not the place for criticism in detail, but it would be easy to select sentences illustrative of this tendency on the part of the author.

Up to a certain limit, indeed, such a method of procedure is legitimate; and undoubtedly the clue furnished by the working-hypothesis of unconscious telepathic communication has rendered easier of belief a great many strange legends and asserted experiences. But to regard it as the only legitimate clue, to test all facts by means of it, and to reject with contumely those which it does not explain, which it can by no contortions be made to explain, is not so legitimate. And if Mr. Podmore has at all fallen into error—as it is only human that he should—it is in this direction that he has erred. I desire to review with extreme delicacy the work of a deceased writer, especially one to whom the subject of psychical research is largely indebted for acute criticism and remarkable industry. Yet I cannot fail to notice in many parts of the book, and, indeed, in his other writings generally, something that may be called *bias* in favour of the supremacy or monopoly of his favourite explanation.

It is true that some of the most recent investigations by members of the society, those which can be summarised briefly under the title *Cross correspondence*, went some distance towards shaking Mr. Podmore's robust scepticism in everything except telepathy—telepathy, that is, between living persons no matter how distant and disconnected from each other they may be; but though he showed signs of an opening mind in this direction, in many others it remained firmly, and as most will think reasonably, closed. Mr. Podmore was one of those who some time ago had believed too easily and too much—at least so his later self would have claimed—and accordingly he had swung over in the opposite direction; certainly nothing in the nature of what are called "physical phenomena"—a title which is used to summarise a group of cases relating to the movement of objects without apparent contact—could ever find lodgment in his mind.

In this he may turn out to be right, for these so-called physical phenomena are among the most incredible of all; they do not appear to have any immediate or necessary connection with the question of human survival—if true, they appear to be a physiological but extraordinary and, so to speak, ridiculous extension of human faculty—and it would be a great simplification if they could all be relegated to the easy and comprehensive category of fraud. But the evidence will not in my judgment permit this simplification of the problems presented by a hitherto uncharted portion of the universe; and I confess I do not feel that Mr. Podmore's training made him a competent critic of this division of the subject. It is the part of his book which will meet with readiest acceptance, however, inasmuch as it postulates no causes but what are only too well known, such as human deceit, quackery, and gullibility; so it puts no strain on the believing power of the reader, even to the moderate extent of demanding the acceptance of an obscure faculty like telepathy.

But I am bound to say that the treatment here is not as worthy of a careful and responsible critic as is his treatment of subjects more closely allied with telepathy. I would even go so far as to say that his criticism of some experiments, such as those made by Sir W. Crookes, for instance, exhibits clear traces of what I may call conscientious or forensic unfairness; not only because definite assertions are questioned in a way which would undermine the record of any experiment ever made, but because their quotation is preceded by accounts of similar phenomena by over-enthusiastic and incompetent witnesses, whose accounts could not have any weight attached to them, and are only quoted in order to prejudice a fair contemplation of the subject.

If I am wrong in attaching some credence to careful records of unusual physical phenomena, on the strength of actual experience of my own, I wish the statement that I do so to stand as a personal confession in the pages of this scientific journal which will be readily accessible to posterity.

Concerning Mr. Podmore's other scepticisms, however, though I do not by any means in every case agree with them, his criticisms are reasonable and competent; and all the disbelief that he possessed on those subjects he was entitled to, inasmuch as he devoted much time to their consideration, and made a careful scrutiny of the evidence. He was not exactly a first-hand investigator himself, but he diligently studied the work of others. His opinion, therefore, is of weight, and, whether unduly sceptical or not, cannot be lightly estimated like that of persons who pronounce a positive and dogmatic judgment on no evidence at all.

The objection which I sometimes feel to Mr. Podmore's books is that they appear to furnish readers with a succinct summary of the evidence available, whereas they really only furnish selections of that evidence—made to some extent from the point of view of their bearing on his favourite hypothesis. These very readable and in some respects learned books may be useful in opening up the question and arousing interest, provided always that they do not quench it, but they have the flaws inseparable from second-hand testimony. The evidence cannot really be studied in any such volumes. It is probably true that conviction can only be attained by first-hand experience of the facts themselves; but, short of this, the evidence must be scrutinised in the recorded observations of the actual experimenters—such records, for instance, as are contained in the Proceedings of the Society for Psychical Research, and those made by earlier pioneers who in face of much obloquy and ridicule preceded and rendered possible its work.

OLIVER LODGE.

FOSSIL CLUB-MOSSES AND FERNS.

Fossil Plants: a Text-book for Students of Botany and Geology. By Prof. A. C. Seward, F.R.S. Vol. II. Cambridge Biological Series. Pp. xxii+624, with 265 figures and frontispiece. (Cambridge University Press, 1910.) Price 15*s*. net.

IT is twelve years since the first volume of Prof. Seward's important text-book appeared. The progress of fossil botany has never been so rapid as during the interval, and we may congratulate ourselves, with the author, that the delay has enabled him to produce a really up-to-date treatise on some of the most important classes of fossil plants.

The present volume is essentially concerned with the Lycopods and "Ferns"—it is necessary to put the latter word in quotation marks, for in these days nothing is more difficult than to tell whether a reputed fossil fern deserves the name or not.

Two short chapters at the beginning of the volume are devoted to the Sphenophyllales and the Psilotales; the account of the former group given in Vol. I. is here completed by the description of some types of fructification recorded since that volume appeared. The relation of the little family Psilotaceæ to the Palæozoic group of the Sphenophylls is fully recognised, but the author does well to put the former in a class of its own. Some authors have been too hasty in uniting these families, which, though they have important characters in common, are distinguished by features no less striking.

The great class of the Lycopodiales, perhaps the most prominent of all in the Carboniferous flora, occupies a space commensurate with its importance, extending to about 250 pages. The description of the fossil representatives is preceded by a sketch of the recent members of the group, illustrated by some excellent figures both of the habit and the anatomy. This method, which the author extends to all groups which have living representatives, is eminently suitable for a book which is intended for geologists as well as for those who have had a botanical training. The best known of the fossil Lycopods were trees; recently, however, we have learnt a good deal about herbaceous club-mosses which also flourished in Palæozoic times. These are fully described, and it is interesting to note how closely, in habit and reproductive methods, some of them approached the living genus Selaginella. On the other hand, we still have no proof of the early occurrence of Lycopodium, which on theoretical grounds is regarded as the more primitive type.

The great family of the Lepidodendreæ is admirably treated, with equal regard to external features and internal structure. Some progress has now been made in correlating the two, and the results are sometimes a little surprising. Thus the well-marked anatomical species *Lepidodendron fuliginosum*, Williamson, is shown to correspond to at least three species based on external characters—a Lepidophloios and two species of Lepidodendron proper. Thus the two genera last-mentioned are indistinguishable, even specifically, by their anatomical characters, and it is very doubtful whether their claim to generic rank can be upheld.

Until quite recently we had but little knowledge of the structure of the well-known genus Sigillaria, but now, thanks to the work of Bertrand in France and of Kidston and Arber and Parkin in our own country, we have become acquainted with the anatomy of a number of species. The new evidence, together with the characters of the fructifications, has finally confirmed Williamson's view of the close affinity between Sigillaria and Lepidodendron, and of the cryptogamic nature of both alike. At the same time, facts have come to light which might once have been regarded as favouring Phanerogamic affinities, for in two genera of Palæozoic Lycopods organs closely analogous to true seeds have been discovered; in both cases the plants, one herbaceous, the other probably arborescent, are in all other respects typical members of the Lycopodiales. Their seed-like reproductive bodies are regarded by many palæobotanists as a striking instance of parallel development; the author, however, is inclined to see in them evidence of a genetic connection between the Palæozoic Lycopods and certain Conifers.

The second half of the volume is devoted to the Fern-like plants, and here the effect of recent discoveries makes itself felt in an even greater degree than elsewhere. As is well known, a large proportion of the Palæozoic Ferns, formerly so-called, are now under well-founded suspicion of not having been real Ferns at all, but seed-bearing plants of fern-like habit. In several cases this has been definitely proved, and in a majority of the plants in question all the available evidence points towards their spermophytic affinities. At the same time, the resemblance to Ferns, which for so long misled investigators, is by no means wholly fallacious, but, as shown by anatomical and other evidence, indicates a real relationship to the Fern-stock, while on the other hand the connection with the Cycad type of seed-plant is manifest. The practical difficulty is to distinguish between these "Ferns with seeds" and the true cryptogamic Ferns which no doubt really existed side by side with them; habit is no criterion, anatomy is only available in exceptional cases; even where the sporangia are present it is often impossible to say whether they were cryptogamic sporangia or pollen-sacs. The author takes a moderate and reasonable view of the difficult position; he recognises a considerable group of generalised Ferns, his Cœnopterideæ (the Primofilices of Mr. Arber), in which our knowledge of structure and of reproductive processes is sufficient to establish the Fern kinship; he is further inclined to admit a certain number of Palæozoic Marattiales (highly organised Ferns now only represented by a small tropical family), though here the evidence is a good deal more doubtful.

The Pteridosperms, as such, do not come into the present volume, but the last chapter is devoted to a number of genera of more or less uncertain position, most of which will no doubt prove to be seed-bearing plants, while a few may retain their traditional position among true Ferns. The clearly established types of Pteridosperms will be considered in vol. iii., which is to be devoted to seed-plants. This part of the work will be looked forward to with keen interest, for a number of questions of the utmost importance for the theory of evolution will then have to be considered.

The present volume, in its full and impartial treatment of habit and structure, of morphology and distribution, is beyond question the best handbook extant for the important fossil groups of which it treats. It is abundantly illustrated, and provided with an excellent index, and with a bibliography; the latter, taken in connection with that of vol i., is singularly complete, so far as works of any importance are concerned.

Botanists are certain to appreciate Prof. Seward's work; we hope that it may receive equal recognition from geologists, who, even more than their botanical colleagues, stand in need of a modern text-book of fossil plants.

D. H. S.

THE COLLECTED WORKS OF HUYGENS.

Œuvres complètes de Christiaan Huygens. Publiées par la Société Hollandaise des Sciences. Tome douzième, Travaux de Mathématiques pures 1652–1656. Pp. vi+296. (La Haye: Martinus Nijhoff, 1910.)

THIS volume is the second one which contains reprints of published writings of Huygens, the ten first volumes having been devoted to his correspondence. During the years 1652 to 1656 Huygens had still to divide his attention between his scientific work and the study of law, but the extracts from his note-books given in this volume show how little the law was able to fill his mind. In January, 1652, he began to occupy himself with various geometrical problems leading to equations of the second or third degree, of most of which he gave solutions in his "Illustrium quorundam Problematum Constructiones," which came out in 1654 as an appendix to his work on the quadrature of the circle. Both the rough work and the printed essay are reproduced in the present volume, and it is interesting to follow the stages by which he succeeded in submitting problems to algebraical analysis which Archimedes, Nicomedes, and other Greek mathematicians had treated by pure geometry.

The principal publication from this period of Huygens' life is his book on the quadrature of the circle, by which he took his place among the leading mathematicians of the day. It was a time when circle squarers flourished, several of them men of some distinction, such as Grégoire de St. Vincent, whose bulky work appeared in 1647 and called forth several polemical writings. Huygens entered the field in 1651 with his "Ἐξέτασις Cyclometriæ" (reprinted in T. XI. of the new edition), in which he showed the fallacy of St. Vincent's quadrature of the circle. In 1654 he brought out a larger work, "De Circuli Magnitudine Inventa." In this he developed further the use of the properties of the centre of gravity on the basis of the theorems he had published in 1651, and rigorously proved some propositions used by Snellius without proof, as well as a number of new theorems about sums of polygonal perimeters and various quantities, between which the length of the circumference of the circle is intermediate. Finally he calculated π by means of a 60-sided polygon within the limits of three units of the tenth decimal. The number of decimals is, of course, inferior to that previously attained by Van Ceulen and others, but the result was found without the appalling labours which these had gone through, and the investigation is valuable on account of the theorems proved by Huygens.

The lucidity and force of the arguments in the "Ἐξέτασις" had made its author hope that they had convinced Grégoire de St. Vincent of his mistakes. He exchanged a number of civil letters with St. Vincent, but the latter could never be induced to enter on a discussion of the matter, but always evaded it by saying that some day he would answer all his critics at the same time. But several of his pupils entered the lists for him, among whom was the Jesuit Ainscom, who in 1656 published what he imagined was a refutation of all the adversaries of his master, and did his best to convince people of the truth of the four methods of squaring the circle set forth by St. Vincent, but never put into practice by him. Huygens lost no time in replying; his "Epistola" to Ainscomb was published at the Hague in the same year. It forms the concluding portion of the present volume of his works, and in accordance with the praiseworthy rule of the editors of this most valuable edition of Huygens' works, the part of Ainscom's essay dealing with the attack of Huygens is also reprinted.

J. L. E. D.

A PRIMER ON COAL MINING.

First Steps in Coal Mining. For Use in Supplementary and Continuation Classes. By Alexander Forbes. Pp. viii+320. (London, Glasgow, and Bombay: Blackie and Sons, Ltd., 1910.) Price 2s. 6d.

THE present adds one more to the already long list of primers on coal-mining that have been produced so freely of recent years, and unfortunately it cannot be said that it is sufficiently an improvement upon some of its predecessors to justify its publication. It is difficult to see to what class of student such a book as the present one can address itself, or which it can expect to benefit; if it is intended for the instruction of youths actually engaged in mining operations, such definitions as "the men engaged in the excavation of the material are termed *sinkers*," "the portion of the twenty-four hours during which each set works being called a *shift*," "the extreme end of the road . . . is called the *face*," &c., are surely superfluous, as these expressions must be familiar to every boy about a pit. If, on the other hand, the book is intended for those who have no personal knowledge of coal-mining, the amount of information afforded upon the majority of mining operations cannot possibly be sufficient to enlighten them; for instance, it is hopeless to expect that the subject of coal-cutting by machinery can be adequately taught in three pages; in the same way, only twenty pages are devoted to the whole subject of shaft-sinking, including all the special methods, entirely out of place though these are in an elementary book.

Just about one-third of the book has been devoted to an outline of geology, and this is the most, if not the only, satisfactory part of it. The remainder is made up of "scrappy" chapters on the various departments of mining, with some fragments of elementary chemistry and physics distributed amongst them. Not content with this wide range, the author has not hesitated to include even mine surveying, to which he devotes nearly four pages! Of what use he imagines that these can possibly be to anyone it is hard to conceive, even though he has inserted an illustration, without a word of description, of an old-fashioned theodolite, possibly with the object of giving an air of completeness to his index. Had the author contented himself with writing an elementary text-book of geology for the use of miners, he might probably have produced a work of greater use than the more ambitious effort now before us; at the same time, it cannot but be admitted that not even in the geological section has the author displayed the faintest evidence of originality in thought or treatment. This want of novelty throughout the book is shown very strikingly in the illustrations, every one of which appears to have been published before in other works. Their selection has, moreover, not always been a happy one, as witness the picture of the theodolite already referred to. For sheer futility it would be difficult to surpass some of the illustrations to the chemical section, such, for example, as Fig. 129, which represents water being poured out of a jug.

The very best thing that can be said of the book is that it is comparatively free from serious mistakes.

OUR BOOK SHELF.

A History of British Mammals. By G. E. H. Barrett-Hamilton. Part i., October. Pp. xvi+88. (London: Gurney and Jackson, 1910.) Price 2*s.* 6*d.* net.

A thoroughly up-to-date and scientific account of the mammals of the British Isles, written in such a style that it may be acceptable to the field-naturalist as well as to the specialist, has long been a desideratum. So far as it is possible to judge from the first part this want promises to be supplied, at all events, from the scientific aspect, by Major Barrett-Hamilton's work, which is to be published in twenty-four monthly parts, so arranged as, when complete, to form three volumes, of which the first is to be devoted to the bats, while the third is to include the whales and dolphins, with an appendix on extinct and domesticated species. Whether the work will appeal with equal strength to that section of the general public interested in natural history remains to be seen. A distinctly popular element is, however, supplied by the twenty-seven coloured plates, reproduced from sketches made for the work by that accomplished artist-naturalist, Mr. E. A. Wilson. The plate in the present part is a group of dormice in a sloe-bush, which we hope will prove the least successful of the series, as the two uppermost figures are scarcely satisfactory, while the eyes of all the individuals appear too small and lacking in prominence.

Except for an instalment of the introduction to the Chiroptera and the general account of the family Vespertilionidæ, the present part is devoted to the noctule and Leisler's bat, each of which has an appalling list of synonyms. The only fault we have to find with these lists is that, beyond a statement on an earlier page (6) to the effect that the generic term Nyctalus was applied to the group by Dr. K. Andersen in 1908, there is no clue to the authority for the names *Nyctalus noctula* and *N. leisleri.* It is true that these names do not actually appear in Dr. Andersen's paper in the "Annals" for the year cited, but reference to that paper ought certainly to have been made in the lists. The work has our best wishes for success.

R. L.

Bacteriology for Nurses. By Isabel McIsaac. Pp. xii+179. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1909.) Price 5*s.* net.

While agreeing with the proposition that the nurse should have a clear and definite knowledge of the principles of the germ theory of infective diseases, we doubt if this book will really aid her to attain this end. It is too much an elementary text-book of bacteriology, and does not contain sufficient of the practical application of bacteriological principles in the every-day routine of the nurse's work. The greater part of the book is occupied by descriptions of the causative organisms of the various infective diseases, but far too little is said about the why and the wherefore of surgical cleanliness and the means of attaining it, and the methods of preventing the spread of infection in the ward and household. Thus the section on sterilisation and the use of disinfectants occupies a bare nine pages, and the principles of antiseptic and aseptic surgery are almost omitted, yet these subjects constitute almost the beginning and the end of the surgical nurse's work. In the section on malaria, while the importance of protection from mosquitoes as a preventive is fully recognised and the "screening" of houses recommended, not one word is said of the mosquito net, which may often be the only means available for carrying out any form of "screening."

These instances of omissions might be multiplied. While, therefore, the book may prove a readable elementary text-book of pathogenic bacteriology for the general public, including the nurse, we cannot but regard it as lacking in many of the bacteriological details which are so essential to the intelligent work of the nurse for whom it is avowedly written.

R. T. H.

The Inherent Law of Life: A New Theory of Life and of Disease. By Dr. Franz Kleinschrod. Translated from the German and edited by Louise C. Appel. Pp. vii+214. (London: G. Bell and Sons, Ltd., 1910.) Price 3*s.* 6*d.* net.

Dr. Kleinschrod is a vitalist of the order of his celebrated countryman, Dr. Hans Driesch. He holds that life is not explicable from a mechanistic point of view. It has its own laws, beyond all physical and chemical formularies. Moreover, as we know life better—at closer quarters, so to speak—than inorganic nature, it is absurd to explain the former by the latter. "All our ideas of nature are obtained directly from the law of life; are vitalisms, as Prof. Lipps, the psychologist, so aptly terms them. Force, energy, gravitation, pressure, &c., are ideas derived from life and transferred to the lifeless world." It is more sensible to interpret the inanimate from the standpoint of the living than conversely.

Disease and healing are, equally, life-processes. A true remedy is a remedy which calls forth the healing processes, and does not merely suppress symptoms, as in the application of ice to inflamed parts. The thing to do is to stimulate function. Digitalis does not increase cardiac strength; it merely whips up the action, and uses up life-force too fast. Graduated exercises really strengthen the heart. Similarly with other pathological conditions. Less drugging, more "nature-cure."

There is much that is debatable in this book, but it is certainly suggestive. On its practical side it is in accord with the trend of modern practice, and the author sensibly admits the *auxiliary* uses of surgery and drugs, thus steering clear of the extremes into which some nature-cure propagandists are apt to rush.

Philosophics. By Prof. Ronald Ross, F.R.S., C.B. Pp. viii+56. (London: John Murray, 1910.) Price 1*s.* net.

The title of this brochure is rather unhappily chosen, for, coupled with the author's scientific and academic distinctions, it may give an untrue impression. As a matter of fact, the book is a collection of short poems, written in the leisure time of a busy and useful career. All are tuneful and satisfying to the ear, and many have the genuine inspiration which distinguishes poetry from mere verse—*e.g.* the "Vision of Nescience," and many a line in the longer poem, "In Exile." Prof. Ross is, of course, best known by his researches on malarial fever, and his discovery of the part played by mosquitoes in carrying infection. The results of his work are world-wide. It seems probable that, largely in consequence of his discoveries, many uninhabitable districts may be rendered fairly healthy; this is already being done in parts of Brazil. The following couple of verses, written at Bangalore, admirably portray the pity in a noble worker's mind, and the pathos of suffering humanity. The title is "Indian Fevers."

> "In this, O Nature, yield I pray to me.
> I pace and pace, and think and think, and take
> The fever'd hands, and note down all I see,
> That some dim distant light may haply break.
> The painful faces ask, can we not cure?
> We answer, No, not yet; we seek the laws.
> O God, reveal thro' all this thing obscure
> The unseen, small, but million-murdering cause."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

Early Burial Customs in Egypt.

As the subject of early burials has been raised in Nature with reference to the results of my excavations (pp. 461–2), I suppose some reply will be expected.

The whole question lies in a nutshell. Many thousand graves have been examined by one party of observers, and certain results repeatedly found. Many thousand graves have been examined by another party of observers, in other localities, and such customs are not found. Many people accept the results of both groups; Dr. Elliott Smith will only accept one group. To take an exactly parallel case: by one group of observers a dozen vases with figures of boats have been found among these graves, but by the other group (as I am informed) no examples have been found. The negative evidence of the latter cannot prove the uniformity of customs throughout the country.

To repeat here the statements of most careful observations already published would be a waste of space and attention. All the possible causes named on p. 462 for the accidental shifting of bones were fully before myself and other observers, as we together examined skeletons in unplundered graves; the cases were considered at length before shifting a single bone; and our most careful observations of facts cannot be disproved by differences of ancient custom in other places.

The custom of unfleshing is well known in early Italy and Europe, and practised to this day (with ceremonial anthropophagy) in Africa. It is not surprising that it should also be present in Egypt. Indeed, the references to early anthropophagy in Egyptian ritual and myth would point to its being known, even apart from any physical evidence.

This year, again, we found two unquestionable examples showing the unfleshing and wrapping of every bone separately in linen, without leaving any flesh or skin except a little on the skull. If the corpse had been buried entire—as Dr. Elliott Smith suggests—and subsequently plundered of valuables, no relatives would have then honoured it by breaking it entirely to pieces to rebury it. The unfleshing must have been a primary burial ceremony; and these bodies were of the highest nobles of the third dynasty, and not merely of barbarous peoples. These were published, and the specimens subsequently exhibited for a month in London. I regret that Prof. Elliott Smith did not examine them, nor, indeed, honour our excavations by a single inspection during the years when he was in Egypt.

W. M. Flinders Petrie.

Lord Morton's Quagga Hybrid and Origin of Dun Horses.

May I be allowed to return to the two suggestions made in Nature of September 15, viz. (1) that Lord Morton's quagga hybrid was not a hybrid at all, and (2) that the dun colour in horses is not a reversion?

The first of these was based upon Prof. Cossar Ewart's statement in "The Penicuik Experiments" that "in their body colour none" of his zebra hybrids took after their zebra sire, and on the theory, now well proved, that chestnut is recessive to all other horse colours. It thus seemed impossible that Lord Morton's hybrid, which, according to its portrait, is undoubtedly a bay, could be the progeny of a quagga horse and a chestnut mare.

Some years ago I saw half a dozen of Prof. Ewart's zebra hybrids, and, although I did not observe them as closely then as I would now, they all impressed me as having the colour of their dams *plus* the striping they had got from their sire the zebra. A few days ago Prof. Ewart very kindly showed me over his stud again, and showed me also the skins of some zebra-horse hybrids, and these skins follow the dams in colour. A brown skin had a brown dam, a bay skin a bay dam, a chestnut skin a chestnut dam, and so on. The chestnut skin was highly rufous, but it was still chestnut. There were also two brown-looking skins, yellowish below and about the flanks, belonging to the progeny of a zebra mare and a horse, which Prof. Ewart had not bred; but in this case, I understand, the colour of the horse is unknown.

In support of the first contention, I said it was very unlikely a quagga with whitish "points" and a chestnut mare should have a foal with dark points such as are seen in the portrait of Lord Morton's hybrid. Prof. Ewart points out that "crosses between zebras and ponies have, usually, dark patches at the fetlocks." That may be; but my point was that this would not occur if the dam were a *chestnut*. Every other colour but chestnut might be expected to give foals dark at the fetlocks.

The second suggestion, that dun is not a reversion, was based upon work of my own published last spring. At the time I had only few data with regard to dun, but it indicated dun to be dominant to chestnut, black, bay, and brown, and recessive to grey. Since then I have collected more than 200 matings concerning dun; and leaving out creams (which seem a variety of dun), dun roans, and cases in which the colours of the second parent were unknown, the following table shows the results of mating dun with itself and with the other five usual colours:—

Colours of Parents	Colours of Foals					
	Chestnut	Plack	Bay	Brown	Dun	Grey
Dun × Chestnut...	3	—	4	—	9	—
Dun × Black ...	—	4	—	—	4	—
Dun × Bay... ...	4	3	21	3	8	—
Dun × Brown ...	—	—	2	7	8	—
Dun × Dun ...	1	—	1	—	6	—
Dun × Grey ...	3	4	7	5	16	10

That dun is recessive to grey is shown by the fact that it gets no grey foals unless mated with grey, while its matings with the other colours, as well as with grey, show that it is dominant to, *i.e.* contains, them all. In addition, there are two matings of grey with grey producing duns, and two of grey with black producing duns.

It follows from the above that a dun foal can only be got when one parent is either dun, dun roan, or grey, and that dun can be a reversion, if it can be called such, to grey only. But it could not be expected that among 200 cases there would be no exceptions to the rule. However, I have found only four in which a dun foal had neither a dun nor a grey nor a dun roan parent. But these exceptions help to emphasise the rule, for in each of them one of the two parents was a bay—the second parent being brown in three cases and bay in one—and bay and dun are occasionally mistaken for each other. These cases may, therefore, be taken as misdescriptions.

The Przewalsky horse is a case in point. He has been called dun; but he is not such. He is a bay, a sandy bay, with a large bright nostril patch such as is found among light bay, sandy bay, and "yellow bay" Clydesdales.

I have just come upon the following in Darwin's "Animals and Plants under Domestication" which is *apropos* of the present discussion:—"I have endeavoured, but with poor success, to discover whether duns, which are so much oftener striped than other coloured horses, are ever produced from the crossing of two horses, neither of which are duns. Most persons to whom I have applied believe that one parent must be a dun."

James Wilson.

Royal College of Science, Dublin, October 3.

The colour of Lord Morton's hybrid may not suggest its mixed origin, but this is sufficiently indicated by the mane, tail, and conformation.

A white-legged Iceland pony produced a brown hybrid with dark "points" to a Burchell zebra (Matopo) white below the knees and hocks, and a chestnut Iceland mare produced a bay hybrid to a Przewalsky stallion. Why should not a chestnut mare produce a bay-dun or bay, hybrid to a white-legged quagga?

Lord Morton's quagga was more a bay than a dun, and there are good reasons for assuming that both the quagga and the Burchell zebras are descended from ancestors in colour like the wild horse still surviving in Mongolia. Of three zebra hybrids out of a chestnut mare, two are rufous (or chestnut), but one is fawn-coloured and has dark "patches at the fetlocks." Doubtless dun may contain bay, brown, and black, but on one occasion I obtained a striped dun by crossing a black Shetland pony with a striped bay Arab—an Arab which mated with a yellow-dun Connemara mare produced a pure black. These may only be exceptions that prove the rule.

J. C. Ewart.

Tests for Colour-Blindness.

I am surprised to see in the review of my book in Nature of September 1 the statement:—

"We do not see that Dr. Edridge-Green has furnished us with any increased security, or indeed that any better security is needed, than is obtained from Holmgren's test when this is employed in the precise manner directed by its originator."

In this issue of my book I have devoted nearly nine pages to the detailed condemnation of the Holmgren test, and this portion remains as it was in the 1891 edition. The statements there have been confirmed by numerous observers, amongst whom are some of the ablest scientific men the world contains. In fact, at the recent International Physiological Congress I did not meet with a single man who was satisfied with the Holmgren test.

I will only refer to the statements of Prof. Nagel, who has done so much in connection with colour-blindness.

I pointed out that normal-sighted persons were rejected by this test, and this is abundantly evident by the number of men rejected by the Board of Trade who get through on appeal.

Prof. Nagel in 1898 found thirty-nine cases (2·75 per cent.!) in 1420 examinations in which typical dichromic (red-green blind) mistakes were made with the Holmgren test, and yet when examined by other and more trustworthy methods, as, for instance, the spectroscope, were found not to be dichromics.

I stated that the test green was not the best colour for a first test. Nagel says the same thing. In the reports of the Board of Trade it will be seen that many have passed the green test and failed with the rose test. It may be noted that the Board of Trade have never at any time used the test in strict accordance with Holmgren's instructions, because they have used all three test skeins, whereas Holmgren stated that when the green test had been passed the person might be regarded as normal sighted. Nagel points out the varieties and number of colour-blind persons who are passed by the Holmgren test, and gives the reasons, which are similar to mine.

F. W. Edridge-Green.

The Institute of Physiology, University College, London, October 7.

In 1890 or 1891 the Royal Society appointed a very strong committee, of which Lord Rayleigh was chairman, and it included, among other "able scientific men," Lord Kelvin, Sir George Stokes, Sir William Abney, and Prof. Michael Foster, to report on the general subject of colour-vision and on the tests proper to be used in connection with it. Dr. Edridge-Green gave evidence before this committee, stated fully his objections to Holmgren's test, and displayed the methods which he recommended in lieu thereof. His book was published before he gave evidence; and, as his original objections to the Holmgren test are reprinted *verbatim* in the 1909 edition, it is fair to suppose that no fresh evidence in support of them has been obtained during the intervening time. Besides hearing many witnesses, the committee carried out an extended series of practical investigations, and on April 28, 1892, it unanimously recommended the Holmgren test for adoption by railway companies, ship-owners, and the Board of Trade. The committee pointed out that variations in the amount of deficiency in colour-perception are numerous, and, "when small, are often difficult to classify." No one claims for the Holmgren test that it affords a sufficient basis for a minute classification, but it does afford the surest and most convenient means of excluding from certain industries the small number of persons who could not engage in them without danger to the community.

The Reviewer.

Water Vapour on Mars.

The statement attributed to Director Campbell on p. 317 of Nature for September 8, to the effect that the nights in September, 1909, on which his spectrograms of Mars were taken, "were as perfect for the purpose as could be wished," is open to question. Though the sky may have been clear and the surface humidity low, this does not prove that the aqueous vapour in the upper air was small in amount. September is the month when the total vapour-content of the atmosphere is a maximum, and February is the month when the vapour-content is a minimum, in north temperate latitudes. This is well shown in the curves of energy in the infra-red solar spectrum for February 19, 1903, and September 14, 1903, in the article on "The Absorption of Water Vapour in the Infra-red Solar Spectrum," by F. E. Fowle, jun. (Smithsonian Miscellaneous Collections, quarterly issue, vol ii., part i., p. 1, 1904, Plate i.). The ratio of the intensities of the bands of aqueous absorption {(Mars + earth)/earth} will be greatest when the total absorbent column of the earth's atmosphere contains least water, that is, other things being equal, the ratio may be expected to be smallest in September and largest in February. Director Campbell has chosen the worst month, and Dr. Slipher, who observed in January and February, the best months for making the experiment.

The statement that "with a nearly evanescent α band, the more water vapour one attributes to the terrestrial atmosphere the less remains attributable to that of Mars" is, of course, true, and because the water vapour of Mars is not great in amount it is not desirable to attempt to observe it at a time when the feeble Martian absorption band is swamped in a more powerful terrestrial band.

The depths of the aqueous absorption bands in Mr. Fowle's figure (*loc. cit.*) is many times greater in September than in February; but this does not express the degree of unfavourableness of the September observation adequately, for it is increasingly difficult to detect an increment of absorption due to the addition of a constant amount of vapour, as the total absorption grows greater, and this for the reason that many of the absorption lines have reached a maximum intensity already, so that any further increase of the depth of the absorbent only affects the feebler lines. It should be understood that, with the low power employed, the band is not resolved into its separate lines in the Martian spectrum.

Through the favour of Dr. Percival Lowell I have been permitted to measure the spectra of Mars and the moon photographed by Dr. Slipher at the Lowell Observatory in January and February, 1908. The seasonal gain from lower temperature and diminished moisture in the upper air in winter at Flagstaff is more than an equivalent for any gain in this respect to be obtained by even a double altitude in summer. I have made quantitative measures of the absolute intensity of the little α band in both spectra. The ratio, α(Mars)/α(moon), obtained from six different plates on as many nights, varies from night to night as changes in the terrestrial atmospheric humidity may determine, but all of the plates unite in telling the same story, and show that little α is stronger in the spectrum of Mars.

One of Dr. Slipher's plates, which is, unfortunately, not the best one photographically, although it is better in this respect than any of Director Campbell's, was taken under almost ideal conditions, the air at the surface having a dew point of $-14{\cdot}8^\circ$ C., and the exposure on Mars being equally divided on either side of the lunar exposure with both bodies at the same altitude (40°). The result is conclusive, and shows that the Martian band on this occasion was two and one-half times as intense as the telluric one. Still larger ratios were obtained from other plates.

Similar consistent measures have also been made of the oxygen band, great B, showing that it is in like manner stronger in the spectrum of Mars, although the measurement is a difficult one, because the earth's atmosphere is much denser than that of Mars, and the further small addition of absorbent has but little effect.

A Caution.

Fellows of the Zoological and other scientific societies, museum officials and others, are warned against an individual representing himself as a consumptive and asking for a recommendation to a hospital and temporary help.

The *modus operandi* is to call upon you with a bogus introduction from another fellow of your society or someone known to you, and to mention a few other well-known persons as interested in his case.

The individual is rather tall, thin, of wan appearance, and has a dark moustache. His manner shows some refinement and education, and is also persuasive, as proved by the number of those known to have, unfortunately, been victimised by his false representations.

E. A. S.

Dr. John Peile: A Correction.

Owing to the omission of a comma (which is doubtless due to my faulty and hasty writing) in the article in your last issue on the late Master of Christ's, the personages of Prof. Percy Gardner and the President of Queens' College have been merged into one.

Prof. Percy Gardiner is, of course, the professor of classical archæology at Oxford, and the President of Queens' (which should be spelt with the apostrophe *after* the "s," it having been founded by two queens) is the physicist, the Rev. T. C. Fitzpatrick, chairman of the board of physics and chemistry at Cambridge.

I need hardly say that the list of those who were at Christ's College under Dr. Peile was confined to those who acquired a position in certain branches of science. An equally strong list could be drawn up of those who have achieved success in other walks of life.

October 14. The Writer of the Article.

THE CENTENARY OF BERLIN UNIVERSITY.

A BRIEF account of the first day of the centenary festival at Berlin, and of the notable utterance of the German Emperor at its opening *Festakt*, was given in last week's issue of Nature. The celebration lasted over three days (October 10–12), with some sporadic entertainments on the fourth. Unter den Linden, from the Brandenburg gate to the royal castle and the cathedral, showed the chief, if not the only, signs that something unusual was in hand. For Berlin, as one of the academic orators remarked, is not a university city; it is a city containing a university. The well-known building itself, with its statues of the Humboldts and Helmholtz, was decked with garlands, and flags fluttered about the opera square and the new *Aula*, which is the old library. Figures in evening dress, or uniform, or quaint university costume, flitted here and there among the city crowds, and students in the caps and colours of their *corps* drove in open carriages along the wide alleys of the central avenue of Berlin. But except when the torchlight procession was in motion, or the Emperor with his guards passed swiftly along, the hurrying population was little stirred, and traffic followed its usual course.

At noon on Monday, October 10, the delegates met at the University to receive instructions. Each was presented with a commemorative bronze medallion bearing the Kaiser's image, and with two massive volumes of the history of the University, and a useful guide to "Berlin in Wissenschaft und Kunst," prepared by Dr. W. Paszkowski. Those of each nation were requested to choose one of their number to speak for them at the presentation of addresses next day. The venerable Lord Strathcona, Chancellor of Aberdeen and of McGill University, Montreal, was acclaimed the representative of the British delegation. One orator was to be appointed to reply at the festival banquet to the toast of the whole of the non-German delegates, and the choice fell upon Dr. Mahaffy, of Dublin. When the time came, be it said, the versatile Irish scholar played his part in fluent German amid universal applause.

In the evening a solemn thanksgiving was held in the new cathedral. Court-preacher Dryander led the service, which was richly choral, and the sermon was preached by Dr. Kaftan, dean of the theological faculty. His theme was diversity in unity, "many members and one body." On leaving the cathedral, the congregation found the streets lined with soldiers and police, and cheerful crowds awaiting the students' torchlight procession. A large and informal company gathered in the halls and balconies of the University building to welcome the students as they passed in long and well-kept lines, dressed in all the bravery of their *Burschenschaften*. The rector magnificus, Dr. Erich Schmidt, met the students' leaders, who, through their spokesman, Studiosus Heyl, pledged their faith to Alma mater, and raised a thundering cheer for "His Magnificence" and his colleagues. The 3000 members of the procession then dispersed, to spend the night in the time-hallowed ceremonies of the *Kommers*. The professors and their guests promenaded the halls of the University, where a light collation was served in every room. Acquaintances were made and renewed in easy and unceremonious fashion, and a lively conversazione was kept going for several hours.

Next morning (October 11), the more formal celebration began at an early hour in the *Neue Aula*, the centenary gift of the Ministry of Education to the University. The guard of the Alexander regiment was drawn up in front. The corridors and staircases and the hall itself were lined with uniformed students carrying swords and banners. Delegates in strange academic robes, nobles, courtiers, and statesmen, in full-dress and gleaming with decorations, filed into their places. By the time that the Emperor and Empress, accompanied by a number of princes, the Imperial Chancellor, and a brilliant Court-party, entered to the sound of trumpets, the hall presented a dazzling display of military and academic pomp. The rector ascended the rostrum and greeted the assembly in a sonorous oration. Objective science with individual culture, he set forth as the aim of the University from its first foundation. The Emperor nimbly mounted in the rector's place, and amid tense silence delivered an energetic discourse, the substance of which was given in last week's Nature. When he announced his intention to found an imperial association for the foundation and maintenance of institutes for scientific research, with an initial capital of some half-million pounds sterling, the audience broke into long and clamorous applause.

The rector expressed the thanks of the nation in moving words, and called for a *Hoch* for the Emperor, which was given with full-throated enthusiasm, the students clashing their swords and waving their banners in time to the shrill strains of bugles and trumpets.

The Minister of Education, and the Oberbürgermeister Kirchner, next spoke for the governments of state and city, the latter presenting the rector with the deeds of a municipal endowment of 10,000*l.* for the establishment of travelling scholarships for university students. Then followed the presentation of addresses by delegates of home and foreign universities and academies. Those of each nationality came forward in a group, the countries being called up in alphabetical order. The speeches of the respective leaders were supposed to occupy not more than three minutes each, but some at least stretched far beyond that limit. Each delegate as he passed bowed to their Majesties, announced his university, handed in his document, and was greeted by the rector. This part of the proceedings went forward quietly, though at intervals applause broke out as well-known personages were recognised. Thus Poincaré, of Paris, Sir J. J. Thomson, of Cambridge, Lord Strathcona, of Montreal, Macan, of Oxford, Mittag-Leffler, of Stockholm, and Hadley, of Yale, were specially cheered.

Thereupon the prorector, Dr. Kahl, read a long list of jubilee gifts and benefactions. They included one of 5000*l*. from Frau von Wildenbruch for scholarships, a large but unnamed sum from friends of the University for the foundation of students' hostels or residential colleges, 7500*l*. from Dr. Hans Meyer, of Leipzig, for the endowment of a chair of colonial geography, and a multitude of other donations in money and kind. For all of these grateful acknowledgments were expressed, and then, by the whole assembly, the Emperor leading, the *Gaudeamus igitur* was intoned as a finale. The ceremony had lasted over three hours.

Immediately after the ceremony, it was officially announced that the titles of Excellency and full Privy Councillor had been bestowed upon Prof. Harnack, royal librarian; Prof. Diels, philologist; Prof. Wilamowitz-Möllendorf, classical scholar; Prof. Emil Fischer, chemist; Prof. Brunner, jurist; and that a host of decorations of all grades had been conferred upon other officers of the University. Even the chief janitor or *bedellus* was not forgotten.

At three o'clock a banquet for six hundred was served in the hall of the exhibition park. The feast and the speeches lasted until nearly eight in the evening. Prince Rupert of Bavaria, Prince August William of Prussia, the Chancellor von Bethmann-Hollweg, formerly a Berlin professor, and the Minister of Education, Count von Trott zu Solz, were among the guests. The Chancellor and the Minister spoke for the German Government; the Prorector and Dr. Wilamowitz-Möllendorf for the University and its staff; Rector Hölder, of Leipzig, and Prof. Mahaffy, of Dublin, for the Teutonic and non-Teutonic guests respectively; the President of the Gymnastic Association, "Arminia," for the students. To him Prof. Harnack replied, thanking the undergraduates *utriusque sexus*, and draining the newly presented loving-cup to their welfare. Some ominous head-shakings among the professors were observable as the one lady student present, Miss Ilse Tesch, of the faculty of medicine, came up to join in the pledge. The situation was saved by Prince August William, himself a Berlin student, who promptly shook hands with his "Commilitonen" *utriusque sexus*, and solemnly shared the cup with them. The assembly dissolved in laughter and loud applause. Presently the company reassembled at the Royal Theatre, where, in the presence of his Majesty and the Court, a festal performance of Mozart's "Marriage of Figaro" was given in honour of the University and its guests.

On Wednesday morning, October 12, the new *Aula* was the scene of the second *Festakt*. The Emperor was represented by his son, and the place of the courtiers was taken by the city fathers and other representatives of municipal institutions. But in other respects the gathering resembled that of the preceding day. Prof. Lenz, the historiographer of the University, delivered an eloquent and impassioned address on its origin, evolution, and present position. The ideas of its first sponsors, Fichte, Schleiermacher, and William von Humboldt, had been realised or surpassed. Even in the dark days of the Fatherland, the University had not despaired. Hundreds of its members had given their labours and laid down their lives for the unity of Germany. Based on that unity, now once for all achieved, the University had risen triumphant to its present glory. Its watchword was "freedom of research"; its guiding conviction that knowledge is the power that conquers.

Then followed the academic ceremony of conferring honorary degrees. In accordance with German custom, the list of graduands had been kept a secret. For days before the newspapers had speculated regarding the recipients, but, except in a few instances, the current guesses appear to have been wide of the mark. The precedence of the faculties in Berlin rests with divinity; it is followed by law, medicine, and philosophy. It was therefore at once surmised that something abnormal was about to happen when the dean of the law faculty came first to the daïs. In a few words of German he explained his mission, and then in stately Latin proceeded to create, pronounce, and proclaim the Emperor himself a *doctor utriusque juris, cujus auctoritate juris civilis Germanorum codex post sæculi labores prodiit*. The announcement brought the assembly to its feet; a loud fanfare, and cheer after cheer, welcomed the new graduate. The dean of the faculty of theology followed, in a formal and courtly protest, waiving his precedence for that occasion only. He, by resolution of the Senate, and with the approval of his Majesty, proclaimed some fifteen or sixteen doctors of divinity. The Burgomaster of Hamburg, a distinguished merchant, and Dr. James Hope Moulton, of Cambridge and Manchester, were among the number. The dean of the law faculty reappeared, and conferred the LL.D. degree on Prince Rupert of Bavaria, Judge Oliver Wendell Holmes, of New York, Prof. Vinogradoff, of Oxford, the Burgomaster of Berlin, and a long series of professors and high officials holding office in the German civil service. In medicine, professors of philology, philosophy, and law were promoted, side by side with Poincaré, de Vries, Richards (Harvard), the painter Thoma, the musician Reger, the humorist Raabe, of Brunswick, and the master of ceremonies, Knesebeck. It needed all the dean's ingenuity to relate the functions of the honorary doctors of medicine to those of his faculty.

The list of the philosophical faculty, which includes all the departments not covered by the other three, was of considerable length. Some forty names were read out, and a few words were said on each. Prof. Ashley, of Birmingham, Dr. Arthur Evans, of Oxford, and Dr. Lazarus Fletcher, of the British Museum, represented British learning; and the Presidents of Harvard, Yale, and Columbia were selected for the United States. The Imperial Chancellor and the President of the Reichstag, with many other exalted personages, military and administrative, and one lady, Frau Cosima Wagner, of Bayreuth, were included. It gave rise to some remark that none of the British delegates, though Lord Strathcona, Lord Reay, Sir William Ramsay, Sir J. J. Thomson, and Sir Joseph Larmor were among them, received any academic recognition.

The solemnities of the seniors were thus accomplished. But the junior members of the University had festivities of their own to celebrate. The afternoon was occupied by a popular *Gartenfest* in the exhibition park, where students in the costume of 1810 and earlier, old alumni, professors, citizens, and somewhat bewildered guests, held high carnival. The halls of the exhibition, and the arches of the railway viaduct that spans the grounds, were thronged by thousands of cheerful spectators of the numerous entertainments, organised by the students' committee. As the public were admitted on payment, the crowds made sightseeing difficult, and conversation well-nigh impossible. As the evening fell, the academic element receded altogether, and the park assumed a bank-holiday aspect.

At night a vast *Kommers* of the entire body of students took place in the Zoological Gardens. There, under the strict regulations which tradition prescribes, the ceremonies of the *Biercomment* were performed for the edification of the initiated and the entertainment of the foreign visitors. But the present writer had to leave by the midnight express, while the ordered revelry was at its height.

The foreign university delegates included Principal G. Adam Smith (Aberdeen), Zeeman (Amsterdam), Sir J. J. Thomson (Cambridge), Mahaffy (Dublin), Sir Donald MacAlister (Glasgow), Chwostow (Kasan), Brögger (Christiania), Sir W. Ramsay (London), Lord Strathcona (Montreal), President Hadley (Yale), President Butler (Columbia, New York), Macan (Oxford), Poincaré (Paris), Grünert (Prag), Blaserna (Rome), Mittag-Leffler (Stockholm), Bernatzik (Vienna), and A. Meyer (Zurich). Among the representatives of foreign academies and societies were Thomsen (Copenhagen), Johannessen (Norway), Lord Reay (British Academy), Sir J. Larmor (Royal Society), Keen (Philadelphia), Montelius (Sweden), Miura (Tokyo), and Böhm-Bawerk (Austria). The German universities and academies were represented for the most part by their rectors or presidents.

TOWN-PLANNING.

TOWN-PLANNING has always had a fascination for the sociological amateur, and the creation of a model town is one of the most pleasing and least harmful of Utopian dreams. Mr. Burns's Town Planning Act is well-intentioned; under the conditions this is enough, for in the evolution of a town the method of trial is inevitable, the problem *solvitur ambulando.* The one thing needful is the guiding idea, the working principle.

The discussions at the Town Planning Conference have been full of interest. There have been felicitous analogies, ingenious suggestions, and brilliant forecasts. But it is a commonplace that the permanent institutions are those which have not been planned, but have grown by a sort of felicitous adaptation, an unconsciously purposive concurrence of atoms. Throughout the conference it was taken for granted that the town of the future will be evolved from the town of the present by small, continuous modifications. Here is a curious analogy to Darwin's view of the evolution of a new species, by the summation of small variations. Again, throughout the conference there has emerged no master-principle, no architectonic impulse, for the guidance of those who will apply the Act. Still less possible was the emergence of any universal and permanent plan.

What is to be our plan, and what our principle for the evolution of the town of the future? Is the ideal town to be a garden city, with factories in the country, or a combination of gardens and factories? Mr. Lanchester has ingeniously explained the "West End" tendency by suggesting that in the evening, when work is over, one's steps naturally turn to the region of the setting sun, and that this quarter therefore is unconsciously chosen as the place of home and relaxation. Or is the ideal town to be an aërial maze of skyscrapers, overhead ways and wires, somewhat as imagined by Mr. Wells? Will this have roof-gardens? Will different forms of traffic be confined to different levels? Or, again, will the city be half underground? Such questions would be futile, were it not necessary that the working plan of the town-planner must allow for all such eventualities.

It is argued by many that plan must precede structure. As applied to individual units, this is a truism, but it can hardy be applied to a complex growth like a town. It involves the Platonic notion that there is a pre-existing idea of a town. But the idea, that is, the plan, of a town develops with its growth as surely as it originated with its inception. The moral of this is that the plan which every body of town-planners must work upon must be a *dynamic plan*; a moving, shifting, developing, and shrinking, growing and changing plan, the germ of which is to-day's town conditioned by its environment.

There has been, and will be for a time, much useless talk about town-geometry. The straight line and right angle with which street-plans commence, to be varied by curves, other angles, circles, and triangles, according to the circumstances, are fundamental. Æsthetic play with these elements is misguided in the case of streets and areas, no less than in the case of individual houses and blocks. For architectural beauty should be a by-product of adaptation of structure and function. Town-planners need to keep an eye on traditional architecture, which has long lost this essential principle. There is a real danger, in the enthusiasm of a new movement, that the conventional architect may create a body of useless expenditure if allowed to indulge his unscientific ideal of ornament for ornament's sake. He is really more dangerous than the jerry-builder. In the one sphere where he may seem harmless, if not desirable, the designing of public buildings, he is really unnecessary. At the conference, engineers were conspicuous by their absence, but in the town-building of the future the engineer will be the main adviser and collaborator of the builder.

As for a guiding principle in the working of a dynamic plan, there is none, unless we say—science. In the town, as in the house, ease of communication, light, air, and sanitation are the essential needs which scientific building has before it. There are no other components of a golden rule. Continuously applied when circumstances permit, these considerations will gradually improve our cities as science advances. One or two details are useful for discussion. It has long been established that urban populations tend to be more intellectual but physically more degenerate than the rural. Yet East End populations, though degenerate in some respects, have developed a high power of resistance to insanitary conditions. Again, there is some evidence that the town populations of Sweden, once a feeble race, have become, through physical training and scientific environments, physically superior to the country populations, and as fine a race as any in Europe. Parks and open spaces will be permanent blessings, supplying a touch of nature for the soul of the town dweller, though we may come to realise that we have over-estimated the value of light, and may some day artificially purify our air. Such suggestions as a great ring-road round London —certainly concentric communication is defective—and the removal of the great railway termini to one small central area, must be balanced by the possibility of the evolution of other methods of locomotion. Some day London may need great open spaces for aëroplane stages.

Town-planning is a continuous process, and its results are in the future, and themselves to be superseded. But there is one sphere, more or less untouched at the conference, which admits of immediate attention. One of the great obstacles to progress is the slowness with which new inventions are brought into the personal environment of the mass of the population. A striking example of this is the average house. But in the case of house-building, which, after all, is the most important function of architecture, and the one supreme concern of the town-planner, invention has done less than in any department of material civilisation. Only in the matter of artificial lighting, and in sanitation, if in that, is the average house of to-day superior to the average house of two thousand years ago. In the matters of hot-water supply and plumber's work generally, of cooking apparatus, cleaning arrangements, heating, and ventilation, the modern house is a disgrace to a scientific age. What has been done for centuries towards the improvement of door and window mechanism? Even the external material of houses is the same as was used five or six thousand years ago, and is no more damp-proof now than it was then.

Take care of the houses and the town will take care of itself. Here is a work, of vital importance for the welfare of the race, which may well be the first care of those who apply the Act.

A. E. CRAWLEY.

THE MELANESIANS OF BRITISH NEW GUINEA.[1]

IN this volume is presented for the first time an adequate account of the sociology of a portion of the people of British New Guinea. The material which it embodies was collected during two visits of the author to New Guinea, and he has been ably assisted by various members of the Government and of the missions resident in the island. The book is a conspicuous example of what may be achieved by expert inquiry combined with local knowledge.

Dr. Seligmann uses the term Papuasian to signify all the inhabitants of New Guinea and the adjacent archipelagoes. These form two distinct groups. For the taller, darker, and more frizzly-haired people of the west he retains the term Papuan. The smaller, lighter-coloured peoples of the eastern peninsula and islands, in which the true Melanesian element is dominant, are called Papuo-Melanesians. With these Dr. Seligmann deals in the present volume, the Papuans being only alluded to when their physical characteristics or customs refer to the subject of discussion. Following Dr. Haddon's suggestion in the "Decorative Art of New Guinea," the author divides the Papuo-Melanesian peoples into two main groups, the western Papuo-Melanesians and the Massim of the east.

An introduction gives a succinct account of the general sociology and culture of the two groups. These agree in certain physical and cultural characters, which clearly differentiate them from the Papuan, but differ in many respects from one another. The amount of variation among the western Papuo-Melanesians is much greater than that found among the Massim peoples. The greater uniformity of the latter is regarded by Dr. Seligmann as due to a geographical factor. The small islands and peninsulas of the eastern district afforded less shelter for fugitives than the swamps and forests of the west, so that the Melanesian conquest was there more rapid and complete. Owing also to the slower mingling of the Melanesians with the original populations of the west, Dr. Seligmann considers that there is not only a considerable Papuan element in their composition, but that they have also in some cases adopted Papuan languages differing from each other as do the Papuan languages spoken by Papuans. If the Papuan elements were sufficiently strong to impose their language upon their conquerors, they must have been sufficient to have imposed their customs, or, at least, to have modified those which the invaders brought with them.

With the Motu of Port Moresby and the neighbourhood, who are the best known of the western Papuo-Melanesians, the author associates the Koita. The latter speak a Papuan language, and have for generations inter-married with, and built their villages adjoining, the Motu. The fact that the Koita language shows no trace of Melanesian influence, and has names for indigenous plants and animals, which are unnamed by the Motu, presents a difficulty which Dr. Seligmann has not discussed. From the latter, too, they have adopted certain customs and arts. The Ikoro, Gaboni, and Sinaugolo tribes, which closely resemble the Motu, occupy the district inland from Kapakapa and the basin of the Kemp Welch River. All these people are distinguished by the use of the open ceremonial

platform, or *dubu*. Eastward from Hood Peninsula the coast is occupied by a rather different tribe, among whom the *dubu* gives place to the *koge*, or steeple-house. All three groups have a general likeness in culture and sociology. There is a clan organisation and patrilinear descent. The first sixteen chapters of Dr. Seligmann's work deals in detail with the Koita regulation of public and family life, customs, trade, and religion, and includes an interesting account by Capt. F. R. Barton, of the *Hiri* or annual trading voyage made from Port Moresby to the Papuan Gulf. Another colony of Papuo-Melanesians (Mailu) dwelling around Milport Harbour and Port Glasgow, and speaking a Papuan language, are not discussed in detail by the author, neither are the Koiari and similar people of the hinterland, whom he regards as possessing more Melanesian than Papuan blood.

[1] "The Melanesians of British New Guinea." By Dr. C. G. Seligmann, with a chapter by F. R. Barton, C.M.G., and an appendix by E. L. Giblin. Pp. xxiv+766. (Cambridge: The University Press, 1910.) 21s. net.

The most western group of the immigrant Melanesians are the Roro and Mekeo people of the St. Joseph River, with whom are closely related the Pokao and Kapatsi between Hall Sound and Cape Suckling. In chapters xvii.–xxxi. the social relations and family life of the Roro are detailed, with an account of the clans and village organisation of the Mekeo, and a note on Pokao. This region is characterised by the greater importance attached to the right than to the left side in ceremonial matters, and by the prominence of geometrical design in the decorative art. Among the Mekeo there are traces of mother-right, though descent is patrilineal. A prominent feature in the Mekeo village is the highly decorated *ufu*, or club-house.

Fig. 2.—Popungapi *ufu* of Rarai Village. From "The Melanesians of British New Guinea."

The Massim people of the east are more homogeneous than the western Papuo-Melanesians. Dr. Seligmann makes two divisions, the northern in the Trobriands, Marshall-Bennet, Woodlark, Laughlan, and some smaller islands, the southern in the south-east peninsula of New Guinea between the south shore of Milne Bay and Goodenough Bay, with some of the Louisiades. Each division has its distinctive features. In the north there is a higher cephalic index and cranial capacity, a hereditary chieftainship, and absence of cannibalism. Both sections are remarkable for the building and use of large sea-going canoes, and the characteristic Massim decorative art reaches its highest development in the ornamental prows of these vessels in the north. The author's account of the sociology of the southern Massim includes a collection of folk-tales. The people live in hamlet-groups, the inhabitants of which are more or less closely related by birth or marriage. There is also a peculiar form of totemism in which the members of a clan have as totems a series of associated animals or plants, as, *e.g.* a bird, fish, snake, and plant, the number and nature of these varying in different places.

The northern Massim are described in similar detail as regards the Trobriands, Marshall-Bennets, and Murua. Shorter accounts are given of the Louisiades and Mukaua on the southern and western borders.

The volume is exceedingly well illustrated. There are seventy-nine plates from photographs or native drawings. Most of the former are exceptionally good. In addition there are fifty figures in the text drawn by Mr. Norman H. Hardy, a good map, a glossary of native words, and a very useful index. Dr. Seligmann has produced an interesting, trustworthy, and scholarly work on a most interesting section of the Melanesian people.

S. H. Ray.

THE CENTENARY OF FILIPPO CAVOLINI.

THE first centenary of the death of Filippo Cavolini, the great Neapolitan naturalist, was celebrated on September 12–13, the function having been arranged by the Society of Naturalists in Naples. Citizens, as well as the scientific and the political authorities, answered enthusiastically to the appeal of the society. The municipality and the University united, formed a powerful honorary general committee, the patronage of which was assumed by King Victor Emmanuel III. The chairman of the ordinary committee, composed of members of the Society of Naturalists, was the president of the society, Prof. F. S. Monticelli. The committee published an attractive booklet, giving a *résumé* of the life and works of F. Cavolini.

On September 12 the *aula magna* of the University was thronged by delegates of the Italian and foreign universities, by members of the International Zoological Congress, and by others who had been invited. Amongst the many supporters, apart from the Italian Ministries of Public Instruction and of Agriculture, we note those of many academies and universities of Europe and America, and also the Prince of Monaco.

Prof. Pasquale del Pezzo, rector of the University, thanked the Ministry of Public Instruction, and greeted all who took part in the commemoration in honour of Filippo Cavolini. Commander Rodino presented a welcome from the municipality of Naples, and thanked the Italian Sovereign, patron of the commemoration. Prof. Paladino spoke on behalf of the Royal Academy of Sciences and Letters, recalling at length the personality of Cavolini as citizen and man of science. Prof. Camerano, rector of the Turin University, made an appropriate speech, and Prof. Apáthy, representing the Hungarian University of Kolozsvàr, offered the greetings of the foreign men of science. Dr. F. S. Monticelli, ordinary professor of zoology at the Naples University, then delivered a speech in which, having alluded to the life of Cavolini, and summarily traced his scientific work, he concluded:—"Filippo Cavolini was a biologist in the true and modern sense of the word, both in observation and in experiment; his work marked a new direction in the study of life, a direction that has been corroborated in later times, a direction which Cavolini, in his day, professed and practised."

"The perusal of his works, which will be re-edited by the committee, fully proves that a century ago he, precursor of the present time, experimented on the same lines as those of the present day. This man, to whom, with patriotic pride, we must accord the honour of the scientific discoveries which he first revealed, well merits the remembrance of his fellow-citizens in to-day's centennial festivities, in order that they, not forgetting our ancient culture, should recollect that in times less fortunate for Italy's destiny, Filippo Cavolini, honouring his country, maintained his country's name in science."

The rector afterwards held a reception in the great academic hall. In the evening the Society of Naturalists received the delegates in the Galleria Vittoria. The following day the delegates and congressists were invited by the committee to join an excursion by steamer to Capo Posillipo, to the Villa de Mellis, once Cavolini's property. President Monticelli, in the presence of a large gathering, consigned to the representative of the municipality a commemorative marble tablet, which had been fixed to the house in which the great naturalist achieved his work.

JOHN WILLIS CLARK.

By the death of John Willis Clark, on October 10, the University of Cambridge has lost one of its best known and best loved members. Failing health had quite recently induced him to send in his resignation of the office of registrary of the University, as from the end of September. The interval allowed by statute for filling up this important post is only fourteen days, and it thus happened that his successor was elected on October 12, the day before his funeral took place.

J. W. Clark was to an exceptional extent a product of Cambridge, and the circumstances of his birth and training combined to give him, from early youth, an intimate knowledge of the University. He was born in Cambridge on June 24, 1833. His father, the Rev. W. Clark, fellow of Trinity College, was professor of anatomy from 1817 to 1866. His uncle, Robert Willis, fellow of Gonville and Caius College, held the Jacksonian professorship of natural experimental philosophy from 1837 to 1875. J. W. Clark was thus brought up in an environment which made him familiar with the University at an age when his contemporaries in academic standing of later years had not yet commenced their acquaintance with Cambridge. He was educated at Eton, and from there proceeded to Trinity College, of which he became a scholar, and later a fellow, having obtained a first class in the classical tripos of 1856.

On the death of Prof. Clark, in 1866, a professorship of zoology and comparative anatomy was founded, and the first occupant of the chair was Alfred Newton. At about the same time the zoological specimens which had been contained in the museum of anatomy, some of them dating from the time of Sir Busick Harwood, professor of anatomy from 1785 to 1814, were placed in a museum of their own, reinforced by the collections of the Cambridge Philosophical Society. J. W. Clark was the first superintendent of the new museum of zoology, and he acted in that capacity from 1866 to 1891, when he resigned the office on being elected registrary. During his tenure of the superintendentship, his own efforts, combined with those of Prof. Newton and Prof. (later Sir George) Humphry, gave the museum a character which was eminently suited for the instruction of students of zoology, and made it an educational instrument of the greatest value. Throughout these years Clark was on terms of intimate friendship with Prof. (later Sir William) Flower, at that time conservator of the museum of the Royal College of Surgeons. A series of specimens illustrating the comparative anatomy of vertebrates was formed by a mutual arrangement between the two museums, of such a nature that, for instance, the limb-bones of one side of a particular animal found their way into the museum of the College of Surgeons, and those of the other side into the Cambridge comparative series. Clark was fully impressed with the importance of illustrating the structure of animals in his scheme of exhibits, and the collection over which he presided was distinguished by possessing preparations both of vertebrates and invertebrates, which placed it far in advance of the majority of provincial museums.

During the whole of his period of office at the museum, Clark had, however, wider duties to perform. He found time to act as secretary to the Museums and Lecture Rooms Syndicate, a body which is charged with the care of the buildings, and, to a large extent, with the finance of the scientific and other departments. This was a highly critical period in the history of natural science in the University, since it coincided with the remarkable growth of scientific studies which was so marked a feature of Cambridge at that time. Clark's wise and capable management of affairs, and in particular the interest he took in supervising the planning and erection of the buildings required to provide accommodation for the new studies, have earned for him the well-deserved gratitude of all who have had the scientific interests of the University at heart.

The duties in connection with the museum and with the growth of the scientific departments generally would have been enough to find full scope for the energies of an ordinary man. But this was only one side of Clark's remarkable character, and some of his most notable achievements lay in entirely different directions. His highly valued services to the University as a member of innumerable syndicates and boards must be passed over without comment. The work by which he is best known to many students was connected with the history of the University. The monumental "Architectural History of the University of Cambridge," by the late R. Willis and J. W. Clark, was published in 1886, in four large volumes. It originated in a lecture given by Prof. Willis in 1854, and it was based in the first instance on the materials which had been accumulated by him. The work was taken over by Clark at Prof. Willis's death; and the volumes, as finally brought out by him, are a mine of information in all matters connected with the growth of the University and its colleges, as well as of Eton College. Four years later, in 1890, "The Life and Letters of Adam Sedgwick" was published by J. W. Clark, in collaboration with Prof. T. McKenny Hughes.

As an antiquary, Clark was specially concerned with libraries, and he was an acknowledged master in matters relating to their furniture and fittings. Some of his results in this line of investigation were published in 1901, under the title of "The Care of Books." His interest in libraries took a practical shape in the work he devoted to the University library, as shown, for instance, by his success in raising, within the last few years, a sum of 20,000*l.* in order to place the finances of that institution on a more satisfactory basis. The Fitzwilliam Museum is another institution to which Clark devoted much of his time, and to which he rendered innumerable services. He was a member of the council of the Cambridge Antiquarian Society for forty-nine years, and he read more than fifty papers at meetings of the society.

As a zoologist, Clark's principal interests were connected with marine mammals, as is exemplified by the fine collections of Cetacea, Sirenia, and Pinnipedia which he made for the museum of zoology. His best-known zoological publications refer to these groups of animals, and special reference must be made to his papers on eared seals, published in the Proceedings of the Zoological Society in 1873 to 1884.

During the last nineteen years of his life, Clark was fully occupied by the duties devolving on him as registrary of the University. In this capacity his extraordinary knowledge of the early history of Cambridge and of its forms and ceremonials, his ability in the care and publication of documents, and his acquaintance with procedure were all of the greatest service to the University.

It is difficult to speak dispassionately of Clark's singularly attractive personality, and of the ready sympathy he showed with all sorts and conditions of men.

Advancing years did not take from him the capacity of making new friends, many of whom were chosen from among the younger members of the University.

> "Gracious and apt to win the youngest heart,
> Yet keep the oldest true!"

These words, written of him by his friend, Mr. A. C. Benson, will express the affectionate regard felt for him by many with whom his loss leaves a blank that cannot be filled. Sidney F. Harmer.

PROF MAURICE LÉVY.

In Nature of last week the death was announced of M. Maurice Lévy, sometime inspector-general of the Ponts et Chaussés, and professor at the Collège de France. An interesting account of Levy's investigations in pure and applied mathematics and mechanics is given by M. Émile Picard in an address to the Académie des Sciences, read on October 3 (*Comptes rendus*, cli., 14).

In infinitesimal geometry, Lévy obtained the doctorate in 1867, for an essay on orthogonal coordinates embodying several new and important results. His investigations in this subject also included the study of spiral surfaces. His treatise on graphical statics, of which the first edition appeared in 1874, practically initiated the study of this important branch of applied mathematics in France. The notes at the end of the first edition really constitute original papers on the tension of elastic rods, and on the systems of maximum strength with given amount of material; in them the author discusses the advantages of structures without superfluous connections. A second and enlarged edition appeared in due course, and the completion of a third edition has been unfortunately cut short by Lévy's recent death.

The subject of elasticity occupied a large share—perhaps the main share—of Lévy's attention. After he entered the École polytechnique in 1856, at the age of eighteen, he indicated a new and simple method of investigating the resistance of continuous beams. The problems presented by systems, one of the dimensions of which is small compared with the others, greatly interested him, and a long memoir was published by him on the flexure of elastic plates. M. Picard speaks in high terms of the ingenuity and ability displayed in this essay, while remarking that a more complete solution of the difficulties occurring in this problem is to be sought elsewhere.

A second problem in elasticity was afforded by the stability of rods or prisms under end-thrust, and Levy extended the investigation from straight to circular rods, obtaining extremely interesting conditions of stability by means of an analysis involving elliptic functions. To M. Lévy is assigned the credit also of obtaining for the first time the general equations for ductile bodies strained beyond the limits of elasticity, thus responding to the question put by Saint Venant, arising out of Tresca's experiments.

Hydrodynamics formed the subject of Lévy's second paper, dealing with rectilinear vortex motion. In this, the author took a leaf out of Cauchy's theory of optical dispersion in his application of the higher differential coefficients in studying the mutual action of two vortices.

A development of a more practical character was M. Lévy's investigation of the equilibrium of earth and the strength of masonry supporting walls. Starting with the laws of friction, Lévy found the differential equation of the lines of rupture in limiting equilibrium, and showed that, contrary to Coulomb's results, the surfaces of rupture for a prismatic mass of earth are not in all cases planes parallel to the edges of the prism.

It will thus be seen that M. Lévy played an important part in applying analytical methods to the solution of problems of practical interest, and his works constitute a heritage from which workers in applied science cannot fail to benefit greatly.

NOTES.

The council of the Royal Scottish Geographical Society has resolved to award the society's medal to Prof. James Geikie, F.R.S., for his numerous contributions to geographical research and his great services to the society; and the Livingstone gold medal to Sir John Murray, K.C.B., F.R.S., in recognition of his oceanographical work, and more particularly in commemoration of the completion of the bathymetrical survey of Scottish fresh-water lochs.

We regret to see the announcement of the death, on October 14, of Dr. Sydney Ringer, F.R.S., at seventy-six years of age.

According to a Reuter message from Santiago de Chile, official returns show that the world's consumption of nitrate during the past year amounted to 43,996,966 quintals, an increase of 8,000,000 quintals as compared with the previous twelve months.

Prof. Howard C. Butler, of Princeton, has just returned to that University with an encouraging report of the archæological expedition he has been directing at Sardis, in Asia Minor. The discoveries include a part of the pavement of the ancient city, and the substructure of a large temple of the fourth century B.C. In the necropolis across the river from the city the explorers have discovered fragments of statuary and many gold ornaments of much beauty.

Three members at least of the Yale faculty have lately returned from exploring tours which have occupied them during the long vacation. Prof. C. Schuchert, curator of the Peabody Museum, has investigated the geological formations of southern Labrador, and brought back a ton of specimens. Prof. R. S. Lull has spent several months in Europe studying mainly the European equivalents of the American dinosaurs. Mr. G. G. MacCurdy, curator of the anthropological collection, has been engaged in researches in the Indian antiquities of southern Mexico.

The Home Secretary has appointed a committee to consider the organisation for rescue and aid in the case of accidents in mines, and to frame proposals for the making of an Order or Orders under the Mines Accidents (Rescue and Aid) Act, 1910. The members of the committee are:—Mr. C. F. G. Masterman M.P. (chairman); Mr. R. A. S. Redmayne, H.M. Chief Inspector of Mines; Mr. W. N. Atkinson, H.M. Inspector of Mines; Mr. E. M. Hann; Mr. W. C. Blackett; Mr. John Wilson, M.P.; and Mr. John Wadsworth, M.P. The secretary of the committee is Mr. A. Maxwell, of the Home Office.

In a letter published in the *Times* of October 17 Mr. J. Reid Moir, of Ipswich, announced his discovery of worked flints beneath undisturbed deposits of Crag in the neighbourhood of Ipswich and elsewhere in eastern Suffolk. The flints occur on the eroded surface of the London Clay, at the base of Pliocene deposits, and associated in some cases with phosphatic nodules and fossil bones. It is inferred that the ancient clay surface was inhabited by "pre-Crag man," whose implements, on submergence of the land beneath the Pliocene sea, became covered with Red Crag. The handiwork on the flints is of a more advanced character than that of the eoliths. Two types, at least, of the early East Anglian flints may be recognised; and it is notable that though they must be, if Pliocene, very much older than the Great Ice age, some of them exhibit on their worked surface deep striæ suggestive of glacial action.

In a letter to the Press, Lord Braye and Mr. Frank Hedges Butler state that it is proposed to erect a pillar as a memorial to Percy S. Pilcher, who was killed at Market Harborough on September 30, 1899, while making a flight with his soaring machine or aëroplane. Pilcher was the first Englishman who put into practice the project of gliding through the air with rigid wings, and he had the intention of propelling with a motor the machine he had made. Many who knew him and appreciated his self-devotion and zeal in promoting aviation may like to contribute to the proposed memorial, near the spot where he fell. Subscriptions should be sent to the Pilcher Memorial Fund, Messrs. Barclay and Co. (Gosling Branch), 19 Fleet Street, E.C.

The name of Thorvald Nicolai Thiele, professor emeritus in the University of Copenhagen, has been before the astronomical public for many years, and by his lamented death on September 26 science has lost an able and original worker distinguished in several branches of natural knowledge. As a pupil of D'Arrest and as director of the Copenhagen Observatory he gave much, but not undivided, attention to astronomy, and was known for his careful discussion of double-star observations, and particularly for his criticism of Otto Struve's measures. The problem of the theory of errors in its many applications interested him, and he will be remembered for his discussion of special cases of the problem of three bodies. Outside astronomy he wrote much on insurance problems and statistics connected with tables of mortality. On these subjects he was a recognised authority, and on account of his pre-eminence was one of the few foreigners elected into the Institute of Actuaries. As a teacher he preferred to lecture on the more abstruse problems of astronomy, and never attracted a large class; consequently, his pupils were few and his influence small in comparison with his reputation, but those who were willing to penetrate deeply found in him an encouraging and illuminating master.

The Board of Agriculture is understood to have applied to the commissioners appointed under the Development Act for an annual grant of 50,000*l.* for the purpose of research work in agriculture and for giving technical advice to farmers. A number of agricultural institutions have sent in applications for financial help, but the Board and two of the commissioners—Messrs. A. D. Hall and Sydney Webb—are engaged on a comprehensive scheme that shall ensure the best use being made of the present material. The Board has appointed a special advisory committee, including the Duke of Devonshire, Lord Reay, Sir Edward Thorpe, Dr. Dobbie, Mr. S. U. Pickering, Prof. J. B. Farmer, Lieut.-Colonel Prain, Drs. Teall, Harmer, MacDougall, and Wilson, and Messrs. Davies, Middleton, Staveley-Hill, and Stockman to help generally in the work. Details of the scheme are not yet available. The occasion is a critical one for agricultural science. The amount of money is considerable, and much will be expected in return for it; if those engaged in agricultural research can justify its expenditure they will be rendering good service, not only to agriculture, but to science in general.

Nomenclature occupies a necessary part of scientific activity, and in no branch of science are the difficulties of nomenclature so great as in zoology. The greatest of these difficulties is occasioned by the rules of priority, since if these were strictly applied, many familiar names would fall into disuse, and great loss of time, misunderstanding, and trouble would result. The British Association and the eastern branch of the American Society of Zoologists have recently appealed for support in a movement to exempt animal names of long standing from change under the rule of priority, and have presented a proposition on the subject to the Commission on Nomenclature of the International Zoological Congress. This commission has just issued its triennial report, the chief interest of which lies in a reference to this matter. The secretary (Dr. C. W. Stiles, Smithsonian Institution, Washington, D.C., U.S.A.) now asks all zoologists to send him a list of 100 generic names (with their authors' names) for consideration in connection with this proposition by November 1, together with a list of standard text-books used in zoological or palæontological courses of study. Specialists are also asked to furnish a list of 100 type-species, with full references to their names as determined by Art. 30 of the international rules. All zoologists who wish to preserve the older nomenclature would do valuable service by sending in such lists without delay.

The *Times* of October 7 contains an interesting account of recent Norwegian explorations in Spitsbergen carried out by an expedition under Captain Gunnar Isachsen, which returned to Christiania on September 18 last. The chief land-work of the expedition was done in the north-western part of the main island, the most striking result being the discovery of a not long extinct volcano and hot-springs in Bock Bay, a branch of Wood Bay (not Wijde Bay, as first reported). When the brief announcement of this discovery first reached Europe two months ago some doubt was felt as to the recentness of volcanic action in this quarter, but the details now given seem to prove that the volcanic cone is at any rate of Quaternary age and later than the general glaciation of the region. The cone, about 1650 feet high, is described as consisting partly of lapilli; it occurs in lat. 78° (? 79°) 28′ north, and long. 13° 28′ east (Greenwich), in the vicinity of a north-south fault, which brings Devonian sandstones into juxtaposition with granite. The expedition encountered unusual and difficult ice-conditions, and reports that Bell Sound, in the south-west of the island, was already blocked up by ice toward the end of August, and that hunting sloops are now there frozen up. The weather was very fine until the middle of August, but afterwards there was scarcely one clear day in the western part of Spitsbergen. The large Geological Congress party that visited Ice Fiord under the leadership of Prof. G. de Geer early in August are evidently to be congratulated on their good fortune in having chanced upon the finest weather of the season.

IN *Travel and Exploration* for October Mr. A. de C. Sowerby, in the service of the United States National Museum, describes the exploration of a hitherto little known district in China, the country drained by the Fen-ho, a large tributary of the Yellow River, running north and south through the western part of the Shansi Province. He was successful in procuring a number of new or uncommon specimens, such as moles, polecats, striped hamsters, pikas, and other quadrupeds, but there were practically no birds except bustards, crows, and larks. Sport is abundant; and Mr. Sowerby, who was accompanied by his wife, seems to have been well received by the people.

THE increasing importance of the museum of the University of Pennsylvania has encouraged the director, Mr. G. B. Gordon, to commence the issue of a quarterly journal, of which we have received the first number. The past history and condition of the museum, and several new and interesting acquisitions, have been here described by the sectional officers. It illustrates the liberality of American citizens towards scientific institutions, and the value which they attribute to museums as factors in educational work, that the director now appeals, with confident hopes of success, for the collection of an endowment fund which will give an annual income of seventy-five thousand dollars, which will, it is estimated, meet immediate requirements.

IN the September number of the *Quarterly Journal of Microscopical Science* (vol. lv., part iii.) Mr. A. M. Carr Saunders and Miss Margaret Poole discuss the development of *Aphysia punctata*, with special reference to the origin of the kidney, heart, and pericardium, concerning which very different opinions have been expressed by previous writers. This paper illustrates well the great accuracy in the determination of cell-lineage which is expected of the modern embryologist, and by which alone such problems can be solved. The necessity for such accurate observation is also clearly brought out in a short controversial paper, published in the same number, by Prof. Hubrecht, who endeavours from the study of very early stages in the development of Galeopithecus and Tarsius to demonstrate the untenability of Mr. Assheton's theory of the hypoblastic origin of the mammalian trophoblast. The extremely early segregation of the trophoblast cells in the types referred to certainly seems to afford strong support to Prof. Hubrecht's contention.

IN the *Centralblatt fur Bakteriologie, Parasitenkunde, &c.* (Originale Band 53, 1909), Dr. C. Elders describes and figures a trypanosome found in the blood of a patient in Sumatra. It was observed that at the beginning of the rainy season the Javanese coolies on a rubber plantation situated near the edge of the virgin forest often suffered from a sickness characterised by "continuous, atypical attacks of fever, with painful enlargement of the spleen, liver, and lymphatic glands, sometimes with œdema pedis, often with aches in the head, back, and limbs, and always with increase of the large mononuclear leucocytes." It was in a smear of blood from one of these patients that a single specimen of a trypanosome was found, which appears to differ in its characters, and especially in its small size (8 μ in length), from the African *Trypanosoma gambiense* or the Brazilian *T.* (*Schizotrypanum*) *cruzi*, of which an account was given recently (August 4) in NATURE. Should this discovery be confirmed, this species (which is not yet named) will be at least the third distinct species of trypanosome parasitic on human beings.

A MEMOIR entitled "Flagellaten-studien," by M. Hartmann and C. Chagas, in the *Memorias do Instituto Oswaldo Cruz*, vol. ii., part i., is a very important contribution to the cytology of the Flagellata. The authors have studied the relations between the nuclear and flagellar apparatus, both in the resting condition and during mitosis, in a number of species of this class of Protozoa, and they distinguish four types of flagellar insertion, as follows:—(1) the flagellum takes origin directly from the centriole contained in the nucleus (Rhizomastigina); (2) the flagellum arises from a basal granule or secondary centriole, connected by a filament or rhizoplast with the primary centriole in the nucleus (Protomonadina and Phytomonadina); (3) as in (2), but the basal granule of the flagellum is connected with the centriole of a special kinetic nucleus, and the organism is binucleate (trypanosomes and allied forms); (4) the basal granule (secondary centriole) of the flagellum is connected by a rhizoplast with a centriole of the third order, lying outside the nucleus altogether, and distinct from the primary centriole contained in the nucleus (Euglenoidina). A natural classification of the Flagellata is put forward, based principally on the above-mentioned differences of structure. In this connection it may be mentioned that, as pointed out by Minchin, the two primary subdivisions of calcareous sponges, in the "natural" classification of this class, also exhibit, amongst other characteristic points of difference, distinct types of flagellar insertion in the collar-cells.

THE nomenclature of some of the species indigenous to or visiting the United Kingdom is discussed by Dr. Hartert in the October number of *British Birds*. Among other items, we are told that the thrush "must henceforth be called" *Turdus philomelos*, while the redwing is to be known as *T. musicus*. Nevertheless, in the recently published "Guide to the British Vertebrates in the British Museum" the latter name is retained for the thrush, as is *Turdus iliacus* for the redwing.

IN the Transactions of the Lincolnshire Naturalists' Union for 1909 Mr. G. W. Mason completes his list of the Lepidoptera of the county, while Messrs. Thornley and Wallace continue their synopsis of the local Coleoptera, dealing in this instance with the family Staphylinidæ. In the presidential address we are informed that measures were to be taken for a malacological survey of the county with the view of publishing a complete list of the land and fresh-water molluscs.

DESPITE the usual insufficiency of funds, supplemented in this instance by an inadequate staff, lack of space, and absence of proper show-cases, the Rhodesia Museum at Bulawayo is stated in the report for 1909 to be making continued and in some respects rapid progress. A considerable amount of original research was carried out during the year by various members of the staff. The report concludes with an appendix on the gold-bearing rocks of Rhodesia, and a second on the minerals of the district, both by Mr. A. E. V. Zealley.

Great credit is due to the staff of the Exeter Museum for the rapidity with which they have prepared and arranged for public exhibition the fine series of about 4000 species and 20,000 specimens of land-shells received towards the latter part of 1909 as a bequest from the late Miss Linter. According to the terms of the will, the collection was to be made accessible to the public within a specified period, and this heavy task has been successfully accomplished. Lack of space prevented, however, the whole collection being shown at once, and it has accordingly been arranged to exhibit it in sections. In the October issue of the *Museums Journal* Mr. Rowley describes the manner in which this was done, and likewise the methods of mounting, which he thinks may prove useful to other museums.

While Great Britain has produced many brilliant examples of self-educated men who have won for themselves more or less distinguished positions in science, Ireland, according to the October number of the *Irish Naturalist*, can lay claim to only one such hero of the highest type. This was Samuel Alexander Stewart, who was born in Philadelphia on February 5, 1826, whence he came in 1837 with his father to Belfast, where he eventually worked as a miller. Details of his life and work are recorded in two separate articles in the serial quoted, the former being described by the Rev. C. H. Waddell and the latter by Mr. R. L. Praeger. Most of his papers were devoted to botanical subjects, although local zoology and botany likewise claimed a share of his attention. Mr. Stewart died on June 15 last as the result of a street accident.

The relation of palæobotany to plant-phylogeny forms the subject of an article by Prof. Penhallow, of McGill University, in the October number of the *Popular Science Monthly*. Although considerable progress has been made in the matter of tracing the descent of plants through the geological ages, many gaps remain to be filled. The bryophytes, for instance, which, from their low organisation, ought to date at least from the Silurian, are unknown before the later Tertiary; in this instance the deficiency in their past history may perhaps be attributed, at least in part, to the "imperfection of the geological record," and if this be so the need of caution in making generalisations in this and other cases is self-evident. In conclusion, the author observes that "if palæontology teaches us anything, it is that each great phylum, as well as its various subdivisions, finally reaches its culmination in a terminal member from which no further evolution is possible. But that from some inferior member, possessing high potentialities, a side line of development arises." In an earlier paragraph it is stated that although evolution is still in progress, the possibilities of its continuation are steadily diminishing, and will eventually come to an end.

In part i. of vol. xli. of *Travaux de la Société Impériale des Naturalistes de St. Pétersbourg* Mr. K. Derjugin gives a summary of the contents of a forthcoming memoir on the fauna of the Kola Fjord, in the Arctic Ocean, based on the survey carried on by the yacht *Alexander Kowalevsky* during the summer of 1908. The investigations were carried on by dredging and surface netting, especial attention being directed to the mouth of the fjord, into which both the Kola and the Tulima discharge, and the line of division between the fluviatile and marine faunas determined. The interesting forms included the isopod *Limnoria liguorum*, the mollusc *Xylophaga dorsalis*, and certain bryozoans, such as Loxosoma and Stomatopora, while the plankton contained a rare and remarkable type of Sagitta. In the same issue Mr. W. Schitz directs attention to the northward extension of the range of blue roller and the thicknee. Nests of the former were observed during the past summer in the governments of St. Petersburg and Novgorod, where they had never previously been seen, while in the summer of 1909 the latter bird was noticed near Lake Celigner, in the government of Twer.

Messrs. John Wheldon and Co., 38 Great Queen Street, have recently issued a catalogue of general and economic botanical publications, including a few early herbals and works of Linnæus.

The report for 1910 of the Lichen Exchange Club of the British Isles contains the report of the secretary, Mr. A. R. Horwood, and notes on critical specimens. Two species new to science are recorded under the genera Lecidea and Arthopyrenia.

The Department of Lands in New Zealand is responsible for the management of the State nurseries and plantations and for the operations connected with scenery preservation, for which separate reports for the year 1909–10 have been published. The output of five nurseries amounted to 12,000,000 young trees, of which 8,000,000 were planted, largely by prison labour, on seven plantations. It is surprising to find that nearly all of these are European trees, chiefly the larch, *Pinus laricio*, the spruce, and *Pinus ponderosa*; of the eucalypts, *Eucalyptus Stuartiana* has proved to be a fast grower and is being planted, while the only reference to indigenous conifers states that, owing to failures, it has been decided to discontinue raising plants of *Podocarpus Totara*. It is also noted that deciduous trees and mixed plantations have for the most part proved unsuccessful. The report on scenery preservation indicates that additional areas amounting to 1500 acres were reserved during the year.

A volume (Publication No. 129) emanating from the Carnegie Institution of Washington is devoted to an account of field observations near the desert laboratory at Tucson, Arizona, and experimental cultures in connection with the conditions of parasitism in plants. Dr. W. A. Cannon has discovered parasitism, apparently facultative, in two species of Krameria, a genus assumed to be autotrophic. The species, *Krameria canescens*, was found attached to several hosts, most frequently to *Covillea tridentata*, probably on account of a similar growth habit. The experimental work conducted by Dr. D. T. Macdougal was directed towards inducing dependent nutrition by the insertion of prepared slips into a host plant. The selected hosts were succulents, as Opuntia, Echinocactus, and the "xeno-parasites"—to use the author's name—were species of Cissus, Agave, and others. In the more successful cultures, the xeno-parasites formed roots and showed some degree of development for a year or longer. It was found that a superior osmotic activity on the part of the parasite is an essential. The pamphlet closes with a discussion on the origination of parasitism.

We have received from Mr. E. Leitz a booklet on "Some Hints on the Use of the Sliding Microtome," which contains a good description of the operations of imbedding an object in paraffin, trimming the block, making the "ritzer" lines on one face of the block, and cutting it into sections. The causes of curling, splitting, and wrinkling of the sections, and of sundry other troubles which confront the beginner, are pointed out and the remedies given. Most workers use xylol after dehydration of the tissue to replace the alcohol and to act as the paraffin solvent, but the author advocates the use of toluene; he also recommends dammar as a mounting medium in preference to balsam.

An anonymous contributor to *Symons's Meteorological Magazine* for September communicates an article on "The Meteorological Outlook in South Africa." He points out that this pre-eminent vantage ground for the study of that science has not been utilised as it might have been, and expresses the hope that the new Union Parliament will favourably consider the matter. There are only some half-dozen of the more important stations, and some of these are poorly equipped; in nearly all cases the sites are not satisfactory, and have been chosen with a view to astronomical observations, and none can hope to undertake good magnetical work. A single service for the whole country is advocated, instead of separate services for each State as at present. The writer recommends the establishment of a series of first-order observatories suitably distributed geographically, *e.g.* in one line from Durban to Port Nolloth, and in another line from Bulawayo to East London; also a systematic discussion of all the observations at present in existence, and particularly of the anemometric records kept at some of the ports. Attention is also directed to the necessity of uniformity of times of observation and of the measures used in publications.

The results of the Italian aëronautical experiments near Zanzibar during the last week of July, 1908 (the period selected for international balloon ascents), are published in the *Annali* of the Central Meteorological Office (vol. xxx., part i.). The Italian Government lent the cruiser *Caprera* for the purpose, and deputed Prof. L. Palazzo to superintend the work. The weather during the whole of the time was unfortunately unfavourable; only two successful ascents were made with registering balloons, and ten ascents of pilot balloons could only be observed in the lower strata of the atmosphere. Some useful observations were, however, made with the latter, and showed that the wind direction during the summer monsoon was practically southerly, with more or less easterly components. On July 30 the registering balloon reached an altitude of 4940 metres; at 1500 m. and 3500 m. a small inversion of temperature was observed, both in ascending and descending. The lowest temperature, $-2{\cdot}8°$ C., was registered at 4690 m. during the descent. In the ascent of July 31 the altitude of 6630 m. was reached; the minimum temperature, $-12{\cdot}0°$ C., occurred at 6610 m., during the descent. There was a tendency to an inversion at 3500 m., and a more decided one at about 6200 m., both in ascending and descending.

In the October number of the *American Journal of Science* Mr. A. McAdie directs attention to the urgent necessity of replacing the present bewildering diversity of systems of notation in meteorology by an international system. The work now in progress with the help of kites and the rapid strides which the art of aviation is making both point to an early extension of our knowledge of the properties and motions of the atmosphere, and it is important that the results should be expressed in a form readily understood by all. With Dr. W. N. Shaw, the author advocates the expression of pressures in terms of the barie of one million dynes per square centimetre, which is the pressure at a height of 106 metres in the atmosphere. Temperature to be expressed on the absolute scale, reckoned from $-273°$ C.; humidity in terms of the weight, in grams, of water vapour in 1000 cubic metres of air; and the direction of the wind in degrees from the north towards the east.

The *Revue scientifique* for October 1 reproduces a lecture given by Prof. Jean Becquerel on modern ideas as to the constitution of matter. Although no mathematical symbols are used, the author succeeds in giving a clear and interesting account of the steps by which, since the discovery of the kathode rays, physicists have been driven to the conclusion that, like matter, electricity is atomic in constitution, that the kathode rays are, in fact, streams of atoms of negative electricity. In virtue of their motion these atoms possess an inertia equal to one two-thousandth part of that which an atom of hydrogen would possess, and it seems possible that they form one of the primordial elements out of which matter as we know it is built. How each atom of matter is constructed remains to be discovered, but if the above view is correct it is no longer possible to conceive of the atoms of the chemists as immutable; we must, in fact, turn alchemists.

We learn from an article in *Engineering* for October 14, dealing with the annual report of Lloyd's Register of Shipping, that the Diesel oil engine is now being fitted to three fairly large vessels being built on the Continent under the supervision of the surveyors of Lloyd's Register. One set is being constructed on the older principle of the four-stroke cycle with single-acting cylinders, and will be of about 450 indicated horse-power. A two-stroke cycle, in which the reversal is effected in the engine itself, the crank-shaft being directly coupled to the screw-shaft, has been successfully adopted. A single-acting set on the two-stroke cycle is being fitted to a twin-screw vessel, the power being about 900 indicated horse-power on each shaft. The third set is being made on the two-stroke cycle double-acting system, each cylinder providing two impulses per revolution. This will also be fitted in a twin-screw vessel, the total power being about 1800 indicated horse-power.

In the same report of Lloyd's Register are described several novel features possessed by a set of internal-combustion engines which is being constructed in this country, under the society's survey, for a vessel of about 260 tons. Gas for the engines is to be produced on board from anthracite coal. The cylinders are to be of comparatively small size, and the engines are intended to run at a high rate of revolution, and will not be reversible. The connection with the screw-shaft will be made by means of a hydrodynamic transformer, in which a turbine pump driven by the engine delivers water to another turbine coupled direct to the screw-shaft. The arrangement is such that the screw-shaft will rotate at a much less rate of speed than the engines, and provision is also made for reversing its direction of rotation. The experience which will be obtained from these four applications of the internal-combustion engine is being looked forward to with great interest, and will provide data of great value.

Messrs. E. B. Atkinson and Co., 24 Dock Street, Hull, have sent us a copy of their new catalogue of balances and weights. In addition to containing particulars of the balances of their own designs, the catalogue provides prices and details of all other well-known makes of balance and accessories which Messrs. Atkinson and Co. are prepared to supply.

With the close of the year 1909 the hundredth volume of the *Chemical News* was completed; and as these volumes cover a period of fifty years' progress in chemistry and physics, the announcement that a general index has now been prepared, and is in the press, will be widely welcomed. The price of the general index on publication will be 2*l*., but to subscribers who order it before the date of publication the price will be 1*l*. 15*s*.

The first part of an important work on "The Birds of Australia," by Mr. G. M. Matthews, will be issued by Messrs. Witherby and Co. next month. The author has lived all his life in Australia, and has been a devoted student of its avifauna. He has secured the active assistance of a large number of field-ornithologists in all parts of Australia, and his work will incorporate all the available information upon the subject with which it deals. There will also be hand-coloured plates depicting all the known species of Australian birds. The edition of the complete work is limited to three hundred numbered sets.

OUR ASTRONOMICAL COLUMN.

A Bright Projection on Saturn.—In No. 4445 of the *Astronomische Nachrichten* Signor M. Maggini describes a brilliant projection which he observed on the west limb of Saturn at 23h. 36m. (Cent. E.M.T.) on September 29. The observation was made at the Ximeniano Observatory, Florence, with a 350 mm. Calver telescope, and the projection was seen in profile against the shadow cast by the planet on the ring. It was also seen to be near a large whitish spot at the edge of the south equatorial band. The phenomenon remained visible until the whitish spot left the terminator, and was last seen at 0h. 20m. September 30.

Spectrum and Radial Velocity of ϕ Persei.—The spectrum of ϕ Persei is a peculiar one, in which a dark, narrow, Hγ absorption line appears to be bordered by very bright lines, and as this is the most prominent line on which radial-velocity determinations have been made, the values of the line-of-sight motion have not been in full agreement.

An investigation carried out by Dr. Ludendorff has explained some of the anomalies, and the results now appear in No. 4442 of the *Astronomische Nachrichten*. Photographs were taken at Potsdam on which other faint lines, which could be identified with solar lines in Rowlands's tables, were measurable, and the radial velocities have been determined from these independently. Among other results, Dr. Ludendorff finds that the intensities of the components of the Hγ line oscillate, so that when the emission lines are faint the absorption line is strong, and *vice versa*, but he has been unable to discover any law for the complementary oscillations. The variation curves and the departures from them during several revolutions show that the conditions in the system of ϕ Persei are very complicated and unusual.

Metcalf's Comet, 1910*b*.—Observations of Metcalf's comet, made by M. Quénisset at the Juvisy Observatory, are placed on record in the October number of the *Bulletin de la Société astronomique de France*. On August 24 the comet was seen as a tenth-magnitude nebulosity having a well-marked condensation and a tail about 4′ long in position-angle 120°; with an exposure of sixteen minutes, using a portrait lens working at *f*.3, a tail 45′ long was shown on the photograph.

New elements and a daily ephemeris for this comet are published by Dr. Kobold in No. 4445 of the *Astronomische Nachrichten*. The elements give the time of perihelion passage as September 16, and, according to the ephemeris, the brightness is now slowly declining from magnitude 11·8. The comet is now travelling northward slowly through Serpens, its position for October 20 being given as $\alpha = 15h.\ 28m.$, $\delta = +19^\circ\ 12{\cdot}5'$.

Comets and Electrons.—In an address to the Royal Academy of Science, Bologna, Prof. Righi discussed at length the functions of electrons in producing cometary phenomena; this address now appears, with a French translation, in No. 16, vol. viii., of *Scientia*. Prof. Righi outlined the several theories which have been evolved to account for the various phenomena, paying special attention to the experimental proof of light-pressure, and then showed how the electrons emitted by the sun could produce ionisation, which in turn would lead to such repulsion as would cause the development of a tail. In concluding, he described the results of some experiments carried out at Bologna during the earth's passage through the tail of Halley's comet on May 19. No remarkable variations in the atmospheric potential were recorded, but a greater degree of ionisation than usual was found to exist. The existence of radiations capable of travelling through black paper to a photographic plate was also demonstrated, but this experiment alone is not considered definite enough to warrant the assumption that these radiations could be ascribed to the proximity of the cometary matter.

Measures of Double Stars.—In No. 4445 of the *Astronomische Nachrichten* the measures of double stars made by Mr. Sellors at the Sydney Observatory during 1897–1900 are published. Notes appended to many of the sets of measures give important information as to changes in position-angle and distance during definite periods, &c. No double-star observations were made at Sydney during the years 1901–8.

Recent Results in Solar Physics.—As an extract from the *Atti della Società italiana per il progresso delle scienze* we have received a brochure in which Prof. Riccò gives a very interesting, important, and comprehensive *résumé* of the results obtained from the study of solar physics during recent years. After briefly summarising the earlier researches, Prof. Riccò directs attention to the importance of correlating solar and meteorological phenomena, and refers briefly to the results obtained by Meldrum, Köppen, Lockyer, Bigelow, Nordmann, and others. Then he describes the different organisations which deal with solar research, and passes on to the spectroscopic results. This leads to a long discussion of the spectroheliographic results, and finally to the knowledge obtained from eclipse work.

THE NINTH INTERNATIONAL CONFERENCE ON TUBERCULOSIS.

The International Conference on Tuberculosis held its ninth series of sessions at Brussels on October 5–8 under the patronage of King Albert of Belgium, who throughout took a very keen interest in the conference. The first day, October 5, was devoted to the meetings of the council and to the organisation of permanent commissions, some dealing with entirely new subjects, others with subjects already under consideration. To six of these commissions are referred questions of a more or less scientific character; to another six questions in which social elements predominate.

In the first group predisposition occupies the first place. In this group also are the commissions dealing with channels of infection; milk; methods of treatment, scientific and vaccinal; international method of notation; and the action of the solar rays.

In the second group are included the part played by women in the crusade against tuberculosis; child life and school hygiene; prophylaxis and the part played by the dispensary; the cure (?) of tuberculosis; public measures to be taken against tuberculosis; and the statistics concerning tuberculosis.

On these commissions are represented, so far as possible, the different nationalities taking part in the work of the congress.

On Thursday morning, October 6, the opening ceremony of the conference was under the presidency of M. Berryer, Minister of the Interior, who in a thoughtful and well-informed address compared the Tuberculosis Congress to the great Peace Congress at the Hague, "both inspired by the same profound thought and both wishing to obtain the same results," the former, indeed, helping the latter, "the warring of man against man being gradually replaced, thanks to a more humane sentiment, by a bringing together of all men in common action against the universal ills, vice, misery, disease, and death," a sentiment that was echoed most eloquently by M. Bourgeois, the president of the conference.

Prof. Landouzy, introducing the first subject for discussion, the influence of predisposition and heredity, claimed that these were almost as important from the practical point of view as was the bacillus of Koch itself. He maintained that the tubercle bacillus in the parent might act in one of two ways, either by direct passage from the parent to the offspring, or by some toxic action on the ovum or upon the fœtus. He pointed out that these two sets of conditions were necessarily perfectly distinct, but maintained that the latter was of far more importance than the former, and that it accounted for the peculiar tubercular diathesis so frequently met with in patients. His thesis was that the subjects of this diathesis are degenerates who may "come into the world before their time, are under weight, short in stature, with thin, delicate bones, flattened chests, a skin delicate and soft, small extremities, pale and sickly face, veins very transparent, hair prematurely developed, long eyelashes, glands easily enlarged, aspect weakly." Such characteristics he has found specially amongst his tuberculous patients, and, curiously enough, this is exactly the type taken by the Venetian masters for their models, in whom we see silky golden or red hair, pale, transparent, and delicate freckled skin. This Venetian type, *vir rufus*, he maintained, was specially subject to tuberculosis. Moreover, animals with non-pigmented coats appeared to be more susceptible to tuberculosis than those of darker skin. In the discussion that followed it was agreed that tuberculosis was seldom communicated directly from mother to child, but that a certain transmitted functional debility might leave the child open to the ready invasion of various causes of disease and death, and that in this transmission the mother played a more important part than the father. It was suggested, however, that it was a very difficult matter indeed to demonstrate experimentally any predisposition, native or hereditary, to tuberculosis, though this was a matter that required further consideration.

The natural portals of entry were considered to be the lungs, the mucous membranes of the throat, the tonsils, the intestinal mucous membrane, and the epidermis, whilst the lymphatic glands were looked upon as playing a great part in sifting out and destroying the bacilli, though as they become lowered in vitality and no longer able to cope with the tubercle bacilli they may be broken down, and the scrofulous condition results.

Prof. Calmette, in speaking of the special susceptibility of children of tuberculous parents, said that this receptivity was not specific as regards tuberculosis, but applied generally to various infections and intoxications. The predisposed of the clinicians, he maintained, are very often the subjects of infection already. They are, he thinks, more or less gravely affected, especially as regards the lymphatic glands, and in almost all cases react positively to the various tuberculin tests. Moreover, he finds that if in place of tuberculin he injects mallein, he obtains a marked loss of weight. The stigmata of tuberculosis appearing at certain ages are, he thinks, the result of earlier infections, for he found that of children coming up to be vaccinated 90 per cent. of those from the town of Lille are already infected with the bacillus of tuberculosis even in cases where no definite lesions are developed, whilst in one lunatic asylum he found no fewer than 87·68 per cent. of the patients giving the skin reaction, so that if they were not already tuberculous they were already the bearers of the tuberculous germs.

Other speakers laid stress on tissue predisposition; on the marked respiratory changes that occur, not only in tuberculosis, but in other acute diseases; on the low arterial tension observed in those predisposed to tuberculosis; and on the importance of the observation that in cases where recovery took place pigmentation was both rapid and complete, whilst in those that succumbed such pigmentation did not occur.

One speaker, M. Piery, agreed that the offspring of tuberculous parents are undoubtedly specially liable to tuberculosis, and that the types of the disease in these patients are very varied, but on the other hand he thinks that a certain proportion of such offspring are actually immune, and that these patients, immune to a grave tuberculosis, are just the types in which the so-called stigmata of hereditary predisposition are present. Moreover, he believes with M. Calmette that many of the patients with these "stigmata of hereditary susceptibility" are really already suffering from the disease.

It seemed to be the general opinion that small numbers of slightly virulent tubercle bacilli taken into the alimentary canal might in certain cases act as immunising agents, but that in larger numbers and in virulent form they might set up typical lesions, especially in susceptible animals; that both immunity and predisposition might arise from the same cause, the bacilli in the one case setting up a kind of negative phase, in the other a positive phase, and that until the conditions under which these two phases are produced had been settled it was difficult to determine the part played by heredity in immunising or predisposing to the action of the bacillus.

Of the English delegates, Dr. Nathan Raw said that, as the result of an analysis of 232 cases of tuberculosis that had terminated fatally, he found that pulmonary tuberculosis was most frequently brought about first by direct inhalation of the *Bacillus tuberculosis* into the bronchioles; secondly, by extension from a bronchial gland to the parenchyma of the lung, this being specially associated with or following an attack of some acute infective fever such as measles, scarlatina, or diphtheria; by extension upwards from the abdomen by the diaphragm to the bronchial glands, and then to the lungs; by extension downwards from the glands of the neck directly to the pleura, and then to the apex of the lung; and, finally, by a general infection of the circulating blood, as in acute miliary tuberculosis.

Dr. C. Theodore Williams, following, insisted upon the importance of predisposition and on the wisdom of trying to ascertain the conditions of the human system which cause disposition to tubercle, and, conversely, those which confer immunity from tubercle. Analysing 1000 cases of consumption that occurred in the upper classes, he finds that the age of attack is earlier amongst females than amongst males, and that amongst males affected by hereditary predisposition it is earlier by three years than among those free from hereditary predisposition, and in females by six and a half years. Similarly analysing 400 consumptive cases seen in the out-patient department of the Brompton Hospital, he found that his former conclusion as regards the age of attack being hastened on by family predisposition was confirmed, though here the relative influence on the two sexes differs greatly from what was noted in the richer classes. Among the out-patients, the age of attack was about the same for male as females, the males being attacked earlier than among the rich, the females later. The age of attack in those free from family taint was later in both sexes, and the predisposition influence greater in the male than in the female.

One or two of the later speakers were of opinion that although many of the points raised that afternoon were of undoubted interest and of great importance to the individual, it was somewhat inadvisable to lay too much stress on this question of predisposition, except in so far as it pointed to the necessity to keep these patients out of the range of the attack of the tubercle bacillus. Of course, it was useful in connection with both prognosis and treatment, but at present the campaign must be carried on on a large scale against the tubercle bacillus and to remove the conditions under which it does its work most effectively, the predisposition being taken up specially in connection with the raising of the standard of health and of improving general hygienic conditions. There seemed to be some danger that the importance of the *rôle* of Koch's bacillus might be overshadowed in the popular mind, and it appeared to be necessary to insist that, although the tubercle bacillus does not always set up tuberculosis, no tuberculosis is ever set up without the presence of the tubercle bacillus. If heredity and predisposition are to be put so prominently forward, those who are dealing with the question might sometimes lose heart. At the same time, the acknowledgment that they may play a part should be followed by a call to the physician to look after the building up and strengthening of the patient. Then, again, it was always well to point out that on the one hand many blondes escape tuberculosis, whilst those richer in pigment, the negroes, are often affected, sometimes evincing even a high predisposition.

The morning sittings on Friday, October 7, were devoted entirely to tuberculosis in the child and in the schools, and in the afternoon to women's work in connection with tuberculosis. Mrs. Nathan Raw and Dr. J. Walker both took part in the discussion, stating the case for England. Perhaps the most interesting contribution of the afternoon was that made by Dr. Hermann von Schrötter on the action of sunlight and high altitudes, and their relation to the treatment of tuberculosis. It was of all the greater interest to English workers in that he had collaborated with Dr. Barcroft, who had been sent out to do similar work at Teneriffe. Some of his observations on the pigmentation of the skin seemed to bear out Prof. Landouzy's thesis. Dr. Schrötter believes that the pigment is formed by the cell, probably by the nucleus, that it does not come directly from the blood, and that the capacity to form pigment under stimulation gives some information as to the activity and stability of the cells. He also spoke of the effect of light, especially the ultra-violet rays, and high altitudes upon respiration, circulation, and metabolism, and is decidedly of opinion that not only is tuberculosis a disease of obscurity, but that it is a disease of concentration of population.

Saturday morning, October 8, was devoted to the nomination of committees and to the reports brought by the various foreign delegates. From these reports it may be gathered that not only in England, Ireland, and Scotland, but in many Continental countries, especially Sweden, tuberculosis is a gradually diminishing factor in both mortality and morbidity.

The social functions held during the conference were almost as interesting as the scientific sederunts. The receptions given by M. Beço, the Governor of Brabant, in the Government buildings of the province, and of the Burgomeister and the Town Council of Brussels in the Hôtel de Ville, were as interesting from the associations of the places in which they were held as from the people one met there. The annual dinner was also a great success, and the speaking was of a very high order. Amongst the congratulations and messages sent to the conference was one from King George dated from Balmoral Castle:—"The Queen joins me in thanking you and the members for your kind telegram. We earnestly pray that successful results may attend your labours, and that a further stimulus may be given to the great international campaign that is being carried out against this terrible disease. George, R. et I." Telegrams were also received from the Queen of Denmark, from the Kings of Rumania, Sweden, Spain, and Norway, from the Emperor of Germany and from President Taft, all of them expressing similar interest in the work of the conference. It may perhaps be held that no outstanding work was brought forward at the conference, but those who were privileged to take part in it could not but feel that these international conferences serve as admirable "stock-taking" occasions, and, as successes and failures are recorded, of determining, or at any rate of obtaining information as to, the best method of carrying on the campaign against the White Scourge. As they are held in a different country each year, they also afford opportunities of seeing how the work is being tackled and how far it is succeeding in various parts of the world.

THE INTERNATIONAL SCIENTIFIC CONGRESS AT BUENOS AIRES.

ONE of the important features of the celebration of the Centenario of the Revolution of May 25, 1810, was the International Scientific Congress. This congress was held in Buenos Aires from July 11 to 25, 1910, inclusive, under the auspices and direct management of the Argentine Scientific Society.

Great interest was manifested in this, as in other portions of the celebration, by the residents of Argentina. In spite of the distance from the populous northern hemisphere, the congress was well attended, there was great interest manifested in all the sections, and it can well be said that it was successful.

The opening session of the congress took place on the afternoon of July 11 in the Colón Theatre, the magnificent playhouse of Buenos Aires. The great popular interest was evidenced by the very large and fashionable attendance at these opening exercises. A short address of welcome was pronounced by the Minister of Public Instruction, Dr. Rómulo S. Naón. The principal address was made by the president of the congress, Engineer Luis A. Huergo, and short addresses by the foreign delegates, the whole being interspersed with excellent music.

The serious work of the congress began on the following day, when the various sections met at the principal scientific headquarters of the city. One of the sections held meetings in the library of the patriot Bartolomé Mitre, whose residence is now preserved as a museum by the city.

The work of the congress was divided into eleven principal sections as follows:—Mathematics, physics, and astronomy; chemistry; geology and geography; biology; anthropology; engineering; agriculture; psychology and pedagogy; jurisprudence and social science; military science; and naval science.

In the limits of a short account such as this it will be entirely impossible to give even the *titles* of all the papers presented. It is necessary, therefore, to refer only to those which appear to be of the greater interest to the general readers of NATURE, at the risk of omitting many of equal or perhaps greater importance.

Several of the delegates delivered public lectures in Buenos Aires and La Plata. A special meeting of the delegates from Spanish-speaking countries was held at the rooms of the Argentine Scientific Society to inaugurate a movement "to purify, to enrich, and to unify" the technology of the Spanish language.

Mathematics, Physics, and Astronomy.

Several interesting papers were presented in the field of pure mathematics, notably those by Volterra upon integral equations and their applications, and by Dr. Franck upon the surface of the second order of Lie and their relations to a point upon any surface whatever. Prof. Torres y Quevedo gave an exposition of the mathematical theory of an electromechanical calculating machine. A paper was sent by Prof. L. A. Bauer giving an account of the work done with the new magnetic survey vessel of the Carnegie Institution of Washington, the *Carnegie*. This vessel has proven successful beyond expectation.

In the subsection of astronomy, the observatories of Santiago, Chile, the temporary observatory of the Carnegie Institution at San Luis, La Plata Observatory, and the Argentine National Observatory at Córdoba were represented. The plans for the new Chilean National Observatory were shown by Dr. Ristenpart, as well as photographs of Halley's comet; two charts of the series being prepared by that Observatory from the Cape Photographic Durchmusterung. Prof. Tucker, in charge of the Carnegie branch observatory at San Luis, read a paper dealing with the fundamental system of star positions, which is being prepared by the department of Meridian Astrometry of that institution under the direction of Prof. Boss. Sunrise and sunset tables to 1950 were presented by the La Plata Observatory. Several papers were presented by the Córdoba Observatory dealing with the work in progress there, as well as a series of photographs of Halley's comet which had been obtained there. A proposition was discussed to publish an astronomical ephemeris suitable for the South American countries in place of those now issued by several of the observatories.

Chemistry.

Among the many important papers presented in this section were contributions to the study of Argentine oil, by Dr. Sabatini; composition of the alfalfa and other forages grown in Argentina, by Engineers Lavenir and Negri. These investigators demonstrated the superiority of corn grown in the Argentine. Dr. Quiroga presented a new chemical nomenclature of inorganic bodies.

Geology and Geography.

The principal papers in this section related to the countries of Argentina, Chile, and those adjoining to the east and north. The subject of mines and the laws relating to them, including fuel deposits, occupied a chief place. Engineer Patron presented a paper on the development of geographic and geodetic work of Chile, Prof. Codazzi one on mining in Colombia, Señor Maurtúa on geographical work in Peru. Engineer Machado presented a paper on petroleum in Chile, Engineer Hermitte and Lieut.-Col. Romero on the petroleum formation of Argentina. The topography and mineralogy of the Andes region was treated of in various papers.

The Argentine Meteorological Office presented a large number of interesting papers, chiefly upon the meteorology of Argentina and the southern ocean. The director, Dr. Davis, presented a paper upon the temperature of Argentina as compared with other portions of the globe. A paper by Prof. Clayton dealt with a new method of forecasting which promises to cover periods much longer than is now possible. Profs. Mossman and Solyom presented papers on the effect of the antarctic currents upon the weather of South America, and the cyclones and anti-cyclones of the South American continent, respectively.

Dr. Knoche presented a paper descriptive of the organisation of the meteorological service of Chile, and Dr. Montessus de Ballore a paper on a convention of the seismological services of Chile and Argentina. Dr. Negri read a paper on two seismical laws discovered by himself.

Biology.

The communications to this section included the following:—The action of the principal alkaloids on protozoas, Prof. Scala; a contribution to the study of some arthropods of Chile-Argentina, Prof. Porter; contribution to the study of sea fishes in Uruguay, Prof. Bouyat; the mosquitoes, gad-flies, and serpents of Argentina, Señor Brethes; the marsupials of Chile, Dr. Wolffsohn; the vegetation of the north-western portion of Argentina, Dr. Seckt; a reclassification of Argentine vascular plants, Dr. Stuckert.

Anthropology.

Two papers were presented by Dr. Ameghino relating to three fossil human skeletons found in Arroyo Siasgo and El Moro. Other papers discussed different characteristics of the Indians and indigenous inhabitants of certain regions of South America, particularly Argentina, and of means of caring for such peoples and preserving accurate data respecting them. The origin of the American races and the languages of different South American races were subjects of investigation. Of especial interest were the results presented by Prof. Mercante of a comparative study of 1200 of the Argentine youth between the ages of six and twenty years, the sexes being nearly equally divided.

Engineering.

Many of the papers in this section dealt with architecture, particularly that of the Latin American countries. Notable among these were the papers of Engineer González. Engineer Selva discussed the advisability of houses for workmen and the best forms of such houses. A sentiment was adopted emphasising the absolute necessity of finding a solution for the question of reducing house rent for workmen and employees of modest salary. The same author also discussed the subject of earthquake construction. The subject of reinforced cement construction occupied the attention of one session. Railway and bridge questions occupied another session. The question of irrigation is a very important one in several of the South American republics, particularly Argentina. Conforming to the importance of the subject, two sessions were devoted to the discussion of the laws and systems of irrigation in Argentina, and with various plans for betterments. Rivers and harbours and their various needs received attention in another session, as did various municipal matters relating to sanitation, transportation, and streets, in another. The engineering section attracted unusual attention.

Agriculture.

Engineer Juan A. Devoto presented a paper detailing his investigations of the micro-organisms of milk. Dr. Wolffhugel read a paper on the zooparasites of the domestic animals of the Argentine Republic. Recommendations were made to protect the guanaco and vicuña. Great interest was manifested in this section, and a large number of papers were presented dealing with the practical details of this branch of science. One which attracted much attention was on the degeneration of the Malbeck, by Señor Suárez.

Psychology and Pedagogy.

In this section Prof. Jakob gave the inaugural address, discussing human beings with defective brains. Among the papers were:—Value of psychological statistics in pedagogy, Señor Mercante; necessity of methodical investigation of the child and all abnormal persons, Dr. Piñero; abnormal psychology and education, Prof. Senet; investigations of the nervous system, Dr. Roveda; the measurement of intelligence, Dr. Vidal; experiments upon the sensitiveness of the human skin, Dr. Duceschi.

RESOLUTIONS.

During the congress a large number of resolutions were adopted by the various sections, which at the close were ratified by the entire congress. The substance of some of the most important is given below.

The necessity of solving the problem of reduced rent for the workman and the employee, so that they may live near their work, which is usually in the centre of the city. It may be remarked in passing that this question is especially important in Buenos Aires, where the population is spread over a very large area in one-story houses, instead of the tall structures of Anglo-Saxon cities.

Reiterating the necessity of prosecuting and accelerating the Pan-American railroad according to a fixed plan.

The advisability of studying the causes which hinder the more general adoption of reinforced concrete constructions

The strong approval of a project for the formation of a "Union Internacional Hispanoamericana de Bibliografía y Tecnología Cientificas." The details of such an organisation were worked out.

Recognising the convenience of a reform of the Gregorian calendar.

Recognising the advantage of adopting the meridian of Greenwich for all American countries and from January, 1911, basing their time on meridians differing by an exact number of hours from Greenwich, as is already in use in the United States.

The urgent necessity of preventing adulterations and frauds in foods.

Recommending the adoption of standards of purity for the potable water of the Republic (Argentina); the necessity of forming an American society of chemists; the establishment of biological stations with a view to the study of marine life and the development of the fish industry; the advantage of legislation which will encourage the development of the petroleum industry and prevent all monopolies in this industry; the study of the German language in science courses along with French and English; the utility of employing the "altazimetro" invented by Rear-Admiral Mansilla, to facilitate nautical calculations; the stereographic method of locating the stars for nautical purposes, proposed by Captain Ballvé; an international American commission of psychological and pedagogical studies and a children's congress of specialists; the formation of agrarian societies modelled after those of France; the greater use of agricultural machinery, and the teaching of the use of such machines; the study of the conditions and regions suitable for the growth of the sugar beet with the view of extending its production; the development of the cotton-growing industry; uniform regulations in all American countries governing the importation and exportation of animals; legislation looking to the protection of working women before and after childbirth, and making compulsory the providing of time and suitable accommodation by employers for the necessary attention to babes.

C. D. PERRINE.

RECENT INVESTIGATIONS ON THE CULTIVATION OF RUBBER.[1]

EXPERIMENTS on the cultivation and preparation of rubber are being pushed forward at several stations, and the results are discussed in the agricultural journals circulating in tropical and subtropical countries. Methods of tapping the tree have been studied in Hawaii, and found to have a marked effect on the yield of latex. Trees

[1] *Tropical Life.*

Bulletins of the Federated Malay States, and of the Hawaii Agricultural Experiment Stations.

tapped with a V-cut gave much less than others with a vertical cut, the greater yield, however, being partly due to the fact that the length of the incision in the latter case is greater than in the former. No advantage was gained from the use of four cuts daily instead of two. The effects of nitrate of soda on the flow of latex have also been studied. Fertilisers are in use in rubber plantations for increasing the growth and vigour of the trees, and it now appears that nitrate of soda also increases the flow of latex. In one experiment a group of five trees yielded 0·9 oz. of dry rubber in three days before applying the nitrate, and 1·3 oz. in the three days following its application, each tree receiving half a pound of the fertiliser. How far the method is economical has yet to be determined. All these experiments were made with Ceara rubber trees.

A number of analyses have been made of the latex from the plants growing in the Botanic Gardens, Singapore. A thirty-two-year-old tree of *Hevea brasiliensis* gave at one tapping 27 fluid ounces of latex, of which 61·08 per cent. was water, 2·3 per cent. serum solids, mainly organic matter, and 36·29 per cent. coagulum was obtained by means of acetic acid. Almost the whole of the coagulum was rubber, only a little resin being present. From another variety, *Landolphia Heudelotii*, the dry rubber yielded 89·5 per cent. of pure rubber and 10·5 per cent. of resin.

The question of preparing the rubber after the latex is obtained is of very great importance. Fine hard Pará rubber containing 10 or 20 per cent. of moisture has a higher relative value than the practically pure sheets from the East. It is considered that the difference in value is partly due to the difference in method of dealing with the latex, and a process has recently been devised in which the latex is treated with smoke, creosote, and acetic acid, so that it may coagulate under conditions comparable with those obtaining in Brazil. In this process, steam at a pressure of 30 or 35 lb., mixed with the fumes from strongly heated green palm leaves or other green parts of trees, is forced by a steam injector into tanks containing the strained latex. In about ten minutes the caoutchouc globules coagulate and rise to the surface.

An incidental problem is the most economical way of dealing with a rubber plantation until the trees come into yielding. A Bulletin from the Federated Malay States Department of Agriculture sets out the advantages of *Coffee robusta*. This plant, discovered wild in the Congo region in 1898, grows more rapidly and fruits sooner than the well-known *C. liberica*. When grown in rubber plantations, it yields a small return in the second year and a good return in the third and following years, but after five years it competes so seriously with the rubber that it must be cut out.

THE MINERAL RESOURCES OF THE UNITED STATES.[1]

IN response to the latest of the periodic scares of impending bankruptcy due to the exhaustion of fuel, ore, or soil, the Geological Survey of the United States has been instructed to estimate the national economic mineral resources. Its report (Bull. No. 394), dealing with quantities on a continental scale, may excite the envy of the single countries of Europe; and though the factors are uncertain, the available supplies of most minerals are sufficient to render political restriction of output unnecessary. Thus, in the case of coal, Pennsylvania is known to have enough to last for 492 years at the rate at which the material was being exhausted in 1907. Ohio has only used 0·9 per cent. of its proved supplies, and at the rate of production in 1907 they will last for two thousand years. In Maryland the coal will last for another 948 years. Mr. Gannet, in a general summary of the extent of the coal reserves, estimates that only one-third of one per cent. of the known and easily accessible supply was mined during the last century.

In regard to the other fuels, the future is less assured for natural gas and petroleum. Assuming that petroleum generally comes from beds 5 feet in thickness, and with 10 per cent. of pore space, an acre would yield 5000 barrels of 42 gallons each. The extent of proved oil land in the States is enormous. Thus, it is expected that the State of California alone will supply 5,000,000,000 barrels. There has been a steady increase in the yield from 2000 barrels in 1859 to 166,000,000 in 1907. The yield, however, has fallen in many of the States, including Pennsylvania and New York, where, according to Dr. Day, it will be negligible ten years hence. The yield has fallen in Ohio, West Virginia, Kentucky, Colorado, Indiana, Texas, and Louisiana; but it has risen in California, Illinois, and Kansas. Dr. Day concludes that if the present production is not increased, the available supply will last the States for ninety years; but if the demand increases as rapidly as during the past few years, the end may come in 1935. He therefore suggests that oil should be limited to the purposes for which it is indispensable, such as lighting in scattered houses and as a lubricant. As half a pint of oil is used in an engine for every ton of coal burnt, the exhaustion of cheap lubricants would be an industrial disaster.

Dr. Day reports on the supplies of natural gas. In most cases the wells have a short life, and 1,000,000,000 cubic feet are still being wasted daily. Much of the waste is said to be unavoidable, as the gas cannot be saved economically from wells from which oil is being pumped; but legislation to prevent unnecessary waste is recommended. After a well has ceased to yield gas under high pressure, a supply can be obtained for years by pumping.

A mineral famine in the United States is most often predicted for iron, as the ores of present value are restricted in depth. The estimates compiled by Mr. Hayes show that there is no immediate fear of the end of the Iron age. He estimates the ore supply now available in the United States at 4,788,000,000 tons. If the present rate of increase in the consumption of iron be maintained, this quantity would, however, be used during the next thirty years; so that before 1940 American iron production would have begun to decline, and low-grade ores not included in the estimate quoted would have to be used. Mr. Hayes, however, concludes that the factors are so indeterminable that any further prediction as to the date of exhaustion of American iron ores " is so uncertain as to be wholly unprofitable and unwarranted."

The United States have been one of the leading producers of phosphates since 1867, and nearly half the phosphate manufactured is exported for the benefit of the exhausted soils of Europe. At the present rate of increase, the supply will only last twenty-five years, and Mr. van Horn, the author of the report on phosphates, therefore recommends that future leases should only be granted on condition that the phosphate shall be used in the States.

That predictions of a coal famine in America are idle may be realised from the reports on the little-known coalfields of the western and central States in Bulletin 341. It is edited by Mr. Marius R. Campbell, and includes twenty-two separate memoirs and a bibliography. The coals are partly Eocene, belonging especially to the Fort Union Series, and partly Cretaceous, coming mainly from the Mesaverde Series. The Sentinel Butte Field in North Dakota and Montana yields an Eocene lignite, of which 33,000,000,000 tons are available within a thousand feet of the surface, and in seams 3 feet or more in thickness. The coal yields excellent producer gas, and can be made into briquettes without the addition of any binder. The coal contains 34 to 45 per cent. of water, and after it is air-dried its calorific efficiency is from 8200 to 8600 British thermal units. From Sentinel Butte a series of coal fields extends south-westward through Montana, Utah, Colorado, Nevada, and New Mexico. The Eocene coals become less important, and the Cretaceous coals more important to the

south-west. Thus the Cretaceous coals at Crazy Mountain, Montana, are too thin to be mined, except for local use; but at Lewiston, Montana, the Lower Cretaceous coal from the Kootenai formation is of great value, though high in sulphur; the Grand Mesa field in Colorado has an estimated supply of 15,000,000,000 tons of Mesaverde coal, of a calorific value of from 8000 to 13,000 thermal units.

A second Bulletin (No. 380), "Contributions to Economic Geology, 1908," deals with minerals except fuels. Mr. C. W. Hayes has superintended the preparation of the reports on the non-metals and iron ores, and Mr. W. Lindgren those on the rest. The Bulletin consists of twenty-five papers and numerous bibliographies. Some of the reports are based upon only a few hours' or a day's visit, but others are preliminary reports based upon a longer study. J. S. Diller and G. F. Kay describe the Grants Pass goldfield in Oregon, which is one of those frequent and disappointing fields where the gold is very widely distributed through innumerable small veins and veinlets; the absence of well-defined lodes is unfavourable to profitable mining, until some clue be discovered to the distribution of the richer patches. The ores are found in association with greenstones and granodiorites intruded into altered sediments. The placer deposits are widely scattered, and are worked by many small mines, employing from three to five men each. Some of the placers are Cretaceous shore deposits.

Mr. F. L. Hess reports upon the tin, wolfram, and tantalum deposits of South Dakota. Tin is so scarce in the United States that much interest was excited by its discovery in pegmatite dykes traversing the Algonkian schists at Harney Peak. Assays showed the presence of up to 6 per cent. of tin, and the Harney Peak Tin Company was established to work the deposits on a big scale. Three million dollars of English money, in addition to some American, was spent in the venture, and Mr. Hess tells us that the 5000 tons of ore put through the mill yielded only 0·25 per cent. of tin. The tin cost more than its weight of gold. This failure is, perhaps, not surprising, as pegmatite dykes have never been found to pay as tin ores except on a small scale. The wolfram ores of the same locality are known from the descriptions of Mr. J. D. Irving, and though Mr. Hess does not altogether agree with his theoretical conclusions, he remarks that Mr. Irving's prediction as to the limited economic value of the deposits has been fully justified. This wolfram ore is of some interest, as it occurs as a replacement of dolomite and was introduced by solutions rising along vertical fractures.

Of the four papers in this Bulletin dealing with iron ores, one of the most interesting is by Mr. E. C. Harder, on the ores of the Appalachian region in Virginia. Some of the ores occur in the pre-Cambrian schists and crystalline rocks of the country at the eastern foot of the Alleghany Mountains; but the ores are not commercially important. They, however, include the interesting titaniferous magnetites of the Blue Ridge, which have been formed as segregations in a basic syenite (unakite); and the truly magmatic origin of these small bunches of ore is shown by the many included specks of minerals belonging to the enclosing rocks. The more important ores occur in the Palæozoic rocks of the Appalachian plateau, including "brown ores" of three distinct origins. They are "mountain ores" associated with Lower Cambrian quartzites, "valley ores" found in residual material formed from Cambrian limestone, and the Oriskany ores, which occur as replacements in the Silurian Lewistown limestone.

The manganese ores of the United States have been studied by Mr. Harder, who promises a special bulletin upon them. The ores are widely distributed, but are not much mined, since they usually occur in pockets of not exceeding 25,000 tons, and cannot compete with the imports.

Among reports on the non-metallic minerals is a short note on the mica deposits of southern Dakota, by Mr. D. B. Sterrett. The mica is found in pegmatites, which are sometimes intrusive dykes and sometimes veins due to pneumatolytic action. The two types pass imperceptibly into one another. The supply of sheet mica for lamps and furnace doors exceeds the demand, and most of the mica obtained is employed for the manufacture of electric machinery. There is a short report by E. G. Woodrow on the sulphur deposits near Thermopolis, Wyoming; the sulphur is deposited by hot springs, where the water comes in contact with limestone. The sulphur is deposited as crystals, and also as masses replacing the limestone.

Mr. Matson contributes some notes on the clays of Florida, and describes the ball clays, which are usually described as kaolin, as they are white burning, and can be used for either porcelain or white earthenware. As they are sedimentary, Mr. Matson seems unnecessarily doubtful as to whether they can be included in kaolin.

Bulletin No. 374 describes the mineral resources of the Kotsina-Chitina region of Alaska, by F. H. Moffit and A. G. Maddren. The name Chitina means "copper river," and copper is the most promising mineral of the district, though it has not yet been proved to occur in conditions under which it can be profitably mined. The district also contains some coal and alluvial gold, which has been worked since 1902. The copper is mostly found in the lower part of the Triassic Chitistone limestone, where it rests on the Nikolai greenstone, a series of basaltic lava flows, from which the copper is thought to have been derived.

The investigations on the general mineral resources of Alaska made in 1908 are reported in Bulletin 379, in a series of nineteen papers, edited by Mr. A. H. Brooks. The mining industry as a whole suffered a decline in output during that year owing to the diminished yield of copper. Gold is still the main source of wealth, though the yield fell slightly below that of 1906. Four-fifths of the supply is alluvial, and the cost of working the placers is so heavy that only the richest are worked. The lode mines, on the other hand, are low grade, the most important being those of the Alaska Treadwell group. Its ore yields only 2·3 dollars of gold per ton, but, owing to the large quantity and easy methods of mining, it can be worked at a cost of one dollar a ton. In spite of local predictions, dredges have already proved successful, and their use must add greatly to the available mineral wealth of the district. The most interesting placer deposits are those at Nome, on the Seward Peninsula, where the famous Third Beach, discovered in 1905, is still being worked. Alaskan shore placers are at present the most important that are being worked anywhere for gold. The report by Moffit and Knopf on the Nabesma-White River district shows that the copper there occurs in Carboniferous basaltic amygdaloids and in limestone along the contact with some intrusive diorites; but the fabulously rich copper deposits reported have not yet been found.

J. W. G.

AIRSHIP FLIGHTS.

FOR some time public attention has been directed chiefly upon the records achieved by aëroplanes. Two airship flights undertaken during the past few days serve to illustrate what may be accomplished by dirigible balloons. On October 15, at about 8 a.m., Mr. Walter Wellman left Atlantic City in his gigantic airship *America* with the object of voyaging to Europe; and on the following day the frameless airship *Clément-Bayard No. 2* travelled from Lamotte-Breuil by Compiègne to Wormwood Scrubbs—a distance of nearly 260 miles—in six hours.

The *Clément-Bayard No. 2* is 251 feet long, and its greatest diameter 44 feet 4 inches. The *Times* gives the following particulars of the construction of this airship.

Inside the bag there are two compensating air balloons which can be filled separately. The car, 26 feet 3 inches beneath the envelope, is 147 feet 5 inches long. The stern is provided with a keel to preserve stability. The metallic framework is composed of triangular steel rafters, except in the portion occupied by the motors, crew, and passengers, where they are quadrangular. At the hind extremity this framework takes a turn upwards to support the equilibrator, a large triplane-like apparatus with eight square compartments resembling the main cell of a Voisin aëroplane, controlling ascent and descent. The equilibrator, comprising the rudder, composed of two mobile planes on vertical axes at either end of the triplane, is worked by an irreversible mechanism. There are two propellers driven by two 120 horse-power Clément-Bayard motors mounted on a steel frame furnished with springs to deaden the vibration. Each propeller is driven by its own motor, but, in case of need, one single motor can drive the two propellers at the same time. The gear for the reduction of speed is placed in the prolongation of the driving shaft, beyond the propeller. The two propellers, of polished wood, have a diameter of 19 feet 8 inches, and are placed laterally in front, one on each side of the car, projecting beyond the sides of the steel framework. They occupy a position midway between the car and the balloon. The tractive power of each propeller is ascertainable at any moment. The dirigible is built to be able to ascend to an altitude of 6560 feet, and it is capable of travelling about 750 miles without replenishing its supplies of gas and fuel.

The *Clément-Bayard No.* 2 left Lamotte-Breuil with a crew of seven people, including M. Clément, the designer of the vessel, on October 16 at 7.5 a.m. (G.M.T.), passed over Amiens at 8.29 and Boulogne at 10.15. The Channel was crossed in some fifty-five minutes, and Ashford seen at 11.45 a.m. Tonbridge was passed at 12.20 p.m., the Tower Bridge at 1.4, and Wormwood Scrubbs was reached at 1.25. The whole distance, of nearly 260 miles, was thus covered in a little more than six hours at an average speed of about 43 miles an hour. The greatest altitude attained during the flight was between 800 feet and 900 feet, but most of the travelling was done between 600 feet and 700 feet. The average temperature was 60° F. The success of the enterprise must be attributed largely to the very favourable weather conditions which prevailed during the flight. There was only a slight wind, and it was in a direction which assisted the movement of the airship, so that the demand made upon the power of independent navigability was not great. We still await the construction of an airship which will satisfy the War Office tests, one of which is that the vessel has to traverse a triangular course of 300 miles within a fixed time-limit. When this has been done it will be possible to form a satisfactory estimate of the advantages of power-driven airships over the ordinary spherical balloon.

The *America*, in which Mr. Wellman with five companions made the daring attempt to cross the Atlantic, is a dirigible of the frameless type; it is 228 feet long, its greatest diameter 52 feet; and it has a volume of 345,000 cubic feet. According to the *Daily Telegraph* (under the auspices of which, with the *New York Times* and other American papers the flight was undertaken), the balloon is composed of three thicknesses of cotton and silk gummed together with rubber to make it gas-tight, and weighs 4850 lb. Underneath the balloon is suspended by steel cables the car, weighing 4400 lb. This car is built of the highest grade steel tubing, and in places withstands stresses of twelve tons. It is 156 feet in length, and the steel tank at its base is 75 feet long, with a capacity of 1250 gallons of gasoline. The engines, three in number (two of 80 horse-power and a service motor of ten horse-power), are placed in the steel car. Each of the large motors drives a pair of twin screws, and each propulsion system is independent of the other. The motors and other machinery weigh about 1500 lb. An electric light system, a wireless telegraph equipment, and a telephone connecting the different parts of the ship were installed.

Hanging from the airship by a steel cable is the equilibrator, a part of which floated upon the sea, the other being suspended vertically in the air. The purpose of this is to act as an automatic regulator of the upward and downward movements of the airship. When the ship rises it must lift some of the equilibrator from the sea in order to go up, and this added weight checks the rising movement. Conversely, when change of temperature or accumulation of moisture caused the airship to descend, a greater part of the equilibrator was let down upon the sea, thus reducing the weight carried by the balloon and checking the descent.

The total supply of gasoline carried was 10,000 lb., or about 1800 gallons, which was considered sufficient to drive the airship from Atlantic City to Europe. The distance is about 3000 miles. With one engine running the airship could make a speed of 20 miles per hour, and the quantity of gasoline carried would run one engine 200 hours. With both engines running the ship's speed in still air could be about 26 miles per hour.

After leaving Atlantic City at 8.5 a.m. on Saturday morning, October 15, the *America* travelled 20 miles in the first hour, but later the rate was reduced to 15 miles an hour. Nantucket Island, which is about 300 miles from the starting place, was reached in twenty-four hours. A wireless message was received from Mr. Wellman at 12.45 p.m. on Sunday, October 16, when the airship passed out of range of communication with Nantucket Island. The vessel was then directed to the north-east, and early on the morning of October 17 was believed to be travelling between Nantucket Island and Nova Scotia. At 4.30 on October 18 the airship was sighted in distress by the Royal Mail Steam Packet Company's steamer *Trent*, and after some difficulty Mr. Wellman and his crew were rescued and taken on board, the airship being abandoned. The position in which this occurred was latitude 35° 43′ N. and longitude 68° 18′ W., which is nearly 400 miles east of Cape Hatteras, on the North Carolina coast. The total distance covered by the airship appears to have been about 900 miles, and the duration of the voyage, during which she was in the air continuously, was sixty-nine hours.

MATHEMATICS AND PHYSICS AT THE BRITISH ASSOCIATION.

THE address of the president of Section A, Prof. E. W. Hobson, was read on Thursday, September 1; this has appeared in full in these columns (NATURE, September 1, p. 284). It was succeeded by a paper—probably the most important paper read at the meeting—by Sir J. J. Thomson on positive rays. By the use of very large vacuum tubes Sir Joseph has been able to investigate the discharge at higher vacua than hitherto. Specially studying the rays which pass through a hole in the kathode, he detects:—(1) Rays undeviated by magnetic or electric forces. (2) Secondary positive rays, produced by these, which are deflectable by both forces, have a constant velocity of about 2×10^8 cm./sec. at all pressures and potential differences. The value of e/m for these is 10^4. They are accompanied by negatively charged ones similar in every respect to the positive ones, except in respect to charge. (3) Rays characteristic of the gases in the tube, conspicuous only when the pressure is low. Their velocity varies with the potential difference. When several gases are present, the maximum kinetic energy of the rays from each gas appears to be the same and equal to that due to a fall through the potential difference between the negative glow and the kathode. The value of e/m is inversely proportional to the atomic weight of the gas. They are probably atoms carrying unit positive charge; in the case of hydrogen there are rays corresponding to the molecule as well. Some of these have negatively charged rays associated with them. In a magnetic field the rays from a mixture of gases spread out into a sort of spectrum. With carbon monoxide two bands are formed, one due to carbon, the other to oxygen. As exceedingly small quantities of gas may be dealt with in this way, it appears probable that interesting results may follow from the application of this method to the analysis of gases in vacuum tubes. (4) Retrograde rays, travelling from the kathode in the same direction as the kathode rays. These are of types (1) and (2). They have negative constituents.

Dr. R. A. Houston followed with an exhibition of a spectrophotometer of the Hüfner type, which he has previously described in the *Phil. Mag.* for February, 1908, and with a description of a new and simple means of producing interference bands. An approximately right-angled prism is placed in front of a slit; the two emergent beams produce interference bands in front of the prism. This is being used as a student's exercise; it does not appear, however, that the bands can be put to any practical use. A new gyroscopic apparatus was next exhibited by Prof. A. E. H. Love. The machine consists essentially of a pair of bicycle wheels fixed to a round steel bar as an axle. The bar is prolonged beyond one wheel to carry a wooden wheel, by means of which it can be set spinning, and the other wheel carries a square tin plate on which is fixed a card coloured in squares. The machine is so mounted that it can turn freely about its centre of gravity. To throw it out of truth without disturbing the centre of gravity two small bolts are inserted in the rims, one in each, at opposite points. The machine is set spinning about the axis of the wheels. When the instantaneous axis cuts the card at a point well within a square, a patch of the colour of that square is seen distinctly, and the rest of the card appears confused. As the axis moves, a series of distinct patches are seen at short intervals.

On Friday, September 2, the section divided. In the mathematical department Major P. A. MacMahon opened the proceedings by reading a paper on functions derived from complete and incomplete lattices in two dimensions, and the derivation therefrom of functions which enumerate the two-dimensional partition of numbers. The investigation was suggested by the solution of a ballot problem of finding the chance that at every stage of the voting the candidates are in their final order.

Dr. Baker in his paper on a certain permutation group said that he had been led to inquire into its properties by becoming interested in a game played by some children. The game consisted in writing down a series of letters and then rearranging them by writing the last first, the first second, the last but one third, the second fourth, and so on. When the rearrangement was completed it was performed again, and so on repeatedly. Finally, it was found that, after a certain number of rearrangements, the original order of the letters was obtained.

For instance, the set of seven letters

$$a \quad b \quad c \quad d \quad e \quad f \quad g$$

gives

$$\begin{array}{ccccccc} g & a & f & b & e & c & d \\ d & g & c & a & e & f & b \\ b & d & f & g & e & c & a \\ a & b & c & d & e & f & g \end{array}$$

Dr. Baker showed that when there are n letters the number of rearrangements required to reobtain the original order is the least number r, such that one of the two numbers 2^r-1, 2^r+1, is divisible by $2n+1$.

Dr. Baker also read a paper on the trisection of elliptic functions, in which the problem was discussed in connection with the theory of the quartic equation.

Lieut.-Colonel Allan Cunningham read two notes of great interest on the theory of numbers, one on the factorisation of $(2^{77}+1)$, and the second on the question whether (2^p-2) is divisible by p^2 (p a prime). Upon these Dr. Baker made the following remarks:—

We are often told that the problems of the physicist are set to him by nature itself, but the problems of the mathematician are invented by himself, and therefore worthy of less attention. Those to whom this seems a sound criticism will probably admit that the puzzling problems of integral numbers are put to us from without. We should therefore regard the theory of numbers with especial concern, quite apart from its own extraordinary interest. In Germany at the present time great progress is being made in the subject; it touches our reputation as English-speaking mathematicians to encourage, so far as we can, a similar interest in the theory of numbers here.

Prof. A. W. Conway read a paper on the convergence of a certain series used in electron theory. The series was one obtained by means of Lagrange's expansion.

Dr. J. W. Nicholson read a paper on some problems of initial motion of electrified spheres, in which he referred to the work of G. W. Walker and Prof. Conway. Starting with an electron having a small Newtonian mass, it was shown that difficulties are met with when this mass is reduced to zero; it appears impossible to ascribe an initial acceleration to a conducting sphere without introducing imperfection in the conductivity, although the electrical distribution on the sphere tends to become uniform very rapidly. These results have a bearing on a possible conception of the electron. These difficulties are absent from the corresponding problem for an insulating sphere.

Dr. Duncan M. Y. Somerville pointed out the need of a non-Euclidean bibliography. It is now thirty years ago since Halsted published the first bibliography of non-Euclidean geometry, and one still finds it referred to as a standard work. In the discussion Prof. Love suggested that a report on the subject would be more valuable. (The general committee has since appointed a small committee to consider this question and draw up a report if considered advisable.)

Mr. H. Bateman read a paper on the present state of the theory of integral equations, in which he sketched the history of the subject and indicated some of the physical applications. Prof. Conway and Prof. Webster remarked that in the problems they had tried it was very difficult to get a simple solution by means of integral equations. In answer to this, Dr. Hobson pointed out that in the problems referred to the theory of integral equations fails to give a simple solution because a simple form of the solution does not exist; but by studying the theory we can hope to obtain some idea of the form and behaviour of the solution, although the analytical expression for it is not suitable for calculation. This important, exhaustive report of Mr. Bateman's has been ordered to be printed *in extenso*.

Mr. Bateman also read a paper on the foci of a circle in space and some geometrical theorems connected therewith. Special attention was paid to twisted polygons formed of isotropic lines.

Prof. J. C. Fields read a paper on the theory of ideals. Starting from Hensel's power-series, he defined adjointness relative to a prime p in a manner analogous to that in which he has defined the property in connection with the algebraic functions. If ϵ is the solution of an algebraic equation, it was shown that we can construct a rational function $R(\epsilon)$ possessing any assigned set of adjoint orders of coincidence corresponding to a prime p. It is deduced that we can construct a general function $R(\epsilon)$ which represents only integral algebraic numbers, and possesses a single coincidence with the branches of an assigned one of the cycles corresponding to any prime, while it is not conditioned with regard to any other specific prime or any other cycle corresponding to the prime in question. The aggregate of numbers so represented is a prime ideal.

The report of the committee on the further tabulation of Bessel functions was taken as read. This committee is proceeding to calculate the functions $I_n(x)$ and $K_n(x)$. Its scope has been extended so as to empower it to proceed to the calculation of any necessary functions.

Meanwhile, a joint meeting of the physics department and Section B (Chemistry) was being held. The proceedings of this meeting will be in part reported by the chemical section. Two papers only will be dealt with here. A paper was read by Mr. J. A. Crowther on the number of electrons in the atom. From the mean scattering of β particles in passing through a substance, it is deduced that the number in question is three times the atomic weight, provided that the positive electricity in the atom has a volume comparable with the atom itself. The substances considered are carbon, aluminium, copper, silver, and platinum. The numbers obtained, if the positive electricity be assumed to be divided into small particles comparable in size with the negative, are not proportional to the atomic weight—a result which would be in conflict with experiments on the scattering of Röntgen rays—and it is thence concluded that this alternative hypothesis is not correct.

The second paper was by Dr. R. D. Kleeman, on the attractive constant of a molecule of a compound and its chemical properties. Making use of previous deductions from surface tension and latent heat data, Dr. Kleeman shows that the various chemical compounds can be divided into groups, and it is found that this grouping corresponds with that obtained from purely chemical considerations; for example, the amines fall into three groups. The property specially studied is the ratio $T_c/\Sigma\sqrt{(A)}$, where T_c is the critical temperature and the denominator is the sum of the square roots of the atomic weights of the components of the compound.

The proceedings on Monday, September 5, began with a demonstration by Dr. H. J. S. Sand of vacuum-tight seals between iron and glass. An iron wire is sealed into a glass tube. While the glass is hot a small piece of heated steel tube surrounding the wire is pushed a few millimetres into the glass. After cooling, the tube is soldered to the wire. The vacuum-tight seal is produced between the inner surface of the elastic steel tube, which on cooling is put under tension, and the glass, which comes under compression. Seals with wires of 1 mm. diameter have been produced in this way.

Dr. T. H. Havelock followed with deductions from the relations between densities and refractive indices. Dr. A. G. Webster (of Worcester, Massachusetts) gave a detailed account of a complete apparatus for the measurement of sound. The producer of the sound was a steel diaphragm rigidly driven by an electrically maintained tuning-fork, and made the back of a resonator of the form of a small hollow chamber or of a tube of variable length. The reaction of the sound upon the amplitude of the fork enables the constants of the resonator to be accurately determined, so that the rate of emission may be measured in watts. The phonometer (or measurer of the sound) is a glass diaphragm, made the base of a resonator, and bearing a light mirror, which constitutes one mirror of a Michelson interferometer. The displacement is measured stroboscopically by a telescope, and the amplitude of the pressure change is read off on a scale in dynes cm.$^{-2}$. The instrument is as sensitive as the ear for a pitch of 256 vibrations per second, and an accuracy within 10 per cent. is claimed.

In the short discussion aroused by this paper some doubt seemed to be felt of the agreement of results given with those obtained by Lord Rayleigh, but in the absence of trustworthy memories the point was left unsettled. Questioned as to the power exerted while he himself had been speaking, Prof. Webster left it to be inferred from the statement that ten million cornets (each of which could be heard half a mile away) emitted at the rate of a horse-power.

Prof. W. M. Hicks followed with a paper on the relation of spectra to the periodic series of the elements. In this he described some results recently obtained by him in a critical study of the spectral series of the second and third groups of the periodic table of elements, more especially their dependence upon the atomic volume of the element. Values for atomic volume or of density very close to observational values can be deduced in the case of the first three groups of the periodic series. Applying the method to the spectrum of europium as given by Exner and Hashek, a density of 13·1 was predicted for that element. Sir Norman Lockyer, discussing the paper, emphasised the importance of a study of series, especially in regard to the stars. In a paper on the series spectrum of the mercury arc, Dr. S. R. Milner gave the results of a photographic study of the mercury arc *in vacuo*, thus avoiding the faint continuous background which fogs the plate when the arc is observed in air; very much longer exposures can for this reason be given, and many new lines are then observed, among which the lines forming the continuation of the various series of mercury were strikingly developed. Measurements have been made up to the fifteenth line in the diffuse series and the thirteenth of the sharp series. Rydberg's difference law is exactly satisfied.

Mr. A. E. Oxley described an apparatus for a production of circularly polarised light obviating the lateral displacement of the beam produced by Fresnel's rhomb, but possessing the advantages of this rhomb in other respects. Two similar rhombs of glass are placed end to end in contact so as to form a *bent* double rhomb. By suitably choosing the dimensions the required object is attained. The angle of the rhomb chosen is $74° 38·2'$ for glass of index 1·5035. The length (15 cm.) is, however, inconveniently long. A much shorter form, in which three reflections of the light occur, is obtained by putting in close contact two trapezium-sectioned prisms, the faces in contact being those containing the shorter of the two parallel edges of the trapezium. The relative retardation can be made $2\pi + \pi/2$, and the emergent light will then be circularly polarised. The apparatus can advantageously replace a quarter-wave plate in the quantitative study of elliptic vibrations. Mr. Oxley also described a new half-shade analyser, consisting of a double rhomb of glass of suitable angle to produce a retardation of 3π, which is equivalent to $-\pi$.

Section G (Engineering) then joined to participate in a discussion on the principles of mechanical flight, opened by Prof. G. H. Bryan. This discussion wandered away from the title, and developed into one on the relative positions of the mathematician and the practical engineer in the origination and development of new ideas on the subject of aviation. The engineers were present in strength, and the evidence brought forward from the parallel case of motion on water seemed to be greatly in their favour. Of the points more particularly bearing upon the advertised title of the discussion we may mention Mr. Dugald Clerk's advocacy of much lighter engines and of a considerable modification of the usual thermodynamic cycle. He recommended differences of pressure of two to one instead of five or more to one as at present. Mr. Scoble's account of his propeller tests was also of much value.

The proceedings of Tuesday, September 6, were opened with a discussion on atmospheric electricity, initiated by Dr. Charles Chree. He explained that atmospheric electricity includes a great variety of phenomena. Omitting aurora as a subject so large as to require a separate discussion, there are the questions of the potential gradient in the atmosphere, the influence of potential gradient and electrical charges on the growth of vegetation, the phenomena of thunderstorms, the loss the charge experienced by insulated bodies, the number and nature of the positive and negative ions in the air, the vertical earth-air currents, and the phenomena of radio-activity. The potential gradient and its diurnal and annual variation have been the subject of study for a good many years, and we know that the phenomena vary largely with the season of the year at any given station, and that there are notable differences between different stations at ground-level. As yet but little is known of the diurnal and annual changes at different heights in the free atmosphere. Observations made near the top of the Eiffel Tower suggest that the phenomena alter rapidly as the height above the ground increases. Thus observations from balloons and kites, if these could be maintained at a fixed level, would be of great importance. The influence of electricity on the growth of plants, first seriously studied by Prof. Lemström, seems not unlikely to prove in the future to be of economic importance. The phenomena of thunderstorms have received considerable attention from meteorologists, but many lines of investigation present themselves. The loss of charge of insulated bodies and the ionic charges in the atmosphere have been studied most in Austria and Germany—Elster and Geitel, in particular, having done much pioneer work. In this country Mr. C. T. R. Wilson has investigated the electric charge brought down by rain, and has invented an instrument for measuring the earth-air current. While a great number of theories have been advanced to account for the several phenomena, there are few, if any, of them which command anything like universal acceptance.

Sir Oliver Lodge referred to the existence of a positive gradient of potential during fine weather and a negative gradient during wet weather, and spoke of the possibility of influencing the weather by varying the potential gradient, and thought that rain might be produced in this way, and that here was a field of experiment for the enterprising capitalist. Referring to the effect of electricity on plant life, he explained that the experiments with which he had been connected showed that in dull weather the plants were stimulated by the electricity, and the effect was good, but in bright, sunny weather they were over-stimulated, with consequent bad results. He did not think that the action on plants was due to nitrification, but to some effect on the growing tips.

Dr. Shaw pointed out that in order to produce rain in considerable quantities it would be necessary to find a source for an enormous amount of energy, and he urged that any attempt to reverse the electric field should be first of all thoroughly worked out in the laboratory. He asked whether fine weather electricity had anything to do with thunderstorms. The two phenomena seemed to be distinct from one another.

Sir J. J. Thomson thought the real difficulty about producing rain by electrical methods would be political. If one's efforts resulted in deluging neighbouring countries with rain they did not want, or in depriving them of their normal supply, difficulties would begin. As he understood Sir Oliver Lodge, it was not a question of supplying energy, but of transforming energy already existent in the atmosphere in order to produce rain. He referred also to the difficulty of explaining the return to earth of the outward flowing negative electricity, and mentioned, in conclusion, the relation between the radio-active contents of the air and its previous history; air which had travelled over the sea was much less radio-active than that which had been for some time over the land.

Dr. Chree in his reply emphasised the fact that during rainfalls there are fluctuations of potential, and in conclusion urged the necessity of observations over much wider areas before many of the problems of atmospheric electricity could be settled.

At this stage the section divided. In the department of cosmical physics Dr. W. Schmidt, of Vienna, communicated an interesting description of a new instrument, the variograph, designed by him for measuring short waves in atmospheric pressure. He showed records obtained by it at Innsbruck and Vienna. Conditions at Innsbruck, especially in the winter months, are very favourable for the production of waves, the cold air in the valley lying beneath a warmer upper layer. By recording with two instruments 2 km. apart, Dr. Schmidt deduced that both progressive and standing waves occurred, the period of the latter being considerably greater than that of the former; in a particular case the periods were 3·5 minutes and 9 minutes respectively, and the record showed the interference of the two sets of waves. Dr. Schmidt showed, too, that in Föhn weather, when regular waves were recorded, the regularity ceased when the Föhn wind actually broke through the cold layer and blew at Innsbruck, proving that the layer of discontinuity was essential to the formation of the waves. In some cases regular waves preceded by several hours the occurrence of line-squalls, corroborating Russell's observations of cirrus clouds.

Mr. Dines spoke on the records from the upper atmosphere obtained during the passage of the earth through the tail of Halley's comet. The traces obtained by Mr. Dines in ordinary cases are of two kinds, one in which the up and down curves coincide, the other in which loops are formed. The traces at the time of the comet showed an abnormally large proportion of the second kind, but it was not possible to say if the peculiarity was due to the comet or to the type of the prevailing weather.

Dr. Nicholson in a paper on radiation pressure in cosmical problems showed that more extended calculations do not confirm Schwarzschild's results in detail, but the general character of these results is preserved.

Miss Margaret White showed a series of slides giving the results of the hourly balloon ascents made from Manchester in March. The results corroborated in their main features those obtained in June, 1909, and communicated at the Winnipeg meeting.

Mr. Stupart gave some results of an inquiry into the vertical temperature gradients in Canada in the winter months. The principal conclusions were:—(1) that in cold winters in Manitoba the temperature increased upwards, the mountains being warmer than the plains; (2) that in warm winters the mountains were colder than the plains, and the vertical gradient approached the adiabatic value.

Mr. Gold communicated the results of an investigation into the effect of radiation on H_c, the height, and T_c the temperature of the advective region. So far as radiation is concerned, the variation both in the temperature and in the absolute humidity of the atmosphere tend to increase the value of H_c with approach towards the equator, but their effects on T_c are in opposite directions. A necessary condition for the existing state of affairs is that the atmosphere should be very nearly transparent to low temperature radiation for considerable regions in the spectrum.

Prof. F. G. Baily described a sensitive bifilar seismograph for recording undulatory movements of the earth's surface of short period. By a system of multiplying levers, great sensibility is attained, and it may be expected that, when the present experimental instrument is replaced by a final form exposed in a suitable chamber, valuable results will be obtained.

In the department of general physics, which sat simultaneously with the above, Mr. Twyman described, on behalf of Prof. C. Féry, a successful attempt to simplify the long-range spectrograph to make it suitable for industrial investigations concerning metals, alloys, &c. The principle of auto-collimation is employed, a 30° quartz prism being traversed twice by the beam of light. By giving suitable curvatures to the two sides of the prism it acts also as the lens-system, producing a sharp spectrum on a cylindrical surface, exactly as with a curved reflecting grating, and with a much less inclination of the plate.

In a paper on the magnetic field produced by the motion of a charged condenser through space, Mr. W. F. G. Swann discussed the possibility of detecting the presumed field by means of a rotating coil, even though the impossibility of detecting it by a magnetic needle is admitted. His analysis seemed to indicate that if the specific inductive capacity may be looked upon as a quantity absolutely continuous throughout the dielectric, a magnetic flux through the coil should exist, but that if the dielectric action is to be explained by electric charges or doublets, no resultant magnetic flux is to be anticipated. Experiments made by the author gave a null effect, and this is taken to support the doublet theory of dielectric action.

Three papers were read by Prof. J. C. McLennan on behalf of the authors, who are his students at Toronto. In the first Mr. V. E. Pound details the results of experiments on the secondary radiation from carbon at low temperatures when bombarded by the α rays from polonium. Fifty per cent. more is produced at the temperature of liquid air than at atmospheric temperature. This is attributed to the much larger amount of air occluded in the carbon. The second paper, by Prof. McLennan and Mr. N. Macallum, was on a resolution of the spectral lines of mercury by a high-grade echelon spectroscope made by Messrs. A. Hilger. A number of slides were exhibited showing the components of the green and blue mercury lines and their resolution under the action of a magnetic field. The third paper was by Mr. W. T. Kennedy, on the active deposit obtained when the emanation from actinium is allowed to diffuse freely between two parallel plates placed about 2 millimetres apart over the actinium salt, the plates being maintained at a difference of potential of 250 volts. The deposit is found to reach a maximum for a particular gas-pressure. It was concluded that the proportionate amount of emanation which possesses a positive charge varies with the pressure.

Dr. H. S. Allen followed with an important summary of our present knowledge of photoelectric fatigue. This was accompanied with a bibliography, which has been ordered to be printed *in extenso*. This was succeeded by an interesting paper by Drs. W. Makower and S. Russ and Mr. E. J. Evans on the recoil of radium B from radium A. The magnitude of the effect observed was of the order to be expected if radium B carries the atomic charge of electricity and if its atomic weight is 214, as is to be expected on the transformation theory of radio-active processes.

The proceedings on Wednesday, September 7, began with a very interesting account by Sir Norman Lockyer of his work on stars and their temperatures. The spectra of the hottest stars indicate that in them we have to deal simply with hydrogen and with another form of hydrogen produced from it: but helium runs hydrogen very close as one of the constituents of a star's earliest atmosphere. Iron, even in a proto-form, enters into a star's atmosphere at a much later stage, and iron such as we know it in our laboratories at a later stage still. The general conclusion from Sir Norman's work is that we are able to establish a palæontology of chemical substances.

Prof. W. M. Hicks sketched some of the evolutions of a vortex, and was succeeded by Dr. C. Chree, who read a critical paper on the rate of propagation of magnetic disturbances. Dr. Bauer, of the Carnegie Institution, believes he has established as a fact that the so-called "sudden commencements" of magnetic storms are propagated at such a rate as to take, on an average, about $3\frac{3}{4}$ minutes to go round the earth, and he believes that the cause of these disturbances is a peculiar form of overhead electric current in the plane of the earth's equator due to charged ions, the height of which, on the average, is about fifty miles. Dr. Chree considers that the theory which Dr. Bauer has advanced to account for the motion of these charged ions is unsatisfactory in several respects, and he further considers that the experimental evidence which has been brought forward by Mr. Faris to support Dr. Bauer's theory is inconclusive.

Then followed several reports of committees, which were either outlined or taken as read. These included the report of the seismological committee, in which reference is made to the interesting results on the semi-diurnal change in level (caused by the tide) obtained by Plummer at Bidston Observatory. The meeting of the section then came to an end.

CHEMISTRY AT THE BRITISH ASSOCIATION.

IN arranging the programme for the Sheffield meeting the organising sectional committee had made it the main object to discuss broader questions of interest to other sections rather than to encourage the reading of papers appealing mainly to specialists; further, in view of the special character of the industries of Sheffield, much of the programme was devoted to metallurgical subjects. The results of the meeting fully justified this departure, and the three joint discussions not only proved of the greatest interest, but were most stimulating in character; indeed, it is probable that in two cases, at least, they will serve as points of departure for much new research. The metallurgical papers were equally stimulating and in harmony with the tone set by the president's address—the meeting as a whole should do much to inspire the filling of some of the gaps in our knowledge to which Mr. Stead made reference.

The joint discussion with Section A attracted a very large audience. The subject chosen—combustion—should have had the cooperation of the engineers, who were discussing the report of their committee on gaseous explosions on the same morning, but could not see their way to attend the joint meeting. Prof. Bone presented a report giving a very complete summary of the principal researches upon the chemical aspects of gaseous combustion during the past thirty years. He dealt in turn with ignition temperatures, the explosion wave, the pressures produced in gaseous explosions, the influence of moisture upon combustion, the combustion of hydrocarbons, and the influence of hot surfaces upon combustion. This last question is of considerable technical importance, hot surfaces accelerating dissociation, and probably also combustion, and hence playing a potent part in the development and concentration of the heat in gas-fired furnaces. The line of attack followed has been to determine the rates of combination of different gases with oxygen when the reacting mixtures are brought into contact with various solid surfaces at selected constant temperatures.

Sir J. J. Thomson directed attention to the fact that combustion was concerned, not only with atoms and molecules, but also with electrons, *i.e.* bodies of much smaller dimensions and moving with very high velocities. These may precede the explosion wave and prepare the way for it by ionising the gas. The motion of the ions can be stopped at once by means of a transverse magnetic field, and it would be of great interest to repeat Prof. Dixon's experiments on the photography of the explosive wave under such conditions.

It had been shown by the work of Townsend and others that in carefully dried gases the velocity of the negative electrons might be 100 times as great as the velocity of the positive electrons. The amount of moisture required to reduce this velocity to its ordinary lower value was exceedingly small, and comparable with that required to initiate chemical change. It was not unlikely that the two phenomena were very closely related.

In reference to the influence of hot surfaces in promoting combustion, it was not improbable that the emission of charged particles from the surface was a factor of primary importance. Hot lime gave out an enormous stream of negative electrons; hot metals emitted an excess of positive electrons. These electrons might produce very important effects by uniting (perhaps selectively) with moisture, with the oxygen or with the inflammable constituent of the gaseous mixture. The action of surfaces might ultimately be found to depend on the fact that they formed a support for layers of electrified gas in which chemical changes proceeded with high velocity.

Sir Oliver Lodge referred to the fact that the velocity of sound was not a constant quantity. If a bullet were to travel with a velocity greater than that of sound the air would be shattered as if by an explosion. This result was in practice prevented by the compression, and consequent heating, of the air in front of the bullet, whereby the velocity of sound was momentarily raised to perhaps three times its ordinary value. Whilst hot surfaces promoted combustion, cool surfaces had an opposite effect; this was responsible for the production of vast quantities of soot and smoke, especially in firing steam boilers. The discovery of a surface which would promote combustion even at lower temperatures would be of very great value.

Prof. H. B. Dixon stated that the explosion of hydrogen and chlorine by light was of special interest, as it did not occur in the well-dried gas. Both Mellor and Chapman and Burgess had failed to find any evidence of ignition by light of a mixture of two substances—three kinds of molecules seemed to be necessary. But when once the explosion wave was started it proceeded independently of moisture, and, indeed, was actually most rapid in the dry gas; the explosion was then propagated by molecular collisions between pairs of molecules. It was not unlikely that invisible compression waves might travel a little in front of the visible flame, the particles being thereby raised to a higher temperature, but remaining uncombined until they collided with one another.

Prof. Armstrong denied the possibility of any interaction taking place between two substances if neither was an electrolyte. Highly purified materials must be used for work of this kind. Perhaps the most suggestive experiment was that of Sir James Dewar, who had purified helium so perfectly by the use of charcoal cooled in liquid air that it would not permit an electric discharge to pass through it, although the presence of the gas was clearly shown by the radiometer.

A paper on the molecular weight of radium emanation, by Sir Wm. Ramsay and Dr. R. W. Gray, was delivered by Dr. Gray, who first described in detail the construction of the micro-balance used, and showed how the exact volume of emanation weighed was determined. The mean value of 221 was obtained for the molecular weight of the emanation, and the fact emphasised that the radium emanation was in every sense a true chemical element. Chemically it is absolutely inert, and the atomic weight shows that it falls into the argon series in the periodic table, filling the second vacant space below xenon. The name "niton" (shining) and the chemical symbol Nt was proposed for the emanation. Sir J. J. Thomson suggested that the name should be left to the Congress of Radiology at Brussels (see NATURE, October 13).

The more purely physical papers read at the joint meeting are dealt with in the account of the proceedings of the physical section.

The report on solubility submitted by Dr. J. V. Eyre is the outcome of a systematic study of the literature; the material is classified chronologically and according to subject, and contains a brief statement of the main conclusions arrived at by the various authors.

The conjoint discussion on the biochemistry of respiration was of the greatest value in enabling workers on the subject, representing the three sciences concerned, to correlate their views. Mr. F. F. Blackman, who opened the proceedings, gave a very complete summary of the present position of the subject, dividing it into three sections:—(1) the nature of the chemical reaction (or complex of reactions) that constitutes respiration; (2) the extent to which this reaction in the cell conforms to the laws of general chemistry; (3) the influence on the progress of the reaction of the peculiar medium (protoplasm) in which it takes place. A summary statement of respiration takes the form of the equation for the complete oxidation of glucose, but actually the process is most complicated. The existing theories as to the stages in which glucose undergoes oxidation and the part played by oxidases were all fully described.

Mr. Blackman advocated the hypothesis that normal respiration consists of two processes, a small "protoplasmic respiration" which cannot be suppressed without death, and a larger "floating respiration" which depends on the available sugar supply, and can be reduced or abolished by starvation.

A brief summary of the oxidative breakdown in animal tissues was given by Mr. H. M. Vernon, who described some of his own work on the subject.

Dr. E. F. Armstrong summarised the existing knowledge with regard to the oxydases, and debated whether they are to be regarded as organic enzymes or as inorganic catalysts in a colloidal substrate. The facts that oxydase solutions retain their activity after somewhat drastric purification, that they invariably contain, even after the most thorough purification, traces of manganese, iron, or calcium salts, and that their action may be imitated by colloidal suspensions of the salts of these metals, are all in favour of the later view. On the other hand, there is distinct evidence of the specific nature of oxydases and of the existence of different oxydases. He further described the remarkable blackening of the leaf of *Aucuba japonica* produced when this is exposed to toluene or chloroform vapour, the change being attributed to an oxidative effect produced by an oxydase. A systematic investigation of what substances were able to cause this blackening showed it to be produced by most organic vapours, *e.g.* ethyl acetate, ether, benzene, &c., by carbon dioxide, and by such salts in aqueous solution as cadmium iodide, mercuric chloride, and sodium and potassium fluorides. All these substances possess but little affinity for water, and it is supposed that they are therefore able to pass through the differential septa, enter the cell, and set up osmotic disturbances whereby the cell contents become diluted and hydrolysis sets in to restore equilibrium. This brings the various cell enzymes into play, and a general degradation takes place. Measurements of the amount of sugar or starch or glucoside in the leaf before and after stimulation confirm this view—a great increase in the amount of reducing sugar is produced.

The stimulative effect of chloroform on respiration formed the subject of a paper by Mr. D. Thoday, whose results appeared to harmonise very closely with those of Dr. Armstrong; this paper will be more appropriately discussed under Section K. Prof. Armstrong, who followed, made a critical examination of the mechanism of the oxidative changes, and laid stress on the extremely complicated nature of the respiratory phenomenon.

The joint meeting with the Educational Section to discuss the neglect of science by industry and commerce attracted a large audience. Mr. Blair, who opened, spoke at considerable length in detailing evidence which he had collected from 150 past students of universities or institutions of university rank—all belonging to a class for whom the earning of a living was imperative. His paper appeared in full in NATURE of September 15. Following a supplemental paper by Sir Wm. Tilden, the subject was debated in turn by Dr. H. T. Bovey, Principal Griffiths, Dr. Beilby, Sir Wm. White, Mr. J. E. Stead, and Prof. Armstrong. The general tone expressed, both in Mr. Blair's address and by subsequent speakers, was one of hope, and it was agreed that England is not so far behind other countries in the application of science to commerce and industry as is often asserted. The main fact emphasised was that it was, above all, necessary to educate the public and bring home to them the advantages of pure science, and, further, it was all-important to establish some easy means to bring about a better understanding and more frequent communication between those who studied science and those concerned in its application.

On Tuesday, September 6, it was necessary to divide the section, the metallurgical and the organic chemistry papers being taken separately. The first paper, by Prof. J. O. Arnold, dealt with a fourth recalescence in steel. Steel in cooling contracts to a certain point, and then suddenly expands. It is agreed that this takes place three times; but Prof. Arnold, as the result of several years' experience, considers there is a fourth recalescence due to constitutional segregation, namely, the falling out between Ar_3 and Ar_1 of the ferrite and hardenite from their state of solid solution into microscopically visible masses. Numerous photomicrographs and cooling curves were shown to support this view. In the ensuing discussion Dr. C. H. Carpenter contended there was no need to term the process a fourth recalescence, and interpreted it as a prolongation of the Ar_3 and Ar_2 inversions. He criticised adversely the apparatus employed by Prof. Arnold, advocating in its place the differential method of registering recalescence. Prof. Arnold, in replying, stated this method to be quite untrustworthy. Mr. Stead said it is well known that in steels containing under the eutectoid proportion of carbon, when cooling from Ar_3 to Ar_{1-2-3}, the carbides and ferrite segregate. Prof. Arnold by his very careful research was the first to show that this segregation is coincident with an evolution of heat.

Prof. H. M. Howe, in a brief paper on allotropy or transmutation, took the view that changes such as that from the diamond to lampblack in reality involve transmutation, and the fact that but a single series of derivatives is given by such compounds was explained as meaning that the derivativeless element inevitably transmutes whenever it enters into combination.

A second paper dealt with the closing and welding of blow-holes in steel ingots, in which the author supported the practice of allowing blow-holes to form rather abundantly, so as to prevent the formation of a pipe, and then, relying on the ease with which such steel welds, trying to get flawless metal by welding these blow-holes up in the process of rolling the ingot out into its final form. This procedure is of great economic importance in that it enables the steel maker to avoid the serious discarding which would be necessary in case his ingots were free from blow-holes, and hence deeply piped. Many metallurgists have condemned the practice on the ground that the closing of blow-holes is impossible, because the gas which they contained must remain ever present during the rolling, even though somewhat compressed. Prof. Howe described in detail experiments showing that the blow-hole gases had been reabsorbed by the metal to a very great degree, and suggested prolonging the exposure to a temperature above the welding point, so as to complete the reabsorption of the gas while the metal was still weldable. The welding of the blow-holes should be promoted rather by the practice of "reheating" than by that of "direct rolling." Following some remarks by Prof. Arnold and Mr. Hadfield, Mr. Stead described an investigation carried out with Mr. F. M. Parkin on the same subject, which proved conclusively that when two metallic surfaces, quite free from oxide or any foreign matter, are brought together and hammered at temperatures from 1100°–1150° C., they weld up completely. The question as to what becomes of the imprisoned gas requires careful research; when the cavities are large the gases are enormously compressed, and must interfere with efficient welding. As a result, blisters occasionally appear on finished sheets if afterwards reheated. The gases extracted from a large blister in a soft steel slab gave on analysis:—CO_2, 23 per cent.; CO, 50·5 per cent.; hydrogen, 17 per cent.; marsh gas, 3·5 per cent.

The next paper, on the provident use of coal, by Prof. H. E. Armstrong, gave rise to a very considerable discussion. During the early stages of combustion a variety of volatile inflammable substances are given off which burn with a smoky flame. By first coking the coal at a low temperature these may be removed and recovered, and a fuel obtained which burns as readily as coal and gives a hotter fire. The gas given off by the coking process is very rich, and it was advocated that this be substituted for the product now produced by carbonising coal at very high temperatures, so as to obtain the maximum possible yield. It is essential that the quality of gas be improved; since the sulphur clauses of the Gas Acts were repealed there has been a steady deterioration. There is no reason why the coal now used in the raw state by the community should not be first coked at a low temperature. The gas would be available as an illuminant and for heating; the residual coke could be burnt without producing smoke, and a variety of bye-products would have considerable commercial value.

Prof. A. Smithells stated that the point to be proved was whether fuel of the type advocated could be produced under conditions which would enable it to compete economically with the coal and products as put on the market under existing conditions. He considered the whole question to be in the experimental stage.

Dr. Beilby pointed out that in order to supply the public with soft coke instead of the 40 million tons of coal now required for domestic purposes the gas industry would have to be completely revolutionised, and some other very large uses found for the gas and other bye-products. It would not be possible to get chemical uses for such a large quantity, and it would have to be largely burnt as fuel. Mr. Archbutt emphasised the evil caused by sulphur in the gas; the public is not aware of this being the cause of the corrosion of brass, tarnishing of silver, and the destruction of books and furniture. Mr. A. W. Oke defended the gas companies, and other speakers supported Prof. Armstrong, who, in replying, stated that the use of a very large radiant and the supply of a greater quantity of gas was progress in the wrong direction. He agreed with Dr. Beilby that it would be necessary to regard the products of coking from the point of view of their fuel value, but that was a largely enhanced fuel value.

Prof. McWilliam described the properties of a series of steels with varying carbon contents, but containing, in addition, about 1 per cent. manganese, and a similar series containing 2 per cent. chromium, from results recently obtained by him in conjunction with Mr. E. J. Barnes. In pure iron-carbon steels the strength rises steadily with the amount of carbon up to 1·25 per cent. carbon, a further increase resulting in a reduced strength. The carbon is present as iron carbide, and other elements mainly influence the nature, composition, or distribution of the carbide in the steel. The effects of heat treatments such as long annealing and quenching, followed by tempering at different temperatures, are comparatively small when the carbon is low, but greater as the carbon is increased. Comparative tables were shown of steels with carbon contents and heat treatments as nearly alike as could be selected, and varying only in the special element added, to illustrate the very considerable and abiding influence of the fundamental chemical composition.

In the absence of the author, a communication by Dr. Rosenhain, on the crystalline structure of iron at high temperatures, was taken as read. The conclusions drawn from the research are that iron at temperatures up to 1100° C. behaves as a crystalline aggregate; it exists in three different modifications possessing widely different mechanical properties, the temperature range at which these modifications exist being consistent with their identification with the α, β, and γ forms of iron. β Iron, though existing at a higher temperature, is markedly stronger and harder than α iron. Iron as found in approximately pure metal at high temperatures possesses the structure and some of the properties of γ iron as found in certain alloy steels. The failure to harden pure iron by quenching is due to the difficulty of inhibiting the $\beta \rightarrow \alpha$ transformation by rapid cooling except in the presence of carbon. If β iron could be preserved in existence at the ordinary temperature it would possess a very high degree of hardness and strength probably quite comparable with that of hardened steel.

Dr. S. M. Copeman brought forward the subject of ferro-silicon, with special reference to possible dangers arising from its transport and storage. A number of accidents have occurred from the handling or transport of ferro-silicon, particularly cases of sudden illness and death caused by the gases evolved from certain cargoes. The subject has had full inquiry at the hands of the Board of Trade, who entrusted the investigation to Dr. Copeman, with the collaboration of Mr. S. R. Bennett and Dr. Wilson Hake. Most of the high-grade ferro-silicon, containing 50 per cent. of silicon, is produced electrically in France. About 4000 tons are imported annually into England. This alloy is exceedingly brittle, and readily decomposes in a moist atmosphere, when poisonous fumes of phosphoretted hydrogen are evolved. The official recommendations adopted by the Board of Trade comprise the need for ascertaining that the ferro-silicon has been broken into small pieces some time before being taken on board ship; the proper marking of each barrel; the prohibition of conveyance on passenger vessels; and the adoption of certain other precautions during transport. Subsequently Dr. Wilson Hake described the apparatus he had employed for analysing the poisonous gases produced, and Mr. S. R. Bennett showed photomicrographs of certain ferro-silicon alloys. The suggestion was made that the alloy might be protected from moisture by immersion in varnish, but it was stated that it crumbles so readily as to be always presenting new surfaces.

Two rival theories have been suggested to explain the corrosion of iron and steel. The electrolytic theory assumes that pure oxygen (or air) and pure liquid water *alone* are necessary to effect the rusting of pure iron. According to the acid theory, the presence of at least traces of an acid either free or combined with a base is essential to corrosion. Dr. J. N. Friend described a simple form of apparatus by means of which the correctness of the acid theory is established.

A paper embodying researches carried out in the chemical department of Sheffield University, by Messrs. C. Chappell and F. Hodson, dealt with the influence of heat treatment on the corrosion, solubility, and solution pressures of steel. The tests made were simple corrosion, *i.e.* loss of weight after immersion in sea water; galvanic corrosion, *i.e.* loss in sea water in contact with Swedish bar iron; solubility in 1 and 2 per cent. sulphuric acid after seventy-two hours; solution pressure in sea water, 1 per cent. sulphuric acid and N/10 ferrous sulphate. The results show that the solubility tests are untrustworthy as a guide to the relative rates at which the steels corrode. The general effect of heat treatment on the various properties examined is found to be the same in the case of all the tests except simple corrosion, where heat treatment exerts practically the opposite effect. Although heat treatment exerts considerable influence on corrosion, it cannot be expected to make up for the defects due to segregation or inferior material. A research committee, with a grant of 15*l.*, was appointed for the further study of this question, with Mr. W. E. S. Turner as secretary.

The sub-section, under the chairmanship of Prof. Orme-Masson, was occupied mainly with papers from the chemical laboratories of Sheffield University, which testify to the valuable amount of original inquiry which is being carried out there under Prof. Wynne's guidance. Prof. W. P. Wynne and Dr. J. Kenner presented a paper dealing with the nitrochloro- and dichloro-toluene sulphonic acids, whilst Dr. J. Kenner and Mr. E. Witham described the formation of tolane derivatives from benzotrichlorides. A paper on an instance illustrating the relative instability of the trimethylene ring as compared with the tetramethylene ring was read by Dr. J. F. Thorpe (Sorby research fellow). Open-chain nitriles formed from three carbon rings readily pass into imino derivatives of cyclopentene under similar conditions; four carbon rings remain entirely unaffected. A second paper, by Mr. A. D. Mitchell and Dr. J. F. Thorpe, dealt with the elimination of a carbethoxyl group during the closing of the five-membered ring. The closing of an open chain of five carbon atoms to form a five-membered ring imparts to the molecule a condition of tension which limits the capacity of the constituent carbon atoms to combine with groups of more than a certain volume.

Three important physical chemical communications were made by Mr. W. E. S. Turner. The first paper, written jointly with Mr. C. J. Peddle, dealt with molecular association in water, illustrated by substances containing the hydroxyl group. The fact that molecular association may take place in water is not generally recognised, but the authors find it to be quite extensive among aromatic substances. Benzoic acid, for example, is associated in water to a greater extent than in benzene, and the aromatic acids examined nearly all exhibit marked association. A second paper was entitled "The Problem of Molecular Association. 1. The Affinities of the Halogen

Elements." As the result of the determination of the molecular weights of fifty to sixty halogen containing substances of different types, it was shown that molecular association occurs only when the halogen compound is an electrolyte, that there is no special virtue in the halogen elements—such as the existence of a large number of contra or residual valencies—neither is there any virtue in the halogen ion differentiating it from other ions. Molecular association in neutral solvents is the reverse of the supposed electrolytic dissociation in the dissociating solvents.

The third paper, by W. E. S. Turner and E. W. Merry, dealt with the molecular complexity of nitrosoamines. Measurements of the surface energy of three nitrosoamines show that aliphatic nitrosoamines are associated liquids, whilst aromatic nitriles and nitro-compounds are non-associated.

Dr. F. M. Perkin communicated a short note on the action of metals upon alcohols. When ozone is bubbled through lead suspended in a state of fine division in alcohol lead ethoxide is formed, and this substance is readily obtained on boiling up finely divided lead with absolute alcohol. A few drops of alcoholic mercuric chloride solution are added to facilitate the reaction, or dry air is bubbled through the heated mixture for the same reason.

The method has been extended to the preparation of lead methoxide, cadmium ethoxide, mercurous ethoxide, and silver ethoxide.

The reports of the research committees contained much valuable matter. That on dynamic isomerism dealt with the absorption-spectra of camphor and a number of its derivatives. The report of the study of hydroaromatic substances deals with the constitution of the 3 : 5-dichloro-*o*-phthalic acid obtained from dimethyldihydroresorcin and the preparation of 1 : 1 : 2-trimethylcyclohexanone.

The transformation of nitroamines committee report on the chlorination of anilides and the transformation of acylchloroaminobenzenes, and also on the bromination of anilides. The committee on isomorphous sulphonic derivatives of benzene state that during the past year the results obtained by the examination of twenty-nine derivatives of the 1 : 4 series have been discussed from the point of view of the Barlow-Pope theory, correlating crystalline structure with molecular form, and found to be in complete accordance with it.

GEOLOGY AT THE BRITISH ASSOCIATION.

As was perhaps natural in a year when a geologist, Dr. Bonney, was president of the association, there was an excellent gathering at Section C, which was fortunate in being able to welcome, in addition to the president, Prof. A. P. Coleman, three other geologists from Canada, Dr. R. Bell, Mr. J. B. Tyrrell, and Prof. Spencer. The meetings of the section were well attended, the number of papers presented was sufficient to afford a full programme for the last day (Wednesday), and several well-sustained discussions took place. Any account of the sectional proceedings would be incomplete without a reference to the interesting series of excursions arranged by Mr. B. Hobson and Mr. Cosmo Johns. On Saturday there was a whole day excursion to the Castleton district under the leadership of Dr. Arnold Bemrose, while four half-day excursions were carried out. The sectional dinner was attended by more than sixty members. Successful joint meetings were held with the geographical section and agricultural sub-section; the papers read on the latter occasion are referred to in the report of the subsection.

The great majority of the papers and reports read before the section were stratigraphical in character. In pre-Cambrian geology there was, in the first place, the president's address on "The Canadian Shield," already printed *in extenso* in Nature (vol. lxxxiv., p. 333).

Two reports were also presented dealing with pre-Cambrian rocks, one on the composition and origin of the crystalline rocks of Anglesea, and one on Charnwood rocks.

Lower Palæozoic stratigraphy was represented by a paper by Dr. J. E. Marr and Mr. W. G. Fearnsides on the Lower Palæozoic rocks of the Cautly district, Sedburgh, and a further paper by Miss G. R. Whatney and Miss E. G. Welch described the graptolitic zones from the Salopian beds of the same area; the only other region in which the majority of these zones have hitherto been traced is the Welsh border country. Two reports relative to the Lower Palæozoic rocks were also presented; the committee appointed for the excavation of critical sections in the Palæozoic rocks of Wales and the west of England presented an important report drawn up by Mr. E. S. Cobbold on excavations among the Cambrian rocks of Comley, Shropshire, this including a general revision of the results yielded by the excavations of the past three years and a vertical section. An interim report on the rocks of the Glensaul and Lough Nafooey areas, cos. Mayo and Galway, was also read.

A number of papers had reference to Carboniferous strata. Mr. Cosmo Johns' lecture on local geology was chiefly concerned with the Carboniferous rocks, and he further presented a paper on the Yoredale series and its equivalents elsewhere. The report of the committee on the faunal succession of the Lower Carboniferous (Avonian) of the British Isles consisted of an important report drawn up by Dr. A. Vaughan correlating the Belgian succession of the Carboniferous limestone rocks with that of the south-west of England. Mr. E. E. L. Dixon presented a paper on the geology of the Titterstone Clee hills, and three important papers bearing on the Coal-measures of the south Pennine area were read, viz. that by Mr. H. Culpin on marine bands in the Coal-measures of south Yorkshire, that by Mr. W. H. Dyson on the Maltby deep boring, and that of Dr. L. Moysey on some rare fossils from the Derbyshire and Notts coalfield. Members of the section had an opportunity on one of the excursions of inspecting the fine collection of fossils at the Maltby mine, and of obtaining many for themselves, while Dr. Moysey kindly brought his collection to Sheffield, and it was on view during the meeting. A report was also presented by the committee for the investigation of the fossil fauna and flora of the Midland coalfield.

An important discussion took place relative to the concealed coalfield of Notts, Derby, and Yorkshire, which recent discoveries have proved to be far more extensive than was formerly supposed. Prof. P. F. Kendall, in opening the discussion, described the evidence for a great eastward and southward extension of the concealed coalfield, the south-western margin being probably formed by a prolongation of the ancient rocks of the Charnwood area. He further announced that coal had been met with in a boring at Scunthorpe, a point eleven miles to the east of its previously known extent. Triassic geology was represented by a suggestive paper from the Rev. E. C. Spicer on present-day Triassic condition in Australia, and by one by Mr. A. R. Horwood on the origin of the British Trias.

A number of papers and reports had reference to African geology. Dr. J. W. Gregory read a paper on the geology of Cyrenaica, Dr. J. D. Falconer one on the geology of northern Nigeria, and Dr. F. H. Hatch one on the geology of Natal.

A somewhat lengthy report on the correlation and age of South African strata was presented, and a second report on topographical and geological terms used locally in South Africa.

One of the most interesting discussions during the meeting was that following a paper by Mr. G. W. Lamplugh on the shelly moraine of the Sefström Glacier, Spitsbergen, and its teachings. Observations on this glacier, which is subject to somewhat rapid advances and retreats, showed that (1) in a very few years a thickness of some 70 to 80 feet of shelly Boulder-clay could be accumulated, the glacier scooping up the material from the sea bottom and pushing it before itself; (2) that in this clay uninjured shells occurred plentifully; (3) that within a few yards of the spot where the Boulder-clay was accumulating many forms of animal and plant life could flourish—all points of importance in helping to an understanding of British glacial deposits. Other papers referring to glacial geology were a report on erratic blocks, and a paper by Prof. E. Hull on the glacial rocks of Ambleside.

Very few papers dealt with palæontological subjects. Mr. M. Odling described a problematical fossil from the Chipping Norton limestone, and Dr. M. C. Stopes read a paper on structural petrifications from the Mesozoic and their bearing on fossil plant impressions.

Sir T. H. Holland read a suggestive paper on the cause of gravity variations in northern India; Mr. T. Sheppard gave a well-illustrated account of the Humber during the Human period; Dr. Tempest Anderson showed a magnificent series of photographs in illustration of his paper on Matavannu, a new volcano in Savaii (German Samoa); and Dr. A. Irving read papers on the pre-oceanic stage of planetary development and on a buried Tertiary valley through the Mercian chalk range, and its later rubble drift. Prof. A. McWilliam described the metallurgical industries in relation to the rocks of the (Sheffield) district. Finally, reports were presented by Prof. J. Milne on seismology, and by Prof. W. W. Watts on geological photographs.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Gedge prize has been awarded to G. R. Mines, of Sidney Sussex College, for his essay entitled "Researches on the Physiological Action of Inorganic Salts chiefly in Relation to the Cardiac and Skeletal Muscles of the Frog."

R. H. Compton, Gonville and Caius College, has been elected to the Frank Smart (university) studentship.

The State Medicine Syndicate has appointed J. E. Purvis, of St. John's and Corpus Christi Colleges, to be secretary to the syndicate in the place of Dr. Anningson, who has resigned the office after twenty-five years' service.

The council of the Institution of Civil Engineers is prepared to consider applications for a nomination to the Palmer scholarship. The nominee must be the son of a civil engineer, must be desirous of studying and graduating at the University of Cambridge, and must be in such circumstances as to need the scholarship, which is of the annual value of 40*l*. Copies of the regulations may be had from the secretary of the institution, Great George Street, Westminster, S.W.

THE first course, dealing with neurology, of the Page May memorial lectures in physiology, will be delivered by Prof. C. S. Sherrington, F.R.S., at University College (University of London) on the following Mondays and Tuesdays, at 4.30 p.m.:—October 24 and 25, November 7 and 8, November 28 and 29. The lectures are open to the public without fee.

IT is announced in *Science* that at Yale University the salaries of professors and assistant professors have been increased by 9800*l*. from the alumni fund. The salaries of full professors are to be 800*l*. to 900*l*. and 1000*l*., based mainly on length of service, but modified somewhat by university responsibility and personal distinction. In the case of assistant professors the maximum salary is increased to 600*l*.

THE Aëronautical Society offers the following course of lectures at the Northampton Polytechnic Institute, Clerkenwell:—November 2: the study of dynamic flight, J. H. Ledeboer; November 16: the mechanics of the aëroplane, Algernon E. Berriman; November 30: theory and design of propellers, T. W. K. Clarke; January 11, 1911: aëroplane surfaces and controls, with some remarks on chassis, Herbert F. Lloyd; January 18: the motive power in aëroplanes, Captain A. D. Carden, R.E.; January 25: lines of aëronautical research, Bertram G. Cooper. The lectures will be given on Wednesdays at 8 p.m., and applications for tickets are to be addressed to the secretary of the Aëronautical Society, 53 Victoria Street, Westminster, S.W.

A CIRCULAR letter has been issued from the Education Offices of the London County Council inviting from the optical trade an expression of opinion on the advisability of endowing a central opto-technical institute at a cost of probably 30,000*l*. for the building alone. As a successful issue to this project is dependent mainly on the expression of a large volume of trade opinion in its favour, Mr. J. Aitchison arranged for a meeting of opticians to be held on Monday last, October 17, at Anderton's Hotel, Fleet Street, E.C., at which it was resolved to support the suggested establishment of an opto-technical institute in Clerkenwell "to further the work which has been hitherto carried on at the Northampton Institute, and has proved of great value to the optical industry." In his letter convening the meeting Mr. Aitchison remarked:—"Whatever difference may still exist between different parties in the trade, all are agreed to cooperate in whatever seems to be possible for the advancement of our industrial status, by forwarding the course of technical education and concentrating public attention on the importance of the movement."

THE first part of "Statistics of Public Education in England and Wales" for 1908–9 is now available (Cd. 5355). It deals entirely with educational statistics. New tables have been added this year giving particulars as to the occupations of the fathers of pupils and as to the previous education of pupils in secondary schools. The tables dealing with technical education remain much the same as in previous years. Before giving particulars as to the number of technical institutions in England, it must be pointed out that the Board of Education defines a technical institution as one giving an organised course of instruction in day classes, including advanced instruction in science, or in science and art, and provided with a staff and equipment adequate for the purpose. Provision must be made in such institutions for at least a two years' systematic course in science, or in science and art, either alone or in conjunction with subjects of general, commercial, manual, or technological instruction. Except in special cases no student may be admitted to the course unless he has passed through at least a three years' course of instruction in a "recognised" secondary school, or is more than sixteen years of age and qualified by his general education to profit by a course of advanced instruction. In 1908–9 forty such institutions were recognised by the Board of Education, and they provided 121 courses. The number of teachers in the institutions was 787, and the number of students who attended at any time during the year was 3314. Of the teachers 766 were men, and of the students 3091 were boys and men. As regards the age of the students, it may be said that 1046 were under eighteen years of age. The number of efficient secondary schools on the Board's grant list was 804 in 1908–9. These schools provide a progressive course of instruction in the subjects necessary to a good general education upon lines suitable for pupils of an age-range at least as wide as from twelve to sixteen or seventeen. Among other things, an adequate proportion of the pupils must remain at least four years in the school. In these 804 efficient schools there were 4338 men- and 4098 women-teachers teaching 73,270 boys and 62,401 girls.

SOCIETIES AND ACADEMIES.

MANCHESTER.

Literary and Philosophical Society, October 4.—Mr. Francis Jones, president, in the chair.—T. **Thorp**: A method for preventing the tarnishing of silver-on-glass parabolic mirrors. The mirror was carefully levelled on a turntable, and its axis of rotation made coincident with that of the turntable. The whole was then rotated uniformly at the calculated speed required to cause a liquid to assume the same parabolic form as that of the mirror. A 1 per cent. solution of "Schering's" celloidine in amyl acetate (after a lengthy period of settling) was flooded on to the surface of the mirror to a depth of about one-third of a millimetre. This was allowed to dry very slowly, when the resultant film was found to have a perfectly even surface of a thickness of about 1/300th of a millimetre. On testing the mirror no perceptible loss of definition was observed, and in actual use the performance was satisfactory. It is absolutely essential for the success of the method that the mirror be quite enclosed, and exposed only to an atmosphere of amyl acetate so as not to be allowed to dry, for about one hour after the solution has been flooded on, as, without this precaution, a perfectly uniform film cannot be obtained.—Dr. Henry **Wilde**: The origin of cometary bodies and Saturn's rings. The first part of this paper is a further exposition of the author's theory of the origin of comets and cometary bodies from the interior of the planets of the solar system, with new illustrations drawn from experimental mechanics. Dr. Wilde considers that the recently discovered satellites of Jupiter and Saturn, which have retrograde motions, are planetary ejectamenta, and from their comparative minuteness are hardly entitled to rank as satellites. The theory advanced by Olbers, the illustrious discoverer of Pallas and Vesta, that the planetoids are fragments of an exploded planet, finds confirmation in the great irregularities of their orbits and the direct and retrograde motions of cometary bodies. The author next discussed the origin of Saturn's rings, which has for a long time engaged the attention of natural philosophers. Kant assumed that Saturn at an early period of its history had the characteristics of a comet, and that its tails contracted upon the planet and formed a ring. Laplace supposed the rings to be the original nebular substance uncondensed into the form of a satellite. The author ventures to affirm that the rings are the ejectamenta of Saturn when its diminishing energies were insufficient to eject a comet with its train of meteorites, or a cometary satellite. Dr. Wilde adduced evidence to show that the interior rings were formed some time subsequently to the outermost one, which is separated from the others by an annular space of 2585 miles. The author has drawn up a table of distances of the rings from Saturn and the times of their revolutions, calculated from his measurements of the photographs recently taken at the Lick Observatory.

NEW SOUTH WALES.

Linnean Society, August 31.—Mr. C. Hedley, president, in the chair.—Dr. H. G. **Chapman**: A contribution to the study of the precipitins. The paper records the results of an examination, by gravimetric methods, of the relations of the interacting substances in precipitin interactions. It was found that the amount of precipitate yielded by each antiserum was a fixed quantity for each cubic centimetre of antiserum, provided that sufficient homologous protein was present to precipitate completely the precipitin in the antiserum. In total interactions the weight of precipitate was proportional to the amount of antiserum. In partial interactions the weight of precipitate increased with ascending weights of homologous protein. Since the precipitates are derived mainly from the antiserum, it has been possible to determine the weight of the anti-substance in the antiserum. Consequent on the results of the gravimetric study of the interaction, a method has been devised to separate the proteins of closely allied species. Suggestions are made as to the composition of a precipitin-antiserum, as regards the components, giving rise to general avian and specific interactions. The preliminary results of the application of the test to the differentiation of vegetable proteins are recorded. They show that a group-specificity holds for proteins of vegetable origin. The derivation of precipitate from antiserum has not been sufficiently considered in relation to deviation of complement.—Dr. A. J. **Turner**: Revision of Australian Lepidoptera, part v. Part v. deals with the subfamily Geometrinæ of the family Geometridæ, comprising 40 genera and 124 species. The number of known species has been greatly added to, especially from the northern part of Australia, since the publication of Mr. Meyrick's "Revision of Australian Lepidoptera, No. ii., Geometridæ," in the society's Proceedings for 1887 (p. 835).—A. F. Basset **Hull**: Description of a fossil Chiton (Mollusca) from north-west Tasmania. The description is based on an example of a median valve, which shows the species to have been allied to, but distinguishable from, *Lorica affinis*, Ashby and Torr, and the living *L. volvox*, Reeve. The specimen was collected by Mr. W. S. Dun from the base of the Turritella sandstone at the foot of a bluff between Wynyard and Table Cape. The beds are referred to the Jan Jukian by Hall and Pritchard; that is to say, they are near the base of the Tertiary, as developed in southern Australia. Victorian geologists correlate them with the marine series at Spring Creek. The Eocene age attributed to these beds must be regarded as purely relative.

DIARY OF SOCIETIES.

FRIDAY, OCTOBER 21.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—The Standardisation of Locomotives in India, 1910: Cyril Hitchcock.

WEDNESDAY, OCTOBER 26.

BRITISH ASTRONOMICAL ASSOCIATION, at 5.—Annual Meeting.

FRIDAY, OCTOBER 28.

PHYSICAL SOCIETY, at 5.—Demonstration of a New Method for producing High-tension Discharges: Prof. Ernest Wilson and W. H. Wilson.—The Behaviour of Steel under combined Static Stress and Shock: F. Rogers.

ANCIENT PLANTS.

Ancient Plants: being a Simple Account of the Past Vegetation of the Earth and of the Recent Important Discoveries made in this Realm of Nature Study. By Dr. Marie C. Stopes. Pp. viii+198, with 122 figures and frontispiece. (London: Blackie and Son, Ltd., 1910.) Price 4s. 6d. net.

FOSSIL botany, once the very type of a dry-as-dust subject, has attracted a good deal of attention of late years, and its more important discoveries and conclusions have become the common property of students of botany, at least in this country. Miss Stopes aims at interesting a wider class. "There is no book," she says, "in the English language which places this attractive subject before the non-specialist, and to do so is the aim of the present volume"; further on she adds that her book is dedicated "especially to all those who take an interest in plant evolution, because it forms a thread in the web of life whose design they wish to trace."

The author is well qualified for her work, and has attained a considerable measure of success. Her style is interesting, and if sometimes a little careless, that is, after all, a minor point. Miss Stopes is somewhat severe on her predecessors, of whose work she speaks thus: "But, like the records left by the plants themselves, most of this literature is unreadable by any but specialists, and its really vital interest is enclosed in a petrifying medium of technicalities" (p. 2). Her object is to make these dry bones live, but it has been tried before.

The chapters on the various kinds of fossil plants and on coal are very well done, especially the account of coal-balls, those calcareous nodules which contain the wonderful structural specimens on which our knowledge of coal-plants so much depends. On this subject the author is a leading authority.

The "Seven Ages of Plant Life" (chap. iv.) range from the archæan to the present day; the sacred number seven may have a charm for some; otherwise we should have thought a shorter list would have been more useful; there are only four really important periods to be distinguished in the history of plants as known at present. The chapter on stages in plant evolution is wisely kept quite elementary, any general discussion of the evolution of the various groups being necessarily postponed until all have been studied. The assumption that life is "endowed with a continuous impulse to advance" (p. 43) will strike the Darwinian reader as unduly mystical.

The diagrams and curt descriptions of cells and tissues of recent plants given in chap. vi. will scarcely help the general reader very much; unless he has had more training in botany than this, he had better leave the anatomy of fossil plants alone. The truth is that fossil botany, if it is to include structure, is *not* a subject for a beginner. Those, however, who have done some laboratory work before may find this outline of anatomy of some service by way of recapitulation.

Ten chapters are devoted to the past histories of plant families, and form the main division of the book. It is impossible to follow these chapters in detail; on the whole, they give a very good sketch of some of the chief results of modern research, but their merits will be best appreciated by those who have some previous knowledge. The author has some incisive remarks on the modern theory of the origin of Angiosperms from Cycadophyta, allied to the Bennettitales; she says: "We must not forget that the Bennettitales have only recently been realised fully by botanists, and that a new toy is ever particularly charming, a new cure particularly efficacious, and a new theory all-persuasive" (p. 103). This is quite a fair hit, but the next paragraph is less happy. In criticising the supposed primitive position of the Ranales among Angiosperms, the author states that they are most frequently delicate herbs, and that they are peculiarly remote from the group of Bennettitales in their vegetative structure. Really it is the shrubby Magnoliaceæ which chiefly come into the question; in the structure of the wood some of these plants are more like Gymnosperms than any other of the Dicotyledons.

The concluding chapter, which includes an ingenious attempt to forecast the future course of plant-evolution, is very interesting. It is perhaps a pity that in the space of about one page the author tries to give an idea of the mutation theory as opposed to pure Darwinism. An altogether misleading idea of Darwin's position is given, and the whole question would have been better omitted in a book for beginners.

In the appendices some hints on the collection of fossil plants are given, followed by a short bibliography. It is rather hard on Mr. Kidston that he is only represented by his British Museum catalogue of 1886, a list which he would certainly regard as now out of date. The book concludes with a glossary of some botanical and geological terms.

Most of the illustrations are good and useful; a few, especially some of those from photographs, are less clear than is desirable in an elementary book.

Although, as we have seen, there are some points open to criticism, Miss Stopes's book is an enterprising and able attempt to popularise a difficult subject. The really keen student will undoubtedly be stimulated to pursue the study of fossil plants further, and even those who are not students will get some new ideas and derive a certain amount of interest from a book which is sometimes brilliant and never dull.

D. H. S.

BRITISH RAINFALL.

British Rainfall, 1909. By Dr. Hugh Robert Mill. Pp. 120+308. With maps and illustrations. (London: Edward Stanford, 1910.) Price 10s.

THIS volume is the forty-ninth of the series, and the largest hitherto issued, but the price remains the same as when it was a quarter of the size. The value of the work of the British Rainfall Organisation in all questions in which an accurate knowledge of the rainfall is essential has been acknowledged on all sides, and has frequently been referred to in our columns. Owing to the continual growth of the work, the director, who for many years has received no financial help except from the observers themselves and a few subscribers interested in the subject, has in recent years had to meet a considerable deficit. In order to ensure the undertaking "from the risks of mortality," he has made over the unique collection of documents and his interest in the concern to a strong representative body of trustees, who have formed an endowment fund, while Dr. Mill will continue to act as director, as before; this arrangement was referred to in our issue of June 16.

Part i. includes an interesting article by Mr. Gethin Jones on the snowfall of the Snowdonian range; one of the photographs shows a large patch of snow lying on June 29 last; also a discussion of the duration of rainfall in 1909 by the editor. In part ii., eighty pages are occupied by observers' remarks; the director has hinted elsewhere that the space might be more serviceable for printing additional monthly values. In addition to the usual tables, interesting chapters are devoted to the discussion of heavy rains in short periods and on rainfall days, with maps illustrating some of the greatest falls. There are also maps showing (1) the amount of rainfall and (2) percentage of average, with a short discussion, for each month. For the British Isles, as a whole, the rainfall of the year (38·56 inches) was exactly the average; but during the last twenty-one years dry years have been more than twice as frequent as wet ones. Reference is made in the report to a crusade against entering the rainfall to the wrong day. This is most important, and, unless one rule is adhered to, accurate maps of monthly rainfall cannot be drawn. But, notwithstanding the efforts of meteorological conferences to ensure uniformity, differences do still exist in some of the best foreign services. To take only one case, the Austrian "Instructions" (1905, p. 17) correctly direct that, even when known to have fallen in the early morning, the amount should be entered to the previous day, while the Norwegian "Year Book" (1909, p. ix) says the rainfall measured in the morning is entered to the preceding day, except when it is known for certain that it fell after midnight.

INDIAN CRUSTACEA.

Catalogue of the Indian Decapod Crustacea in the Collection of the Indian Museum. By Lt.-Col. A. Alcock, F.R.S. Part i., Brachyura. Fasciculus i., Introduction and Dromides or Dromiacea (Brachyura Primigenia). 1901. Pp ix+80+viii plates. Price 7 rupees. Fasciculus ii., The Indian Fresh-water Crabs—Potamonidæ. 1910. Pp. iv+135+xiv plates. Price 14 rupees. (Calcutta.)

THE "Catalogue of the Indian Decapod Crustacea," which is in course of publication by the Trustees of the Indian Museum, Calcutta, consists of a series of independent fascicles, each complete in itself, and forming a systematic monograph of the Indian species in the group with which it deals. The two parts under notice relate to the Brachyura. The first, published nine years ago, contains a general introduction to the series giving an outline of the morphology of the Decapoda, so far as it is necessary for systematic purposes, and describing as a type *Nephrops andamanica*, a form closely resembling the Norway lobster of our own coasts. This is followed by a statement of the characters distinguishing the Brachyura or true crabs, and a sketch, all too short, of their bionomics, with special reference to the Indian species, prefacing a systematic account of those belonging to the Tribe Dromiacea. This tribe is of special interest on account of the very primitive character of some of its members, which enable the origin of the Brachyura to be traced back, as Bouvier showed, to the lobster-like Nephropsidea. Many important types were captured by the *Investigator* in the Bay of Bengal, and are fully described and figured in this fascicle.

The group of Brachyura dealt with in the second fascicle is also of special interest, although for very different reasons. The river-crabs of the family Potamonidae (formerly known as Telphusidae) are found in fresh waters throughout the tropical regions of the world. Their geographical distribution has been especially studied by Dr. A. E. Ortmann, who used it in his ingenious speculations regarding the former distribution of land and water on the surface of the globe. The geographical relations of any group of organisms, however, can only be studied with profit when their systematic relations have been determined with some degree of certainty, and it happens that the river-crabs, like many other groups of fresh-water animals, present special difficulties to the systematist. There has hitherto been no general agreement with regard to the limits, not only of species and varieties, but even of genera and subfamilies, and the very valuable monograph of the family recently published by Miss M. J. Rathbun in the Archives of the Paris Museum, while immensely lightening the task of subsequent workers, made very obvious the unsatisfactory character of much of our knowledge of the group. Lt.-Col. Alcock now directs attention to certain structural characters, hitherto for the most part overlooked, which enable the species to be grouped in well-defined categories, and he proposes an entirely new classification, in which species hitherto placed side by side in the same subgenus are widely separated in distinct subfamilies. The application of this classification to the river-crabs inhabiting other regions is only hinted at in this memoir, but there can be no doubt that it will greatly modify our conceptions of their geographical relations.

In the power of terse and lucid description, in the acute perception of systematic affinities, and in the breadth of view derived from a familiarity with many diverse groups of the animal kingdom, Lt.-Col. Alcock has few equals among living carcinologists, and it is a matter for congratulation that his retirement from the post of superintendent of the Indian Museum has not terminated the long series of important memoirs on the Indian fauna which we owe to his pen.

W. T. C.

NATURALISTS' NOTES FROM THE OLD SPANISH MAIN.

Our Search for a Wilderness. An account of two ornithological expeditions to Venezuela and to British Guiana. By Mary Blair Beebe and C. William Beebe. Pp. xix+408. (New York: Henry Holt and Co.; London: Constable and Co., Ltd., 1910.) Price 10s. 6d. net.

A FEW years ago the authors wrote a pleasant little book, "Two Bird-lovers in Mexico." The present "Search for a Wilderness" did not prove difficult, because they found one in the mangrove swamps on the old Spanish main, opposite the island of Trinidad. They hired a little sloop, and cruised about on the San Juan river, which falls into the Gulf of Parian. The mud-flats teemed with life, and after nightfall arose the many quaint and mysterious sounds of the tropical jungle. For one of these sounds, a muffled choking, they found an unexpectedly simple explanation. The anaconda makes its lair in a hole in the bank at the waters' edge. When the rising or falling tide laps into or out of the vacated mudhole, a big bubble of air frees itself with a sudden gasping sob. Further up the river they visited La Brea, the strange lake of pitch in the midst of a region of primeval forest.

Whilst on this visit to Venezuela the collecting of birds was incidental; they went in the spring of 1909 to British Guiana, accompanied by an assistant, to collect birds in earnest; but Mr. Beebe is certainly not a destructive ornithologist. His party killed only about one hundred specimens, and these because of some special interest, and there occurs the following passage which deserves quoting. "We were glad to find that the most difficult privilege to obtain is a permit to collect birds, and the very stringent laws in this respect are an honour to the Governor (Sir Frederick Hodgson, K.C.M.G.), and his colonial officials. Thanks to the absence of the plume and general milliner hunter, the game hog, and the wholesale collector, birds are abundant and tame."

From Georgetown as their centre they made several trips. Hospitably entertained, and being spared all the usual annoyances of transportation, they visited, by launch, the Hoorie gold mines in the north-western corner of the colony, an excellent place for studying the ways of its wild inhabitants. Thence they made their way back to the capital, threading little-known rivers and creeks in a canoe, and for five days they were paddled, portaged, towed, and pushed through a wonderland abounding in beautiful birds, butterflies, and orchids, and they were made welcome for the night at little isolated Indian missions.

Next followed a trip up the Essequibo and one of its tributaries to the Aremu mine. In these waters they saw the little freshwater flying fish, *Carnegiella spigatus*, which, however, "did not leave the surface entirely, but skimmed steadily along in a straight line, with the tip of the deep keel of the abdomen just cutting the surface." The travellers were keen and lucky enough to make many interesting observations, which they have recorded in a pleasantly easy style, illustrated with numerous good photographs of scenery and scenes of many creatures, from man to insects. A narrative sparkling with incidents needs no froth like the following: "Most curious of all were the Loricates or armoured catfish, with a double row of large overlapping scales enclosing their body from head to tail. Like the Hoatzin among the birds, these fish are strange relics of the past, preserved almost unchanged from the ancient fossil Devonian fauna." Relics of the past, by all means, but what have the Siluroid Teleostean fishes to do with the Devonian epoch?

A visit to the savannahs and lagoons of the Abary river, with its abundance of bird life, for instance, large colonies of the quaint Hoatzin, was cut short by a broken wrist suffered by the lady. We wish them many more such pleasant trips, and may they not be undeceived in their optimistic opinion as to "the falsity of most of the universal slanders on a tropical climate."

GRAPHICAL CHEMISTRY.

Leitfaden der graphischen Chemie. By Dr. R. Kremann. Pp. 36+5 modelle. (Berlin: Verlag von Gebrüder Borntraeger, 1910.) Price 6.60 marks.

IN view of the importance of a knowledge of the equilibrium relationships which are involved when two or more substances are brought together in different quantities under different conditions of temperature and pressure, and of the rapid progress which has been made in recent years in the study of more complicated cases of such equilibria, it is essential that the student of physical chemistry should be familiar with the various methods which are used for the graphic representation of experimental results.

There can be no doubt that the interpretation of the space models, which are employed with great advantage to depict the equilibrium relationships of ternary and quaternary systems, offer considerable difficulties to those who are not familiar with the subject. This is the author's experience, and the issue of a series of five adjustable cardboard models, with an explanatory guide, is intended to facilitate the acquirement of a knowledge of the rudiments of graphical chemistry.

The cardboard models, which are made to scale from experimental data, represent respectively the equilibrium relationships in the following systems—(1) Silver nitrate and water (2) potassium sulphide, magnesium sulphate and water (3) tin, lead and bismuth (4) ammonium nitrate, water, methyl alcohol and ethyl alcohol (5) water and the reciprocal pairs of salts —sodium chloride + ammonium hydrogen carbonate $\rightleftarrows$ ammonium chloride + sodium hydrogen carbonate.

These systems afford sufficient material for an exposition of the various modes of graphic representation, but it is very doubtful whether prepared models of this character can be of much service to the student whose aim is thoroughly to understand the connection between the space models and the actual experimental data. In the reviewer's opinion the requisite familiarity can only be obtained when these data are directly utilised by the student in the actual construction of equilibrium models. This demands the expenditure of considerable time, but the results obtained are incomparably better than those which follow from the manipulation of prepared models. On the other hand, the cardboard models are to be preferred to the plane projections which form the usual text-book method of graphic representation. From this point of view the series of models may be found to be useful, anl would have been more so if the explanatory matter in the accompanying text had been considerably extended.

AMATEUR ASTRONOMY.

The Amateur Astronomer. By Gideon Riegler. Translated by G. A. Clarke. Pp. 319, with 112 illustrations. (London: T. Fisher Unwin, 1910.) Price 3*s.* 6*d.* net.

DESPITE the host of astronomy books which has appeared in recent years, there may be room for a well-written, concise guide-book for the beginner in practical work; but, even if there is, we fear that the volume under review does not fill it adequately.

The author first deals with the questions of site, instruments, books, &c., and then proceeds to give a series of notes on the characteristics of the individual objects observable with a modest equipment. Thus the constellations are taken, and the peculiarities of selected individual stars described. Then the same form of treatment is given to double-stars, star-clusters and nebulæ, and variable stars, followed by a chapter describing solar features. In the chapter on the moon, which comes next, a large number of individual craters, plains, &c., are described, but, in the absence of a complete map, the beginner will find, despite the inclusion of undefined latitude and longitude, that some of the smaller features figured are not easy to locate. Chapters on the planets, comets, and meteorites and shooting stars complete the tale.

The general scheme of the work is not unattractive, but grave faults mar its execution. Simple points are treated discursively, whilst more difficult ones, on which the amateur should have clear, if elementary, information, are passed over with one or two imposing terms. An example or two will serve to show that it would have been better to omit many items altogether; dogmatic statements may convince the beginner, but the greatest care should be taken to convince him rightly.

For example, oxygen and cadmium (p. 154) are *not* exceptionally prominent elements in the sun, and certainly do not provide the crucial difference between its spectrum and that of Aldebaran; nor is mercury an outstanding feature of the latter. But worse follows, for we are informed that, while hydrogen is not represented in the spectrum of Betelgeuse, thallium is such a prominent feature "that its lines stand out quite plainly, *in spite of the great distance of the star*"; the italics are ours. There are only two or three pages of spectroscopical details, but it is a great pity that they were ever published.

Other matters, apart from spectroscopy, could be quoted to the same effect, but the above will probably suffice to show that the book is marred by serious faults, dangerous for the beginner.

It only remains to add that the work often bears the impress of translation; long and involved sentences are not uncommon, and such inversions as "6 magnitude," "4·5 magnitude," used almost throughout, are annoying.

W. E. ROLSTON.

OUR BOOK SHELF.

A Guide for Medicine and Surgery, compiled for Nurses. A Handbook for Nurses. By Sydney Welham. Pp. ix+230. (London: Mills and Boon, Ltd., 1910.) Price 3*s.* 6*d.* net.

IN order to do their work satisfactorily, nurses require some knowledge of the principles of medicine and surgery. This is fully recognised in every modern hospital, and due provision is made for instruction of the nursing staff in the elements of anatomy, physiology, pathology, medicine, and surgery. Courses of lectures on these subjects are arranged and the nurses are encouraged to supplement lectures by reading. There is no doubt that a small handbook, such as the volume under review, will be found very useful for purposes of reference, although it makes no attempt to replace the recognised text-books. The style is simple and direct, the type is clear, the index is admirable, while a glossary of medical terms, a list of Latin phrases commonly used in prescriptions, with many other practical tables, diet scales, recipes, &c., greatly enhance the value of the book. It is eminently practical and convenient.

It would be ungracious to criticise a small volume which deals with every branch of medicine in 230 pages on the ground that it did not contain original matter. It succeeds in giving a great deal of information, and the views expressed are in accordance with modern thought. In a short preface the author disclaims any attempt to teach nursing, but, nevertheless, many of his hints will be useful even to nurses of considerable experience, while it will be of real value to young probationers. It will help them to understand the cases that come under their care, it will enable them to follow clinical instruction in the wards, and it will serve as a handbook on which they can rely for assistance in practical emergencies, and also when they are preparing themselves for examinations.

The Death-dealing Insects and their Story. By C. Conyers Morrell. (Manchester: H.A.W. Offices, 7 Brazenose Street, 1910.) Price 1*s.* net.

THIS little book is one of the many which have been recently published for the purpose of instructing the laity regarding recent discoveries in connection with insects and disease. It is one of the best of them, and possesses a good style without being too diffuse. The connection of mosquitoes, tsetse-flies, ticks, and fleas with malaria, elephantiasis, sleeping-sickness, tick fever, and plague are described in a manner which will appeal to laymen. We miss the name of Bruce in connection with trypanosomiasis, and though the excellent Campagna experiment of 1900 was useful for advertisement, it can really scarcely be cited as conclusive proof of the mosquito theory of malaria.

The author seems to be rather optimistic as to the results of sanitation in West Africa, regarding which little genuine evidence is forthcoming. He is wise in not paying too much attention to the numerous scientific "Mother Shiptons," who have so frequently attempted to gain credit for discoveries on the strength only of their prophecies. But the book can safely be recommended to such of our lay friends as meditate living in the tropics. R. R.

Abhandlungen Jean Rey's, über die Ursache der Gewichtszunahme von Zinn und Blei beim Verkalken. Deutsch herausgegeben und mit Anmerkungen versehen. By Ernst Ichenhäuser and Max Speter. Pp. 56. (Leipzig: W. Engelmann, 1909.) Price 1.20 marks.

JEAN REY'S "Essais sur la recherche de la cause par la quelle l'estain et le plomb augmentent de poids, quand on les calcine" have been familiar to English readers for some years past, through the valuable agency of the Alembic Club, which has issued an English translation as one of their series of reprints. The present German translation is published as No. 172 of Ostwald's Klassiker der Exakten Wissenschaften. The essays, written in 1630, contain a remarkable discussion on an increase in weight which had been observed, by an apothecary at Bergerac named Brun, to take place during the calcination of metallic tin in an iron vessel. The conclusion, arrived at by argument rather than discussion, that the gain in weight was due to the condensation of air, was a remarkable anticipation of views that were not generally accepted until the time of Lavoisier, 140 years later. The German reprint is provided with a valuable series of notes dealing with the history of the essays and with various points requiring elucidation in the essays themselves.

Elementary Regional Geography. Great Britain and Ireland. By J. B. Reynolds. Pp. viii+184. (London: A. and C. Black, 1910.) Price 1s. 4d.

Cambridge County Geographies. Nottinghamshire. By Dr. H. H. Swinnerton. Pp. xi+153. *Lanarkshire.* By Frederick Mort. Pp. viii+168. (Cambridge: University Press, 1910.) Price 1s. 6d. each.

MISS REYNOLDS has written an interesting and easy account of the geography of the British Isles which will be useful as an introduction to the subject. A few practical exercises for young pupils to work have been introduced; but the book would have been more valuable had this aspect of the teaching been more prominent. The excellent illustrations will certainly secure the attention of juvenile readers.

A very broad view of geography is taken by the writers of the latest additions to the "Cambridge County Geographies." Space is found by each author, in a slight treatment of a large subject, for sections on antiquities, ecclesiastical, military, and domestic architecture, and on the history of the county. Both volumes are well up to the high standard reached by other books in the series.

The Cambridge Pocket Diary for the Academical Year 1910–11. Pp. xv+255. (Cambridge: University Press.) Price 1s. net.

BOTH the staffs and students of schools and colleges will find this pocket diary very convenient. Beginning with September 20, 1910, and extending to September 30, 1911, it covers every length of academic year, and will be useful in all educational centres. Besides this interval of time, for which full space is given, several pages are devoted to the weeks until the end of 1911, so that important engagements for the early part of the succeeding professional year can be booked. The diary also contains a useful miscellany of general information.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Biological Laboratories at Woods Hole.

I HAVE noted with interest a recent discussion in NATURE of August 25 and September 15 and 29 in which the biological laboratories at Woods Hole have received incidental mention. I pray that you may give me this opportunity to correct some very prevalent misconceptions regarding the status of the Government station there. In NATURE of September 15 Prof. MacBride has voiced some of these misconceptions very clearly. "It is true," he writes, "that there are *two* stations in Woods Hole, one supported by the Federal Government and devoted entirely to economic work, and the other supported entirely by zoologists; but the station which has attained world-wide fame, owing to the quantity and quality of the research which has issued from it, is the second and purely scientific one" (pp. 330, 331).

Now, although Prof. Herdman has pointed out in two letters the misleading character of these statements, it appears that Prof. MacBride is "of the same opinion still," for in your issue of September 29 he avers:—"That valuable scientific work of general interest occasionally issues from the laboratory of the U.S. Bureau of Fisheries, which was founded and is maintained for research on economic lines, is totally irrelevant" (p. 396).

What the United States Fish Commission[1] laboratory at Woods Hole was originally founded for may best be gathered from a perusal of the earlier annual reports of the first commissioner, the naturalist Spencer F. Baird. He emphasises more than once the futility of attempting to deal broadly with fisheries problems without an intelligent understanding, not only of marine life as a whole, but of all the various physical and chemical factors which may affect this. (See especially first report of the commissioner, p. xiii.)

The whole history of the United States Fish Commission, and of the Woods Hole station in particular, bear abundant testimony to the sincerity of this broad-minded attitude of its founder. The pioneer faunistic work of Verrill and his colleagues in the 'seventies and 'eighties was carried out very largely under the auspices of the National Fish Commission, and Woods Hole was the chief headquarters from which these explorations were conducted. Furthermore, one need only refer to the past reports of the commission to find in the list of those who have worked at the Woods Hole station many of the most prominent names in American biology. Here we meet, for example, with the names of Farlow and Gill, of E. B. and H. V. Wilson, of Morgan, Bumpus, Andrews and Eigenmann, to say nothing of Brooks and Ryder, who have passed away. These men were not, for the most part, engaged upon "economic" problems in any strict sense of the word. And in more recent years some of the physiological work of G. H. Parker, C. J. Herrick, W. B. Cannon, E. P. Lyon and others, has been conducted in the Fish Commission laboratory, as well as the taxonomic work of such men as Edwin Linton, C. W. Hargitt, C. C. Nutting, W. M. Wheeler, H. L. Clark, and C. B. Wilson.

I regret that anything like a defence of the scientific status of the Fisheries Laboratory has been necessary in these columns, for the facts here stated are well known to every American zoologist who is familiar with conditions at Woods Hole. But unfortunately all zoologists, even in America, are *not* familiar with the conditions at Woods Hole, and the misconceptions voiced by Prof. MacBride are still held tenaciously in certain quarters.

As Prof. Herdman has pointed out, there are two scientific laboratories at Woods Hole. But conditions are even more complicated than this, for the Bureau of Fisheries itself maintains two more or less independent institutions there. One is the biological laboratory, maintained by

[1] Changed in 1903 to the Bureau of Fisheries of the Department of Commerce and Labour.

the Bureau's "Division of Scientific Inquiry," the other the hatching station, maintained by the "Division of Fish Culture." These two establishments are under different heads, and are, so far as possible, independent of one another, though they to a large extent share the same buildings. The biological laboratory, in the general scope of its work, does not differ widely from the other leading marine laboratories of the world. It is true that greater emphasis is laid upon the economic aspect of marine biology, and a number of investigators are each year employed by the Bureau to conduct researches upon such subjects as the food value and chemical composition of marine organisms, or upon problems directly related to the natural history of food fishes; but to say that investigations are restricted to such lines is to do great violence to the facts. The Bureau has always put a liberal construction upon the word "practical," realising that no hard-and-fast line should be drawn between pure and applied science, and regarding all information as ultimately useful which gives us a deeper insight into the life of the sea.

The two biological laboratories at Woods Hole—the "Marine Biological Laboratory" and that of the Bureau of Fisheries—have worked together side by side since the establishment of the former in 1888. The choice of its name by the privately supported institution has—unintentionally, of course—been the source of much of the misapprehension of which I am speaking. The name, "*The* Marine Biological Laboratory," would seem to imply an exclusive occupancy of this field, whereas the United States Fish Commission was conducting biological work at Woods Hole as early as 1871, and its present laboratory building was erected in 1885.

Another source of misconception is the fact that the Fisheries Laboratory has no definite organ of publication. Its scientific results, so far as they are economic or faunistic, or in any way related to the natural history of the sea, are in a large measure published in the Bulletin of the Bureau of Fisheries. The results in other fields of work are embodied in papers—and the number of these is great—scattered through all our various biological journals in this country and abroad. On the other hand there exists the "Biological Bulletin," which is the official organ of the Marine Biological Laboratory, though it also accepts contributions from workers in all parts of our country, oftentimes including those in the Fisheries Laboratory at Woods Hole. It is needless to add that the Marine Biological Laboratory does not make the least pretence that this journal represents its own output in any exclusive sense.

But, after all, the main source of confusion relative to the two laboratories at Woods Hole is the fact that the biologists there form a single scientific community, the members of which mingle freely together without regard to their place of work. In fact, the same investigator may work one year in one laboratory, the next year in the other, or he may even hold tables in both simultaneously; and so the reading public lumps together all our productions as Woods Hole work, and draws no fine distinctions. In the circumstances, it is natural that the laboratory which bears the name of "*The* Marine Biological Laboratory" should be frequently credited with the entire output. This is written in no spirit of resentment, but merely as an explanation of the prevalence of this widespread misconception of the situation at Woods Hole.

It will be cheerfully granted that the "Marine Biological Laboratory" accommodates a much larger number of investigators—perhaps twice as many, on the average—as does its sister institution; and it is not likely that anyone connected with either laboratory fails to recognise that a considerably greater output of scientific results must at present be credited to the former. On the other hand, the Government laboratory had, until recently, the only really efficient steam vessels available for scientific research, and has had other decided advantages in its physical equipment. But we at Woods Hole waste little time in idle comparisons such as these. Most of us are too busy endeavouring to make an occasional contribution to our common science.

Whether or not the two laboratories will continue to cover so largely the same field of activity it remains for the future to decide. These are some good arguments for a greater division of labour than at present exists.

FRANCIS B. SUMNER.
(Director, Biological Laboratory of the U.S. Bureau of Fisheries at Woods Hole, Mass.)

Washington, D.C., October 12.

The Cocos-Keeling Atoll.

I CONSIDER myself fortunate that the author of the review of "Coral and Atolls," which appeared in NATURE of October 6, has addressed two direct questions to me, for in the answering of these questions it may be possible to open in a more frank manner the discussion of those problems with which I have dealt, and which are to be solved by dispassionate argument and investigation rather than by anonymous destructive criticism.

The first question which the reviewer puts to me is couched in the following form: he rightly asserts that I assume the lagoon of an atoll to be a slightly submerged reef, and then he asks, "Why this assumption without evidence?" For answer I would point out that the evidence is given freely in the work which he reviews (notably at pp. 251–2, and elsewhere), and, since he has apparently overlooked it, I will repeat that it consists, among other things, of the fact that submerged atoll-shaped reefs, and reefs also atoll-shaped, but of which some portion of the outer rim is awash, or on which some island débris is piled, are well-known geographical facts. The central part of the submerged reef forms the lagoon of the developed atoll, which is therefore not inaptly described as a "slightly submerged reef."

His second question is in connection with the mode of formation of atolls from the disintegration of high oceanic islands surrounded by a barrier reef. He asks me how I would explain "Agassiz's wonderful series of photographs of Fijian islands within barrier reefs" when I state that "the picture of the high island towards the completion of the process, when, after having stood resisting in a troubled sea, it so conveniently crumbles to pieces within the calm of an encircling barrier reef, appears to me to be contrary to all natural laws." I would give as explanation the very obvious suggestion that the formations illustrated (I presume in Bull. Mus. Comp. Zool. Harv., vol. xxxiii.) are not the outcome of the development of the barrier reef, for similar conditions are found, quite apart from any coral structures, all over the world, the coast-lines of islands in northern seas providing equally good examples.

It may perhaps be permissible to extend this reply so as to embrace the answers to some assertions of the reviewer regarding corals and coral islands, and to point out some misquotations from the work under discussion and some misconceptions of its conclusions.

The variability of the growth forms of corals is one of the problems discussed, and I have urged that sediment—as a factor of the environment—is a potent cause of modified coral growth. That the environment as a whole, and not merely the presence of silt, was considered, may be gleaned from the discussion of the growth of young colonies of Pocillopora (p. 100).

The reviewer turns from this to observe that the variability of corals "may aptly be compared to the growth shown by our forest trees in different environments. Reef corals, too, resemble trees in that they are largely dependent for their food on chlorophyll, which is present in minute algæ living in their digestive cavities. The coloration of most reef corals is largely due to these algæ, and their mode of growth is sympathetic to them in that the coral skeleton is deposited so as to expose the polyps to the maximum amount of light." The reviewer then adds, "Such appear to us the ordinary views of zoologists."

The only logical meaning that I can attach to this is that zoologists as a class ordinarily believe that the variability of the growth forms of corals—and of forest trees—is due to the fact that they contain chlorophyll in their tissues. That zoologists as a class would subscribe to this thesis appears to me unlikely, and the reviewer has yet to explain the variability of those corals which, as is well known, possess no symbiotic algæ.

It would seem almost unnecessary to point out to one who criticises this work as being "in no way scientific" that the argument that, because forest trees are largely dependent on chlorophyll for their food, and corals are also largely dependent on chlorophyll for their food, therefore the reactions of forest trees and corals to varying environments will be similar, is not strictly scientific either. That the final test of specific form of corals must be the characters of the zooid is a fact on which I have insisted throughout, and the similarity of zooids in dissimilar forms is a fact that I have noted, although the reviewer appears to have entirely overlooked it.

That Wayland Vaughan found no difficulty in transplanting corals does not surprise me, for many others (myself among them) have also experienced no difficulty in the mere transplantation—any more than in the mere transplantation of "forest trees"; the difficulty only comes in (as is expressly pointed out, p. 123) when the coral is transplanted to an environment in which its growth-type, developed in a different environment, is unsuitable. In the experiments described I have pointed this fact out, and dwelt especially on cases of removing corals from a rough-water environment to a place where still water and the deposition of sediment were the prevailing conditions. In doing these experiments I was unconsciously repeating those previously carried out by Ehrenberg. Darwin (quoting from Ehrenberg's "Uber die Natur," p. 49) states that "where there is much sediment placed so as to be liable to be moved by the waves, there is little or no coral: and a collection of living specimens placed by him on a sandy shore died in the course of a few days" ("Coral Reefs," p. 89).

To pass to another section of the article, the reviewer correctly says that I describe the encircling reef as "a mosaic inlay of coral fragments cemented together into a solid platform," and then adds, "*but there is no evidence that it was ever really examined*"! Apart from the ungenerous suggestion that in a fifteen months' investigation of the atoll the encircling reef was never really examined, and that the author drew on his imagination or on previous descriptions for what lay for ever open to his inspection, is the gross oversight that a chapter is devoted to this feature, that its structure and formation are described (pp. 163, 254, &c.), and illustrated at Plate xiii., which shows a fractured surface of the "mosaic inlay." Had the reviewer genuinely thought that the encircling reef was never examined he was over-generous in describing me as "a painstaking naturalist"; if he did not entertain this thought, then he did ill in embodying this remark in his article. It is obvious that in places the reviewer has failed to grasp the meaning of the text which he would criticise, and, in speaking of the encircling reef, he charges me with drawing deductions from "a similar platform . . . found at 13 feet above mean tide-level." I presume that this charge is based on the statement at p. 283, that "where these steps are evident, the *island rise* is 13 feet above mean tide-level." The "island rise" is explained (and figured at Plate xiv.) as the rise of débris piled on the breccia platform, and in the sentence immediately preceding that quoted it is definitely said that the "steps of breccia rise one above the other to a total number of three or four, and to a height of almost as many feet." What is actually found, and what the description would appear to clearly depict, is a portion of breccia platform elevated to a height of something less than 4 feet, surmounted by a pile of débris reaching to a total height of 13 feet. What ambiguity might be imputed to the text should have been removed by one glance at Plate xv., which was specially included to depict the condition. I would point out to the reviewer that had intact breccia platforms been found at 13 feet above mean tide-level more dogmatic statements concerning probable elevation might have been made.

The reviewer has not only laid himself open to the charge of having failed to survey with accuracy the material he criticises, but he has also slipped into misquotations. Concerning the base on which coral structures are built, he cites me as saying that "it matters not what the base may be so long as its platform comes within the *wind-stirred* area." This area (above the limiting line of sedimentation) is, in the passage misquoted (p. 246), and consistently throughout, called the *wave-stirred* area. The two things may appear identical to the reviewer, but I think that his failure to grasp the difference diminishes the value of his criticisms upon the point.

F. WOOD-JONES.

St. Thomas's Hospital Medical School.

I HAVE not a copy of Mr. Wood-Jones's work before me, but I regret misquoting him with regard to the *wave-stirred* (not *wind-stirred*) area; I still desire more information on *the limiting line of sedimentation*.

Readers of NATURE must decide how much scientific evidence is given that the lagoon of an atoll is a slightly submerged reef. Perhaps I misunderstand the term "slightly submerged reef." I do not regard the lagoon in an atoll, which was formed, as Darwin suggested, by subsidence, as covering a reef at all. I do not think the borings in the lagoon at Funafuti suggest a reef such as surrounds a lagoon, and I do not consider that the nature of the rock under atoll lagoons is or can be settled without borings. Some evidence was doubtless obtained by Mr. Wood-Jones by dredgings, &c., as his book shows he has as thoroughly examined his atoll as he was able, but I do not regard the existence of atolls and atoll-shaped reefs elsewhere as more than indirect evidence of that which exists at Cocos-Keeling.

In Fiji there are many elevated islands. Some of these have fringing and others barrier reefs, which superficially appear to be of the ordinary coral-reef type. Such reefs cannot have existed when the islands were first elevated, and it seems to me that Agassiz's photographs show that high islands do crumble to pieces within the calm of encircling barrier reefs. This process would certainly be *convenient* for the formation of fringing and barrier reefs round these islands if organisms exist there which prevent the processes of disintegration from extending below the water-line over certain areas around them. In any case, it seems to me certain that islands within barrier reefs are being removed by some agency or other, and that the resulting reefs would simulate atolls.

So far as I can find out in the Madreporaria, the extraordinary variability in growth form has only been described in reef-builders which possess, in some form or other, chlorophyll in their tissues. I do not think my paragraph on the subject will be misunderstood by your readers. I adhere to my statement that "our author does not appear to have examined the zooids to see whether he is really dealing in any genus with one or more species," and leave this question to be settled by your readers.

Of course, the encircling reef was *really* (or genuinely) examined, and with considerable care, but I certainly did not consider, from Mr. Wood-Jones's work, that there was internal evidence that he had *sufficiently closely* examined it. I cannot follow all Mr. Wood-Jones's paragraph, but I quite fail to see where I have charged him with drawing deductions as to the encircling reef from "a similar platform found at 13 feet above mean tide-level." It would perhaps have been better if I had not used the word *similar*.

THE REVIEWER.

Early Burial Customs in Egypt.

IN his letter to NATURE of October 20 (p. 494) Prof. Flinders Petrie says:—"The whole question lies in a nutshell. Many thousand graves have been examined by one party of observers, and certain results repeatedly found. Many thousand graves have been examined by another party of observers, in other localities, and such customs have not been found."

I would analyse the contents of the nutshell in a slightly different manner. Both parties, working in every region in Egypt, have found precisely the same state of affairs. One party, under the influence of the glamour of Egypt and what is said to happen in early Italy and Europe and modern Africa, interprets it as evidence of cannibalism and "Jack-the-Ripper" practices. The other has put forward a simple record of all the facts observed and the obvious explanation of them, and has found, not only no sign of any deliberate mutilation, but overwhelming evidence of the reality of the ancient Egyptian's profound reverence for the bodies of his dead relations, and of his horror of mutilating them, even for the purpose of making the incisions necessary for embalming.

Since this correspondence began, a full discussion of all the data relating to the subject under consideration has been published in the report for 1907–8 on the Archæological Survey of Nubia. There the facts will be found recorded for the use of anyone interested in the matter.

G. Elliot Smith.

Effect of Heat on Soils.

Mr. A. D. Hall in his opening address to the Agricultural Sub-section of the British Association at Sheffield mentioned "a process of heating the soil before sowing" and "a process of firing the soil preparatory to sowing the crop," both of which seem very similar to "burning bush" as practised in the West Indies. On reading Russel and Hutchinson's paper on "Partial Sterilisation of Soil" in *Journ. Agric. Sci.* for October, 1909, it struck me that their work afforded a probable explanation of "burning bush," and I now make the suggestion in the hopes of obtaining some evidence. The process seems to be similar to that known as *chena* in Ceylon, *ladang* in Malaya, and *jhuming* in India (see J. C. Willis, "Agriculture in the Tropics," pp. 1 and 2), and perhaps someone with experience of the East could throw further light on the question.

It is a common practice in Trinidad for a small cultivator to rent a piece of abandoned land, which is cleared by burning the "bush" in the dry season. In the wet season the clearing is generally planted with maize, which is usually followed by cassava, yams, tanias, &c. In a few years the cultivation is no longer remunerative, and the land, once abandoned, quickly goes back to "bush." One explanation is that the ashes of the burnt "bush" supply a certain amount of mineral plant food in a readily available form (the nitrogen in the plants burnt would, of course, be lost). This plant food would presumably produce an increased yield, but the effect would not last many years. Another—and I think a more probable—explanation is that the burning results in a partial sterilisation of the soil, with a greater production of ammonia. The fact that maize is the first crop grown after the "bush" has been burnt is significant, since it is a crop which is benefited by a nitrogenous manure.

The Colours and Spectrum of Water.

A perusal of the articles which have appeared in your journal on this subject (Nature, vol. lxxxiii., pp. 48, 68, 188, 487, and vol. lxxxiv., p. 87) leads me to ask if the spectrum of water has ever been thoroughly investigated. It is difficult to believe that this has not been done, and yet there is but little allusion to the important bearing the character of the spectrum must have upon the colour. I should be glad to learn what is the origin of a feature I have sometimes observed in the spectrum, as seen with a "miniature spectroscope" by Browning. This is a dark band or line at about wave-length 6000, which I noticed in June, 1887, in Sark, in clear water, both in the sea and in fresh water. The latter was bluish-green, and the sea was green. So far as this line would have any influence on the colour of the water, it would tend to make it blue; but the colour would be much more influenced by the very strong general absorption in the whole of the red and orange beyond the dark line. In the sea water this general absorption extended more feebly to the D line of the solar spectrum, and even to the dry-air band δ.

In the deep green water of Lago Maggiore the spectrum was almost identical with that of the sea at Sark; I made the wave-length of the dark line about 6050.

The Lake of Geneva is noted for the deep blue of its clear water. In it I failed to see the dark line, but the general absorption of the red end of the spectrum was very striking.

The bluest water I ever saw—bluer than the Mediterranean, Red Sea, or Indian Ocean (I have not been to Capri)—was, however, the Blaue See, near Kandersteg, and the Lago di Garda. In the former, pieces of pot at the bottom appeared pure Prussian-blue. During a stay of a few days by the Lago di Garda I could not make out the law of its changes in apparent colour, but at times it was far bluer than the bluest sky I ever saw. It usually had a slightly greenish tinge. Both these lakes are extremely clear. I regret not having observed their spectrum.

Luminous Paint.

Mr. C. A. Emery, of Marlborough College, has directed my attention to a passage in Livy (xxxix., 13) where the following occurs:—

"Matronas Baccharum cum ardentibus facibus decurrere ad Tiberim, demissasque in aquam faces, quia vivum sulphur cum calce insit, integra flamma efferre."

This he renders:—

"The Bacchantes would run down to the Tiber with burning torches, and plunging them into the water would take them out with the flame unextinguished, because they were covered with a mixture of living sulphur and lime."

The expression "vivum sulphur" is thus explained by Pliny:—

"In Italia quoque invenitur sulphur. Genera quatuor: vivum, quod Graeci apyron vocant, nascitur solidum, hoc est, gleba: quo solum ex omnibus generibus medici utuntur. Solum (cetera enim liquore constant, et conficiuntur oleo incocta) vivum effoditur, translucetque, et viret."—Plinii Hist Nat. Lib., xxxv., 50.

It would seem, therefore, that calcium sulphide was discovered, and its luminosity observed, about nineteen hundred years before Marggraf, who in 1750 A.D. prepared the substance by "calcining gypsum with combustible matter." Eighteen years later Canton obtained the same effect by "igniting calcined oyster-shells with sulphur." (Inverted commas from Roscoe and Schorlemmer's "Treatise on Chemistry," under "Calcium and Sulphur.")

As neither of these manufacturing methods is difficult, it seems reasonable to suppose that one or other might have been known in Livy's day, and from the Latin text a modification of Canton's method seems probable.

Except for the above, I can find no direct reference to the discovery of calcium sulphide.

I noticed when reading Charles Reade's novel "The Cloister and the Hearth" that one of the more striking incidents depended on the use of a phosphorescent paint. As this powerful story is of the fifteenth century, I considered the phosphorescent paint an anachronism, for Brandt is said to have discovered phosphorus in 1669, and the "Bologna stone" (barium sulphide) was discovered only a few years earlier. But Reade may have been aware of the passage in Livy or may have known about Pliny's "Pholas"—the rock-boring mollusc (Piddock)—the phosphorescence of which is said to remain long after death.

Possibly some readers of Nature may be able to throw more light on the origin of "luminous paint."

Velocity of Negative Ions in Hydrogen at Atmospheric Pressure.

Some time ago Prof. Chattock and I attempted to measure the velocity of the ions from a point discharging in pure and impure hydrogen at atmospheric pressure by the wind-pressure method, in the hope of finding that the negative ion was influenced by the presence of small traces of oxygen. The results were given in *Phil. Mag.*, April, in which it was shown that the change which the complete elimination of oxygen caused was surprisingly great. Thus the apparent specific velocity of the negative ion in pure hydrogen was >230 cm. sec.$^{-1}$, volt cm.$^{-1}$, but it rapidly dropped to 7·6 on the addition of oxygen up to 1 per cent. The velocity of the positive ion was unaffected by traces of oxygen impurity, and was 5·8 throughout.

The change in the case of negative discharge might have been caused in two ways:—(a) by a great diminution with purity in the size of the negative ion in hydrogen; (b) by back discharge from the plate. If the latter were true the wind-pressure method breaks down, and the above values of velocity are not real. As it was certain that some back discharge was present, it seemed reasonable at the time to attribute the whole effect to this cause, but some recent work of Franck shows that it was probably not correct to do so.

Franck has shown (*Verh. d. D. Phys. Ges.*, xii., 291 and 613, 1910) that in gases such as argon and nitrogen the specific velocities of the negative ions obtained by α rays rapidly increased as the last traces of oxygen were removed. Thus in pure argon and nitrogen he obtained values as high as 206·4 and 144·6 respectively. As in the above, however, the positive ions were unaffected.

In the light of these results it is probable that the negative ions in point discharge in hydrogen, like those in other oxygen-free gases, are either corpuscles or are very small, although in our work the unknown amount of back discharge present prevented the determination of their true specific velocity.

These results throw considerable light on various phenomena occurring in point discharge, and I hope to publish later a more complete discussion.

An Irish Pteridosperm.

Readers of Nature familiar with the many valuable additions to knowledge made by British palæobotanists within the last twenty years will be interested to know that in the course of rearrangement of the fossil plants in my charge in the botanical division of the National Museum in Dublin I have found, while comparing the specimens of Sphenopteris in this collection with those in the collection of the Geological Survey of Ireland (of which my colleague, Prof. Grenville Cole, is director), that in the latter collection there is a specimen of *Sphenopteris Hoeninghausi* from the Coal-measures of Glengoole, co. Tipperary, which shows all the characteristic features of *Lyginodendron Oldhamium* (including its spines, sclerotic network, venation, and conchoidal pinnule segments). Moreover, the specimen shows, *in direct continuity* with the vegetative part, the *Calymmatotheca Stangeri* condition regarded first by Scott, and now by many others, as probably the seed-producing part of Lyginodendron, from which the *Lagenostoma Lomaxi* seed has already, as Oliver and Scott have satisfactorily shown, in all probability fallen out. The specimen in question, if my interpretation is right, proves the correctness of the conjecture that *C. Stangeri* is part of the true pteridosperm Lyginodendron. I hope to publish shortly an illustrated account of the find.

Fermat's Theorem.

The following proof of this theorem may be of some interest. Take the scale of notation the radix of which is x, and write down all the numbers of p digits, any or all of which may be zero. The number of these numbers is x^p. From one number we can, in general, derive $p-1$ others by cyclical permutation, the exceptions being those numbers that are periodic with a period that is a submultiple of p. Suppose p to be a prime, so that its only submultiple is unity. Then all the numbers except the x numbers that have their digits the same can be arranged in sets of p each (which are easily seen to be mutually exclusive). Hence the number of these numbers, which is x^p-x, is divisible by p, and if x is prime to p we see immediately that $x^{p-1}-1$ is divisible by p, which is Fermat's theorem. It is clear that this proof depends on permutations and combinations, not really on scales of notation, which, indeed, we have only used because of the clearness that they lend to its statement.

11 Regent Park Terrace, Leeds.

The Uganda-Congo Boundary.

With reference to the note on this subject in Nature of September 1, has not the writer fallen into a slight error in quoting (p. 268) the definition of limits in the "Berlin Act" as applicable to the Congo State? Reference to the text of the Act will show that the passage quoted relates, not to the State, but to the Free Trade area in the Congo basin and neighbouring territories constituted at that time, with limits by no means coincident with those of the State. In fact, the "Berlin Act" had nothing to do with the State (as such), which was constituted, not by the conference, but by agreements with individual Powers negotiated about the same time.

The frontier originally claimed by the State in this region, and definitely accepted by several of the Powers, *was* the thirtieth meridian, for however unsatisfactory this might be, there could hardly, in 1885, have been a question of the adoption of the water-parting, which would at that date have involved far more uncertainty than the meridian. It was even doubtful to which of the two basins Lake Edward belonged. The mistake in 1894 seems to have consisted, not in the gratuitous introduction of the thirtieth meridian, but in its partial retention (viz. in the Ruwenzori district), to the detriment of Uganda, while replaced farther north by the water-parting, greatly to the advantage of the Congo State.

Edward Heawood.

1 Savile Row, September 16.

It is quite true that the definition quoted in the note was that of the Free Trade area, but as the recognition of the Congo State, on our part, contained no definition of frontiers, we were entitled in 1894 to maintain that, in default of any specific deviation agreed upon mutually, the two frontier lines were identical. So far as I am aware, up to the date of the treaty of 1894 we had not admitted, nor, indeed, seriously considered, any claim on behalf of the Congo State to territories outside the Congo basin.

The history of the whole series of transactions is somewhat complicated and difficult, but it seems that, whatever were the intentions of the signatories to the Berlin Act and of the framers of the original agreements with the Congo State, any distinction between the State and the Free Trade area disappeared at an early period of their history, and had ceased to exist by 1894.

The Writer of the Article.

An Agaric with Sterile Gills.

The occurrence of agarics with sterile gills is well known in certain species; it has been noticed most in those with purple spores. A few days ago I met with two specimens of *Panaeolus campanulatus* in Sutton Park, near Birmingham, in which the gills were of a pinkish-grey colour, somewhat closely resembling the tint of the dry pileus. There was a total absence of the usual variegated, grey and black, appearance. The pileus was large and well developed, measuring 1½ inches high and broad, stipe quite 4 inches long, and presenting all the characters of that of *P. campanulatus*. On examining sections of the gills it was seen that numerous basidia were present, projecting beyond the paraphyses; very many of them had the four sterigmata of full size, but not one over the whole of the gills of both specimens had produced a spore, nor were any produced afterwards, so long as the fungi were preserved. Unfortunately, they had been gathered before I saw them, so that it was impossible to ascertain if there was any visible cause for the sterility.

ART THE COMRADE OF SCIENCE.[1]

IT has long been known that Mr. A. H. Thayer, the discoverer of the great principle of countershading in nature, was preparing a fully illustrated exposition of his observations and theories, and that his son was helping him in the enterprise. The present beautifully illustrated and finely printed work is the result. The great discovery of the obliteration of apparent solidity by means of countershading, first published

FIG. 1.—Plymouth Rock Hen, lacking countershading, and therefore conspicuous against a background of Plymouth Rock skins.

in 1896 (*The Auk*, vol. xiii., pp. 124 and 318), was convincingly illustrated in this country by the models prepared by Mr. A. H. Thayer, and presented to the natural history museums of London, Oxford, and Cambridge. An account of the principle, as well as the description of the Oxford model prepared by the present writer, appeared in NATURE for April 24, 1902 (vol. lxv., p. 596).

After the great and wide-reaching discovery which has probably been accepted by all naturalists who have studied it, the author has gradually extended his conclusion that the colours of animals are adapted for concealment, and carried it into regions where a very different interpretation had been accepted. Thus in his papers in the Transactions of the Entomological Society of London (1903, pp. 553–569), and in the *Popular Science Monthly* (December, 1909, p. 550), Mr. Thayer maintains that appearances which have been explained as warning, mimetic, and sexual are to be interpreted by the one dominant and universal principle of concealment in nature. It cannot be said that, in these later developments, Mr. Thayer has succeeded in convincing any large number of naturalists, and it is therefore of especial importance that a detailed, complete, and fully illustrated statement should have appeared in the present volume.

The great bulk of the work, which opens with an introductory essay, dated 1907, by Mr. A. H. Thayer, is occupied, first, by a full and admirable exposition of the principle of obliterative shading and the combination with it of "picture patterns," and secondly, by a sketch of the distribution of these methods of concealment throughout vertebrate animals and insects, the birds being treated in far greater detail than any other group. Mr. Thayer's later views are not expounded separately, but are to be found scattered in various parts of the volume, which must be carefully studied as a whole by any reader who would do justice to the author and his father.

The value of obliterative countershading is well illustrated by figures of two breeds of fowl in which it is lacking. However closely such fowls may harmonise with the colour of a flat background, they must be rendered conspicuous against it by means of shadow, as is at once obvious in Fig. 1.

A series of interesting photographs of models makes it clear that obliterative shading is even more important than markings for the purpose of concealment. Thus, the model in Fig. 2 represents a relatively inconspicuous gap in the pattern of the background; that in Fig. 4, possessing the pattern, is by comparison a strikingly distinct and solid object. We are thus led to conclude that the perfect obliteration represented in Fig. 3 depends in larger measure upon the principle illustrated in Fig. 4 than upon that shown in Fig. 2.

The vast importance of this same principle is demonstrated, not only by diagrams, but by large numbers of representations of actual animals to be found in later pages of the work. A striking example is seen in Fig. 5, where the animal has been photographed in a position which reverses the obliterative tendency of its colouring in the normal position. We here get maximum conspicuousness—the lightest tint in the strongest light, the darkest in the deepest shadow.

The relation of the pattern to perspective is discussed in an extremely interesting and original section (chapter iii.), where the conclusion is reached that "the obliteratively shaded surface must bear *a picture of such background as would be seen through it if it were transparent*." This is well illustrated by the diagram shown in Fig. 6, where the smaller pattern of the highest part of the bird is seen against the receding, and therefore to the eye diminished, details of the background.

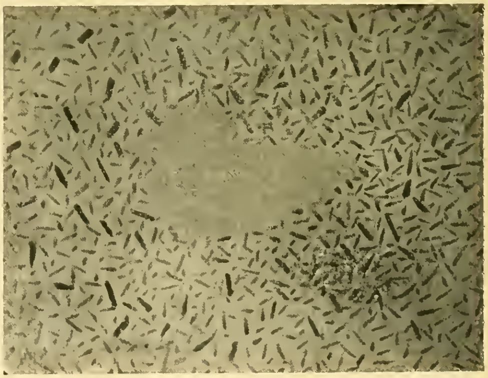

FIG. 2.—Bird-shaped Solid Model, obliteratively shaded in full, and correctly lighted, but revealed by the want of pattern.

Mr. Thayer discriminates sharply between all such *obliterative coloration* depending on countershading combined with background picturing, and *mimicry*, or the simulation of a solid object. He truly points out

[1] "Concealing-Coloration in the Animal Kingdom." An Exposition of the Laws of Disguise through Colour and Pattern: being a Summary of Abbott H. Thayer's Discoveries. By Gerald H. Thayer. With an Introductory Essay by A. H. Thayer. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1909.) Price 31s. 6d. net.

that the goal of the first principle is *invisibility*, of the second *deceptive visibility*. "The latter principle is open to unlimited variations of method and result, whereas the former . . . is in its main essentials strictly limited. There are innumerable kinds of solid objects for animals to simulate in appearance, but there is only *one* way to make a solid object in a natural lighting cease to appear to exist" (p. 25).

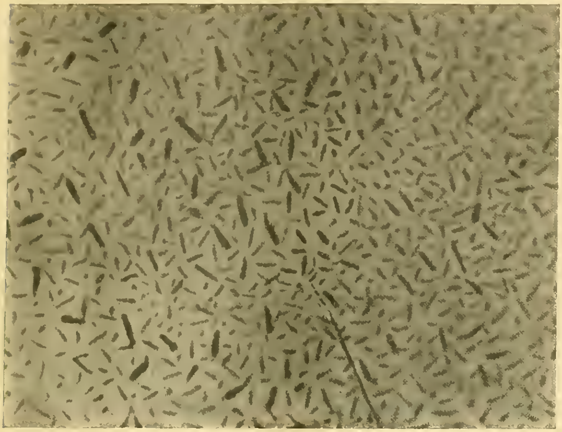

FIG. 3.—Model similar to that shown in Fig. 2, and similarly lighted, but concealed by possessing a pattern like that of the background.

The use of the term "mimicry" to indicate the second category, although common, is to be deprecated. It is inconvenient to apply the same term to the resemblance of a moth to a wasp, and that of a caterpillar to a twig. The wasp-like moth is always spoken of as an example of mimicry; and the term *imitation* may be conveniently used in a technical sense to include the twig-like caterpillar and all the other innumerable examples of special protective resemblance. The important classification of cryptic resemblances, which Mr. Thayer now establishes more thoroughly and correctly than before, may be appropriately expressed by the use of the terms (1) *obliterative* or *aphanistic coloration*, and (2) *imitative* or *eikonic resemblance*.

No fewer than sixteen out of the twenty-seven chapters of the book are concerned with the colouring of birds, the patterns being classified according to the nature or distance of the background that is pictured. A vast amount of patient and loving observation of nature is here summed up and expressed. We shall look forward with the deepest interest to the comments of those special students of bird-life in Europe and America, who will make a point of testing these conclusions by fresh observations made in the field from the author's point of view. This is written in no spirit of doubt, for Mr. Thayer's statements and illustrations are, with certain exceptions, to be considered later, most convincing. No naturalist could reasonably doubt, for example, the significance of the grass-pattern shown in Fig. 7, which the author justly describes as "one of the most remarkable photographs ever taken of obliteratively coloured birds in nature" (p. 46). The two points by which the bird is most easily recognised are the dark eye and the dark shadow under the feathers, so that this wonderful illustration helps us to understand the importance of eye-masking markings (see pp. 81, 82), as well as of obliterative counter-shading.

The coloured plates of the "Male Ruffed Grouse in the forest" (II.), the "Cottontail Rabbit" (VII.), and the "Copperhead Snake on dead leaves" (XI.) are very remarkable illustrations, justly claimed by the author and his father to be "the first ever published, which rightly illustrate and in some respects do justice to the wonderful effects of obliterative coloration, based on the great law of *obliterative shading*" (p. 128).

The five coloured plates of caterpillars (XII.–XVI.) are extremely beautiful, showing for the first time the important part played by obliterative shading in these forms. The attitudes of caterpillars generally must be re-examined in the light now thrown upon them by this great artist-naturalist; for there is little doubt that many of the best-known and commonest illustrations represent an inaccurate position. It is unfortunate that the names of so few of the figured species were ascertained, but there should be little difficulty in the identification of such beautiful reproductions. There is an evident inadvertence in the orientation of Fig. C or D on plate XII., both represented in a similar position, although D is described as the reverse of C.

FIG. 4.—Model similar to that shown in Fig. 3, and similarly patterned, but wrongly lighted and therefore conspicuous.

The necessities of space prevent a further account of this remarkable and splendidly illustrated exposition of the principles of obliterative colouring, and its distribution throughout the animal kingdom. We must now, in the concluding paragraphs, deal with special interpretations and later developments which are likely to cast an entirely undeserved suspicion upon this admirable account of a great discovery.

In the first place, in the present state of our knowledge of a most difficult subject and the great need for numberless exact observations and precise records,

FIG. 5.—Domestic Hare laid on its back, out of doors, so that the oblite ative shading is reversed. Photographed from life.

illustrations in which the background has been "copied, colour-note for colour-note," from the animal itself, are a hindrance and not a help (plates I., III., VI., VIII., IX., X., and Fig. 123). The inferred environment is not necessarily incorrect—the rattlesnake (Fig. 123) at least is almost certainly represented with truth—but the inference is not scientific evidence, and it is likely to act as a hindrance, because some readers may be led into accepting it as a proof, others into scoffing at the whole subject. Furthermore, the inferred significance of the animal's colouring may be wholly mistaken, as I doubt not is the case with the beautiful and poetic plates IX. and X., representing "flamingoes at dawn or sunset, and the skies they picture." Such an interpretation is quite inconsistent with the wonderful representation of flamingo life prepared by Dr. F. M. Chapman for the American Museum of Natural History, New York. The present writer had seen the representation and knew well the unrivalled knowledge and experience which had gone to the making of it, and he therefore wrote to his friend and asked his opinion as to the meaning of the colours of these birds. Dr. Chapman kindly replied as follows:—

My observations of flamingoes (which I should add were made only in the Bahamas) lead to the belief that our American bird (*Phoenicopterus ruber*) is protected by its haunts and habits rather than by its colour. At all times, whether feeding singly or when nesting and solidly massed in hundreds, it is from any point of view an exceedingly conspicuous object. Apparently, therefore, it thrives only when it is beyond the reach of predatory Mammalia and Reptilia, its centres of abundance being oceanic islands, like the Bahamas or Galapagoes, or small keys off the mainland. It is true that flamingoes formerly visited the shores of southern Florida in great numbers, but they have never been known to nest there, and they frequented only the vast shallow bays where they could feed far from land, and where it was almost impossible to approach them; for it should be especially noted that these flamingoes are as shy as they are conspicuous. The character of the regions they frequent usually enables them to see as far as they can be seen, and the brilliancy of their colours seems to be compensated for by their extreme wariness. For example, a professional hunter of flamingoes on the Florida coast tells me that for six days a week for two consecutive weeks he pursued a flock, estimated to contain 2000 flamingoes, without securing a single specimen.

I am, of course, aware that man should not be classed among the natural enemies of the flamingo, nor their colours be explained from the human view-point, but the fact just mentioned at any rate illustrates the bird's alertness and the difficulty with which it is approached.

As, in the Bahamas, at any rate, the flamingo feeds only on molluscs, its colours are apparently not deceptive or aggressive. In short, it is my belief that the flamingo's colours are to be placed among the cases where colour has run riot, unchecked by any need for protection from enemy or prey, and that the bird has continued to exist only where the dangers to which of necessity its colour would expose it are happily absent.

The flamingo has been considered at some length. With regard to the peacock in the wood (plate I.), it can only be said here that the interpretation is hardly likely to be accepted by anyone who has watched the male bird displaying before the female or in rivalry with another male.

Nor are many naturalists likely to be convinced by Mr. Thayer's interpretation of recognition markings and warning colours, an interpretation rendered sufficiently clear by Figs. 8 and 9. Here, as in all other examples of animal colouring, Mr. Thayer considers the one dominant interpretation to be concealment,

FIG. 6.—Diagram showing the picturing of perspective by animals' patterns. The bird is supposed to be looked at from the side and above so that the smaller pattern of its head and neck is against the more distant and therefore reduced pattern of the ground surface.

the Spilogale's "dark stripes passing for vegetation, and his white stripes for the sky." This explanation of warning colours has been recently criticised, and in the opinion of the present writer entirely refuted, by Mr. R. I. Pocock (Proc. Zool. Soc., 1908, pp. 944–959), and the corresponding interpretation of recognition

markings by Mr. E. Thompson Seton ("Life-Histories of Northern Animals"). As regards the interpretation of the mimetic resemblances of butterflies as due to a syncryptic resemblance to flowers and the surrounding vegetation and its interstices, it is impossible to say

more than that such a theory does not explain many well-known characteristics of the mimetic groups.

Whatever be the verdict of the moment, a man will be judged and ought to be judged by what he has done, not by what he has failed to do. It has been said that "What's hit is history, what's missed mystery." While the misses do not make the hits any the less, the mystery may serve to throw light upon the workings of a mind that has made history.

ETHNOGRAPHY AT THE BRITISH MUSEUM.[1]

THE purchaser of this handbook will feel no regret that it is not cast in the form of a guide. Many, perhaps most, of those who buy museum publications do so as they leave the building, and although the fate of such mementoes cannot be determined with certainty, it may be assumed that they are sometimes read at leisure. A descriptive handbook on broad lines is, therefore, a better investment for the average visitor than a guide of the old, and arid, type. The present example is worthy of the best fate that can befall it at the hands of the man who looks in from the street, and it will be cordially welcomed by those whose interest in ethnography is less casual and fortuitous.

The introduction contains a brief survey of the progress of geographical exploration from classical times onward, and traces the discoveries which rendered possible the development of the comparative study of mankind. The scope of ethnography is defined in a concise discussion of man in his relation to the material world, to his fellows, and to the supernatural.

The greater part of the book, which deals with the collections as exhibited in the Museum, is arranged under geographical headings, and the limitations of the collections are naturally reflected in the handbook. Thus, under Persia, India, and Japan, the subject of arms and armour is practically the only one considered, whilst China is only referred to incidentally. The culture of Tibet, Ceylon, Indonesia, and some of the tribes of northern and central Asia, is entered into in greater detail. Useful summaries are given of the general conditions of the life and culture of the peoples of these areas, with reference not only to their arts and industries, but also to their customs and beliefs. Racial origins and affinities are briefly considered, and the latest views are stated. The same treatment is adopted with regard to the peoples of Australia, Oceania, Africa, and America. Special mention may

[1] "Handbook to the Ethnographical Collections." Pp. xv+304. (London: Printed by Order of the Trustees, British Museum, 1910.) Price 2s.

be made of the able condensation of the complex subject of the culture, distribution, and relationships of the Negro and Bantu tribes of Africa.

An important feature, and one which will be widely appreciated, is the large number of illustrations, many of them in the form of plates. The geographical and tribal index also adds greatly to the value of the book for reference purposes.

Whilst giving ungrudging praise to the handbook, the hope must be expressed that the extension of the museum buildings will afford opportunity for the accommodation of the ethnographical collections under conditions that will enable them to be displayed in a manner more worthy of their importance. The provision of a section of technology, for example, would not only be an extremely popular addition, but would immensely increase the educational value of the collections. It seems doubtful, however, whether those who intermittently rule over us have yet been convinced that museums are educational institutions. It is certain that they have not appreciated the importance of the study of man, working-man excepted.

SIGHT TESTS IN THE MERCANTILE MARINE.

THE Board of Trade has issued an important report (Cd. 5256) on the sight tests used in the mercantile marine during the year 1909. Out of 6084 candidates, 56 failed in form vision, and were not re-examined; while out of the remaining 6028 there were 86 failures in colour-vision, of whom 31 appealed and were re-examined, with the result that 15 were passed and 16 were finally rejected. The total absolute rejections were, therefore, 71 in 6084, or 1·49 per cent. During the first ten months of the year, colour vision was tested by the three skeins of wool originally recommended for the purpose by Holmgren; but during November and December two other skeins, a purple and a yellow, were added. With these the rejections were in somewhat larger proportion (1·81 per cent. against 1·17) than when only three skeins were used; but the total number of candidates examined by the new method (882) was hardly sufficient to afford any basis for a conclusion.

In the case of the fifteen men who, having originally been rejected as colour-blind, were re-examined and accepted on appeal, the report gives no information on the very important point of the precise methods employed in testing them, or on the precise "matches" made by them, either at the first examination or at the subsequent one. In the case of those who were finally rejected, we are told what they did. "A.B.," for example, selected "sage-grey, fawn, and greenish-yellow" as matches for the green skein, "greenish-blue" as a match for the pink skein, "blue and carmine," as a match for the red skein, and so on, until he is finally dismissed as "completely green-blind." But of a man who, having been rejected, "appealed and passed," we are not told anything but that he had previously "failed in the colour-vision tests," and we have no information as to how the alleged "failure" was redeemed.

There can be no question that, in every case in which an original rejection has been overruled, very clear evidence of error on the part of the first examiner, and of special care on the part of the second one, should be forthcoming. We believe that failure to reach correct conclusions by means of Holmgren's three skeins would be due, probably in all cases, to neglect of Holmgren's very precise instructions as to the manner in which they should be used; and, if it were found that the original conclusions of any examiner were often overruled on appeal, an urgent necessity for reconsidering his fitness would arise. It is manifest that no original rejection should be set aside except upon the clearest and most satisfactory evidence; because, however much we may sympathise with instances of hardship, if such there be, or with worthy men deprived of a calling, it must be remembered that the difference between red and green is to the normal-sighted so complete and absolute that they can scarcely understand even the possibility of confounding them. A case in which the difference is less than this, a case in which there is any question, any possibility, of confusion between the two colours in any conditions of weather or of illumination, is one in which the benefit of any possible doubt should not be given to the individual examined, but to the persons who may possibly be carried in a ship or a train placed under his control. It follows that the evidence on which a re-examined man has been accepted is of far more public importance than that on which he has been rejected; and it is to be hoped that, in the next report upon the subject, this aspect of the question will be borne in mind.

Of the 71 rejections for colour-blindness, 35 were on account of red-blindness (complete in 20, incomplete in 15), and 36 on account of green-blindness (complete in 23, incomplete in 13), so that the several defects are practically of about equal frequency. No case of monocular colour-defect is recorded.

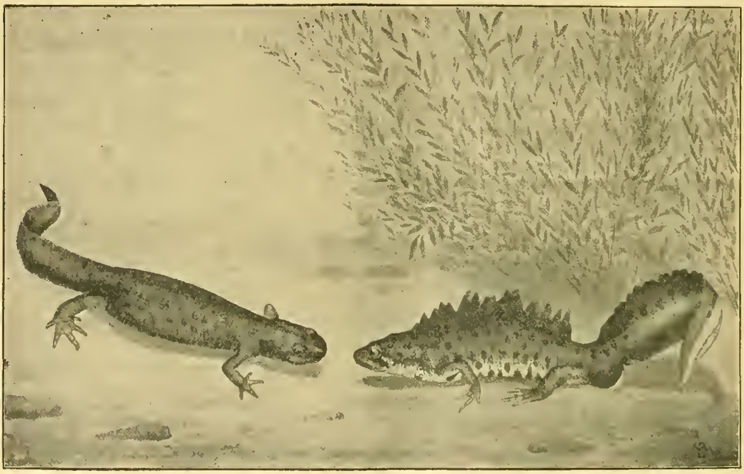
The last paragraph of the report announces that, after January 1, 1914, the standard of form vision in the mercantile marine will be raised, and that candidates will be required to possess full normal vision in one eye, and "at least" half normal vision in the other. It will probably be news to most of our readers that less than this very modest standard has hitherto been required; and ophthalmologists generally will, we think, agree with us that the possession of only half vision, in one of his eyes, by a young or middle-aged mariner, is a circumstance which would fully justify his being submitted to periodical re-examination. "Half-vision" would in many cases indicate disease, often of a character likely to be progressive.

STRUCTURE AND FUNCTION.[1]

THE aim of this stately book is to show how the various types of animals have solved the fundamental problems of life, and how their structure is to be interpreted in terms of their functions and environment. The keynote of the book is to keep the animal alive and to study its adaptations. We must congratulate the author on the success of his endeavour, for he has written a worthy successor to the once-famous, now forgotten "Anatomischphysiologische Uebersicht des Tierreiches," by Bergmann and Leuckart. The outstanding merit of the achievement is in its unified or synthetic presentation of the facts—it is at once anatomical and physiological, œcological and evolutionist. This general biological outlook is very useful for the analytic student.

Dr. Hesse has evidently worked for a long time over his book—it is scholarly, up-to-date, and clear, and commands our warmest admiration. It deals with the individual organism and the processes of its life—such as movement and feeling, nutrition and reproduction. There is nothing remarkable in the mapping out of the subject; it is the working-out that is remarkable in its thoroughness and lucidity. In treating of reproduction, the author necessarily gets beyond the individual, and leads on towards the second volume, in which Prof. Doflein is to deal with the relations of organisms with one another and to environmental influences.

The book is illustrated with quite remarkable generosity and skill. It is not merely that the illustrations are very numerous and beautiful, but they are peculiarly fresh and interesting, and there is a delightful intellectual flavour about them. They not only adorn the tale, they tell a story by themselves. Dr. Hesse's emphatically distinctive book has been well treated by the publishers, and we hope the result will be a great success. We have no counterpart of it in Britain.



Episode in "Courtship" of Crested Newt. From Hesse and Doflein's "Tierbau und Tierleben."

RECENT INVESTIGATIONS ON PELLAGRA.

THE visit of Dr. Louis Sambon to Italy to investigate the cause of pellagra has proved eminently successful. Dr. Sambon was sent out by the Pellagra Investigation Committee in March, 1910, in consequence of his having advocated for some time that pellagra was not caused by the consumption of diseased maize, as has been thought to be the case hitherto. Dr. Sambon was of opinion that pellagra was due to a protozoal infection, and that the disease was conveyed by an insect in much the same way as several other ailments are transmitted, such as malaria, sleeping sickness, kala-azar, filariasis, &c. The members of the Pellagra Investigation Committee, finding Dr. Sambon's idea was based on sound scientific reasonings, proceeded to collect money for the purpose of enabling him to proceed to Italy and pursue investigations on the spot.

Dr. Sambon visited the provinces of Bergamo, Milan, Brescia, Padova, Rome, and Perugia, and wherever he came in contact with the disease he found that the consumption of maize, whether diseased or not, had nothing to do with the prevalence of pellagra. Endemic centres of the disease have existed in Italy persistently for at least a century. The disease is not met with in towns, but only in certain parts of the country, namely, in the districts where a sandfly of the class Simuliidæ, and belonging to the genus Simulium, is met with. No actual parasite has as yet been discovered in the blood; but the geographical distribution of the disease, its epidemiology, and its close resemblance in behaviour to other diseases in which a parasite has been discovered, confirms Dr. Sambon in the belief that it is a protozoal infection carried by a sandfly that is the etiological factor in pellagra.

As a parallel we have the case of yellow fever. In yellow fever we know the agent of transmission to be a mosquito. No parasite has been discovered in the blood in yellow fever, but the experiments carried out are so conclusive that the disease is of the nature of a protozoal infection that yellow fever is classed as one of the protozoal infection with a parasite that is ultra-microscopic. Pellagra is in the same category. There are certain factors in infections of this kind which enable us to conclude that a disease is of a certain class, although the microscope is at fault.

Dr. Sambon proved:—(1) That the endemic centres of pellagra in Italy have remained the same since the disease was first described. (2) That the season of recurrence of pellagra coincides with the season of the appearance of the fully-fledged sandfly to the extent that even if the spring is early or late so the sandfly is early or late in appearing, and synchronously pellagra cases correspond in their appearance. (3) In centres of pellagra infection whole families are attacked at times simultaneously. (4) In non-pellagrous districts when a pellagrin is met with the disease never spreads to others, and the patient acquired infection during a sojourn in a pellagrous district. (5) In the case of a family that has moved from a pellagrous district to a non-pellagrous district the children born in the former are pellagrins, whilst those of the children born subsequent to removal to a non-pellagrous district do not develop the disease. (6) The disease is not hereditary, although infants a few months' old may become infected, especially if taken out to the fields in pellagrous districts, where their mothers work during the season, when the sandflies are in evidence. (7) Pellagra is not contagious, but is transmitted to each individual by an infected sandfly.

Dr. Sambon, from the epidemiological and topographical aspects of pellagra alone, has been able to show by well-nigh conclusive proof that pellagra is an insect-borne disease. It is hoped that money will be forthcoming whereby a study so well began and so fruitful in results shall be further investigated, so that not only Italy but the many countries in which pellagra is a scourge and a calamity may be freed of one of the most frequent causes of insanity.

DR. MELCHIOR TREUB.

THE death of this distinguished botanist, which occurred at Saint Raphaël, Var, on October 3, closes a career of remarkable brilliancy. Born at Voorschoten, near Leyden, on December 26, 1851, Melchior Treub entered the University of Leyden in 1869, and shortly after the completion of his undergraduate career was appointed assistant in the Botanical Institute there. This position he occupied from 1874 until 1880, when he was appointed, in his twenty-ninth year, to the directorship of the Botanic Garden at Buitenzorg, in Java, which had become vacant owing to the untimely death of the talented Scheffer.

The striking quality of Treub's early work, published before and during the tenure of his assistantship at Leyden, more than justified the selection, by the Netherlands Government of so young a man to fill so important a post, and afforded the happiest auguries for his success in this new and wider field. But high as were the expectations which Treub's friends were entitled to entertain, their most sanguine hopes fell far short of what Treub was able to accomplish during the twenty-nine years of his sojourn in Java.

Succeeding as he did a man of high aims, whose unwearied exertions in giving effect to them were largely responsible for his early death, Treub, with rare administrative skill, brought the renowned institution of which he had been given charge to a pitch of material perfection and a position of scientific importance far surpassing his predecessor's fondest aspiration. While developing and extending the economic activities whose foundations had been laid by Scheffer, Treub was able in the midst of his multifarious and engrossing administrative duties to undertake and complete the investigation of many important scientific problems, the details of which enrich the pages of the famous "Annales du Jardin Botanique de Buitenzorg," founded by Scheffer, and edited from the second volume onwards by Treub.

To the herbarium which has been associated with the Buitenzorg Garden since its foundation, and to the museum organised by his predecessor, Treub was able, almost from the outset of his directorship, to add a series of well-equipped and fully-staffed laboratories for the prosecution of technical and scientific research. One of his earliest acts was to persuade his Government to provide a special laboratory reserved for the use of foreign workers, who might care to visit Java and undertake, in the midst of its rich vegetation, original botanical study.

Treub's own contributions to the advancement of natural knowledge have been so numerous and are so well known to all students of general botany that they need not be recapitulated here. One of the outstanding features of his work is its reflection of the catholicity of his interests, which prevented him from ever becoming a specialist. His exceptional capacity for observation and his thorough mastery of method enabled him to enter with equal success many fields of study. Everything he had occasion to say on morphological, embryological, physiological, or phytogeographical subjects was worth saying, while his faculty for exposition enabled him so to present his results as always to arrest attention. The one field of botanical activity which he never entered was that of systematic study, with the needs of which, however, partly from the width of his sympathies, partly owing to his absorbing economic interests, he was fully conversant; perhaps none have benefited more immediately or more greatly by his kind and ungrudging assistance than systematic students.

Equally unnecessary here is any *résumé* of the results of Treub's practical activities or any recapitulation of the benefits thereby accruing to tropical agriculture, forestry, and pharmacology. The great value of the assistance given by him to the industries concerned has, however, lain in the fact that the practical results attained have always depended on scientific research. So ably did he teach the lesson that successful practice must depend on science, that he was enabled, towards the close of his career in Java, to effect the establishment of a truly scientific Department of Agriculture in the island, with himself as its head. In connection with this enterprise, he had occasion to visit various Eastern establishments, among them that organised by the United States Government in the Philippines. While in Manila, he contracted a severe illness the effects of which he was unable to shake off on his return to Buitenzorg, and some time thereafter he was compelled temporarily to relinquish his charge. A sojourn of some months in the mountains of Java effected so much improvement in health that he was able to return to duty. But again his health gave way, and a little over a year ago he was reluctantly compelled to retire from the post he had filled with so much distinction for nearly thirty years. Under medical advice, he spent the winter in Egypt, and in spring went to live at Saint Raphaël, near Cannes.

His retirement was a source of unmixed regret to his colleagues in Java, because of the loss of his hand from the helm. To his many friends in Europe, however, the necessity did not present quite the same aspect; these looked forward to the double pleasure of renewed personal intercourse with Treub, and to that increased scientific activity for which his release from heavy official duties promised him opportunities.

This was not to be, and botanists throughout the world now mourn the loss of one of the ornaments of their science. To those who had the privilege of his personal friendship the blow is greater still. They have lost in Treub a brilliant, stimulating, and sympathetic colleague, one whose width of culture and charm of manner rendered intercourse with him a continual pleasure. Above all, they have lost a kind and constant friend.

DR. SIDNEY RINGER.

THE career of Dr. Sidney Ringer, which came to a close recently at Lastingham, Yorkshire, is a fine refutation of the common statement that the cares of medical practice do not permit of active scientific research in these days. Engaged in a large and successful consulting practice, and in teaching in a large medical school, he yet found time for much work in the advancement of pure science. His interests in medicine lay largely in therapeutics, in which his text-book remains authoritative, and his experimental researches appear to have arisen from the desire to put therapeutics upon a more secure foundation by investigating the effects of drugs on the animal organism. From 1870 to 1880 he published a number of papers dealing with the effect of various alkaloids and other drugs on animals, and these were continued at intervals in his later years. Many of these have been confirmed by later workers, and have taken their place in literature along with the work of the other founders of the modern pharmacological school. Among other subjects taken up at this time, the mutual antagonism exhibited by some of the alkaloids appears to have interested him in particular, and his experience with these probably influenced his later investigations.

From about 1880 Ringer struck out on a line of his own in his investigation of the inorganic salts of the blood and other tissues. At this time practically nothing was known of the biological significance of these, and their presence in the tissues was discounted in the physiology of the time. His investigations were so complete that the laboured investigations of a multitude of foreign observers in recent years have added little of fundamental importance. The essential feature which Ringer demonstrated was that while each of the salts induces abnormal conditions when applied alone to the tissues, each of them is necessary for normal function; living matter requires inorganic salts, but these must be presented in certain proportions.

In particular, the special *rôle* played by lime salts in the economy of the tissues was first demonstrated by Ringer, and its antagonism to sodium and potassium was developed in a number of papers in the *Journal of Physiology*. The sodium and potassium in the body fluids has to be counteracted by lime, and such "balanced" solutions, when formed artificially, are harmless to living tissues, as he showed in a number of instances. The solution of salts introduced by him, and universally known by his name, is to-day to be found in every biological laboratory, and its use has led to developments in many fields of research. The work on which its composition is based has often received too little attention. This may be accounted for by the time at which it appeared: Ringer's work was done before the modern views of diffusion and dissociation of salts in solution found their way into biology. And the investigators who approached the study of the biological relations of the salts from the side of the new physico-chemistry appear to have overlooked the work of those who had investigated the subject without the aid of the newer methods. Quite recently, however, some amends have been made in this respect, and it is now recognised that the pioneer in this work had reached in essentials the same position twenty years ago as has now been attained generally.

From 1895 onwards, Ringer ceased active work in research, but his interest was unabated. Two years ago he might have been seen in his old place in the physiological laboratory at University College investigating some point which had attracted his attention. One cannot help regretting that he could not devote himself wholly to experimental research, in which he showed outstanding powers; but, on the other hand, his clinical work could ill have been spared by medicine. Few in these modern times have been able to combine such insight in the biological aspect of medicine with an equal eminence in practice.

C.

NOTES.

ON Wednesday, October 19, Sir William Ramsay conducted Mr. Francis Fox, chairman (who first suggested the utilisation of the Trenwith Mine pitchblende), and the other directors of the British Radium Corporation over their works at Limehouse. From the ore, which comes from the Trenwith Mine at St. Ives, 550 milligrams of radium as bromide have already been extracted, as well as the uranium which it accompanies, practically without loss. In an account which appeared in the *Times* of October 20, the reporter is in error in stating that Cornish pitchblende is richer in radium than the Austrian ore; on the contrary, the constancy of the ratio between uranium and radium has been repeatedly confirmed. From inspection of the Trenwith Mine, there appears good reason to hope that the present supply will be maintained, if not exceeded. The productive capacity of the works at Limehouse is about 100 milligrams a week.

A REUTER message from Stockholm states that this year's Nobel prize for medicine has been awarded to Prof. Albrecht Kossel, professor of physiology in the University of Heidelberg. Each prize will amount on this occasion to 7734*l*.

IT is proposed to hold in Paris next spring an international exhibition concerned with agriculture, oyster-culture, and fisheries. The organising committee has its office at 161 rue Montmartre, Paris.

The Royal Society informs us that the studentship on the foundation of the late Prof. Tyndall for scientific research on subjects tending to improve the conditions to which miners are subject has been awarded for the ensuing year to Dr. T. L. Llewellyn, of Bargoed, Wales, for research regarding the cause and cure of the disease in miners known as nystagmus.

Dr. Báthori, writing from Nagybecskerek, Hungary, informs us that the Hungarian Academy of Science has this year awarded the Bólyai prize, of the value of 10,000 crowns, to Prof. David Hilbert, university professor of mathematics at Heidelberg. The jury consisted of two foreign mathematicians—Poincaré (to whom the prize was awarded in 1905) and G. Mittag-Leffler—and two Hungarians, Y. König and G. Rados, both from Budapest.

News has been received from Italy of considerable damage wrought in the island of Ischia, accompanied by loss of life, due, in the first instance, to what is described as a cloud-burst. A hurricane has been referred to in the meagre accounts which have as yet reached this country, and from the local character of the phenomenon it seems likely that it was of the nature of a tornado, with torrential rain. The disaster occurred during Sunday night and Monday morning, October 23–24. The Paris *Bulletin International* for Monday, October 24, makes no mention of the disturbance, and contains nothing apparently associated with the occurrence except that at Naples the rainfall, measured at 7 a.m. for the preceding twenty-four hours, was 1·30 inches, and at Rome 0·87 inch. At Naples a further rainfall of 1·28 inches for the twenty-four hours ending October 25 is recorded in the Paris *Bulletin*, making the aggregate fall in forty-eight hours 2·58 inches. At Cette, in the south of France, 3·11 inches of rain fell in the twenty-four hours ending 7 a.m. October 25.

Early in November the University of Leyden proposes to celebrate the eightieth birthday of Prof. J. D. van Bemmelen. Prof. van Bemmelen was born on November 3, 1830, and has been engaged in scientific work since 1856. He has contributed greatly to the foundation of the Dutch school of physical chemistry. Prof. H. A. Lorentz, of Leyden, is the chairman of the committee organising the celebration, and Dr. W. P. Jorissen the secretary. It is proposed to publish as a memorial of the celebration a collection of memoirs by fellow-workers on the subjects with which Prof. van Bemmelen's name is associated, and already some sixty have been received. The memoirs will be published in one volume by M. C. de Boer Junior, Helder, Holland.

The annual general meeting of the Institute of Metals will be held at the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W., on Tuesday and Wednesday, January 17 and 18, 1911. At this meeting a number of papers will be presented, including some of an essentially practical character, together with the preliminary report to the corrosion committee. It will be remembered that this committee was appointed some months ago to investigate cases of corrosion of the non-ferrous metals. The preliminary report will show the present state of our knowledge of the corrosion of non-ferrous metals and alloys, and will contain suggestions for a research into the causes of the corrosion by sea water of brass condenser tubes. The institute has now been founded just two years, and has celebrated its birthday by becoming an incorporated institution.

Speaking at the inaugural meeting of the Oxford branch of the Research Defence Society on Monday, Lord Cromer gave a number of instances of the value of research in medicine. In the course of his remarks he said:—Step by step the micro-organism of all the principal diseases—relapsing fever, leprosy, typhoid, tuberculosis, cholera, diphtheria, tetanus, influenza, plague, and dysentery—has been tracked to its lair. There is so great a wealth of evidence to show the results already achieved that it is difficult to decide which subject to mention particularly. The case of plague may, however, be taken as an example. When this terrible disease broke out in India some fourteen years ago a panic ensued. Vast sums of money were spent on disinfectants and other perfectly useless remedies. All was in vain. The epidemic continued to ravage whole districts. Then science took the matter up. The connection between the plague and the prevalence of rats was noticed. The fact that the rat flea, and not the rat itself, was the propagator of the disease was established. The anti-plague vaccine was discovered by Mr. Haffkine—but it took some years of observation before all these results could be obtained. When they were obtained science at last reaped its proud and well-merited reward. Colonel Bannerman, a distinguished Indian bacteriologist, said that in a number of cases in the Punjab, the aggregate population of which is about 827,000, some 187,000 were inoculated four months before the plague appeared, and that some 640,000 were not inoculated. Only 314 deaths occurred amongst the inoculated, while no fewer than 29,723 occurred amongst those who had not been inoculated. In other words, it may be said that experimental science saved the lives of about 8000 human beings, and those lives would not have been saved had it not been for the series of experiments conducted on living animals.

In the Harveian oration delivered before the Royal College of Physicians of London on October 18, Dr. H. B. Donkin discussed "Some Aspects of Heredity in Relation to Mind." He pointed out that the hypothesis of hereditary criminality lacks substantiation, though "a considerably larger minority of persons with clearly appreciable mental defect, apparently of congenital nature, is found among convicted criminals than in the population at large." It cannot be assumed that the criminal is a racial "degenerate." In inquiring into the causation of "congenital" mental defect, Dr. Donkin retained a severely sceptical position. In some cases a lineal sequence of defectives is sufficiently frequent to render it highly probable that this condition is truly innate, and thus transmissible; in other cases it may be an indirect result of malnutrition and the like in the parent; and there are other possibilities. Dr. Donkin laid emphasis on the difficulty of making sure whether mental and moral characters are inborn or "acquired," but it may be pointed out that his view of the distinction is not exactly that held by most biologists. In regard to the inheritance of mental qualities, he followed Sir Ray Lankester in attaching great importance to "educability." "The innate and transmissible factor of the mind of man is the organic potentiality for making mental acquirements." He did not, however, enter into a discussion of the hereditary reappearance of distinctive mental traits, and we venture to point out that his identification of mental acquirements and modifications will not commend itself to biologists who care for precision. A very interesting feature in the oration was the collection of some of Harvey's observations on heredity, in which Dr. Donkin was inclined to detect an "inkling of the great question regarding 'inherited' and 'acquired' characters."

At the Royal Society of Medicine on October 21 Dr. Franz Nagelschmidt gave a demonstration on "The Thermal Effects produced by High-frequency Currents." D'Arsonval directed attention, twenty-five years ago, to the "disagreeable burning sensation" that invariably accompanies the application of high-frequency currents. In the apparatus now shown this thermal effect is specially encouraged. Instead of the very high voltage (upwards of 100,000 volts) used in the ordinary forms of high-frequency application, the apparatus for diathermy gives about 800 volts, but the current which actually traverses the body reaches as much as $2\frac{1}{2}$ amperes. Stronger currents have been employed, but are not, in Dr. Nagelschmidt's opinion, free from danger. The demonstrator placed two circular electrodes at opposite sides of a piece of raw liver, and showed how the passage of the current produced a solid column of coagulated liver, the borders of which were strictly limited by the diameter of the electrodes, the portions of liver immediately outside the cylindrical coagulated block remaining quite unaffected. The sharply limited action of the current was demonstrated even more graphically by means of a solution of white-of-egg contained in a glass trough. In this case, when the electrodes were placed near opposite ends of the trough, a column of coagulated albumin could be seen to form between them, and if a small current (0·5 ampere) were used the coagulation commenced, not at the electrodes, but at a point midway between them, and extended thence to the electrodes. The practical applications of this current were described, and it was shown how masses of diseased tissue (such as cancers) could be removed without loss of blood and without fear of damaging contiguous parts. Apart from this, many forms of localised pain could be relieved in a few minutes by applying an electrode to the area of skin overlying the painful region. Several other possible therapeutic uses of the diathermal currents were mentioned, including the power of these currents to strengthen and accelerate the heart's action. The high-tension current is obtained by a motor generator giving alternating current. The current to be applied to the patient is easily regulated from a switch table.

Lieut.-Colonel L. A. Waddell, one of the leading authorities on the literature of Tibet, has deposited in the library of the India Office about one thousand books and manuscripts collected by him during the last expedition to Lhasa. These include a remarkable collection of ancient anatomical drawings from the Temple of Medicine at Lhasa, which preserve in pictorial form the old-world Indian beliefs regarding the structure and functions of the internal organs of the body. Much of this Indian surgical lore is probably of Greek origin, but the routes by which it may have reached India have not been clearly traced. This Tibetan series of drawings is believed to have reached Lhasa in the eighth century A.D. The collection will prove of much interest to students of Oriental surgery.

The prehistoric boat discovered at Brigg, Lincolnshire, in 1886, formed the subject of a law-suit, the result of which was that it was awarded to Mr. Cary-Elwes, Lord of the Manor, who has now presented it to the Hull Museum. It is in a rather dilapidated condition, but has been repaired, so far as possible, under the supervision of the curator, Mr. T. Shepherd. In his useful series of museum manuals he has now given full details of the discovery, with various drawings and photographs illustrating this remarkable exhibit. To this is appended a bibliography, which shows that few objects of antiquity discovered in this country have given birth to a more extensive literature.

In a supplement to the Annals of the Transvaal Museum Messrs. Gunning and Haagner have published a check-list of the birds of South Africa, based on Reichenow's "Vögel Afrikas," but bringing the subject up to date. The Zambezi-Cuneni line (lat. 16° S.) is taken as the boundary of the area, in which 919 species are recognised.

To the Annals of the Transvaal Museum for February Mr. J. Hewitt contributes an article on the zoological region of South Africa as deduced from the composition of its Lacertilia. After mentioning that the Zambezi-Cuneni line does not form a natural zoological boundary, as there is an extensive overlap of the southern and tropical faunas, the author expresses the opinion that the southern districts of Africa possess a fauna sufficiently peculiar to entitle this area to be regarded as a distinct zoological region, divisible into several subregions. "As regards the entity of the South African region as a zoological area, there can be no doubt but that the distinction between the peculiar endemic fauna of southern Africa and tropical Africa is too pronounced to permit of our regarding the South African region as merely a province of the large Ethiopian area, and, indeed, but for the infiltration of tropical forms, no one would hesitate to unite South Africa with Madagascar as a region quite distinct from the more northern parts of Africa. But the question of the northern boundary of our area is quite another matter." The author's conclusions seem to be entirely based on reptilian and amphibian evidence.

Great interest attaches to a paper by Mr. G. E. Pilgrim in vol. xl., part i., of the Records of the Geological Survey of India on new genera and species of mammals from the Indian Siwaliks, chiefly, it seems, those of the Punjab and Bugti Hills. Among numerous other forms, special reference may be made to *Sivapithecus indicus*, a new generic type based on the last lower molar of an anthropoid, which agrees in size and general form with the corresponding tooth of the gorilla, but has lower cusps and no cingulum. Upper and lower jaws indicate a second new anthropoid, referred to the European genus Dryopithecus. If rightly assigned to Mœritherium—and the reference is only provisional—a small and primitive proboscidean molar from the Bugti Hills apparently indicates a migration of the ancestors of the elephant-group from northern Africa to north-western India. From a phylogenetic point of view, perhaps the most interesting of all the new "finds" is the genus and species described as *Dorcabune anthracotheroides*. This species, according to Mr. Pilgrim, "shows the most extraordinary mingling of traguloid and anthracotheroid characters. Its upper molars may be described as like those of a Dorcatherium, only of an extreme bunodont and brachyodont type. . . . The same type of structure is displayed in the lower teeth, which, however, differ less, qualitatively, from Dorcatherium than the upper ones. . . . On the whole, the genus may be appropriately placed in the Tragulidæ."

The determinations of a small collection of plants gathered by Dr. Th. Derbeck on the shores of the Gulf of Tartary, near the mouth of the Amur, are communicated by Mr. V. L. Komarov to the *Bulletin du Jardin impérial botanique*, St. Petersburg (vol. x., part iv.). A characteristic littoral formation was prevalent, in which *Elymus mollis*, *Rosa rugosa*, and *Poa glumaris* were conspicuous. Two new species are created in *Leontopodium tataricum* and *Saussurea Derbecki*. The list of 158 plants affords an interesting comparison with the flora of Saghalien.

A short article communicated to the *Gardener's Chronicle* (October 22) by Mr. H. S. Thompson on botanising in County Kerry will interest the keen field botanist. Mt. Carrantual, the highest peak in Ireland (1041 metres), and a noted locality for Alpine plants, was the chief centre of attraction. The discovery of *Juncus trifidus* near the summit practically establishes a new record, and *Sieglingia decumbens* was also collected at an elevation above 1000 metres. Lower down, the two closely related species or varieties, *Saxifraga decipiens* and *S. Sternbergii*, were found in company with *S. stellaris*. Another find of great rarity was supplied by *Sisyrinchium angustifolium* growing with Drosera, *Lobelia Dortmanna* and bog Asphodel by Lough Caragh.

Three generic revisions are published in vol. xliv. of Engler's *Botanische Jahrbücher*: Dr. M. Burret discusses the relationships and distribution of African species of Grewia, Dr. W. Moeser amplifies a former collation of the genus Helichrysum in Africa, and Dr. Heinz Stiefelhagen contributes an account of the genus Scrophularia preparatory to the compilation of a monograph. The last survey of the genus Scrophularia was prepared by Bentham for De Candolle's Prodromus, since which time the species have almost doubled in number, mainly owing to plants collected in Persia, China, and Tibet. The author is of opinion that the genus is in an early stage of development. He fails to find a natural group character in the absence of a staminode, and bases his primary divisions on the habit, *i.e.* whether the plants are herbaceous or shrubby with well-developed leaves or xerophytic undershrubs with scanty leafage.

A sketch of the flora and plant formations of the Kermadec Islands, contributed by Mr. R. B. Oliver to the Transactions of the New Zealand Institute (vol. xlii.), is the outcome of a visit for eleven months to Sunday Island and flying visits on the way home to the three smaller islands. Several species are added to the flora, bringing up the total to 114 ferns and flowering plants. The author makes a new species of a smooth-stemmed lofty tree fern, *Cyathea kermadecensis*, separating it from another endemic species, *C. Milnei*, that has a short, rough stem. The forest formations are the most extensive and important. The dry forest shows three tiers of vegetation; the topmost consists almost entirely of trees of *Metrosideros villosa* about 60 feet in height; smaller trees such as *Rapanea kermadecensis, Myoporum laetum*, the palm *Rhopalostylis Baueri*, and *Cyathea Milnei* form the next tier, while *Pteris comans* supplies the ground vegetation in many districts. The other Cyathea, characteristic of wet zones, in one locality forms a forest as lofty as the Metrosideros. The author proposes to include the Kermadecs, with Lord Howe and Norfolk Islands, in a "subtropical islands' province" of the New Zealand region.

The *Rassegna Contemporanea* for September contains two articles of scientific interest. One is the speech given by Cannizzaro at the complimentary banquet at Rome on the occasion of his receiving the Copley medal of the Royal Society, a copy having been preserved along with his copious scientific and political correspondence. A photograph of part of the manuscript is also reproduced. Another article, by Riccardo Dalla Volta, deals with the International Agricultural Institute recently founded to collect agricultural statistics on an international basis. There is a useful field of work in this direction. The methods of collecting statistics and of crop reporting vary considerably in different countries, and any organisation that makes for greater uniformity is to be welcomed.

The Agricultural Department of the Transvaal is continually suggesting new crops and new industries to farmers, and in a recent issue of its Journal (vol. viii., No. 32) one of its experts discusses the possibility of raising ostriches. The best feathers are only produced when the birds are sufficiently nourished, and a good supply of food is therefore necessary. Lucerne is so valuable a food that wherever it can be grown the birds may be expected to thrive; about 40 lb. of the green crop or 10 lb. of the hay is taken by an ordinary ostrich weighing from 250 to 300 lb. If maize or other concentrated food can be supplied less lucerne becomes necessary, and a larger number of birds can be kept on a given area. A number of districts are indicated where ostriches might be expected to do well.

In the meteorological chart of the North Atlantic Ocean for November, published by the U.S. Weather Bureau, Prof. W. L. Moore points out that this month marks the beginning of the stormy season over the Transatlantic routes. For the purpose of illustrating the general behaviour of the storms, instructive synoptic weather charts are drawn for each day from November 11–16, 1909, inclusive, showing a typical case. The storm in question originated in high northern latitudes, and moved in a more or less easterly direction from Newfoundland to the north-east of the Azores. The chart for November 16 shows that the barometric depression had deepened and increased in size until the entire eastern part of the ocean was affected by the storm area. It also shows that a second barometric depression, apparently an offshoot of the central system, had formed about 500 miles north-westward of the Azores, which gave rise to severe weather along the northern shipping routes. Its approach to the British Islands seems to have been checked by the high-pressure system prevailing there.

Snowfall in the Transvaal is a somewhat exceptional occurrence; so far as can be ascertained, there have been only eleven years out of the last fifty-seven (1853–1909) in which it has been recorded. On two occasions, 1903 and 1904, the falls were very slight, and none was experienced during 1905–8 inclusive. The *South African Journal of Science* for September contains an interesting article on the subject by Mr. H. E. Wood, of the Transvaal Meteorological Service, with special reference to the heavy storm of August 16–18, 1909. Although a rather heavy fall occurred at Johannesburg in May, 1892, the fact of the town being covered to a depth of several inches on the morning of August 17 was such an unusual event, especially for the younger generation, that the day was celebrated as a general holiday. The maps of the distribution of atmospheric pressure show that the snowfall was associated with the rapid approach of a high-pressure system towards a region over which low pressure had previously existed. In the author's experience it has always been found that any widespread rainfall over eastern South Africa is connected with a rising barometer.

Prof. A. Piutti has sent us an abstract of a paper by him, read before the Royal Academy of Naples, on the absorption of helium in salts and minerals. Prof. Piutti has been able to detect helium in the gases extracted from borax and other salts, which have been melted and then suddenly chilled while a current of air has been bubbling through them. This experiment he regards as throwing doubts on Prof. Strutt's conclusions on the measurement of geological time from radio-active data. It is urged that helium may have been absorbed by the molten material of the igneous minerals, either from the atmosphere or from gases existing in the interior of the earth, and that similar processes may even have occurred in the sedimentary rocks.

THE third part of *Terrestrial Magnetism and Atmospheric Electricity* for the present year contains two valuable tables of corrections to the British Admiralty, the German Admiralty, and the United States Hydrographic Department magnetic charts of the North Atlantic, by Dr. L. A. Bauer and Mr. W. J. Peters, based on the observations made by the magnetic ship *Carnegie* during her recent cruise. Over almost the whole area the three charts show too low values for the west magnetic declination, the error being generally less than a degree, but in some cases it is nearly 3°. As the error is in the same direction for 5000 miles, it may result in a serious error in the position of a vessel at the end of a voyage. The corrections to the dip are not always of the same sign; their average magnitude is nearly 2°, and the actual amount in one case exceeds 4°. Over most of the region the values of the horizontal intensity given in the charts are too high by 8 units in the third decimal, C.G.S. units.

A NEW electric generating station was opened on October 12 at the Northampton Polytechnic Institute. The plant was supplied by Messrs. Siemens Brothers Dynamo Works, Ltd., chiefly for instructional purposes as an example of the latest ideas in central station practice, and comprises electrical apparatus for alternating- and for continuous-current working. The buildings of the polytechnic are sufficiently large to present experimental facilities on an engineering scale for most of the problems which have to be handled in larger stations. It is intended to run the station on a thoroughly commercial basis; the coal, wages, and other expenses will be strictly charged up, and every unit of electrical energy supplied for the purposes of the work of the polytechnic will be metered regularly and sold to it. The senior students, with the help of the technical staff, will take charge of this work. The main features of the plant are two gas-driven sets, each consisting of one continuous-current generator and one high-voltage alternator in tandem. The polytechnic authorities have issued for the use of intending students and others a full and well-illustrated description of the details of the whole plant, including gas-engines, suction gas-producer plants, alternators, motor-generator set, switchboards, transformers, and so on.

COMMENTING on the *Atlantic* airship voyage, the *Engineer* for October 21 does not pretend to any regret that the attempt has been an unqualified failure. Nothing of any value could have been expected from such a voyage arranged for spectacular purposes only. Enough, and more than enough, has been done to make the conquest of the air spectacular. If flight in its varied forms is to rise above the level of a mere sport, it is time that a little steady humdrum, useful work was entered upon, and that the praise of the public and the winning of prizes were forgotten. Much remains to be done, and it is well that it should be done steadily and scientifically by honest spade-work, and not under the glamour of popular sensationalism.

THE successful launch of the White Star liner *Olympic* at Belfast on October 20 gives occasion for a long illustrated article in *Engineering* for October 21. With a total weight of 27,000 tons, it can be understood that very careful provision had to be made to ensure the successful floating of the ship. The standing ways were about 800 feet long and the sliding ways about 700 feet long. The ship overhung the cradle aft to the extent of 80 feet, and forward to about 50 feet. The average pressure on the ways was only just above 3 tons per square foot. The declivity of the ways forward was $\frac{3}{8}$-inch per foot, and aft $\frac{1}{2}$-inch per foot. On the occasion of the launch the weather was perfect, with a slight stern wind. The pressure on the hydraulic ram of the trigger arrangement was 435 tons, and on this being released the ship moved at once, the hydraulic starting jacks not being used. The time taken was sixty-two seconds, and the maximum speed attained was $12\frac{1}{2}$ knots. When brought to rest, the bow of the vessel was 500 feet from the end of the ways. Messrs. Harland and Wolff deserve most hearty congratulations on their success, this success being due, in a large measure, to the minuteness and precision with which every detail connected with the operation had been anticipated.

A BOOK on "English Philosophy," by Mr. Thomas M. Forsyth, is shortly to be issued by Messrs. A. and C. Black. Its aim is to give an outline of the development of English philosophy from Bacon to the present day.

ERRATUM.—The author of the review of Prof. Seward's "Fossil Plants" in NATURE of October 20 writes:—"May I point out a slip, for which I am responsible, in my review? On p. 491, column 1, Arber and Parkin should be Arber and *Thomas*."

OUR ASTRONOMICAL COLUMN.

A BRILLIANT METEOR ON OCTOBER 23.—Mr. W. F. Denning writes:—"A splendid meteor was seen by Mr. J. E. Clark at Purley, Surrey, on October 23, at 8h. $12\frac{1}{2}$m. It shot slowly from $52°+34°$ to $72°+40°$, and left a streak for six seconds. The flight was directed from a radiant in the head of Aries, and the duration was four seconds. From Lincolnshire and the eastern counties the meteor must have appeared a magnificent object, and further descriptions of its apparent course will be very useful to aid in determining the real path above the earth."

SIMULTANEOUS PHOTOGRAPHIC OBSERVATIONS OF A REMARKABLE METEOR.—Herr Sykora, in No. 4447 of the *Astronomische Nachrichten*, gives particulars of the path of a bright meteor, of which the trail was photographed at three different stations, Taschkent, Iskander, and Tschimgan, on August 11, 1909. The brightness of the meteor varied considerably during the flight, and as the knots and outbursts are similarly shown on all three photographs, it has been possible to determine the heights at which they occurred. The first part of the trail, then very faint, began at 112 km., and suddenly brightened up at 97·7 km.; then there were marked outbursts at 88 and 85 km. respectively, with a sudden falling off at 83 km. At 81 km., however, a sudden recalescence occurred, and final extinction took place at 80·7 km. The radiant was found to lie in the position $\alpha = 44{\cdot}0°$, $\delta = +56{\cdot}9°$.

TWO REMARKABLE PROMINENCES.—No. 2, vol. xxxii., of the *Astrophysical Journal* (September, p. 125) contains a note, by Dr. F. Slocum, describing two remarkable prominences photographed with the Yerkes spectroheliograph during March and April.

One of these was remarkable for the lengthy period of its existence, the other for its extreme activity and brief existence. The former was first seen disappearing over the western limb of the sun on March 4, but reappeared, larger and transformed, on March 16; it was last photographed on April 28. On March 18 the prominence extended from latitude $-20°$ to $+25°$, and its longitude was about 70°; throughout its existence, of probably about 55 days, the southern limit was practically constant, but the northern limit varied considerably. The recorded apparent height varied between 77,000 km. (March 18) and 12,000 km. (April 1); when last photographed (April 28) the height was 61,000 km., but prominence plates secured on May 11, 12, 13, and 14 showed no trace of the outburst. A number of photographs, in H_α, calcium, light are reproduced in the journal, and it is stated that visual observations on April 13 showed the prominence to have the same form and size in the radiations $H\alpha$, $H\beta$, and D_3.

The other prominence was first noticed on a plate taken at 7h. 46·7m. G.M.T. on March 24. It was then conical in form, with a base extending from position-angle 230° to 235°, and an apparent height of 46,500 km. On a photograph taken March 25, at 2h. 54·9m., the prominence had assumed a rugged tree-form, with the trunk in position-angle 229·7°, and the height was 75,500 km. Then a rapid increase of height set in, and by 5h. 55·4m. the greatest altitude shown on the plate was 319,500 km. (nearly 200,000 miles), but the top of the glowing mass was beyond that. The greatest motion was observed between 4h. 56·1m. and 4h. 57·9m., during which period 11,600 km. were covered at a rate of 107 km. (66·8 miles) per second. This increase of height occurred in two ways, first by actual growth and then by detachment from the limb and the upward motion of the complete mass. At 7h. 43·3m. there was no trace of the prominence, which had apparently vanished upwards, and Dr. Slocum suggests that this floating away, rather than subsidence, is characteristic of eruptive prominences.

THE RELATIONS BETWEEN SOLAR AND TERRESTRIAL PHENOMENA.—In No. 4, vol. viii., of *Scientia* Abbe Th. Moreux has a long article (pp. 279–305) dealing with the connections between solar phenomena and terrestrial meteorology, more especially rainfall. He points out that as yet the science is in its infancy, that we are still unable to forecast scientifically, and then proceeds to show, by an excellent review of what has already been done, what progress has been made and what hopes for the future are well founded. The labours of Herschel, Schwabe, Wolf, Norman Lockyer, Meldrum, Chambers, Brückner, Stone, Balfour-Stewart, W. J. S. Lockyer and others, are discussed, and it is shown that a gradual progress in the collection of data and the correlation of phenomena has taken place. A fitting tribute is paid to the English Government for the installation of the Solar Physics Observatory, and the related observatories in India and Mauritius.

Finally, M. Moreux suggests that the excessive floods and rainfall of the present epoch are in accordance with precedent, heavy precipitation following the spot activity of 1905–7, and he suggests that the outlook for the future, in the matter of establishing laws which will warrant forecasting, is hopeful.

SEARCH-EPHEMERIDES FOR WESTPHAL'S COMET, 1852 IV.—Three search-ephemerides for Westphal's comet are given by Herr A. Hnatek in No. 4447 of the *Astronomische Nachrichten*: each ephemeris covers the period November 1, 1910, to January 30, 1911. As the period of the comet is uncertain, these three ephemerides are given, based on elements which give it as 60, 61, or 62 years respectively. The declinations are all between 56° and 60° south, and the computed magnitudes range from 13·1 to 14·8.

THE INTERNATIONAL CANCER CONFERENCE AT PARIS.

THE first International Conference on Cancer was held in Heidelberg in 1906 under the auspices of the German Cancer Committee, on the occasion of the opening ceremony of a cancer hospital and laboratory erected and equipped through the efforts made by Prof. v. Czerny, the distinguished surgeon. Out of that conference there developed an International Association for the Study and Suppression of Cancer, modelled on the lines of the International Association for the Suppression of Tuberculosis. This body, together with the French Association for the Study of Cancer, was responsible for the second conference, held in Paris on October 1–5 under the patronage of the President of the Republic. M. Doumergue, the Minister of Public Instruction, presided over the opening ceremony, attended by 150 delegates, including official representatives of the twenty-three foreign Governments. Dr. E. F. Bashford, director of the Imperial Cancer Research Fund, represented the British Government.

In his opening remarks M. Doumergue, after directing attention to the reunion of the nations in spontaneous congresses for the relief of physical, social, and moral miseries as a characteristic of the present age, pointed out the significance of the unanimity of these humanitarian endeavours, enlarged upon the advantages accruing from exchange of views and from the dissemination of discoveries, and asserted the futility of isolation. In his opinion the publicity obtained for the proceedings of such conferences is bound to bear fruit in a profitable collaboration between the medical profession, the public in general, and patients suffering from cancer.

Prof. von Czerny, the president of the conference, then addressed the delegates, and was followed by Prof. Bouchard, president of the French association, and Prof. Landouzy, dean of the faculty of medicine. Each surveyed the cancer problems from different points of view, the question of parasitic etiology, the alleged increase of the disease, and the possibilities of surgery, radium, and electrotherapeutics being discussed by von Czerny. Landouzy took more the point of view of the physician, seeing in much of the work that had been done on immunity indications of ultimately obtaining a curative serum. The foreign delegates were afterwards called upon.

The scientific papers were grouped in six sections:—(1) histology and histological diagnosis; (2) statistics; (3) clinical diagnosis; (4) treatment; (5) etiology and experimental pathology; (6) comparative pathology. Section (1) appointed a committee to draw up an international nomenclature of new growths. The discussion on statistics and statistical methods revealed strong criticism of the methods and results expounded by Prof. George Meyer, of Berlin, and no progress was made towards the compilation of comparable international cancer statistics. The papers in Section (3), on clinical diagnosis and on the chemistry of cancer, showed that serum diagnosis could not be trusted to replace older methods. The papers on treatment were followed by important discussions on the value of aids to surgical treatment, *e.g.* fulguration, X-rays, radium.

Little was said in favour of fulguration. The employment of radium was very fully discussed. Few of the speakers were prepared to employ it in other than small superficial lesions without previous resort to surgery; although many speakers had employed radium, they appeared to be of the opinion that they had in their possession quantities too small to permit of satisfactory conclusions as to its ultimate value. In Section (5) von Dungern, of Heidelberg, gave an account of the immunity reactions to transplanted cancer; he confirmed the conclusions of the Imperial Cancer Research Fund to the effect that the phenomena in question were due to the artificial induction of active resistance or "active" immunity to the cancer cell. Dr. Fichera had applied the results obtained by immunising animals with normal tissues to the treatment of cancer in man. He claimed to have caused the disappearance or reduction in size of true malignant new growths. Dr. Borrel described the evidence he had collected bearing on the possibility of Cestodes and Demodex fulfilling the part of carriers of a hypothetical cancer virus. Dr. Borrel's cautious statements called forth a vigorous criticism on the part of Durante. In the section of comparative pathology Prof. C. O. Jensen described tumours occurring on beets; no causative parasites were found in them. These tumours had been transplanted into other beets. From their general biological behaviour he very cautiously inclined to regard them as analogous in the vegetable kingdom to cancer in the animal kingdom.

The delegates were entertained in the most hospitable and attentive manner, both officially and privately. Much of the time officially devoted to discussion was absorbed by what were really new unannounced contributions, and, apart from the discussions on clinical matters and on treatment, very little serious discussion took place in the official sittings. This shortcoming was, to some extent, compensated for by the willingness of the delegates to discuss their respective points of view in private intercourse; nevertheless, purely scientific and theoretical questions suffered by being crowded out by matters assumed to be of more pressing importance from the point of view of the lay public.

As in the opening ceremony, so also in the closing ceremonies, interest centred round the utterances of Dr. Bashford with reference to the attitude of Great Britain towards the International Association, the organisation and proceedings of which have, in the past, not met with unanimous approval. The abstention of Great Britain from membership of the International Association was possibly in M. Doumergue's mind during his opening remarks, and was unambiguously referred to at that ceremony by Dr. Bashford, who explained that in Great Britain the opinion is held that the time is hardly ripe for congresses concerning a disease of which so little is known as cancer, and which, at present, it is impossible to prevent, there being at the same time nothing revolutionary for such conferences to agree upon or to discuss. What is wanted at present is rather an army of independent active workers, for, as in the past in regard to other matters, so in the future with regard to cancer, advances in knowledge are to be expected from individual investigation rather than from the deliberations of national committees or international conferences. Still, workers in Great Britain have done all that is practicable to further international intercourse and collaboration, and will do so in the future.

In his closing remarks von Czerny, as president, expressed the hope that the objections to the organisation and assumed functions of the International Association will be removed before the conference is again called together, probably in Dresden in 1913.

It may be recalled that the proposal to hold a second International Conference in Paris was made after a proposal to hold the first International Cancer Congress in London had been rejected by responsible persons in this country.

REPORTS OF METEOROLOGICAL OBSERVATORIES.

BREMEN, "*Meteorological Year-book*" (1909).—This volume, the twentieth of the series, gives a short monthly summary of the weather, observations thrice daily (in the form adopted by the International Committee), two-hourly readings of the self-recording instruments, and monthly and yearly *résumés*. The results for earth temperature at various depths (0–300 cm.), evaporation, solar and terrestrial radiation, &c., for a number of years are shown both graphically and in tabular form. The curves of duration of sunshine, evaporation, and solar radiation all exhibit a similar and peculiar kink from July to August. Dr. Grosse points out that, whereas Hann considers that evaporation is most intimately connected with temperature, he (the author) thinks it is more closely connected with the duration of sunshine. The rainfall at Bremen is greatest between June and October inclusive; July has a decided maximum.

Liverpool Observatory (1909).—The Mersey Docks and Harbour Board, which maintains this important institution in the interest of navigation, has caused a second seismometer to be erected under Prof. Milne's supervision, and some devices of great delicacy were introduced in order to solve certain problems connected with the physics of the earth's crust. The instrument has not been long at work, but it is said that the records indicate clearly a deformation of the surface due to the load of tidal water in the Mersey estuary. We have before pointed out that the automatic meteorological instruments include anemometers designed by Osler, Robinson, and Dines respectively; the tables show for each day the velocities recorded by the Dines' instrument, the horizontal motion of the air, and the extreme pressure on the square foot—in addition to the direction. The mean temperature of the year (mean of maximum and minimum), 48·1°, was 1° below the average; the absolute maximum, 76·4°, occurred in May, and was 12·7° below the highest record; the minimum was 22·3°, in December, 13·8° above the lowest record. The rainfall, 28·45 inches, was very slightly below the normal.

Royal Alfred Observatory, Mauritius (1909).—From tables showing the means and extremes of the principal meteorological elements, it appears that the mean temperature of the year was 72·9° as compared with the average, 73·4° (1875–1905); mean of daily maxima 80·4°, minima 66·7°; absolute maximum 89·3°, in December; minimum 54·7°, in July. Maximum in sun's rays 163·4°, in January; minimum terrestrial radiation 45·7°, in May. Rainfall, 47·83 inches, as compared with an average of 47·95 inches; the principal feature was a total excess of 11·23 inches above the normal in June and July. The rainfall of June was the greatest on record in all parts. The annual amount for the whole of the island (mean of seventy-two stations) was 90·50 inches, as compared with an average of 82·37 inches. During the year eight cyclones occurred in the South Indian Ocean; tracks of six of them in January and March are given. The mean magnetic declination was 9° 16·34′ W. The magnetic disturbance which occurred on September 25–26 was the greatest on record, the total movement in horizontal force being 0·00650 C.G.S. unit. Photographs of the sun were taken daily when weather permitted, and 103 negatives were forwarded to the Solar Physics Committee.

Transvaal Meteorological Department (1908–9).—The number of stations reporting to the Johannesburg Observatory during the year ended June 30, 1909, was 599, an increase of fifty-two since the last report; these are mostly rainfall stations. The year was the wettest since accurate statistics have been collected, but several such rainy seasons will be required before the springs can regain their former activity. The average for the whole colony was 40·6 inches, on eighty-three days; the greatest rainfall was on the eastern slope, in the Leidenburg district, where more than 109 inches on 133 days were recorded. Maps are given showing (1) the rainfall for 1908–9, and (2) the mean for the last five years; the latter shows that only the eastern part of the colony has an average of more than 30 inches. No snowfall was reported by any station. but some was seen on the hills on August 21, 1908. The meteorological tables include hourly or two-hourly readings at Johannesburg and Pretoria. Daily weather forecasts are issued, and are exhibited at all postal telegraph offices. The Johannesburg Observatory is well provided with self-recording instruments, and it is expected that a set of Wiechert's instruments for recording earthquake phenomena will be shortly installed; at present the department distributes and collects postcards giving particulars of any earthquakes noticed.

Deutsche überseeische meteorologische Beobachtungen (*Heft xviii.*).—As in several past years, this very valuable series of observations has been published by the Deutsche Seewarte, with the assistance of the German Colonial Office. The present volume includes monthly and yearly summaries of the stations under the control of the Seewarte, also observations at the imperial observatory at Tsingtau and affiliated stations, and those made in East Africa, some of which are printed *in extenso*. The data refer mostly to 1908, with a few arrears, and useful references are given in many cases as to where the earlier observations may be found. We note in the Acta (1909) of the Solar Commission of the International Meteorological Committee, which proposes to publish certain meteorological data for the whole globe in a condensed form, that the German oversea observations will be turned to good account. The headquarters of the commission (of which Sir Norman Lockyer is president) are at present in London, in connection with the Solar Physics Observatory at South Kensington.

TREES AND TIMBER.

THE difficulty of identifying timbers exported from partially explored countries is only too well known, so that any attempt to arrange an authentic collection of specimens of tropical timbers deserves recognition. With this object, Dr. M. Büsgen has placed on record in the *Mitteilungen aus den Deutschen Schutzgebieten* (vol. xxiii., part ii.) the distinguishing characters of the trees noted on an expedition through the German Cameroons, and has published a series of figures illustrating sections of representative timbers, of which original specimens are stored at the Forestry College in Münden. The author records a preponderance of species for the families Leguminosæ, Apocynaceæ, Euphorbiaceæ, and Moraceæ. Among the more important trees are *Chlorophora excelsa*, apparently identical with African teak; *Enantia chlorantha*, a yellow-wood; *Entandophragma Candollei*, a source of mahogany; *Lophira alata*, known as ironwood; and *Mimusops djave*, that furnishes Congo mahogany.

In connection with the economic side of Indian forestry, Mr. R. S. Troup has prepared reports on the fissibility of some Indian woods and the prospects of the match industry in the Indian Empire, the former published in the Indian Forest Records (vol. ii., part ii.), the latter in the Indian Forest Memoirs (vol. ii., part i.). The experiments on fissibility indicate that splitting depends mainly on the nature of the grain, and that a hard wood with straight grain, such as *Acacia catechu*, splits more readily than a cross-fibred soft wood, such as *Bombax malabaricum*. Tests were also made to compare the cleaving force required in tangential and radial planes, with the result that for most timbers cleavage proved to be easier in the tangential plane. The memoir on match woods is very comprehensive, and sets out the results of practical manipulation with different woods, suitable locations for factories, the possibility of obtaining supplies, and an article on the manufacture of matches. Species of poplar, willow, and alder—the trees that yield wood used in European factories—are found in parts of India, but not in sufficient quantity. Fortunately, a number of Indian trees yield suitable wood, amongst which *Bombax insigne* and *B. malabaricum* are expected to furnish the bulk of supply.

An article in the *Kew Bulletin* (No. 6) on new trees and shrubs, contributed by Mr. W. J. Bean, refers with one exception to Chinese introductions. Three conifers are described: *Larix Potaninii*, a larch attaining a height of 70 feet; *Picea complanata*, a flat-leaved spruce; and *Tsuga yunnanensis*. Of the dicotyledons, a pinnate-leaved species of Syringa is a novelty collected by Mr. Wilson for Messrs. Veitch; *Pyrus Folgneri* is an attractive horticultural addition to the genus, and *Meliosma Veitchiorum* possesses both morphological and horticultural interest, as it is the only tree in the family Sabiaceæ hardy enough for outdoor cultivation in this climate, and promises to be a most ornamental acquisition to the garden. Considerable interest attaches to a revision of the genus Entandophragma communicated by Mr. T. A. Sprague, because various species of the genus, and the allied genera Pseudocedrela and Swietenia, are important sources of timber.

SELECTIONS FROM AMERICAN ZOOLOGICAL WORK.

NATURE for 1908, vol. lviii., p. 140, contained an illustrated account by Mr. N. H. Corquodale of a pair of hartebeest horns attacked by a tineid larva. Another instance of antelope horns—in this instance those of a waterbuck—being attacked by such larvæ is illustrated by Mr. A. Busck in vol. lvi., No. 8, of Smithsonian Miscellaneous Collections. The author claims to have shown the nature of the larval tubes—apparently the work of *Tinea vastella*—more distinctly than has been done before.

The *spolia* of the Smithsonian Expedition to East Africa continue to afford the bases for new work, among which we may refer to a description by Mr. W. H. Dall, in No. 10 of the volume just cited, of three new land-shells, two referable to Buliminus and the third to Limicolaria.

It is always satisfactory when two or more observers arrive independently at the same conclusion. An instance of this is afforded in a paper on chimæroid fishes by Messrs. Bean and Weed, published in Proc. U.S. Nat Mus., No. 1723, where the authors come to the conclusion that the Japanese species described by Mr. S. Tanaka under the new generic title of Anteliochimæra is not separable from the long-beaked chimæras of the genus Harriotta, a view which had been previously adopted by Messrs. Holt and Byrne, although this was unknown to the authors until their paper was in type. Excellent figures are given of the typical *Harriotta raleighana*.

In this connection it may be mentioned that the part of the Journal of the College of Science of Tokyo University containing Mr. S. Tanaka's description of the so-called Anteliochimæra has only lately been received, although it is dated October, 1909.

Among papers relating to the North American fauna, mention may be made of Messrs. Meek and Hildebrand's list of fishes inhabiting the lakes, rivers, and lagoons of the Chicago district, issued as No. 9 of vol. vii. of the Zoological Publications of the Field Museum. Special interest attaches to the fish-fauna of the district owing to the changes caused by the growth of the great city; and it is hoped that the paper will lead to careful study of these changes, as well as to observations on the distribution and habits of the various species.

In another faunistic paper, Proc. U.S. Nat. Mus., No. 1719, Mr. D. Coquillett supplies a list of the type-species of North American genera of Diptera, a subject which comes very opportunely at a time when so much attention is being devoted to the biting flies of the world. That there was need for revision is exemplified by the statement that a certain fly, *Tachina vulgaris*, has been redescribed and renamed 257 times, one writer alone having made from it 245 species, arranged in five genera; this being only one—it may be hoped the worst—out of many cases. The author carries priority in nomenclature to the bitter end, a matter of less moment in this than in many other groups.

Perhaps the most important of all the papers in the batch on which these notes are based is one by Mr. A. H. Clark (Proc. U.S. Nat. Mus., No. 1756), on *Proisocrinus ruberrimus*, a new genus and species of stalked crinoid from the Philippines. The new form is by far the tallest existing member of the group hitherto discovered, the height, exclusive of the root, exceeding 40 inches. In colour it is brilliant scarlet, thereby differing from the purples and greens of the Pentacrinidæ, and the yellows of the Apiocrinidæ and Bourgueticrinidæ. The family position of the new genus is still uncertain; the general structure of the calyx and arm-bases recalling Bathycrinus, while the arms and pinnules are of the type of those of the Pentacrinidæ, although most of the stem resembles that of Calamocrinus. There is also an approximation—apparently more than superficial—to Millericrinus.

In No. 1759 of the aforesaid Proceedings Mr. J. A. Cushman describes a collection of arenaceous Foraminifera obtained by the *Albatross* during her recent cruise in the Philippines. Ten species and one genus (Sphærammina), are believed to be new. In the new genus the test consists of a series of spheroidal or ovate chambers arranged on a straight axis, with the one last formed envleoping the rest. In several respects it recalls the Miocene *Ellipsoidina ellipsoides*.

R. L.

DISTRIBUTION OF WEEDS.

THE numerous means by which nature ensures the distribution or dispersal of seeds of wild plants are well known to students of botany. For example, some seeds (Papaver, Orobanche) are very light and easily scattered by the wind; others (Cnicus, Senecio, Rhinanthus) bear flight organs or "wings," by means of which they sail away on the breeze; some seed vessels are so constructed that on ripening and opening they throw out the seed with considerable force (Lupinus); while some fruits bear hooks, by which they become attached to animals and man, and so secure distribution (Galium, Arctium). Unhappily, many serious weed pests are also distributed by man in agricultural and horticultural seeds and various other means, and doubtless many botanists have read of the emigrant Scotchman who, in the pride of his heart, took specimens of the national emblem to Australia, and so introduced a very harmful weed.

A few months ago an advertisement, resembling a paper butterfly, was widely distributed, and, probably for realism and novelty, it was made to bear the burr of the burdock (*Arctium Lappa*). This advertisement doubtless received attention owing to the fact that recipients attached it (by the "burrs") to the clothing of other members of the household! It appears that the same method has been utilised—perhaps by the same advertisers—in Australia, and the following extract from the *Agricultural Gazette of New South Wales* (August 2) is of interest:—"The Chief Quarantine Officer for Plants has informed the Under-Secretary for Agriculture of a most extraordinary method whereby an objectionable weed might be broadcasted throughout the State. It appears that, as an advertising medium, some printed paper, representative of a flying insect, has been sent to Australia, and the genius who invented this particular style of advertisement, in an endeavour to make it more realistic or uncommon, had attached to each specimen the burr or seed of the noxious weed 'Burdock' (*Arctium Lappa*). The authorities in Western Australia had called the attention of the Director of Quarantine to the use to which the burr of this noxious weed was being put. It is needless to say that business firms stopped the issue of the advertisement under notice as soon as they knew there was a serious objection to its use."

Burdock is a very troublesome weed, and it is clear that our colonial friends have to be on the alert if they are to prevent the introduction of new plants in the manner outlined.

THE LANCASHIRE SEA-FISHERIES LABORATORY.

THE eighteenth report of the Lancashire Sea-Fisheries Laboratory (for the year 1909) contains an account of work carried out at the University of Liverpool, at the sea-fish hatchery at Piel, and at the Port Erin Biological Station. Mr. James Johnstone describes five species of internal parasites of fishes from the Irish Sea, the three genera discussed being Lebouria, Prosthecobothrium, and Echeneibothrium. The same author reports on the measurements of some 55,000 plaice from the district, curves representing the frequency of fish at each unit of length for the most important fishing grounds being given. The average weights of plaice at each unit of length from various fishing grounds have also been determined. Taking Heincke's formula $w = \frac{l^3}{100}k$ where w is the weight in grams and l the length in centimetres, the monthly variations in the value of k have been calculated for several of the grounds. The value shows a maximum in July, and the minimum appears to be in January, at which time of the year very little food is found in the stomachs of the plaice.

A considerable section of the report is occupied by papers on hydrographical work done in the Irish Sea by Mr. Johnstone and Dr. H. Bassett. It is doubtful, however, whether the comparatively slender data contained in the papers of the latter writer can be usefully employed in the way suggested by him, in connection with the prediction of climatic conditions over extended periods of time. Very much more research will be necessary before such predictions can have any but a speculative value.

The report concludes with a paper by Prof. Herdman, Mr. A. Scott, and Mr. Dakin on plankton work carried out off the Isle of Man in 1909. The paper as a whole tends to confirm the doubts, which have often been expressed, as to the value of the quantitative methods of plankton work, as at present practised. Until some trustworthy instrument has been devised for accurately measuring the quantity of water which has passed through the net on each occasion, the elaborate methods of counting the organisms captured would hardly seem to repay the time which must necessarily be employed upon them.

ZOOLOGY AT THE BRITISH ASSOCIATION.

THE attendance of zoologists at the meetings of Section D was affected by the fact that the International Congress of Zoology at Graz and the International Congress of Entomology at Brussels had taken place so recently. These meetings abroad were probably responsible for the absence of a few of those who in previous years have contributed papers to the section. The programme, being a little less crowded than usual, was taken at a more comfortable pace, and reasonable time was available for discussion and remarks on the various subjects under consideration. The attendance at the meetings of the section was very satisfactory, especially in the circumstances, and the interest in the proceedings was fully maintained to the end; indeed, the concluding meeting was one of the best of the series.

Coral Snakes and Peacocks.

The popular lecture, which for several years has been a feature of the programme of the section, was given before a large audience by Dr. H. F. Gadow, F.R.S., who chose for his subject "Coral Snakes and Peacocks," and illustrated his remarks by a series of lantern-slides in colour. He first described some of the physical features of Mexico, during a visit to which country his observations on coral snakes (Elaps) were made. The red, black, and yellow markings of these snakes have been said to be of the nature of "warning coloration," but Dr. Gadow pointed out that, although the markings are conspicuous when the snakes are lying in a dish or other vessel, the colours commingle, especially in the dusk, with the natural surroundings of the animal, so that it becomes very inconspicuous. Coral snakes are entirely nocturnal in habit; they lie in hiding during the day, so that the explanation of their coloration as "warning" is unwarrantable. Many harmless snakes are coloured in a similar manner to the coral snakes, *e.g.* among a large collection of Coronella from various places in Mexico examples of one species were found which seem to have "mimicked" several of the colour patterns exhibited by species of Elaps. But Dr. Gadow pointed out that the specimens of Elaps and Coronella found in the same locality do not exhibit the same colour pattern. Dr. Gadow's conclusion, stated briefly, was that the resemblances in colour pattern between Coronella and Elaps are instances of pseudo-mimicry. In the second part of his address Dr. Gadow traced the gradual transition from a comparatively simple feather with light and dark bands to the "eyed" feather, with fully developed metallic lustre, of the mature peacock's "fan." He then described the retrogressive changes leading from the "eyed" feathers to the modified feathers of the back and margin of the "fan."

Coccidia and Coccidiosis in Birds.

Dr. H. B. Fantham described his observations on the life cycle of the sporozoon *Eimeria* (*Coccidium*) *avium*, which produces a form of "enteritis" in grouse, fowls, and pheasants, especially in young birds. Resistant oöcysts of the parasite are voided in the fæces of the infected birds, and are acquired by other birds in their food or drink. A mature oöcyst contains four sporocysts, in each of which are two active motile sporozoites. After the oöcysts have been swallowed by a bird, the cyst wall is softened by the pancreatic juice, the sporozoites creep out and penetrate the epithelial cells of the duodenum, in which they become rounded and grow, feeding passively on the host cell. After attaining a certain size, the nucleus and protoplasm of the parasite—now a schizont—divides into a cluster of merozoites arranged *en barillet*, *i.e.* like the segments of an orange. Very little residual protoplasm remains after the formation of merozoites. These small, vermicular merozoites glide away and invade other cells, within which they grow to schizonts and multiply. A number of generations of merozoites is produced in this way, and the destruction of the epithelium and the derangements resulting therefrom in some cases cause death of the host. In most instances some merozoites pass down into the cæca, where they grow and multiply, producing intense inflammation. Sooner or later a limit is reached, both to the power of the bird to provide nourishment for the parasites and to the multiplicative capacity of the parasite itself, and then sexual forms are produced. Some of the organisms become large and contain much reserve food material. These are the macrogametocytes, each of which, after the maturation changes, becomes a single macrogamete. Slightly smaller parasites, with little or no reserve material, undergo nuclear multiplication and give rise to many minute biflagellate microgametes, which disperse and swim away in search of macrogametes. Each of the latter has precociously invested itself with a cyst wall, in which a micropyle is left for the entry of the microgamete. One microgamete only fuses with the macrogamete, and then the oöcyst wall is completed by closure of the micropyle. This series of changes, from infection to the formation of oöcysts, extends over about eight or ten days in the grouse. At first the oöcysts are uninucleate, and their contents completely fill them; later the contents concentrate into a spherical mass, the nucleus divides into four, around each of which the protoplasm aggregates, forming four round sporoblasts. Each sporoblast develops into an oval sporocyst, in which two sporozoites are formed. The oöcysts, when dropped, are very hardy; some which had been taken from a moor a year previously were found to be still alive.

Coccidiosis is accompanied by an increase in the number of polymorphonuclear leucocytes in the blood of the host, together with a decrease in the number of the erythrocytes. Young birds are much more susceptible to coccidiosis than older ones, but older birds which have become "chronics" serve as reservoirs of oöcysts, and are constant sources of infection. Lime dressing of the soil, which destroys oöcysts, is the most effective treatment at present known for combating coccidiosis.

The Formation and Arrangement of the Opercular Chaetae of Sabellaria.

Mr. Arnold T. Watson contributed an account of the opercular chætae of *Sabellaria alveolata*. The operculum, with which this tube-building polychæte defends the opening of its tube, consists of two crescent-shaped structures, each of which is composed of three concentric rows of paleæ, of characteristic form, borne at the distal extremity of the peristomial lobe. Viewed from above, the exposed portions of the paleæ of the outer and middle rows are seen to be arranged in an imbricated manner, their free ends directed outwards, while the free ends of the paleæ of the innermost row, the chætae of which alternate in position with those of the middle row, are directed inwards and upwards. Mr. Watson has found that there are two "nests" for the formation of the chætae, an outer one supplying the outer paleæ and an inner one producing the middle and inner paleæ, which are packed alternately in the nest. The chætae can be traced, and evidently travel, in a somewhat spiral fashion to reach, in rotation, their respective positions at the dorsal end of each opercular crescent. A similar process was observed in *Sabellaria spinulosa*, but in this species there are, in each lobe, two or three long, curved, acicular dorsal chætae in addition to the three rows of chætae which form the operculum. In certain members of the family, *e.g.* Pallasia, the operculum is armed with only two rows of paleæ, but there exist, in addition, two or more hooks, placed dorsally, in positions corresponding to the acicula above mentioned. These hooks have been regarded by some zoologists as homologous with the missing middle row of opercular paleæ, but this view is rendered very doubtful by the conditions found, and described above, in *Sabellaria spinulosa*.

The Anatomy and Physiology of Calma glaucoides.

Calma is a small nudibranch mollusc living exclusively on the eggs of fishes, which it simulates closely in appearance. Mr. T. J. Evans described the modifications which this animal has undergone in response to its specialised diet. The radula, a rasping instrument in other gastropods, has become a saw for cutting open the eggs, the teeth being reduced to a single row. The stomach is enormously enlarged, and in well-fed specimens is filled with a hard, albuminous mass. During the feeding period the growth of the genital organs is retarded; they do not develop until the contents of the stomach have been digested, by which time space is available for the growing gonads. The gonads are not massed as in an ordinary Eolid, but are packed in the angles between the liver diverticula, and the male duct has been pushed forward to the level of the mouth. There is no intestine or anus, and the excreta of the first year remain on the floor of the stomach and liver branches under the food of the second year. In the cerata certain amœboid cells of the hæmocœl enter into relations with the liver cells and absorb protein from them. When fully impregnated with nutritive material they fall back into the hæmocœl as oval glassy cells, and the protein contents are gradually absorbed during the winter fast.

Sex and Immunity.

Mr. Geoffrey Smith gave the results of further work on the effects of the parasitic cirripede Sacculina on the spider crab Inachus. He has previously shown that the effect of the parasite is to cause the male host to assume adult female characters externally, and, after the death of the parasite, internally also, for large ova were produced in the testes. The effect of the parasite on the young female crab is of a similar nature, for the young infected female is forced to assume adult female characters at a premature stage. Mr. Smith suggested an ingenious explanation of these phenomena. He showed that, in an infected Inachus of either sex, the Sacculina-roots manufacture yolk similar to the ovarian yolk of a normal female Inachus. The parasite thus forces the crab, whether male or female, to produce substances in the blood from which the Sacculina-roots can manufacture yolk; as fast as these substances are produced the Sacculina takes them up and, by anchoring them, stimulates their continued production. These yolk-forming substances, saturating the body fluids of infected crabs, both male and female, cause the development of the secondary sexual characters. When the parasite dies and its roots no longer assimilate the yolk-forming substances, they are taken up by the remains of the gonad (which, while the crab was parasitised, had been reduced and non-functional), which consequently proceeds to form ova. In the parallel case of Peltogaster, parasitic on Eupagurus, Mr. Potts has shown that small ova are formed in the testes of the host while the parasite is still alive, so that, in this case, the excess of yolk-forming substances is taken up by the gonad during the life of the parasite. This over-production of a substance which is being anchored by a parasite is regarded by Mr. Smith as closely analogous to the production of antibody in immunisation. By supplying the Sacculina with the yolk-forming substances, the crab protects other nutritional substances necessary for its vital organs from being abstracted by the parasite.

In answer to comments by Prof. Bateson, F.R.S., and Prof. Hartog, regarding the nature of the eggs found in the testes of male crabs recovering from the attacks of Sacculina, Mr. Smith stated that such ova are as large and as fully formed as normal eggs, become pigmented (red) like the latter, and, so far as structure is concerned, are entitled to be regarded as ordinary eggs. Replying to observations by Mr. Doncaster regarding the presence or absence of "femaleness" in the male crab, Mr. Smith said that the conditions indicated that the male contains latent female potentialities, for these latter could not be introduced by the Sacculina, and yet complete formation of morphological female characters took place in recovering males.

The Colours of Insect Larvae.

Prof. Walter Garstang described a series of experiments which he had carried out this summer on the effects of foods deficient in chlorophyll on the coloration of phytophagous larvæ of Lepidoptera. The experiments were designed to confirm and extend the results obtained in 1892 by Prof. Poulton, who showed that, in the case of *Tryphaena pronuba*, larvæ fed on the white mid-ribs of cabbage retained a white ground colour (with the addition of superficial black pigment in the later stages), while larvæ fed on yellow etiolated leaves developed the same green and brown pigments as those fed on green leaves. Prof. Garstang obtained very similar results, using the larvæ of *Euplexia lucipara*. Larvæ fed from the time of hatching on the yellow inner leaves of lettuce developed the same green pigments as those fed on green leaves, while larvæ fed on the mid-ribs acquired a semi-transparent whitish colour, very faintly tinged with green or yellow. The superficial blackish markings developed in all cases.

On the other hand, the larvæ of *Mamestra brassicae* fed on mid-rib of lettuce and on carrot, while failing to produce the normal green colours, also showed a marked deficiency of the black superficial pigments which formed a conspicuous element in the coloration of normal green-fed larvæ during the last two stages. Several larvæ fed on mid-rib were practically white at the time of pupation; those fed on carrot were slightly darker. Further experiments would be necessary to show whether the deficiency of black pigments was due to altered metabolism or was comparable with the many cases among Geometrid and Vanessid pupæ, &c., in which the formation of black superficial pigment-screens is subject to inhibition from white or yellow backgrounds. The latter interpretation of this case was regarded by Prof. Garstang as improbable on the evidence available, for the mid-rib set had been kept for the most part in a dark cupboard, and two of these larvæ, transferred, when half grown, to purple cabbage in the light, had shown the same features to a pronounced degree.

In the discussion which followed, Mr. Doncaster inclined to the other interpretation, and suggested that the light reflected from the alimentary canal of the specimens on purple cabbage (which became blue-green after ingestion) may have had an inhibitive effect.

Insect Coloration.

Mr. Mark L. Sykes exhibited specimens of various insects among leaves and other natural objects, and in his remarks held that the colours of these insects supported the view of protective coloration. Mr. G. Storey, commenting on some remarks of Mr. Sykes on mimicry, mentioned Prof. Punnett's experiments on certain Ceylon butterflies of the genus Papilio, which are supposed to afford one of the most striking cases of mimicry. These experiments, he thought, were by no means sufficient to overthrow the theory of mimicry, but they showed that the mimickers derived little protection from their deception from certain classes of their enemies.

The Biology of Teleost and Elasmobranch Eggs.

Dr. W. J. Dakin confirmed the results reached by Botazzi and others which indicated that the osmotic pressure and salinity of the blood of marine teleosts were different from that of the external medium in which they lived, but were affected by changes in the salinity of the water. The blood of the eel has a lower osmotic pressure in fresh water than in the sea, and the blood of fresh-water fishes is less saline than that of marine fishes.

The osmotic pressure of the blood of elasmobranchs is almost identical with that of the sea water in which they live.

Dr. Dakin extended his observations to the eggs of certain fishes, and showed that the specific gravity of plaice eggs can be altered by varying the salinity of the water in which they are living. The egg-contents are therefore not independent of the sea water. He also showed that the salinity and osmotic pressure of the egg-contents was much less than that of the medium in which the eggs were living, and about the same as that of the blood of the adult fish. There is therefore an equilibrium between the sea water and the egg-contents which does not consist in an equality of osmotic pressures; while both osmotic pressures are very different, a change in that of the water produces a small but definite change in that of the egg-contents. Death of the egg-contents destroys the conditions under which this equilibrium is sustained, and the egg-contents increase in salinity by reason of the influence of the surrounding sea water; a corresponding increase in specific gravity takes place, and the egg is no longer able to float.

The osmotic pressure of elasmobranch eggs is very different from that of teleost eggs, though both may be living in water of the same salinity. The relation existing between the egg-contents of dog-fish eggs and the water is the same as that between the blood of the adult fish and the medium in which they live.

Semination in the Sanderling.

Prof. C. J. Patten has already pointed out that examples of the sanderling (*Calidris arenaria*), apparently in nuptial plumage, and occurring along our shores at the height of the breeding season, are not fully matured, their plumage presenting a slight difference from the true nuptial garb. To this plumage the name pre-nuptial was applied. Prof. Patten found, on examining the testes of such birds, that although a certain amount of spermatogenesis had taken place, no real functional activity had been reached. Of the sanderlings which occur on our coasts during the period when they ought to be nesting, those birds not pairing seem to divide into small parties and to lead a sort of nomadic life from shore to shore until about the end of August, when they tend to muster; in September they join company with migrants coming from northern climes, the latter, as a rule, being young birds in first autumn plumage. There are thus formed flocks of young and partially matured birds. The fully adult birds arrive about October. Prof. Patten considers that there is reason to believe that other species of shore-birds take more than a year to reach maturity, and that, prior to this period, their desultory migratory movements correspond in the main with those of the sanderling. Investigations into the question of semination in these cases would afford elucidation of some points of importance regarding avian migration and geographical distribution.

Anatomical Adaptations in Seals to Aquatic Life.

Dr. H. W. Marett Tims exhibited a series of lantern-slides illustrating some of his observations on the collection of embryo seals obtained by the *Discovery* expedition, and directed attention to the adaptations to aquatic life which these animals present. The rotation of the limbs to the adult position takes place at an early stage of development. The shortening of the neck is produced by a great ventral curvature of the spine in the cervical and anterior dorsal regions. This, too, is indicated at a very early embryonic stage in both male and female. Dr. Tims remarked, incidentally, that the manner in which the cervical region of the skeletons of seals in our museums was set up, namely, with the vertebræ almost in a straight line, was quite wrong. The prevention of the entrance of water into the lungs is brought about by a secondary growth of the posterior edge of the soft palate, which becomes fused with the wall of the œsophagus. The fact of the very early establishment of these modifications affords an instance of what some would regard as examples of the inheritance of acquired characters.

The Temporal Bone in Primates.

Prof. R. J. Anderson contributed some notes on the temporal bone in primates, pointing out that the squamosal shell, which has three or four ossific centres, sometimes shows a separate zygomatic part and occasionally a separate upper triangular part. The antero-posterior and vertical measurements of the bone in several primates were given; they vary from 5 : 1 in Pithecia to less than 2 : 1 in Semnopithecus. The various antero-posterior dimensions were regarded as evidence of facial influence and the vertical ones of cranial influence.

The Oxford Anthropometrical Laboratory.

Dr. E. Schuster presented some first results from the Oxford Anthropometrical Laboratory. One of the most interesting tests there carried out was that devised to measure the power of concentration. A pattern, made by pricking nine holes in a piece of cardboard, was shown to the subject five times, on each occasion for only a small fraction of a second. The subject was then asked to make a map of it on squared paper, which he generally failed to do correctly; he was shown the pattern again five times, and asked to make a fresh map, and so on until he produced a correct one. It was found that those men acquitted themselves best under this test who subsequently did well in the final schools, and that men reading science and mathematics were, on the whole, better than those reading other subjects.

The Relation of Regeneration and Developmental Processes.

After dealing with a large number of examples illustrating this subject, Dr. J. W. Jenkinson pointed out that, in development, three processes are clearly recognisable—cell and nuclear division, growth, differentiation. Differentiation—the main problem—is determined by external factors, such as the physical and chemical environment, and by internal factors, *e.g.* the initial structure of the germ and the interaction of developing parts. Experiments prove that there exist in the cytoplasm definite organ-forming substances arranged in a definite manner, and sometimes stratified and graded. Such an arrangement accounts for the observed progressive restriction of the potentialities of parts. During cleavage these substances are segregated into cells, but the order in which this takes place seems to be immaterial; the essence of segmentation is the reduction of the ratio of cytoplasm to nucleus.

In regeneration—the production of a whole structure by a part in a differentiated organism—similar processes and factors may be observed. The regenerate often differs quantitatively or qualitatively (heteromorphosis) from the original; reversal of polarity is a special case of the latter. Features common to all regeneration are:—(1) the covering of the wound; (2) cell multiplication (resulting in the reduction of the cytoplasm-nucleus ratio); (3) growth, always at right angles to the cut surface, and at a rate which alters like the ontogenetic rate; (4) differentiation, which usually follows the ontogenetic order, but may differ from it (anomalous behaviour of germ layers). Of the external factors concerned little is known except that the actual injury is the prime stimulus; the internal factors are:—(1) interaction of parts; (2) size (there is a minimal size); (3) degree of differentiation (power of regeneration decreases with age); (4) level or material (necessarily cytoplasmic, since the nuclei are all alike); (5) polarity, which may be expressed in terms of a graded stratification of materials. The adult organism contains the same organ-forming substances as were present in the germ, and arranged in a similar way; the difficulty is that the former is divided into cells. A further difficulty is presented by the anomalous behaviour of the germ layers and by the fact that a part, in which these substances exist, *ex hypothesi*, in other than the correct proportions, can yet form a whole. This indicates that the problem is fundamentally one of assimilation; and Dr. Jenkinson pointed out, in conclusion, that metabolism and regeneration in the protozoa are solely dependent on the presence of the nucleus.

Prof. C. S. Minot gave an address, which, however, cannot be summarised in a few lines and without the aid of diagrams, dealing with the relations of the primitive streak, blastopore, neurenteric canal, and medullary folds in various vertebrates.

Cytological papers by Prof. Hartog and Dr. Edwin Hindle were contributed to the joint meeting of Sections D and K, and Dr. E. J. Russell read, to the joint meeting of Section D and Sub-section B, a paper on the part played by micro-organisms, other than bacteria, in determining soil fertility. A notice of these papers will be found in the reports of the proceedings of Section K and of Sub-section B. J. H. ASHWORTH.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

IN his presidential address on some of the more pressing needs of geography, Prof. A. J. Herbertson spoke of geographical classification and terminology especially with regard to the genetic classification of land forms, and gave suggestions as to a suitable form of notation. In speaking of geographical units, he laid great stress on the significance of vegetation to the geographer, for which a study of climatic regions is as necessary as a study of morphological ones. Dr. Herbertson's address was printed in full in NATURE of September 22.

The first paper was by Dr. J. D. Falconer, on the origin of some of the more characteristic features of the topography of northern Nigeria. The rivers belong to two great hydrographical systems, the Niger-Benue and the Chad systems. The watersheds are lofty plains of a mature topography, while the prominent hills exert only a secondary influence on the drainage system. In their upper and middle courses the rivers flow over open plains the surface of which is diversified by numerous isolated granite domes, turtlebacks, and inselberge. In their lower courses they often flow in deep valleys bounded on either side by ranges of flat-topped hills. These hills have been carved out of horizontal sedimentary rocks, while the isolated domes of the upper plains are clear evidence of a crystalline floor. The peculiar character of the river valleys is entirely due to the recent origin of the whole river system.

Two papers were read by Dr. W. S. Bruce, the first on Prince Charles Foreland, Spitsbergen, the second on his plans for a second Scottish National Antarctic Expedition. During the summers of 1906, 1907, and 1909, Prince Charles Foreland was explored by Scottish expeditions under Dr. Bruce's leadership. The expedition of last year in the steam-trawler *Conqueror* was on the most extensive scale of the three, and practically completed the exploration of the island. The chief object of the work was to make a detailed map of the Foreland on a scale of two miles to the inch. This map is a continuation of similar work carried on by the Prince of Monaco on the mainland, and by Norwegians under his direction. The island is about fifty-four miles long and from three to seven and a half miles broad, with an area of 262 square miles. An almost continuous range of hills, the northern Grampians, occupies the northern two-thirds of the island, and rises to 3800 feet in Mount Monaco and 3300 in Mount Jessie. Separating these from the Ross heights at the southern end is an extensive low-lying part, called the Foreland Laichs, apparently a raised sea bottom. On the east an almost continuous ice-sheet flows from the northern Grampians to Foul Sound, but the west is free from glaciers. A bathymetrical survey of Foul Sound demonstrated a bar towards the northern end over which vessels drawing more than 12 or 15 feet have difficulty in finding a passage. The rocks are mainly Hekla Hook schists and graywackès, with a small pocket of tertiary beds on the east near Ferrier Haven. The completed topographical map will be one of the most detailed ever made of any part of the polar regions.

The plans for a second Scottish National Antarctic Expedition were first published in 1908, but have since been matured and elaborated. It is intended first of all to complete the bathymetrical survey of the South Atlantic between Buenos Aires and Cape Town, and Cape Town and the South Sandwich group. A course will then be set for Coats Land, discovered by Dr. Bruce in 1904. Wherever a suitable landing-place can be found along this coast, the base of the expedition will be established. From this base Dr. Bruce will endeavour in the following summer to cross Antarctica *viâ* the Pole to Victoria Land, a long journey, but one which for the greater part of the way will be over entirely new ground, and must result in considerable light being thrown on the complex and difficult problem of the structure of Antarctica. After landing Dr. Bruce and his party on Coats Land the ship will continue eastward, conducting oceanographical work along the edge of Antarctica. On this work Dr. Bruce lays particular stress. It is also hoped to map in the "missing" coast line between Coats Land and Kaiser Wilhelm Land. After refitting at Melbourne, the ship will proceed southward to pick up Dr. Bruce at some point on Victoria Land, and then make for New Zealand. Thence *viâ* Cape Horn a course will be made for Coats Land to embark the remainder of the party left there, who will have been conducting meteorological work during two winters and one summer. From Coats Land the expedition will return home. The exploratory work will be conducted entirely in the Weddell and Biscoe quadrants, for Dr. Bruce recognises that the Ross sea and adjacent lands are the special province of Captain R. F. Scott and Sir Ernest Shackleton. The total cost of the expedition will be about 50,000*l*.

In the afternoon Captain J. K. Davis, of Sir Ernest Shackleton's recent expedition, read a paper on the voyage of the *Nimrod* from Sydney to Monte Video. Attempts were made to locate certain doubtful islands, viz., Royal Company Islands, Emerald Island, the Nimrod group, and Dougherty Island. None of these islands were found, and deep soundings were obtained on or near their supposed positions. They may therefore be removed from the chart. A visit to Macquarie Island resulted in some interesting collections. The two-hourly meteorological observations taken during this voyage, which extended through May and June, should prove of great importance.

Friday morning was devoted to a joint meeting with Section C. Three of the papers dealt with local geography. Mr. C. Johns gave an account of the geology of the Sheffield district. He was followed by Prof. A. McWilliam, who read a paper on the metallurgical industries in relation to the rocks of the district. Sheffield is a striking example of a town that has arisen in response to local geographical controls. In past times the thick woods of the district supplied the principal metallurgical fuel, charcoal. The clay ironstone yields excellent pig-iron suitable for castings and the best qualities of wrought iron. The bulk of the ironstone now used, however, is brown iron-ore, hydrated ferric-oxide, from Northampton, Leicester, and Lincoln, though for the best steels the hematite ores of Lancashire, Cumberland, and Spain are imported, and Swedish wrought irons are used for cutlery and edge tools. The district is one of the richest in the kingdom in regard to coal supply. Different beds are found suitable for making coke for crucible, cupola, and blast furnaces, and even one that fulfils the very exacting needs of the cementation furnace. The sandstones of the coal measures, often containing 98 per cent. of SiO_2, yield excellent ganister. Fireclay is abundant and of exceedingly good quality. The sandstones of the coal measures, not millstone grit, are now principally employed for grindstones. The carboniferous limestone is available as a flux, while fluorspar, easily obtainable in the great heaps of gangue left by the lead miners of Derbyshire, is used to help in desulphurising steel. Lastly, a soft Upper Permian sandstone makes an ideal moulding sand, since, from the nature of the component grains, it exactly strikes a compromise between binding properties on the one hand and porosity on the other. Speaking after this paper, Prof. Kendall directed attention to the importance to Sheffield of the unoxidised iron ores of Leicestershire and Lincolnshire, which are almost identical with the Cleveland iron ore. When the oxidised ores of Northamptonshire and Lincolnshire are exhausted in about thirty years' time, these will be of great value to Sheffield. Prof. Herbertson insisted on the importance of improving the Trent as a waterway in connection with the eastward extension of the coal-field.

The Humber during the human period was the subject of a communication by Mr. T. Sheppard. With the help of a series of maps, he showed the changes that have occurred in the Humber and on the coast of Holderness from the time of Henry VIII. until the present day. The rapid destruction of the coast at the rate of several feet a year is, in a sense, compensated for by the silting up of the Humber and the growth of new land. Hull is slowly but steadily moving southward to maintain its position as a deep-water port.

Dr. Tempest Anderson gave a description of Matavanu, a new volcano which broke out in Savaii in the Samoa Islands in 1905. Other papers read before the joint meeting of Section E and C were, on the present Triassic conditions in Australia, by Mr. E. C. Spicer, and one by Dr. W. H. Hobbs on some considerations concerning the alimentation and the losses of existing Continental glaciers.

In the afternoon Dr. Hamilton Rice gave a lecture on his journey across South America from Bogotà to Manáos, the object of which was to discover the sources of the Uaupés River. The route from Bogotà was to Villavicencio, and thence over the Andes to San Martin and the densely forested area of the Amazon basin. He described the aborigines inhabiting the banks of the Uaupés, among whom he found both Caucasian and Mongoloid types.

On Monday, September 5, the first paper was by Mr. J. Howard Reed on the geography of British cotton-growing. A shortage in the supply of raw cotton threatens seriously to affect Lancashire. The quantity of cotton used to-day in Lancashire is only a trifle more than was the case twenty years ago, but the amount used on the Continent has nearly doubled, and the total is now more than twice that of the British figure. The American mills now consume an amount nearly equal to the whole of the continental demand and about double the British demand. Mr. Howard Reed foresees a serious crisis for the Lancashire mills unless supplies of raw cotton can be obtained from other than American fields. It is only by fostering and developing cotton-growing in British colonies that, he believes, the English cotton industry can be saved from virtual extinction. Hence the efforts of the British Cotton-growing Association. Considerable success has attended the efforts of the association in the British West Indies, but the greatest results are expected from Uganda, Nyasaland, and Nigeria. The increased production of cotton, due to the efforts of the association, has been progressive from year to year, but the needs are so enormous and the work so colossal that the increased supplies obtained during seven years only reach about one-thirtieth of Lancashire's average yearly demand. Mr. Reed said that a sum of five millions might well be employed in the development of cotton-growing, and the African colonies he looked upon as an incomparable field. Mr. G. G. Chisholm, in making some remarks on this paper, declined to take anything like so pessimistic a view with regard to the future of our cotton industry, nor, on the other hand, was he so hopeful with regard to the effect on Lancashire of the remedies suggested.

Major R. G. T. Bright followed with a paper on the Uganda-Congo boundary survey, in which he described the country on the western frontier of the Uganda protectorate. Captain E. M. Jack communicated a report on the survey of the 30th meridian arc, Uganda protectorate, 1908–9.

Lieutenant P. T. Etherton, Indian Army, gave an account of a journey from India through Gilgit, Hanza, across the Pamirs, and thence by Chinese Turkestan, Mongolia, and Siberia to the Trans-Siberian railway. Lieutenant Etherton left Lansdowne in the Himalayas in March, 1909, and reached the Siberian railway in February, 1910. From the Pamirs the route was by the Ili Su Pass (16,750 feet) to the Yarkand River, and thence to the Kulan Urgu valley by a previously unexplored pass at 17,400 feet. Three months were spent in the Tian Shan mountains, during which time the little-known Great Yulduz valley was traversed. Thence the expedition passed by the Ili valley to the town of Kulja. From here Lieutenant Etherton struck through the Sairam Nor and Ebi Nor country to Chuguchak, and reached the foot of the Altai mountains on the northern side of the Black Irtish valley in the depths of winter. After considerable difficulty the expedition reached Zaisan, a small town on the Siberian-Mongolian frontier, early in January this year. Big game shooting was the chief object of the journey.

On Tuesday, September 6, the first paper was by Mr. William Wilson, on a new globe-map of the world. The author emphasises the importance of the globe in geographical teaching, and he overcomes the drawbacks of its high price and cumbrous nature by mounting a special globe map on thin cardboard and cutting out the gores. The two ends of the map are joined to form a cylinder by a clip at the equator; a spindle is introduced, and the tips of the gores are passed down over the ends of the spindle by means of holes punched at the ends of each gore where the poles would be. A metal clip at each end holds the tips in position, and serves as a convenient means of handling the globe. The apparatus can be made up or dismantled in a few minutes, and can be studied flat or as a globe. The world from equator to pole is divided into three belts of 30° each, which form the primary divisions of latitude. The longitudes are divided primarily into eight groups of 45° each, a group forming a gore. By these primary divisions the world is divided into forty-eight sections. The sections can be enlarged to any extent, forming an atlas on a simple equal scale that is readily grasped. A set of "window" diagrams, each one combining a section of one belt on this plan and the same area as shown on Mercator, makes an instructive demonstration of the exaggeration necessary to Mercator.

Two papers followed dealing with regional surveys of selected areas of the British Isles on the lines indicated some years ago by Dr. H. R. Mill. Mr. James Cossar dealt with the Midlothian district. After pointing out the configuration of the area, Mr. Cossar dwelt on its geology so far as it affects the place relations, local conditions, or economic development. Thus the volcanic action of the past gave rise to hills and ridges in the western part of the region, which have in cases offered sites for fortifications, as Edinburgh Castle and Inchkeith, and have materially affected the lines of communication. The export of road metal and the physical conditions at Queensferry, which favoured the construction of the Forth Bridge, both entail a discussion of geological facts. The importance of the glacial period was considered, firstly in its influence on the physical structure, secondly on the drainage system, and thirdly on the economic resources. In this connection

Mr. Cossar examined and described a remarkable series of dry valleys which have resulted from glacial action. The history of the rivers and their present economic value were discussed, and then successively Mr. Cossar examined the climate, vegetation, mineral resources, industries, occupations, and distribution of the population.

Mr. O. G. S. Crawford's regional survey was of the Andover district, which he discussed under the successive headings of physical features, natural vegetation, industries, including agriculture, settlements, and communications, concluding with a survey of the reaction of man upon his natural surroundings.

Mr. H. Brodrick read a paper on the underground waters of the Castleton district of Derbyshire. To the west of Castleton is a long valley, in the base of which runs one of the transverse Pennine faults which brings down the carboniferous limestone, so that the streams to the north run over the Yoredale beds to sink into the limestone. Of the several streams, only one ends in a cave of any size, the Giant's Hole. It was this stream principally that Mr. Brodrick explored.

Dr. C. A. Hill read a paper on the further exploration of the Mitchelstown caves in Ireland, carried out by himself and Mr. Brodrick. At the Dublin meeting in 1908 the author gave an account of these caves, but since that date an exhaustive survey of both caves has been carried out.

Several papers of geographical interest were contributed to other sections, but special attention must be directed to the discussion, opened by Prof. P. F. Kendall in Section C, on the concealed coalfield of Nottingham. In the course of his remarks Mr. Kendall announced that the coal measures had been reached at Scunthorpe, eleven miles east of Thorne. Borings are also in course of progress at Thorne, Snaith, Selby, and Newark. This coalfield, he considered, would be the hope and support of industrial England in the future.

ENGINEERING AT THE BRITISH ASSOCIATION.

THE first meeting of the engineering section was held on Thursday, September 1, when, in addition to the president's address, only one paper was taken—the testing of lathe tool steels, by Prof. Ripper. Two methods of testing lathe tools are commonly employed; in one, the object of the test is to ascertain the length of time the tool will run under given conditions before it has to be reground: in the second, the object is to ascertain the actual cutting speed which would entirely destroy the tool in twenty minutes. Prof. Ripper was of opinion that both these methods were of doubtful utility, the latter because, in order to determine the standard speed, so many tests had to be made. He had, therefore, devised another method, which he called the speed-increment test. In this method the tool was started at a standard cut—at a surface speed of, say, 30 feet per minute—and the speed of cutting was then gradually increased by equal increments of 1 foot per minute until the tool broke down. Prof. Ripper showed a number of curves to illustrate the results obtained by this method of testing, and, after the reading of the paper, he gave a demonstration in the University laboratory. The variation of the speed was obtained by means of an electrical drive.

The first business of the section on Friday, September 2, was the discussion on the third report of the committee on gaseous explosions. The chief experimental work undertaken by the members of the committee had been the determination of the amount of radiation from flames. Prof. Callendar had experimented on the radiation from open flames in the laboratory, and Prof. Hopkinson on radiation from gases in a closed combustion chamber. These experiments showed that a flame was, to a certain extent, transparent to the same radiation that it emitted, Prof. Callendar finding that two similar flames placed one behind the other radiated nearly twice as much as a single flame. Before the discussion opened, Prof. Dixon described the experiments he had recently carried out on the ignition of gases by adiabatic compression. The gases were rapidly compressed in closed glass tubes, and a continuous photograph was taken by means of rapidly moving films. Prof. Dixon pointed out that it had been anticipated that such gases would be uniformly heated, and that they would, therefore, ignite simultaneously at all points; he did not, however, find this to be the case—the explosion was never sharp nor violent; the ignition invariably began at one point, and then spread throughout the tube. The discussion largely turned on the question of the part played by radiation in regard to the missing quantity in gas-engine heat balances. Captain Sankey pointed out that the modern gas engine had an efficiency of 80 per cent. to 90 per cent. when compared with the standard theoretical gas engine, and that there was thus only a loss of some 10 per cent. to 20 per cent., there being, therefore, not much scope for further improvement.

The remaining business for the day was the reading by Prof. Ripper of a paper on a new method of testing the cutting quality of files. Until the invention of the Herbert file-testing machine a few years ago, the only method of testing the cutting power of files had been the hand tests carried out by expert workmen. From some experiments he had been asked to carry out, the author was of opinion that the results obtained in the Herbert file-testing machine were not normal, and he considered that this machine had a serious defect; owing to the fact that the file moved across the face of the test bar through an absolutely constant path, the teeth of the file, each stroke, worked in identically the same grooves or furrows on the face of the test bar, the result was that the surface of the test bar became occasionally, as it were, glazed, and the file ceased to cut properly. With the view of overcoming this defect, Prof. Ripper designed an addition to the Herbert machine with the object of making the path of the file no longer a constant one. To secure this result the file was no longer held rigidly at each end, but was connected by ball joints, the effect of which was equivalent to the wrist movement at each end of the file during ordinary hand-filing. The eccentric motion at one end of the file was obtained by a worm gearing actuated by the reciprocation of the machine. The author found that with this addition the Herbert file-testing machine gave extremely concordant results, and a number of curves were shown to illustrate this point. After the conclusion of the day's proceedings a demonstration of the machine was given in the engineering laboratory.

The section opened its proceedings on Monday with a paper by Mr. P. Dawson on the electrification of the London, Brighton and South Coast Railway between Victoria and London Bridge. The author had been responsible for the design of this important work. Bearing in mind the possibility of future developments, he had decided to adopt single-phase electric traction at 6700 volts, with a periodicity of 25. The motors would develop 115 horse-power for one hour, with a rise of temperature of only 70°, and 60 horse-power for twelve hours continuously under the same conditions; there were four motors to each car. Great trouble was experienced in overcoming the difficulties due to the low head room at certain of the overhead bridges; thus while the normal height of the overhead wires was 21 feet 6 inches above rail-level, there was only available a height of 13 feet 9 inches at some of the bridges, and the collector bow had to be adapted to this extreme variation in height. So far the installation had proved entirely satisfactory.

This paper was followed by one by Mr. H. E. Wimperis on the use of an accelerometer in the measurement of road resistance and horse-power. The accelerometer designed by the author consists of a brass box, which contains a copper disc mounted on a vertical pivot, with its motions damped by a permanent magnet. The centre of gravity of the disc is not in the axis, hence, when the box moves forward, one side of the disc tends to lag behind, and thus to wind up partially a coiled spring, and so actuate a pointer moving over a scale. An ingenious gearing prevents the reading from being affected by any accelerations at right angles to the direction of motion. By the use of this instrument road resistances can be read off at sight, and the brake and indicated horse-power of the engine can be obtained for various speeds.

Prof. Coker next described his experiments on the cyclical changes of temperature in a gas-engine cylinder near the walls; it was found that the highest temperature near the walls could be measured by couples made from 10 per cent. alloys of iridium and rhodium with platinum; the author estimated that the maximum temperature at the place of measurement was between 1850° and 1900° C.

The business of the day concluded with a discussion on the principles of mechanical flight, opened by Prof. Bryan. As a matter of fact, owing to the line of argument adopted by the opener, there was practically no discussion on principles, but there was a somewhat heated debate as to the respective provinces of the mathematician, the physicist, and the engineer in solving the problems of mechanical flight. If the engineer is to wait until the mathematician has evolved a completely satisfactory theory as to the stability, &c., of aëroplanes, it is quite clear that little further progress will be made. The successful developments of most of the mechanical devices now employed by man have followed lines very different from those which seem good to Prof. Bryan; and mathematical theory has generally followed, and not preceded, the engineer's victory over the forces of nature.

The proceedings were opened on Tuesday, September 6, by a paper by Prof. Coker on the optical determination of stress. Prof. Coker has been working for some time at this problem, utilising the well-known fact that glass is rendered doubly refractive by stress; as glass, however, owing to the difficulty of obtaining suitable pieces free from initial strains, has proved unsuitable, the author has fallen back on the use of xylonite, which answers admirably. The apparatus necessary included an arc lamp to supply the beam of light, and lenses and prisms. The author showed a number of lantern-slides of the permanent records he had obtained by making use of Lumière colour plates.

Prof. Dalby then read his paper on the measurement of the air supply to a gas-engine cylinder; the air on its way to the engine flows through an orifice into a chamber, from which it passes to the suction valve; the engine is fitted with an apparatus which enables the temperature corresponding to the pressure and volume at an assigned crank angle to be measured, and thus all the data required for calculating the weight of air passing through the orifice per second are accurately known.

Prof. S. P. Thompson next read a paper on the laws of electromechanics; the author stated that his object was to put into concrete form the chief laws governing the performance of various electromagnetic mechanisms, and a number of formulæ was deduced.

Mr. F. Bacon then read his paper on heat insulation, in which he described his researches into the heat-insulating efficiency of a number of materials; the heat which was transmitted was produced electrically, and electrical methods were employed to measure the temperatures. In the discussion it was pointed out that in lagging steam-pipes there was with each material a definite thickness which it was uneconomical to increase, as the increase of external surface increased the radiation at a greater rate than the increased thickness diminished it.

The last paper of the day was by Prof. E. Wilson and Mr. W. H. Wilson on a new method of producing high-tension electrical discharges. In this method energy is taken from an alternating or continuous current source, and is stored in a magnetic field by inductance; it is then allowed to surge into a condenser, which together with the inductance forms a low-frequency oscillatory circuit. When the energy has accumulated in the condenser, the condenser is mechanically bridged across the primary winding of an induction coil, with which it forms a high-frequency oscillatory circuit. The energy is then transmitted by the secondary winding of the induction coil to the work circuit, and may be either oscillatory or unidirectional. The apparatus is suitable for radio-telegraphy or any work employing high-tension electricity.

The concluding meeting of the section was held on Wednesday, September 7, when the first paper was one by Mr. R. W. Weekes on self-raising rollers for maps and plans, descriptive of an ingenious arrangement for mounting plans, maps, and diagrams.

The next paper was entitled "Machine for Testing Rubber by Means of its Mechanical Hysteresis," by Prof. Schwartz. The author had designed a machine in which a specimen of rubber of standard dimensions was loaded at a given rate to a given percentage of the maximum load. The load was then gradually removed, and a complete stress-strain diagram automatically taken; as rubber possesses very considerable mechanical hysteresis, the stress diagram was of a loop form; from this the chief physical characteristics of the sample could be readily deduced.

Prof. Fessenden then gave his paper on the utilisation of solar radiation, wind power, and other intermittent natural sources of energy. The author estimated that the total first cost of the solar plant per horse-power would be about 20*l.*, and the annual charge about 30*s.* per horse-power; he stated that a plant of 3000 horse-power was at present in course of erection. In the discussion Sir William White expressed the view that in all these schemes for the working of intermittent sources of energy the cost of works of construction generally proved prohibitive.

The last paper was by Mr. Cook on an experimental investigation of the strength of thick cylinders. The author described his investigations into the strength of cast-iron and mild steel thick cylinders when subjected to gradually increasing internal pressure up to the bursting point. Mr. Cook had found in the case of the mild steel cylinder that the tensile stress at the yield point, as calculated by Lamé's equation, agreed closely with the value of the tensile stress at the yield point in an ordinary tension test of the steel.

The proceedings closed with votes of thanks to the president and secretaries of the section.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BRISTOL.—The first congregation for the presentation of degrees in the University of Bristol was held on October 20 before a crowded assembly. Owing to failing health, the Chancellor, Mr. H. O. Wills, was not present, and his place was filled by the Vice-Chancellor, Sir Isambard Owen. The degree list was a long one, as besides the ordinary graduating students there were fifty-two old students of University College and the Merchant Venturers' Technical College, who, having taken degrees in other universities, were admitted to *ad eundem* degrees in the University. In a few special cases, also, degrees of Bachelor were awarded to associates of these institutions. Only one honorary degree was conferred, and that, the Doctorate of Science, on Prof. Conwy Lloyd Morgan, F.R.S., lately Vice-Chancellor of the University and sometime principal of University College, Bristol. He was introduced by Prof. F. R. Barrell, dean of the science faculty, who in the course of his address said:—"Expert in knowledge of the fossil past, expert in knowledge of the living present, he stands renowned in varied fields of thought; keenly has he observed, acutely has he analysed the workings of the mind in man and bird and beast; at his behest the artless infant and the unfeathered chick alike disclose the secrets of their nascent reason; psychology, zoology, geology, all acknowledge in him a master. A teacher of teachers, he has o'erstepped the boundaries of this isle; in southern Africa he has dwelt and taught; not once or twice alone has he been called across Atlantic seas to inform the wisdom of the West. With fertile pen and with lucid speech he has made clear the subtle mazes of philosophy; his written word is read where'er the English language penetrates, and done into the German tongue it guides the Teuton in the study of nature."

CAMBRIDGE.—Mr. A. E. Shipley, F.R.S., fellow and tutor of Christ's College, has been elected master of the college in succession to the late Dr. John Peile.

Dr. Tempest Anderson will deliver a lecture in the Sedgwick Museum on "Matavanu, a New Volcano in Savaii, German Samoa," illustrated with lantern photographs, on Saturday, November 5, at 5 p.m.

The Henry Sidgwick memorial lecture, to be given by Sir George Darwin, K.C.B., F.R.S., on "William and Caroline Herschel," will take place in the hall of Newnham College at 5 p.m. on Saturday, December 3, instead of November 12, as previously announced.

IT is stated in *Science* that the Tuskegee Institute will receive about 80,000*l.* from the estate of Mrs. Dotger, and the Hampden Institute will receive about 50,000*l.* from the estate of Miss Alice Byington. By the death of Mrs. Loomis, the estate of the late Colonel John Mason Loomis, amounting to more than 200,000*l.*, will, it is said, go to the establishment of a technical school at Windsor, Conn.

The College of the City of New York has acquired, says *Science*, the complete private library of the late Prof. Simon Newcomb, consisting of about 4000 volumes and 7000 pamphlets dealing with astronomy, mathematics, and physics. Both pamphlets and books are being catalogued, and are now accessible to research students, in accordance with the expressed desire of Prof. and Mrs. Newcomb.

On October 22 Mr. T. Fenwick Harrison laid the foundation-stone of new engineering laboratories for the University of Liverpool. The cost of the building will be met by a gift of 35,000*l.* received from Mr. Fenwick Harrison, Mr. J. W. Hughes, and Mr. Heath Harrison. Prof. Watkinson thanked Mr. Harrison for laying the foundation-stone, and in the course of his remarks said it is intended to make special provision for teaching and research work in connection with all branches of engineering, internal-combustion engines, steam turbine engines, refrigeration, and fuel testing, and in this respect the laboratories will be second to none in the kingdom. The donors intend that the subject of heat engines, and particularly of internal-combustion engines, shall be developed on a much more important scale than has been hitherto attempted. As shipowners who use three hundred thousand tons of coal a year they see the advantages to be derived from the successful application of the internal-combustion engine, so far as ships are concerned, for it means the reduction of coal consumption to one-half, and possibly to one-third, of that now required for steam engines. It is humiliating, said Prof. Watkinson, that the names associated with the invention of internal-combustion engines are almost without exception German, and nearly all the internal-combustion engines being built to-day in this country are being built under licence from Germany. Greater scientific knowledge is required than in the design of steam engines, and it is reasonable to conclude that the greater success of the Germans is due to their better training in scientific principles. Last year Prof. Watkinson visited all the principal schools of engineering in the United States and in Canada, and in nearly every one he found that their gigantic laboratories were being greatly extended. Both the Germans and the Americans realise far more than we do in this country the value of a university training, and they also realise that in this age, when machinery plays such a large part in almost every industry, that this training is the best for those who are to control and direct most of the great industries. That is well illustrated, said Prof. Watkinson, by the fact that there are about 17,000 students taking a four years' course in the American schools of engineering, which is about eight times the number of students taking the normal three years' course in this country.

The introductory address at the London School of Tropical Medicine was this year delivered by Dr. Henry A. Miers, F.R.S., principal of the University of London. The subject of the address was scientific observation, and Dr. Miers directed attention to an aspect of scientific research and of training in scientific investigation which, he said, seemed in danger of escaping notice. Under present conditions scientific research is seldom pursued save by those whose object is clear and whose minds are concentrated upon a special line of investigation in which they are alive and alert to the exclusion of any distracting side-issues. Each new discovery is pursued with ever-increasing rapidity and with a system which is fruitful in results; the searchlight of investigation is turned with mechanical precision upon every new problem, and it would appear unlikely that anything of importance should be overlooked. But teachers and investigators do not sufficiently bear in mind two possible dangers that beset them under modern conditions of work. It is inherent in our senses and our intelligence, first, that those whose attention is too minutely fixed upon one thing will fail to perceive other things which are equally discernible and equally important; and, secondly, that those who look or listen too intently for a thing may actually see or hear that which they desire, even though it be not there. Later in his address Dr. Miers gave it as his opinion that, taken as a whole, scientific men are not better general observers than other people, though some among them undoubtedly are. It has been too often assumed that scientific training has a special value as developing the general powers of observation, and that because students have been exercised in special observations they have become practised observers of things in general, whereas the reverse may be nearer the truth, and in many instances certainly is so. Some practice in all-round observation should be incorporated in the training of the specialist if we are to have our students quick to observe details that do not form part of their conscious exercises; neither should they be led to suppose that, because they have been practised in observing one thing, they are therefore good observers of everything else. To him who has eyes to see, the most trivial detail may be the germ of an important discovery. Our laboratory training gives the student his eyes, but does not always teach him to use them widely or wisely.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, October 10.—M. Émile Picard in the chair.—The president announced the death of M. Treub, correspondant in the section of botany, and of Ernst von Leyden, correspondant in the section of medicine and surgery.—Henri **Douvillé**: The formation of the loam of the plateaux. This loam, consisting of a very intimate mixture of clay and fine sand, is well developed in the neighbourhood of Paris and in the north of France. Two hypotheses have been put forward to explain its formation, deposition from water and transport by wind. The former hypothesis is shown to be in better accord with the observed facts; to explain the height above the sea at which these deposits are found, the floods carrying the deposits are supposed to have been caused by the sudden melting of snows, the lower portion of the valley being blocked by glacier.—Serge **Bernstein**: A generalisation of the theorems of Liouville and Picard.—F. **Robin**: The law of resistance to crushing of cylindrical bodies as a function of their dimensions. The general law of resistance to crushing as a function of the dimensions of the test-pieces is expressed geometrically by a hyperbolic paraboloid.—H. **Pelabon**: Batteries with antimony and antimony selenides. An element formed of antimony and antimony selenide, with an acid solution of antimony trichloride as the electrolyte, shows varying electromotive force under the action of light. If sulphur or tellurium is substituted for the selenium the phenomena described are not produced. The effect is strongest when the element is exposed to the yellow and red rays.—G. **Charpy** and S. **Bonnerot**: The reduction of oxide of iron by solid carbon. Ferric oxide and graphite, intimately mixed, were heated in a vacuum at temperatures up to 950° C., and the reaction studied by measuring the amount of gas evolved per hour. The speed of reaction diminished as the pressure maintained in the apparatus was reduced, and became practically zero when the pressure in the tube was of the order of 0·001 mm. of mercury. Hence it is concluded that solid carbon does not reduce oxide of iron at 950° C.—P. **Mahler** and J. **Denet**: The presence of a small quantity of carbon monoxide in the air of coal mines. The amounts found varied between 0 and 40 volumes per million, with an average of 19. The maximum amount of carbon monoxide corresponded with the minimum of methane, and the maximum methane was found in the sample containing no carbon monoxide.—Paul **Vuillemin**: A natural preventative to the oak-tree disease. The disease of the oak, caused by an Oidium, is kept in check by a Cicinnobolus, a parasite preventing the multiplication of the Oidium by conidia, and its preservation by the mycelium.—E. L. **Trouessart**: The mammalian fauna of Europe.—Ch. **Gravier**: The coral reefs of the Gulf of Aden and their madrepores.—Paul **Marchal**: Contributions to the biological study of Chermes.—Edouard **Chatton**: The existence of Dinoflagellæ, cœlomic parasites. Syndinium in the pelagic copepods.—A. **Fernbach** and E. **Vulquin**: The microbicidal power of macerations of yeast and cereals. The poison elaborated by yeast is not identical with that obtained from cereals.—A. **Briquet**: Geology of the Gallo-Belgic region.

October 17.—M. Émile Picard in the chair.—P. **Helbronner**: The complementary geodesic triangulations of the upper regions of the French Alps (eighth expedition). The work done included fixing the position of eighty-seven stations, twenty of which were above 3000 metres altitude.—A. **Jacquerod** and M. **Turpaïan**: The application of the principle of Archimides to the exact determination of gaseous densities. A bulb of about 200 c.c. in volume is suspended inside a tube of slightly larger dimensions by means of a platinum wire to the arm of a balance, a suitable counterpoise being suspended from the other arm. The suspended bulb is surrounded by the gas the density of which is being measured, the exact temperature being maintained by an external water bath. The instrument was calibrated by hydrogen and oxygen, the densities of which are exactly known. The accuracy obtainable is of the order of 1 in 10,000.—G. A. **Hemsalech**: The relative duration of the lines of the spectrum emitted by magnesium in the electric spark. The results tabulated confirm the view put forward in a previous paper, that the observation of the relative durations of the lines of the spectrum may, in certain cases, furnish useful indications in the analyses of bodies containing unknown impurities.—A. **Lafay**: The influence of a local heating on the value of the pressures supported by a body placed in a regular stream of air.—Léo **Vignon**: The influence of chemical affinity in certain adsorption phenomena.—Jean de Rufz **de Lavison**: The elective *rôle* of the root in the absorption of salts. The stem absorbs indifferently, and in the same proportion, salts which are presented to it in solution, whilst, on the contrary, the plant furnished with roots exercises a marked selective action on certain salts.—Victor **Henri**, A. **Helbronner**, and Max **de Recklinghausen**: New researches on the sterilisation of large quantities of water by the ultra-violet rays. A description of an improvement of the form of apparatus given in an earlier paper. Three-fourths of the rays emitted by the tube are now utilised. An experiment was carried on for six weeks continuously, during which 25 cubic metres of water per hour were passed through the apparatus, with an expenditure of 26 watt-hours per cubic metre of water, the exit water being sterile.—Jules **Amar**: A singularity in the working of the human machine.—A. **Knaoen**: Should materials be impermeable or porous?—L. **Landouzy**, H. **Gougerot**, and H. **Salin**: Experimental bacillary serious arthritis.—Charles **Nicolle**, A. **Conor**, and E. **Conseil**: Some properties of the exanthematic virus.—Eugène Daday **de Dées**: A new phyllopod collected by the Antarctic expedition of the *Pourquoi Pas?*—Edouard **Danois**: The spermaceti organ of *Kogia breviceps*.—A. **Pécsi**: The lines of fracture of the earth's crust.—Louis **Besson**: Observations of the upper bitangent arc of the halo of 46°.

GÖTTINGEN.

Royal **Society of Sciences**.—The *Nachrichten* (physico-mathematical section), part iv. for 1910, contains the following memoirs communicated to the society:—

May 28.—L. **Geiger**: Determination of earthquake foci from the times of arrival.—D. **Hilbert**: Outlines of a general theory of linear integral equations (vi.).

July 23.—O. **Mügge**: Deformations in the crystals of potassium chlorate ($KClO_3$), according to investigations by Paul Fischer.—E. **Hecke**: Non-regular prime numbers and Fermat's theorem.

DIARY OF SOCIETIES.

WEDNESDAY, NOVEMBER 2.

ENTOMOLOGICAL SOCIETY, at 8.—Experiments in 1909 and 1910 upon the Colour-relation between Lepidopterous Larvæ and Pupæ and their surroundings: Elizabeth Briggs.

SOCIETY OF PUBLIC ANALYSTS, at 8.—The Estimation of Lactose in the presence of the commonly occurring Sugars: Julian L. Baker and H. F. E. Hulton.—The Colorimetric Estimation of Hydrogen Cyanide: A. Chaston Chapman.—The Polarimetric Estimation of Milk Sugar: H. Droop Richmond.—A New Method of Estimating Phosphoric Acid: G. F. Wesley Martin.

THURSDAY, NOVEMBER 3.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: The Origin of the Hydrochloric Acid in the Gastric Tubules: Miss M. P. Fitzgerald.—(1) Trypanosome Diseases of Domestic Animals in Uganda. II. *Trypanosoma Brucei*. (Plimmer and Bradford); (2) Trypanosome Diseases of Domestic Animals in Uganda. III. *Trypanosoma vivax* (Ziemann): Colonel Sir D. Bruce, C.B., F.R.S., and others.—Further Results of the Experimental Treatment of Trypanosomiasis; being a Progress Report to a Committee of the Royal Society: H. G. Plimmer, F.R.S., Capt. W. B. Fry, and Lieut H. S. Ranken.—On the Peculiar Morphology of a Trypanosome from a case of Sleeping Sickness and the possibility of its being a new Species: Dr. J. W. Stephens and Dr. H. B. Fantham.—Note upon the Examination of the Tissues of the Central Nervous System, with Negative Results, of a case of Human Trypanosomiasis, which apparently had been cured for years by Atoxyl Injections: Dr. F. W. Mott, F.R.S.—On a remarkable Pharetronid Sponge from Christmas Island: R. Kirkpatrick.

LINNEAN SOCIETY, at 8.—Biscayan Plankton, Part XIII. The Siphonophora: H. B. Bigelow.—Plankton Fishing in Hebridean Seas: Prof. W. A. Herdman, F.R.S.

RÖNTGEN SOCIETY, at 8.15.—Presidential Address: Dr. G. H. Rodman.

NATURE

A WEEKLY ILLUSTRATED JOURNAL OF SCIENCE.

" To the solid ground
Of Nature trusts the mind which builds for aye."—WORDSWORTH.

No. 2139, Vol. 84] THURSDAY, OCTOBER 27, 1910 [Price Sixpence

Registered as a Newspaper at the General Post Office.]

DERBYSHIRE EDUCATION COMMITTEE.

CHESTERFIELD GIRLS HIGH SCHOOL.

The Governors invite applications for the post of HEADMISTRESS the above School. Candidates must be Graduates of a University or ve an equivalent qualification. Commencing salary, £250.
Applications, to be made in writing (on foolscap paper) and accompanied copies of three recent testimonials, should be addressed to the underned on or before November 21, 1910.

EVAN W. SMALL, Director of Education.
County Education Office, Derby.

NIVERSITY COLLEGE OF SOUTH WALES AND MONMOUTHSHIRE.

LEG PRIFATHROFAOL DEHEUDIR CYMRU A MYNWY.

he Council of the College invites applications for the post of REGIS-AR. The salary will be £400 per annum.
urther particulars may be obtained from the undersigned, by whom lications, with not more than four testimonials, must be received on or ore Wednesday, November 2, 1910.

D. J. A. BROWN, Acting-Registrar.
niversity College, Cardiff, October, 1910.

O SCIENCE AND MATHEMATICAL MASTERS.

January (1911) Vacancies.

raduates in Science and other well-qualified masters seeking posts in blic and other Schools should apply at once, giving full details as to lifications, &c., and enclosing copies of testimonials, to:—

MESSRS. GRIFFITHS, SMITH, POWELL & SMITH,
Tutorial Agents (Estd. 1833),
34 Bedford Street, Strand, London.
Immediate notice of all the best vacancies will be sent.

CITY AND GUILDS OF LONDON INSTITUTE.

pplications are invited for the post of DEMONSTRATOR OF AP-IED MECHANICS AND MATHEMATICS at the City and Guilds chnical College, Finsbury. He will be required to take charge of the boratory of Applied Mechanics. Candidates must have had a college ining and practical engineering experience. Salary, £100 per annum. pies of the Programme of the College and particulars of the conditions ached to the appointment may be obtained on application to the REGIS-AR, City and Guilds Technical College, Leonard Street, Finsbury, ndon, E.C.

BIRMINGHAM MUNICIPAL TECHNICAL SCHOOL.

plications are invited for the post of SENIOR LECTURER in THEMATICS. Commencing salary, £200. Appointment to date (if sible) from January 1, 1911. Applications by November 25, 1910. For particulars apply to

GEO. MELLOR, Secretary.
Offices of the School, Suffolk Street, October 19, 1910.

CIVIL SERVICE COMMISSION.

FORTHCOMING EXAMINATION.

CARTOGRAPHERS in the Hydrographic Department of the miralty (17–25), November 10.
he date specified is the latest at which applications can be received. ey must be made on forms to be obtained, with particulars, from the CRETARY, Civil Service Comm ssion, Burlington Gardens, London, W.

UNIVERSITY OF MANCHESTER.

Applications are invited for the post of SENIOR DEMONSTRATOR ND ASSISTANT LECTURER IN ZOOLOGY, now vacant in conuence of the appointment of Dr. W. D. Henderson to the Lectureship Zoology in the University of Bristol. Details as to the emoluments of post and further particulars may be obtained on application to the GISTRAR. Applications must be sent in before Monday, October 31.

ITISH BIRDS' EGGS.—For Sale, with cabinet, over two thousand Eggs, in sets. They represent nearly all the birds breeding in British Islands. All in perfect order and condition. To be had a bargain. Particulars on application to "AVIS," c/o Mr. O'Neil, Post Office, Handsworth, Birmingham.

OR SALE.—Analytical Balance of superior make by Becker—sensible $\frac{1}{10}$ milligramme; never been used; bought recently, will take 8 Guineas. A genuine bargain.—OWEN, 3 Adelaide Road, Shepherd's Bush.

BROWNING'S SPECTROSCOPES.

THE MINIATURE SPECTROSCOPE.

These Instruments will show many of the Fraunhofer lines, the bright lines of the metals and gases, and the absorption bands in coloured gases, crystals or liquids, and may be used for showing many of the leading experiments in Spectrum Analysis. They are made with combinations of **three prisms** at prices from **20s.** to **35s.**, or with **five prisms**, giving much greater dispersion, and therefore showing the lines and bands more distinctly, at prices from **25s. 6d.** to **70s.**

RAINBAND SPECTROSCOPE (Grace's).

This instrument is specially adapted for predicting coming rain. It is a very powerful, portable, and efficient spectroscope, and is applicable to every purpose for which a Direct Vision Spectroscope can be used.

PRICES: **£3 8 6, £4 0 0,** AND **£5 15 0**

"HOW TO WORK WITH THE SPECTROSCOPE"

By JOHN BROWNING, F.R.A.S., &c. Fourth Edition, entirely rewritten and revised. Price **9d.**, or with Coloured Chart of 14 Spectra, **1s. 6d.** Post Free.

Price Lists of Spectroscopes, Telescopes, &c., Post Free.

JOHN BROWNING, Man'f'g Optician, **146 STRAND, LONDON**
ESTAB. 1765. TEL. NO.: 7804 CENTRAL.

H.M. DOCKYARD SCHOOLS.

WANTED, a JUNIOR ASSISTANT MASTER. Candidates must possess a University degree or some equivalent qualification, and should have had experience in laboratory work.
The scale of salary is £150, rising to £200 by annual increments of £10, with a pension and prospects of promotion. Duties will commence on January 1, 1911.
Applications should be addressed to the SECRETARY OF THE ADMIRALTY (C. E.), Whitehall, London, S.W.

UNIVERSITY OF MANCHESTER.

A Course of about Twenty Lectures on "FOSSIL REPTILIA" will be given by Mr. D. M. S. WATSON, M.Sc., on Mondays, Wednesdays, and Fridays, at 5 p.m. First Lecture, November 7 next. Fee, £1 1s.

FOR SALE.—Contents of the private Chemical Laboratory of a gentleman going abroad. Comprising large collection of Metallic and Organic Compounds, large stock of Glass and Iron Chemical Apparatus, Combustion Furnace, Töpler Mercury Pump, Gas Analysis Apparatus, Glass Taps, 7-inch Harvey & Peak's Induction Coil, X-Ray Tubes and Screens, Gas Cylinders, Reagent Bottles, Rare Minerals, &c., &c. Can be seen by appointment. Apply "C., Box 6," c/o NATURE.

OLD PLATINUM, GOLD

Scrap, &c., valued or purchased.

SPINK & SON, Ltd.,

17 & 18 PICCADILLY, W., and at 6 KING STREET, ST. JAMES', LONDON, S.W.
ESTD. 1772.
Gems for experimental work at moderate prices.

PLATINUM. Extraordinary prices given for platinum scrap Cash or offer by return post. 40 ozs. wanted this week.—R. OLPHERT, Jeweller, 19 Elm Grove Parade, Barnes, S.W. Bankers: London, City and Midland (Barnes branch). 500 ozs. wanted.

TYPEWRITING OF HIGHEST QUALITY.

General MSS., 10*d.* per 1000 words. Carbon copies, 3*d.* per 1000 words. Accuracy Guaranteed.
NORA DICKINSON, 1 Sackville Gardens, Ilford, Essex.
